It is now possible to use enzymes to strip off the A or B surface antigens from RBCs and create Type O blood in the laboratory. The procedure is expensive and time-consuming and has limited use in emergency treatment. Still, cross-reactions can occur, even to Type O^- blood, because at least 48 other surface antigens are present. As a result, whenever time and facilities permit, further testing is performed to ensure complete compatibility between donor blood and recipient blood. **Cross-match testing** involves exposing the donor's RBCs to a sample of the recipient's plasma under controlled conditions. This procedure reveals the presence of significant cross-reactions involving surface antigens other than A, B, or Rh. Another way to avoid compatibility problems is to replace lost blood with synthetic blood substitutes, which do not contain surface antigens that can trigger a cross-reaction. AM: Transfusions and Synthetic Blood

Because blood groups are inherited, blood tests are also used as paternity tests and in crime detection. The blood collected cannot prove that a particular individual *is* a certain child's father or *is* guilty of a specific crime, but it can prove that the individual is *not* involved. It is impossible, for example, for an adult with Type AB blood to be the parent of an infant with Type O blood. Testing for additional surface antigens, other than the standard ABO groups, can increase the accuracy of the conclusions.

White Blood Cells

Objective

- Categorize the various white blood cells on the basis of their structures and functions and discuss the factors that regulate the production of each type.

Unlike red blood cells, white blood cells (WBCs) have nuclei and other organelles, but they lack hemoglobin. White blood cells, or leukocytes, help defend the body against invasion by pathogens, and they remove toxins, wastes, and abnormal or damaged cells. Several types of WBCs can be distinguished in a blood smear by using either of two standard stains used in blood work: *Wright's stain* or *Giemsa stain*. Traditionally, WBCs have been divided into two groups on the basis of their appearance after such staining: (1) *granular leukocytes*, or *granulocytes* (with abundant stained granules)—the *neutrophils, eosinophils*, and *basophils*; and

(2) *agranular leukocytes*, or *agranulocytes* (with few, if any, stained granules)—the *monocytes* and *lymphocytes*. This categorization is convenient but somewhat misleading, because the granules in "granular leukocytes" are secretory vesicles and lysosomes, and the "agranular leukocytes" also contain vesicles and lysosomes; they are just smaller and difficult to see with the light microscope.

A typical microliter of blood contains 6000 to 9000 WBCs, compared with 4.2 to 6.3 million RBCs. Most of the WBCs in the body at any moment are in connective tissue proper or in organs of the lymphatic system. Circulating WBCs thus represent only a small fraction of the total WBC population.

WBC Circulation and Movement

Unlike RBCs, WBCs circulate for only a short portion of their life span. White blood cells migrate through the loose and dense connective tissues of the body, using the bloodstream primarily to travel from one organ to another and for rapid transportation to areas of infection or injury. As they travel along the miles of capillaries, WBCs can detect the chemical signs of damage to surrounding tissues. When problems are detected, these cells leave the bloodstream and enter the damaged area.

Circulating WBCs have four characteristics:

1. **1.** *All Can Migrate out of the Bloodstream.* When white blood cells in the bloodstream become activated, they contact and adhere to the vessel walls in a process called *margination*. After further interaction with endothelial cells, the activated WBCs squeeze between adjacent endothelial cells and enter the surrounding tissue. This process is called *emigration*, or *diapedesis*.

2. **2.** *All Are Capable of Amoeboid Movement. Amoeboid movement* is a gliding motion accomplished by the flow of cytoplasm into slender cellular processes extended in front of the cell. (The movement is so named because it is similar to that of an *amoeba*, a type of protozoan.) The mechanism is not fully understood, but it involves the continuous rearrangement of bonds between actin filaments in the cytoskeleton, and it requires calcium ions and ATP. This mobility allows WBCs to move through the endothelial lining and into peripheral tissues.

3. *All Are Attracted to Specific Chemical Stimuli.* This characteristic, called **positive chemotaxis** (k

¯ o

¯ e

-m

to invading pathogens, damaged tissues, and other active WBCs.

4. *Neutrophils, Eosinophils, and Monocytes Are Capable of Phagocytosis.* These cells may engulf pathogens, cell debris, or other materials. Neutrophils and eosinophils are sometimes called *microphages*, to distinguish them from the larger macrophages in connective tissues. Macrophages are monocytes that have moved out of the bloodstream and have become actively phagocytic.

l**p. 119**

Types of WBCs

Neutrophils, eosinophils, basophils, and monocytes contribute to the body’s *nonspecific defenses*. Such defenses are activated by a variety of stimuli, but they do not discriminate between one type of threat and another. Lymphocytes, in contrast, are responsible for *specific defenses:* the mounting of a counterattack against specific types of invading pathogens or foreign proteins. We will discuss the interactions among WBCs and the relationships between specific and nonspecific defenses in Chapter 22.

Neutrophils

-TAK-sis), guides WBCs

Fifty to 70 percent of the circulating WBCs are **neutrophils** (NOO-tr

¯o

-filz). This name reflects the fact that the granules of these WBCs are chemically neutral and thus are difficult to stain with either acidic or basic dyes. A mature neutrophil has a very dense, segmented nucleus with two to five lobes resembling beads on a string (Figure 19–9a•). This structure has given neutrophils another name: **polymorphonuclear** (pol-ē-mor-fō-NOO-klē-ar) **leukocytes** (*poly*, many + *morphe*, form), or *PMNs*. “Polymorphs,” or “polys,” as they are often called, are roughly 12 mm in diameter. Their cytoplasm is packed with pale granules containing lysosomal enzymes and bactericidal (bacteria-killing) compounds.

Neutrophils are highly mobile, and consequently are generally the first of the WBCs to arrive at the site of an injury. These very active cells specialize in attacking and digesting bacteria that have been “marked” with antibodies or with *complement proteins*—plasma proteins involved in tissue defenses. (We will discuss the complement system in Chapter 22.)

Upon encountering a bacterium, a neutrophil quickly engulfs it, and the metabolic rate of the neutrophil increases dramatically. This *respiratory burst* accompanies the production of highly reactive, destructive chemical agents, including *hydrogen peroxide* (H2O2) and *superoxide anions* (O^{-}); which can kill bacteria.

Meanwhile, the vesicle containing the engulfed pathogen fuses with lysosomes that contain digestive enzymes and small peptides called **defensins**. This process, which reduces the number of granules in the cytoplasm, is called **degranulation**. Defensins kill a variety of pathogens, including bacteria, fungi, and some viruses, by combining to form large channels in their cell membranes. The digestive enzymes then break down the bacterial remains. While actively engaged in attacking bacteria, a neutrophil releases prostaglandins and leukotrienes. l**p. 595** The prostaglandins increase capillary permeability in the affected region, thereby contributing to local inflammation and restricting the spread of injury and infection. Leukotrienes are hormones that attract other phagocytes and help coordinate the immune response.

Most neutrophils have a short life span, surviving in the bloodstream for only about 10 hours. When actively engulfing debris or pathogens, they may last 30 minutes or less. A neutrophil dies after engulfing one to two dozen bacteria, but its breakdown releases chemicals that attract other neutrophils to the site. A mixture of dead neutrophils, cellular debris, and other waste products form the *pus* associated with infected wounds.

2

Eosinophils

Eosinophils (
¯e
-
¯o
-SIN-
¯o
-filz) were so named because their granules stain darkly with *eosin*, a red dye. The granules also stain
with other acid dyes, so the name **acidophils** (a-SID-
¯o
-filz) applies as well. Eosinophils, which generally represent 2–4 percent
of the circulating WBCs, are similar in size to neutrophils. However, the combination of deep red granules and a bilobed (twolobed) nucleus makes eosinophils easy to identify (Figure 19–9b•).

Eosinophils attack objects that are coated with antibodies. Although they will engulf antibody-marked bacteria, protozoa, or cellular debris, their primary mode of attack is the exocytosis of toxic compounds, including nitric oxide and cytotoxic enzymes. This is particularly effective against multicellular parasites, such as flukes or parasitic worms, that are too big to engulf. The number of circulating eosinophils increases dramatically during a parasitic infection. AM: The Nature of Pathogens

Because they are sensitive to circulating *allergens* (materials that trigger allergies), eosinophils increase in number during allergic reactions as well. Eosinophils are also attracted to sites of injury, where they release enzymes that reduce the degree of inflammation produced by mast cells and neutrophils, thus controlling the spread of inflammation to adjacent tissues.

Basophils

¯A

-s

¯o

-filz) have numerous granules that stain darkly with basic dyes. In a standard blood smear, the inclusions are

Basophils (B

deep purple or blue (Figure 19–9c•). Measuring 8–10 mm in diameter, basophils are smaller than neutrophils or eosinophils. They are also relatively rare, accounting for less than 1 percent of the circulating WBC population.

Basophils migrate to injury sites and cross the capillary endothelium to accumulate in the damaged tissues, where they discharge their granules into the interstitial fluids. The granules contain *histamine,* which dilates blood vessels, and *heparin,* a compound that prevents blood clotting. Stimulated basophils release these chemicals into the interstitial fluids, and their arrival en

hances the local inflammation initiated by mast cells. l**p. 136** Although the same compounds are released by mast cells in damaged connective tissues, mast cells and basophils are distinct populations with separate origins. Other chemicals released by stimulated basophils attract eosinophils and other basophils to the area.

Monocytes

Monocytes (MON-

ı red blood cell. When flattened in a blood smear, they look even larger, so monocytes are relatively easy to identify. The nucleus is large and tends to be oval or kidney bean–shaped rather than lobed (Figure 19–9d•). Monocytes normally account for 2–8 percent of circulating WBCs.

An individual monocyte uses the bloodstream for transportation, remaining in circulation for only about 24 hours before entering peripheral tissues to become a tissue macrophage. Macrophages are aggressive phagocytes, often attempting to engulf items as large as or larger than themselves. While phagocytically active, they release chemicals that attract and stimulate neutrophils, monocytes, and other phagocytic cells. Active macrophages also secrete substances that draw fibroblasts into the region. The fibroblasts then begin producing scar tissue, which will wall off the injured area.

Lymphocytes

–

–o

ts) in blood are spherical cells that may exceed 15 m in diameter, nearly twice the diameter of a typical -s

m

Typical **lymphocytes** (LIM-f

ı lymphocytes typically have a relatively large, round nucleus surrounded by a thin halo of cytoplasm (Figure 19–9e•).

Lymphocytes account for 20–30 percent of the circulating WBC population. Lymphocytes continuously migrate from the bloodstream, through peripheral tissues, and back to the bloodstream. Circulating lymphocytes represent only a minute fraction of all lymphocytes, for at any moment most of your body’s lymphocytes are in other connective tissues and in organs of the lymphatic system.

The circulating blood contains three functional classes of lymphocytes, which cannot be distinguished with a light microscope:

1. T cells are responsible for *cell-mediated immunity*, a specific defense mechanism against invading foreign cells and tissues, and for the coordination of the immune response. T cells either enter peripheral tissues and attack foreign cells directly or control

–

the activities of other lymphocytes.

1. **2. B cells** are responsible for *humoral immunity*, a specific defense mechanism that involves the production and distribution of antibodies, which in turn attack foreign antigens throughout the body. Activated B cells differentiate into **plasma cells**, which are specialized to synthesize and secrete antibodies. Whereas the T cells responsible for cellular immunity must migrate to their targets, the antibodies produced by plasma cells in one location can destroy antigens almost anywhere in the body.

2. **3. Natural killer (NK) cells** are responsible for *immune surveillance*—the detection and subsequent destruction of abnormal tissue cells. NK cells, sometimes known as *large granular lymphocytes*, are important in preventing cancer.

The Differential Count and Changes in WBC Profiles

A variety of conditions, including pathogenic infection, inflammation, and allergic reactions, cause characteristic changes in circulating populations of WBCs. By examining a stained blood smear, we can obtain a **differential count** of the WBC population. The values reported indicate the number of each type of cell in a sample of 100 WBCs.

¯o

ts) are slightly larger than RBCs and lack abundant, deeply stained granules. In blood smears, -s

The normal range for each type of WBC is indicated in Table 19–3. The term **leukopenia** (loo-k

¯o

-P

‾E

-ne-uh; *penia*, poverty)

indicates inadequate numbers of WBCs. **Leukocytosis** (loo-k

–

ı cytosis is normal during an infection. Extreme leukocytosis (100,000> ml or more) generally indicates the presence of some form

‾o

-TO-sis) refers to excessive numbers of WBCs. A modest leuko--s

of **leukemia** (loo-K

‾E

-m

‾e

-uh). Treatment helps in some cases, but unless treated, all leukemias are fatal. The endings -*penia* and

-*osis* can also indicate low or high numbers of specific types of WBCs. For example, *lymphopenia* means too few lymphocytes, and *lymphocytosis* means too many. AM: The Leukemias

100 Keys | White blood cells (WBCs) are usually outnumbered by RBCs by a ratio of 1000:1. WBCs are responsible for defending the body against infection, foreign cells, or toxins, and for assisting in the cleanup and repair of damaged tissues. The most numerous are neutrophils, which engulf bacteria, and lymphocytes, which are responsible for the specific defenses of the immune response.

WBC Production

Stem cells responsible for the production of WBCs originate in the bone marrow, with the divisions of hemocytoblasts (Figure 19–10•). As previously noted, hemocytoblast divisions produce myeloid stem cells and lymphoid stem cells. Myeloid stem cell division creates **progenitor cells**, which give rise to all the formed elements except lymphocytes. One type of progenitor cell produces daughter cells that mature into RBCs; a second type produces cells that manufacture platelets. Neutrophils, eosinophils, basophils, and monocytes develop from daughter cells produced by a third type of progenitor cell.

All WBCs except monocytes complete their development in the bone marrow. (Monocytes begin their differentiation in the bone marrow, enter the bloodstream, and complete development when they become free macrophages in peripheral tissues.) Developing basophils, eosinophils, and neutrophils go through a characteristic series of maturational stages, proceeding from *blast cells* to *myelocytes* to *band cells* before becoming mature WBCs. For example, a cell differentiating into a neutrophil goes from a myeloblast to a *neutrophilic myelocyte* and then becomes a *neutrophilic band cell*. Some band cells enter the bloodstream before completing their maturation; normally, 3–5 percent of all circulating WBCs are band cells. Many of the lymphoid stem cells responsible for the production of lymphocytes migrate from the bone marrow to peripheral **lymphoid tissues**, including the thymus, spleen, and lymph nodes. As a result, lymphocytes are produced in these organs as well as in the bone marrow. The process of lymphocyte production is called **lymphopoiesis**.

Regulation of WBC Production

Factors that regulate lymphocyte maturation remain incompletely understood. Until adulthood, hormones produced by the thymus promote the differentiation and maintenance of T cell populations. The importance of the thymus in adults, especially with respect to aging, remains controversial. In adults, the production of B and T lymphocytes is regulated primarily by exposure to antigens (foreign proteins, cells, or toxins). When antigens appear, lymphocyte production escalates. We will describe the control mechanisms in Chapter 22.

Several hormones are involved in the regulation of other WBC populations. The targets of these hormones, called **colony-stimulating factors (CSFs)**, are shown in Figure 19–10•. Four CSFs have been identified, each stimulating the formation of WBCs or both WBCs and RBCs. The designation for each factor indicates its target:

1. **1. M-CSF** stimulates the production of monocytes.
2. **2. G-CSF** stimulates the production of granulocytes (neutrophils, eosinophils, and

basophils).

3. **3. GM-CSF** stimulates the production of both granulocytes and monocytes.

4. **4. Multi-CSF** accelerates the production of granulocytes, monocytes, platelets, and RBCs.

Chemical communication between lymphocytes and other WBCs assists in the coordination of the immune response. For example, active macrophages release chemicals that make lymphocytes more sensitive to antigens and that accelerate the development of specific immunity. In turn, active lymphocytes release multi-CSF and GM-CSF, reinforcing nonspecific defenses. Immune system hormones are currently being studied intensively because of their potential clinical importance. The molecular structures of many of the stimulating factors have been identified, and several can be produced by genetic engineering. The U.S. Food and Drug Administration approved the administration of synthesized forms of EPO, G-CSF, and GM-CSF to stimulate the production of specific blood cell lines. For instance, a genetically engineered form of G-CSF, sold under the name *filgrastim* (*Neupogen*), is used to stimulate the production of neutrophils in patients undergoing cancer chemotherapy.

How do basophils respond during inflammation?

Answers begin on p. A–1

Platelets

Objective

- Describe the structure, function, and production of platelets.

Platelets (PLA¯T-lets) are flattened discs that appear round when viewed from above, and spindle shaped in section or in a blood smear (see Figure 19–9e•). They average about 4 mm in diameter and are roughly 1 mm thick. Platelets in nonmammalian verte

brates are nucleated cells called **thrombocytes** (THROM-b

–

ı than individual cells, the term *platelet* is preferred when referring to our blood. Platelets are a major participant in a vascular *clotting system* that also includes plasma proteins and the cells and tissues of the blood vessels.

Platelets are continuously replaced. Each platelet circulates for 9–12 days before being removed by phagocytes, mainly in the spleen. Each microliter of circulating blood contains 150,000–500,000 platelets; 350,000> ml is the average concentration. Roughly one-third of the platelets in the body at any moment are held in the spleen and other vascular organs, rather than in the bloodstream. These reserves are mobilized during a circulatory crisis, such as severe bleeding.

¯o

ts; *thrombos*, clot). Because in humans they are cell fragments rather -s

An abnormally low platelet count (80,000> ml

–

or less) is known as **thrombocytopenia** (throm-b ı -t

¯o

-P

E¯

-n

¯e

-uh). Throm-

¯o

-s bocytopenia generally indicates excessive platelet destruction or inadequate platelet production. Signs include bleeding along the

digestive tract, within the skin, and occasionally inside the CNS. In **thrombocytosis** (throm-b

¯o

-s

-T

¯O

-sis), platelet counts can

ı exceed 1,000,000> ml. Thrombocytosis generally results from accelerated platelet formation in response to infection, inflammation, or cancer.

Platelet Functions

The functions of platelets include:

- **The Release of Chemicals Important to the Clotting Process.** By releasing enzymes and other factors at the appropriate times,

–

platelets help initiate and control the clotting process.

. - **The Formation of a Temporary Patch in the Walls of Damaged Blood Vessels.** Platelets clump together at an injury site, forming a *platelet plug*, which can slow the rate of blood loss while clotting occurs.

. - **Active Contraction after Clot Formation Has Occurred.** Platelets contain filaments of actin and myosin. After a blood clot has formed, the contraction of platelet filaments shrinks the clot and reduces the size of the break in the vessel wall.

Platelet Production

Platelet production, or **thrombocytopoiesis**, occurs in the bone marrow. Normal bone marrow contains a number of **megakaryo-**

ı nuclei (see Figure 19–10•). During their development and growth, megakaryocytes manufacture structural proteins, enzymes, and membranes. They then begin shedding cytoplasm in small membrane-enclosed packets. These packets are the platelets that enter the bloodstream. A mature megakaryocyte gradually loses all of its cytoplasm, producing about 4000 platelets before the nucleus is engulfed by phagocytes and broken down for recycling.

The rate of megakaryocyte activity and platelet formation is stimulated by (1) *thrombopoietin* (TPO), or *thrombocyte-stimulat-ing factor,* a peptide hormone produced in the kidneys (and perhaps other sites) that accelerates platelet formation and stimulates the production of megakaryocytes; (2) *interleukin-6* (IL-6), a hormone that stimulates platelet formation; and (3) multi-CSF, which stimulates platelet production by promoting the formation and growth of megakaryocytes.

Hemostasis

Objective

- Discuss mechanisms that control blood loss after an injury, and describe the reaction sequences responsible for blood clotting.

The process of **hemostasis** (*haima*, blood + *stasis*, halt), the cessation of bleeding, halts the loss of blood through the walls of

–

damaged vessels. At the same time, it establishes a framework for tissue repairs. Hemostasis consists of three phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase*. However, the boundaries of these phases are somewhat arbitrary. In reality, hemostasis is a complex cascade in which many things happen at once, and all of them interact to some degree.

The Vascular Phase

Cutting the wall of a blood vessel triggers a contraction in the smooth muscle fibers of the vessel wall (Figure 19–11•). This local contraction of the vessel is a **vascular spasm**, which decreases the diameter of the vessel at the site of injury. Such a constriction can slow or even stop the loss of blood through the wall of a small vessel. The vascular spasm lasts about 30 minutes, a period called the **vascular phase** of hemostasis.

During the vascular phase, changes occur in the endothelium of the vessel at the injury site:

. • **The Endothelial Cells Contract and Expose the Underlying Basal**

Lamina to the Bloodstream.

. • **The Endothelial Cells Begin Releasing Chemical Factors and Local Hormones.** We will discuss several of these factors, including *ADP*, *tissue factor*, and *prostacyclin*, in later sections. Endothelial cells also release **endothelins**, peptide hormones that

(1) stimulate smooth muscle contraction and promote vascular spasms and (2) stimulate the division of endothelial cells, smooth muscle cells, and fibroblasts to accelerate the repair process.

- **The Endothelial Cell Membranes Become "Sticky."** A tear in the wall of a small artery or vein may be partially sealed off by the attachment of endothelial cells on either side of the break. In small capillaries, endothelial cells on opposite sides of the vessel may stick together and prevent blood flow along the damaged vessel. The stickiness is also important because it facilitates the attachment of platelets as the platelet phase gets under way.

The Platelet Phase

The attachment of platelets to sticky endothelial surfaces, to the basal lamina, and to exposed collagen fibers marks the start of the **platelet phase** of hemostasis (see Figure 19–11•). The attachment of platelets to exposed surfaces is called **platelet adhesion**. As

cytes (meg-a-KAR-

¯e ¯o

ts; *mega*-, big *karyon*, nucleus -*cyte*, cell), enormous cells (up to 160 m in diameter) with large

+

+

-

-s

m

more and more platelets arrive, they begin sticking to one another as well. This process, called **platelet aggregation**, forms a **platelet plug** that may close the break in the vessel wall if the damage is not severe or the vessel is relatively small. Platelet aggregation begins within 15 seconds after an injury occurs.

As they arrive at the injury site, platelets become activated. The first sign of activation is that they become more spherical and develop cytoplasmic processes that extend toward adjacent platelets. At this time, the platelets begin releasing a wide variety of compounds, including (1) *adenosine diphosphate* (*ADP*), which stimulates platelet aggregation and secretion; (2) *thromboxane* A_2 and *serotonin*, which stimulate vascular spasms; (3) *clotting factors*, proteins that play a role in blood clotting; (4) *platelet-derived growth factor* (*PDGF*), a peptide that promotes vessel repair; and (5) calcium ions, which are required for platelet aggregation and in several steps in the clotting process.

The platelet phase proceeds rapidly, because ADP, thromboxane, and calcium ions released from each arriving platelet stimulate further aggregation. This positive feedback loop ultimately produces a platelet plug that will be reinforced as clotting occurs. However, platelet aggregation must be controlled and restricted to the site of injury. Several key factors limit the growth of the platelet plug: (1) **prostacyclin**, a prostaglandin that inhibits platelet aggregation and is released by endothelial cells; (2) inhibitory compounds released by white blood cells entering the area; (3) circulating plasma enzymes that break down ADP near the plug;

(4) compounds that, when abundant, inhibit plug formation (for example, serotonin, which at high concentrations blocks the action of ADP); and (5) the development of a blood clot, which reinforces the platelet plug, but isolates it from the general circulation.

The Coagulation Phase

The vascular and platelet phases begin within a few seconds after the injury. The **coagulation** (c

¯o

-ag-

¯u

-L

A¯

-shun) **phase** does

not start until 30 seconds or more after the vessel has been damaged. **Coagulation**, or *blood clotting*, involves a complex sequence of steps leading to the conversion of circulating fibrinogen into the insoluble protein fibrin. As the fibrin network grows, it covers the surface of the platelet plug. Passing blood cells and additional platelets are trapped in the fibrous tangle, forming a **blood clot** that effectively seals off the damaged portion of the vessel. Figure 19–12• shows the formation and structure of a blood clot.

Clotting Factors

Normal blood clotting depends on the presence of **clotting factors**, or **procoagulants**, in the plasma. Important clotting factors include Ca^{2+} and 11 different proteins (Table 19–4).

Many of the proteins are **proenzymes**, which, when converted to active enzymes, direct essential reactions in the clotting response. The activation of one proenzyme commonly creates an enzyme that activates a second proenzyme, and so on in a chain reaction, or *cascade*. During the coagulation phase, enzymes and proenzymes interact.

Figure 19–12a• depicts the cascades involved in the *extrinsic*, *intrinsic*, and *common pathways*. The extrinsic pathway begins outside the bloodstream, in the vessel wall; the intrinsic pathway begins inside the bloodstream, with the activation of a circulating proenzyme. These two pathways converge at the common pathway. AM: The Clotting System: A Closer Look

The Extrinsic Pathway

The **extrinsic pathway** begins with the release of **Factor III**, also known as **tissue factor (TF)**, by damaged endothelial cells or

peripheral tissues. The greater the damage, the more tissue factor is released and the faster clotting occurs. Tissue factor then combines with Ca^{2+} and another clotting factor (Factor VII) to form an enzyme complex capable of activating Factor X, the first step in the common pathway.

The Intrinsic Pathway

The **intrinsic pathway** begins with the activation of proenzymes (usually Factor XII) exposed to collagen fibers at the injury site (or a glass surface of a slide or collection tube). This pathway proceeds with the assistance of **PF-3**, a platelet factor released by aggregating platelets. Platelets also release a variety of other factors that accelerate the reactions of the intrinsic pathway. After a series of linked reactions, activated Factors VIII and IX combine to form an enzyme complex capable of activating Factor X.

The Common Pathway

The **common pathway** begins when enzymes from either the extrinsic or intrinsic pathway activate Factor X, forming the enzyme **prothrombinase**. Prothrombinase converts the proenzyme prothrombin into the enzyme **thrombin** (THROM-bin). Thrombin then completes the clotting process by converting fibrinogen, a soluble plasma protein, to insoluble strands of fibrin.

Interactions among the Pathways

When a blood vessel is damaged, both the extrinsic and the intrinsic pathways respond. The extrinsic pathway is shorter and faster than the intrinsic pathway, and it is usually the first to initiate clotting. In essence, the extrinsic pathway produces a small amount of thrombin very quickly. This quick patch is reinforced by the intrinsic pathway, which produces more thrombin, but somewhat later.

The time required to complete clot formation varies with the site and the nature of the injury. In tests of the clotting system, blood held in fine glass tubes normally clots in 8–18 minutes (the *coagulation time*), and a small puncture wound typically stops bleeding in 1–4 minutes (the *bleeding time*).

Feedback Control of Blood Clotting

Thrombin generated in the common pathway stimulates blood clotting by (1) stimulating the formation of tissue factor and (2) stimulating the release of PF-3 by platelets. Thus, the activity of the common pathway stimulates both the intrinsic and extrinsic pathways. This positive feedback loop accelerates the clotting process, and speed can be very important in reducing blood loss after a severe injury.

Blood clotting is restricted by substances that either deactivate or remove clotting factors and other stimulatory agents from the blood. Examples include the following:

. • Normal plasma contains several **anticoagulants**—enzymes that inhibit clotting. One, **antithrombin-III**, inhibits several clotting factors, including thrombin.

. • **Heparin**, a compound released by basophils and mast cells, is a cofactor that accelerates the activation of antithrombin-III. Heparin is used clinically to impede or prevent clotting.

. • **Thrombomodulin** is released by endothelial cells. This protein binds to thrombin and converts it to an enzyme that activates protein C. **Protein C** is a plasma protein that inactivates several clotting factors and stimulates the formation of *plasmin*, an enzyme that gradually breaks down fibrin strands.

. • Prostacyclin released during the platelet phase inhibits platelet aggregation and opposes the stimulatory action of thrombin, ADP, and other factors.

. • Other plasma proteins with anticoagulant properties include *alpha-2-macroglobulin*, which inhibits thrombin, and *C*1 *inactivator*, which inhibits several clotting factors involved in the intrinsic pathway.

The clotting process involves a complex chain of events, and disorders that affect any individual clotting factor can disrupt the entire process. As a result, managing many clinical conditions involves controlling or manipulating the clotting response. AM: Abnormal Hemostasis

Calcium Ions, Vitamin K, and Blood Clotting

Calcium ions and **vitamin K** affect almost every aspect of the clotting process. All three pathways (intrinsic, extrinsic, and common) require Ca^{2+} , so any disorder that lowers plasma Ca^{2+} concentrations will impair blood clotting. Adequate amounts of vitamin K must be present for the liver to be able to synthesize four of the clotting factors, including prothrombin. Vitamin K is a fat-soluble vitamin, present in green vegetables, grain, and organ meats, that is absorbed with dietary lipids. Roughly half of the daily requirement is obtained from the diet, and the other half is manufactured by bacteria in the large intestine. A diet inadequate in fats or in vitamin K, or a disorder that affects fat digestion and absorption (such as problems with bile production), or prolonged use of antibiotics that kill normal intestinal bacteria will lead to a vitamin K deficiency. This condition will cause the eventual breakdown of the common pathway due to a lack of clotting factors and, ultimately, deactivation of the entire clotting system.

Clot Retraction

Once the fibrin meshwork has formed, platelets and red blood cells stick to the fibrin strands. The platelets then contract, and the entire clot begins to undergo **clot retraction**, or *syneresis* (sin-ER--sis; “a drawing together”). Clot retraction, which occurs over
e¯a period of 30–60 minutes, (1) pulls the torn edges of the vessel closer together, reducing residual bleeding and stabilizing the injury site, and (2) reduces the size of the damaged area, making it easier for fibroblasts, smooth muscle cells, and endothelial cells to complete repairs.

Fibrinolysis

As the repairs proceed, the clot gradually dissolves. This process, called **fibrinolysis** (f - bri-NOL-i-sis), begins with the activation
–

ı of the proenzyme **plasminogen** by two enzymes: thrombin, produced by the common pathway, and **tissue plasminogen activator** (t-PA), released by damaged tissues at the site of injury. The activation of plasminogen produces the enzyme **plasmin** (PLAZmin), which begins digesting the fibrin strands and eroding the foundation of the clot.

100 Keys | Platelets are involved in the coordination of hemostasis (blood clotting). When platelets are activated by abnormal changes in their local environment, they release clotting factors and other chemicals. Hemostasis is a complex cascade that establishes a fibrous patch that can subsequently be remodeled and then removed as the damaged area is repaired.

Concept Check

A sample of bone marrow has unusually few megakaryocytes. What body process would you expect to be impaired as a result? Vitamin K is fat soluble, and some dietary fat is required for its absorption. How could a diet of fruit juice and water have an effect on blood clotting? Unless chemically treated, blood will coagulate in a test tube. The process begins when Factor XII becomes activated. Which clotting pathway is involved in this process?

Answers begin on p. A–1

To perform its vital functions, blood must be kept in motion. On average, an RBC completes two circuits around the cardiovascular system each minute. The circulation of blood begins in the third week of embryonic development and continues throughout life. If the blood supply is cut off, dependent tissues may die in a matter of minutes. In Chapter 20, we will examine the structure and function of the heart—the pump that maintains this vital blood flow.

Chapter Review

Selected Clinical Terminology

anemia: A condition in which the oxygen-carrying capacity of blood is reduced, owing to low hematocrit or low blood hemoglobin concentrations. (p. 646 and [AM])

embolism: A condition in which a drifting blood clot (an embolus) becomes stuck in a blood vessel, blocking circulation to the area downstream. [AM]

hematocrit: The value that indicates the percentage of whole blood occupied by cellular elements. (p. 644)

hematuria: The presence of red blood cells in urine. (p. 646)

hemoglobinuria: The presence of hemoglobin in urine. (p. 646)

hemolytic disease of the newborn (HDN): A condition in which fetal red blood cells have been destroyed by maternal antibodies.

(p. 653) **hemophilia:** Inherited disorders characterized by the inadequate production of clotting factors. [AM] **hypervolemic:** Having an excessive blood volume. [AM] **hypovolemic:** Having a low blood volume. [AM] **hypoxia:** Low tissue oxygen levels. (p. 649 and [AM]) **jaundice:** A condition characterized by yellow skin and eyes, caused by abnormally high levels of plasma bilirubin; examples include

hemolytic jaundice and *obstructive jaundice*. (p. 647 and [AM])

leukemia: A condition characterized by extremely elevated levels of circulating white blood cells; includes both *myeloid* and *lymphoid* forms. (p. 657 and [AM])

leukocytosis: Excessive numbers of white blood cells in the bloodstream. (p. 657)

leukopenia: Inadequate numbers of white blood cells in the bloodstream. (p. 657)

normochromic: Having red blood cells that contain normal amounts of hemoglobin. [AM]

normocytic: Having cells of normal size. [AM]

normovolemic: Having a normal blood volume. [AM]

plaque: An abnormal accumulation of large quantities of lipids within a blood vessel. [AM]

RBC tests: These tests include a *reticulocyte count*, *hematocrit*, *hemoglobin concentration*, *RBC count*, *mean corpuscular volume*, and *mean corpuscular hemoglobin concentration*. (p. 649 and [AM])

sickle cell anemia: An anemia resulting from the production of an abnormal form of hemoglobin; causes red blood cells to become sickle shaped at low oxygen levels. [AM]

thalassemia: A disorder resulting from the production of an abnormal form of hemoglobin. (p. 645 and [AM])

thrombus: A blood clot attached to the luminal surface of a blood vessel. [AM]

transfusion: A procedure in which blood components are given to someone to restore blood volume or to remedy a deficiency in blood composition. [AM] **venipuncture:** The puncturing of a vein for any purpose, including the withdrawal of blood or the administration of medication. (p. 642)

Study Outline

The Cardiovascular System: An Introduction p. 640

1. The **cardiovascular system** enables the rapid transport of nutrients, respiratory gases, waste products, and cells within the body.

The Nature of Blood p. 640

1. **1.** **Blood** is a specialized fluid connective tissue. Its functions include (1) transporting dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulating the pH and ion composition of interstitial fluids; (3) restricting fluid losses at injury sites; (4) defending the body against toxins and pathogens; and (5) regulating body temperature by absorbing and redistributing heat.

2. **2.** Blood contains **plasma** and **formed elements—red blood cells (RBCs)**, **white blood cells (WBCs)**, and **platelets**. The plasma and formed elements constitute **whole blood**, which can be **fractionated** for analytical or clinical purposes. *(Figure 19–1)*

3. **3.** **Hemopoiesis** is the process of blood cell formation. Circulating stem cells divide to form all types of blood cells.

4. **4.** Whole blood from any region of the body has roughly the same temperature, viscosity, and pH.

Plasma p. 642

1. **1.** Plasma accounts for 46–63 percent of the volume of blood; roughly 92 percent of plasma is water. *(Figure 19–1)*

2. **2.** Plasma differs from interstitial fluid in terms of its oxygen and carbon dioxide levels and the concentrations and types of dissolved proteins.

Plasma Proteins p. 642

1. **3.** The three primary classes of plasma proteins are *albumins, globulins*, and *fibrinogen*.

2. **4.** **Albumins** constitute about 60 percent of plasma proteins. **Globulins** constitute roughly 35 percent of plasma proteins; they include **antibodies (immunoglobulins)**, which attack foreign proteins and pathogens, and **transport globulins**, which bind ions, hormones, and other compounds. **Fibrinogen** molecules are converted to **fibrin** in the clotting process. The removal of fibrinogen from plasma leaves a fluid called **serum**.

3. **5.** The liver synthesizes and releases more than 90 percent of the plasma proteins.

100 Keys | p. 643

Red Blood Cells p. 643 Abundance of RBCs p. 644

1. Red blood cells account for slightly less than half the blood volume and 99.9 percent of the formed elements. The **hematocrit** value indicates the percentage of whole blood occupied by formed elements and is commonly reported as the *volume of packed red cells (VPRC)*. *(Figure 19–1; Table 19–1)*

Structure of RBCs p. 644

1. **2.** Each RBC is a biconcave disc, providing a large surface-to-volume ratio. This shape allows RBCs to stack, bend, and flex. *(Figure -19–2)*

2. **3.** Red blood cells lack most organelles, including mitochondria and nuclei, retaining only the cytoskeleton. They typically degenerate after about 120 days in the bloodstream.

Hemoglobin p. 644

4. Molecules of **hemoglobin (Hb)** account for more than 95 percent of the proteins in RBCs. Hemoglobin is a globular protein formed from two pairs of polypeptide subunits. Each subunit contains a single molecule of **heme** that can reversibly bind an oxygen molecule. Damaged or dead RBCs are recycled by phagocytes. *(Figures 19–3, 19–4)*

RBC Formation and Turnover p. 646

1. **5.** Damaged RBCs are continuously replaced at a rate of approximately 3 million new RBCs entering the bloodstream per second. They are replaced before they **hemolyze**.

2. **6.** The components of hemoglobin are individually recycled; the heme is stripped of its iron and converted to **biliverdin**, which is converted to **bilirubin**. If bile ducts are blocked, bilirubin builds up in skin and eyes, resulting in **jaundice**. *(Figure 19–4)*

3. **7.** Iron is also recycled by being stored in phagocytic cells or transported through the bloodstream, bound to **transferrin**.

RBC Production p. 648

8. **Erythropoiesis**, the formation of red blood cells, occurs only in *red bone marrow* **(myeloid tissue)**. The process speeds up under stimulation by **erythropoiesis-stimulating**

hormone (erythropoietin, EPO). Stages in RBC development include **erythroblasts** and **reticulocytes**. *(Figure 19–5)*

100 Keys | p. 649

Blood Types p. 650

9. **Blood type** is determined by the presence or absence of specific **surface antigens** (*agglutinogens*) in the RBC cell membranes: antigens **A**, **B**, and **Rh (D)**. Antibodies (*agglutinins*) in the plasma will react with RBCs bearing different surface antigens. When an antibody meets its specific surface antigen, the resulting reaction is a **cross-reaction**. *(Figures 19–6 to 19–8; Table 19–2)*

White Blood Cells p. 654

1. White blood cells (**leukocytes**) have nuclei and other organelles. They defend the body against pathogens and remove toxins, wastes, and abnormal or damaged cells.

WBC Circulation and Movement p. 654

2. White blood cells are capable of *margination*, amoeboid movement, and **positive chemotaxis**. Some WBCs are also capable of *phagocytosis*.

Types of WBCs p. 655

1. **3.** *Granular leukocytes* (*granulocytes*) are subdivided into **neutrophils**, **eosinophils**, and **basophils**. Fifty to 70 percent of circulating WBCs are neutrophils, which are highly mobile phagocytes. The much less common eosinophils are phagocytes attracted to foreign compounds that have reacted with circulating antibodies. The relatively rare basophils migrate to damaged tissues and release *histamine* and *heparin*, aiding the inflammatory response. *(Figure 19–9)*

2. **4.** *Agranular leukocytes* (*agranulocytes*) include **monocytes** and **lymphocytes**. Monocytes that migrate into peripheral tissues become tissue macrophages. Lymphocytes, the primary cells of the lymphatic system, include **T cells** (which enter peripheral tissues and attack foreign cells directly, or affect the activities of other lymphocytes), **B cells** (which produce antibodies), and **natural killer (NK) cells** (which destroy abnormal tissue cells). *(Figure 19–9; Summary Table 19–3)*

The Differential Count and Changes in WBC Profiles p. 657

5. A **differential count** of the WBC population can indicate a variety of disorders. **Leukemia** is indicated by extreme **leukocytosis—** that is, excessive numbers of WBCs. *(Summary Table 19–3)*

100 Keys | p. 657

WBC Production p. 657

1. **6.** Granulocytes and monocytes are produced by myeloid stem cells in the bone marrow that divide to create **progenitor cells**. Stem cells also originate in the bone marrow, but many migrate to peripheral **lymphoid tissues**. *(Figure 19–10)*

2. **7.** Factors that regulate lymphocyte maturation are not completely understood. Several **colony-stimulating factors** (CSFs) are involved in regulating other WBC populations and in coordinating RBC and WBC production. *(Figure 19–10)*

Platelets p. 660

1. Platelets are flattened discs that appear round from above and spindle shaped in section. They circulate for 9–12 days before being removed by phagocytes. *(Figure 19–9)*

Platelet Functions p. 660

2. The functions of platelets include (1) transporting and releasing chemicals important to the clotting process, (2) forming a temporary patch in the walls of damaged blood vessels, and (3) contracting after a clot has formed, to reduce the size of the break in the vessel wall.

Platelet Production p. 660

3. During **thrombocytopoiesis**, **megakaryocytes** in the bone marrow release packets of cytoplasm (platelets) into the circulating blood. The rate of platelet formation is stimulated by thrombopoietin or thrombocyte-stimulating factor, interleukin-6, and multi-CSF.

Hemostasis p. 661

1. **Hemostasis** halts the loss of blood through the walls of damaged vessels. It consists of three phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase*.

The Vascular Phase p. 661

2. The **vascular phase** is a period of local blood vessel constriction, or **vascular spasm**, at the injury site. *(Figure 19–11)*

The Platelet Phase p. 661

3. The **platelet phase** follows as platelets are activated, aggregate at the site, and adhere to the damaged surfaces. *(Figure 19–11)*

The Coagulation Phase p. 662

1. **4.** The **coagulation phase** occurs as factors released by platelets and endothelial cells interact with **clotting factors** (through either the **extrinsic pathway**, the **intrinsic pathway**, or the **common pathway**) to form a **blood clot**. In this reaction sequence, suspended fibrinogen is converted to large, insoluble fibers of fibrin. *(Figure 19–12; Table 19–4)*

2. **5.** During **clot retraction**, platelets contract and pull the torn edges of the damaged vessel closer together.

3. **6.** During **fibrinolysis**, the clot gradually dissolves through the action of **plasmin**, the activated form of circulating **plasminogen**.

Fibrinolysis p. 664

100 Keys | p. 664

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

. **1.** The formed elements of the blood include

. **(a)** plasma, fibrin, and serum

. **(b)** albumins, globulins, and fibrinogen

. **(c)** WBCs, RBCs, and platelets

. **(d)** a, b, and c are correct

. **2.** Blood temperature is approximately _____, and blood pH averages _____.

. **(a)** 36°, 7.0 **(b)** 39°, 7.8

. **(c)** 38°C, 7.4 **(d)** 37°C, 7.0

. **3.** Plasma contributes approximately _____ percent of the volume of whole blood, and water accounts for _____ percent of the plasma volume.

. **(a)** 55, 92 **(b)** 25, 55

. **(c)** 92, 55 **(d)** 35, 72

. **4.** Serum is

. **(a)** the same as blood plasma

. **(b)** plasma minus the formed elements

. **(c)** plasma minus the proteins

. **(d)** plasma minus fibrinogen

. **(e)** plasma minus the electrolytes

. **5.** A hemoglobin molecule is composed of

. **(a)** two protein chains

. **(b)** three protein chains

. **(c)** four protein chains and nothing else

. **(d)** four protein chains and four heme groups

. **(e)** four heme groups but no protein

. **6.** The following is a list of the steps involved in the process of hemostasis.

1. **1.** coagulation **2.** fibrinolysis

2. **3.** vascular spasm **4.** retraction

3. **5.** platelet phase

The correct sequence of these steps is

. **(a)** 5, 1, 4, 2, 3 **(b)** 3, 5, 1, 4, 2

. **(c)** 2, 3, 5, 1, 4 **(d)** 3, 5, 4, 1, 2

. **(e)** 4, 3, 5, 2, 1

. **7.** Stem cells responsible for lymphopoiesis are located in the

. **(a)** thymus and spleen **(b)** lymph nodes

. **(c)** red bone marrow **(d)** a, b, and c are correct

. **8.** _____ and _____ affect almost every aspect of the clotting process.

. **(a)** Calcium and vitamin K

. **(b)** Calcium and vitamin B12

. **(c)** Sodium and vitamin K

. **(d)** Sodium and vitamin B12

2. **9.** What five major functions are performed by blood?

3. **10.** What three primary classes of plasma proteins are in the blood? What is the major function of each?

. **11.** Which type of antibodies does plasma contain for each of the following blood types?

. **(a)** Type A **(b)** Type B

. **(c)** Type AB **(d)** Type O

4. **12.** What four characteristics of WBCs are important to their response to tissue invasion or injury?

5. **13.** Which kinds of WBCs contribute to the body’s nonspecific defenses?

6. **14.** Which three classes of lymphocytes are the primary cells of the lymphatic system? What are the functions of each class?

7. **15.** What are the three functions of platelets during the clotting process?

8. **16.** What four conditions cause the release of erythropoietin?

9. **17.** What contribution from the intrinsic and the extrinsic pathways is necessary for the common pathway to begin?

LEVEL 2 Reviewing Concepts

. **18.** Dehydration would cause

. **(a)** an increase in the hematocrit

. **(b)** a decrease in the hematocrit

. **(c)** no effect on the hematocrit

. **(d)** an increase in plasma volume

. **19.** Erythropoietin directly stimulates RBC formation by

. **(a)** increasing rates of mitotic divisions in erythroblasts

. **(b)** speeding up the maturation of red blood cells

. **(c)** accelerating the rate of hemoglobin synthesis

. **(d)** a, b, and c are correct

. **20.** The waste product bilirubin is formed from

. **(a)** transferrin **(b)** globin

. **(c)** heme **(d)** hemosiderin

. **(e)** ferritin

. **21.** A difference between the A, B, and O blood types and the Rh factor is

. **(a)** Rh agglutinogens are not found on the surface of the red blood cells

. **(b)** Rh agglutinogens do not produce a cross reaction

-

. **(c)** individuals who are Rh do not carry agglutinins to Rh factor unless they have been previously sensitized

. **(d)** Rh agglutinogens are found free in the plasma

. **(e)** Rh agglutinogens are found bound to plasma proteins

1. **22.** How do red blood cells differ from white blood cells in both form and function?
2. **23.** How does blood defend against toxins and pathogens in the body?
3. **24.** What is the role of blood in the stabilization and maintenance of body temperature?
4. **25.** Describe the structure of hemoglobin. How does the structure relate to its function?
5. **26.** Why is aspirin sometimes prescribed for the prevention of vascular problems?

LEVEL 3 Critical Thinking and Clinical Applications

1. **27.** A test for prothrombin time is used to determine deficiencies in the extrinsic clotting pathway and is prolonged if any of the factors are deficient. A test for activated partial thromboplastin time is used in a similar fashion to detect deficiencies in the intrinsic clotting pathway. Which factor would be deficient if a person had a prolonged prothrombin time but a normal partial thromboplastin time?

2. **28.** In the disease mononucleosis (“mono”), the spleen enlarges because of increased numbers of cells—both phagocytic as well as others. Common symptoms of this disease include pale complexion, a tired feeling, and a lack of energy sometimes to the point of not being able to get out of bed. What might cause these symptoms?

3. **29.** Almost half of our vitamin K is synthesized by bacteria that inhabit the large intestine. Based on this information, why would taking a broad spectrum antibiotic produce frequent nosebleeds?

4. **30.** After Randy was diagnosed with stomach cancer, nearly all of his stomach had to be removed. Postoperative treatment included regular injections of vitamin B12. Why was this vitamin prescribed, and why was injection specified?

TABLE 19–1 RBC Tests and Related Terminology

Terms Associated with Abnormal Values

Test Determines Elevated Depressed

| SUMMARY TABLE 19–3 | FORMED ELEMENTS OF THE BLOOD

Abundance Appearance in a Cell (average number per Ml**) Stained Blood Smear Functions Remarks**

RED BLOOD CELLS 5.2 million (range: Flattened, circular Transport oxygen Remain in bloodstream;

4.4–6.0 million) cell; no nucleus, from lungs to tissues 120-day life expectancy; mitochondria, or and carbon dioxide amino acids and iron ribosomes; red from tissues to lungs recycled; produced in

bone marrow

WHITE BLOOD CELLS 7000 (range: 6000–9000)

Neutrophils 4150 (range: Round cell; nucleus 1800–7300) lobed and may Differential count: resemble a string 50–70% of beads; cytoplasm

contains large, pale inclusions

Phagocytic: Engulf Move into tissues after pathogens or debris several hours; may survive in tissues, release minutes to days, cytotoxic enzymes depending on tissue and chemicals activity; produced in

bone marrow

Eosinophils 165 (range: 0–700) Round cell; nucleus Differential count: generally in two 2–4% lobes; cytoplasm

contains large granules that generally stain bright red

Phagocytic: Engulf Move into tissues after antibody-labeled several hours; survive materials, release minutes to days, cytotoxic enzymes, depending on tissue reduce inflammation activity; produced in

bone marrow

Basophils 44 (range: 0–150) Round cell; nucleus Differential count: generally cannot be

6 1 % seen through dense,

blue-stained granules

in cytoplasm

Enter damaged tissues Survival time unknown; and release histamine assist mast cells of and other chemicals tissues in producing that promote inflammation; produced inflammation in bone marrow

Monocytes 456 (range: 200–950) Very large cell; kidney Enter tissues to become Move into tissues after Differential count: bean–shaped nucleus; macrophages; engulf 1–2 days; survive for 2–8% abundant pale pathogens or debris months or longer;

cytoplasm produced primarily in bone marrow

Lymphocytes 2185 (range: Generally round cell, Cells of lymphatic Survive for months to 1500–4000) slightly larger than system, providing decades; circulate from Differential count: RBC; round nucleus; defense against blood to tissues and 20–30% very little cytoplasm specific pathogens back; produced in bone

or toxins marrow and lymphoid tissues

PLATELETS 350,000 (range: Round to spindle-shaped Hemostasis: Clump Remain in bloodstream

150,000–500,000) cytoplasmic fragment; together and stick or in vascular organs; contain enzymes and to vessel wall remain intact for proenzymes; no nucleus (platelet phase); 7–12 days; produced

activate intrinsic by megakaryocytes in pathway of bone marrow coagulation phase

The Organization of the Cardiovascular System

Objective

- Describe the organization of the cardiovascular system and of the heart.

Blood flows through a network of blood vessels that extend between the heart and peripheral tissues. Those blood vessels can be subdivided into a **pulmonary circuit**, which carries blood to and from the gas exchange surfaces of the lungs, and a **systemic circuit**, which transports blood to and from the rest of the body (Figure 20–1•). Each circuit begins and ends at the heart, and blood travels through these circuits in sequence. Thus, blood returning to the heart from the systemic circuit must complete the pulmonary circuit before reentering the systemic circuit.

Blood is carried away from the heart by **arteries**, or *efferent vessels*, and returns to the heart by way of **veins**, or *afferent vessels*. Small, thin-walled vessels called **capillaries** interconnect the smallest arteries and the smallest veins. Capillaries are called **exchange vessels**, because their thin walls permit the exchange of nutrients, dissolved gases, and waste products between the blood and surrounding tissues.

Unlike most other muscles, the heart never rests. This extraordinary organ beats approximately 100,000 times each day, pumping roughly 8000 liters of blood—enough to fill forty 55-gallon drums, or 8800 quart-sized milk cartons. Try transferring a gallon of water by using a squeeze pump, and you'll appreciate just how hard the heart has to work to keep you alive. Despite its impressive workload, the heart is a small organ, roughly the size of a clenched fist.

The heart contains four muscular chambers, two associated with each circuit. The **right atrium** (

¯A

-tr

¯e

-um; entry chamber;

plural, *atria*) receives blood from the systemic circuit and passes it to the **right ventricle** (VEN-tri-kl; little belly), which pumps blood into the pulmonary circuit. The **left atrium** collects blood from the pulmonary circuit and empties it into the **left ventricle**, which pumps blood into the systemic circuit. When the heart beats, first the atria contract, and then the ventricles contract. The two ventricles contract at the same time and eject equal volumes of blood into the pulmonary and systemic circuits.

Anatomy of the Heart

Objectives

- Describe the location and general features of the heart.
- Describe the structure of the pericardium and explain its functions.
- Trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves.
- Identify the layers of the heart wall.
- Describe the vascular supply to the heart.

The heart is located near the anterior chest wall, directly posterior to the sternum (Figure 20–2a•). The great veins and arteries

are connected to the superior end of the heart at the attached base. The base sits posterior to the sternum at the level of the third costal cartilage, centered about 1.2 cm (0.5 in.) to the left side. The inferior, pointed tip of the heart is the free **apex** (A¯-peks). A typical adult heart measures approximately 12.5 cm (5 in.) from the base to the apex, which reaches the fifth intercostal space approximately 7.5 cm (3 in.) to the left of the midline. A midsagittal section through the trunk does not divide the heart into two equal halves, because (1) the center of the base lies slightly to the left of the midline, (2) a line drawn between the center of the base and the apex points further to the left, and (3) the entire heart is rotated to the left around this line, so that the right atrium and right ventricle dominate an anterior view of the heart.

¯e

The heart, surrounded by the *pericardial* (per-i-KAR-d -al) *sac*, sits in the anterior portion of the mediastinum. The **mediastinum**, the region between the two pleural cavities, also contains the great vessels, thymus, esophagus, and trachea. Figure 20–2b• is a sectional view that illustrates the position of the heart relative to other structures in the mediastinum.

The Pericardium

The lining of the pericardial cavity is called the **pericardium**. To visualize the relationship between the heart and the pericardial cavity, imagine pushing your fist toward the center of a large, partially inflated balloon (Figure 20–2c•). The balloon represents the pericardium, and your fist is the heart. Your wrist, where the balloon folds back on itself, corresponds to the *base* of the heart, to which the *great vessels*, the largest veins and arteries in the body, are attached. The air space inside the balloon corresponds to the pericardial cavity.

The pericardium is lined by a delicate serous membrane that can be subdivided into the visceral pericardium and the parietal pericardium. The **visceral pericardium**, or *epicardium*, covers and adheres closely to the outer surface of the heart; the **parietal pericardium** lines the inner surface of the **pericardial sac**, which surrounds the heart (Figure 20–2c•). The pericardial sac, or *fibrous pericardium*, which consists of a dense network of collagen fibers, stabilizes the position of the heart and associated vessels within the mediastinum.

The small space between the parietal and visceral surfaces is the pericardial cavity. It normally contains 15–50 ml of **pericardial fluid**, secreted by the pericardial membranes. This fluid acts as a lubricant, reducing friction between the opposing surfaces as the heart beats. Pathogens can infect the pericardium, producing the condition **pericarditis**. The inflamed pericardial surfaces rub against one another, producing a distinctive scratching sound that can be heard through a stethoscope. The pericardial irritation and inflammation also commonly result in an increased production of pericardial fluid. Fluid then collects in the pericardial cavity, restricting the movement of the heart. This condition, called *cardiac tamponade* (tam-po-NA¯D; *tampon*, plug), can also be caused by traumatic injuries (such as stab wounds) that produce bleeding into the pericardial cavity. AM: Infection and Inflammation of the Heart

Superficial Anatomy of the Heart

The four cardiac chambers can easily be identified in a superficial view of the heart (Figure 20–3•). The two atria have relatively thin muscular walls and are highly expandable. When not filled with blood, the outer portion of each atrium deflates and becomes a lumpy, wrinkled flap. This expandable extension of an atrium is called an *atrial appendage*, or an **auricle** (AW-ri-kl; *auris*, ear), because it reminded early anatomists of the external ear (Figure 20–3a•). The **coronary sulcus**, a deep groove, marks the border between the atria and the ventricles. The **anterior interventricular sulcus** and the **posterior interventricular sulcus**, shallower depressions, mark the boundary between the left and right ventricles (Figure 20–3a,b•).

The connective tissue of the epicardium at the coronary and interventricular sulci generally contains substantial amounts of fat. In fresh or preserved hearts, this fat must be stripped away to expose the underlying grooves. These sulci also contain the arteries and veins that carry blood to and from the cardiac muscle.

The Heart Wall

A section through the wall of the heart reveals three distinct layers: an outer epicardium, a middle myocardium, and an inner endocardium. Figure 20–4a• illustrates these three layers:

1. The **epicardium** is the visceral pericardium that covers the outer surface of the heart. This serous membrane consists of an exposed mesothelium and an underlying layer of loose areolar connective tissue that is attached to the myocardium.

2. The **myocardium**, or muscular wall of the heart, forms both atria and ventricles. This layer contains cardiac muscle tissue, blood vessels, and nerves. The myocardium consists of concentric layers of cardiac muscle tissue. The atrial myocardium contains muscle bundles that wrap around the atria and form figure eights that encircle the great vessels (Figure 20–4b•). Superficial ventricular muscles wrap around both ventricles; deeper muscle layers spiral around and between the ventricles toward the apex.

3. The inner surfaces of the heart, including those of the heart valves, are covered by the **endocardium**, a simple squamous epithelium that is continuous with the endothelium of the attached great vessels.

Cardiac Muscle Tissue

As noted in Chapter 10, **cardiac muscle cells** are interconnected by **intercalated discs** (Figure 20–5a,b•). At an intercalated disc, the interlocking membranes of adjacent cells are held together by desmosomes and linked by gap junctions (Figure 20–5c•). Intercalated discs convey the force of contraction from cell to cell and propagate action potentials. Table 20–1 provides a quick review of the structural and functional differences between cardiac muscle cells and skeletal muscle fibers. Among the histological characteristics of cardiac muscle cells that differ from those of skeletal muscle fibers are (1) small size; (2) a single, centrally located nucleus; (3) branching interconnections between cells; and (4) the presence of intercalated discs.

Internal Anatomy and Organization

In this section we examine the major landmarks and structures visible on the interior surface of the heart. In a sectional view, you can see that the right atrium communicates with the right ventricle, and the left atrium with the left ventricle (Figure 20–6a,c•). The atria are separated by the **interatrial septum** (*septum*, wall); the ventricles are separated by the much thicker **interventricular septum**. Each septum is a muscular partition. **Atrioventricular (AV) valves**, folds of fibrous tissue, extend into the openings be

tween the atria and ventricles. These valves permit blood flow in one direction only: from the atria to the ventricles.

The Right Atrium

The right atrium receives blood from the systemic circuit through the two great veins: the **superior vena cava** (V

¯E

-na K

¯A

-vuh;

plural, *venae cavae*) and the **inferior vena cava**. The superior vena cava, which opens into the posterior and superior portion of the right atrium, delivers blood to the right atrium from the head, neck, upper limbs, and chest. The inferior vena cava, which opens into the posterior and inferior portion of the right atrium, carries blood to the right atrium from the rest of the trunk, the viscera, and the lower limbs. The *cardiac veins* of the heart return blood to the **coronary sinus**, a large, thin-walled vein that opens into the right atrium inferior to the connection with the superior vena cava.

The opening of the coronary sinus lies near the posterior edge of the interatrial septum. From the fifth week of embryonic development until birth, the **foramen ovale**, an oval opening, penetrates the interatrial septum and connects the two atria of the fetal heart. Before birth, the foramen ovale permits blood flow from the right atrium to the left atrium while the lungs are developing. At birth, the foramen ovale closes, and the opening is permanently sealed off within three months of delivery. (If the foramen ovale does not close, serious cardiovascular problems result; these are considered in Chapter 21.) The

fossa ovalis, a small, shallow depression, persists at this site in the adult heart (see Figure 20–6a,c•). ATLAS: Embryology Summary 15: The Development of the Heart

The posterior wall of the right atrium and the interatrial septum have smooth surfaces. In contrast, the anterior atrial wall and the inner surface of the auricle contain prominent muscular ridges called the **pectinate muscles** (*pectin*, comb), or *musculi pectinati* (see Figure 20–6a,c•).

The Right Ventricle

Blood travels from the right atrium into the right ventricle through a broad opening bounded by three fibrous flaps. These flaps,

–

called **cusps** or *leaflets*, are part of the **right atrioventricular (AV) valve**, also known as the **tricuspid** (tr -KUS-pid; *tri*, three)

ı **valve**. The free edge of each cusp is attached to tendinous connective-tissue fibers called the **chordae tendineae** (KOR-d

¯e

TEN-

¯e

; tendinous cords). The fibers originate at the **papillary** (PAP-i-ler-) **muscles**, conical muscular projections that arise from the inner surface of the right ventricle (see Figure 20–6a,b•). The right AV valve closes when the right ventricle contracts, preventing the backflow of blood into the right atrium. Without the chordae tendineae, the cusps would be like swinging doors that permitted blood flow in both directions.

di-n

¯e

-

¯e

The internal surface of the ventricle also contains a series of muscular ridges: the **trabeculae carneae** (tra-BEK-

¯u

-l

¯e

KAR-

n-; *carneus*, fleshy). The *moderator band* is a muscular ridge that extends horizontally from the inferior portion of the interventricular septum and connects to the anterior papillary muscle. This ridge contains a portion of the *conducting system*, an internal network that coordinates the contractions of cardiac muscle cells. The moderator band delivers the stimulus for contraction to the papillary muscles, so that they begin tensing the chordae tendineae before the rest of the ventricle contracts.

The superior end of the right ventricle tapers to the **conus arteriosus**, a conical pouch that ends at the **pulmonary valve**, or *pulmonary semilunar valve*. The pulmonary valve consists of three semilunar (half-moon–shaped) cusps of thick connective tissue. Blood flowing from the right ventricle passes through this valve to enter the **pulmonary trunk**, the start of the pulmonary circuit. The arrangement of cusps prevents backflow as the right ventricle relaxes. Once in the pulmonary trunk, blood flows into the **left pulmonary arteries** and the **right pulmonary arteries**. These vessels branch repeatedly within the lungs before supplying the capillaries where gas exchange occurs.

The Left Atrium

From the respiratory capillaries, blood collects into small veins that ultimately unite to form the four pulmonary veins. The pos-

¯e

terior wall of the left atrium receives blood from two **left** and two **right pulmonary veins**. Like the right atrium, the left atrium

¯e

–

has an auricle. A valve, the **left atrioventricular (AV) valve**, or **bicuspid** (b -KUS-pid) **valve**, guards the entrance to the left ven-

ı tricle (see Figure 20–6a,c•). As the name *bicuspid* implies, the left AV valve contains a pair, not a trio, of cusps. Clinicians often

¯I

call this valve the **mitral** (M -tral; *mitre*, a bishop's hat) **valve**. The left AV valve permits the flow of blood from the left atrium into the left ventricle but prevents backflow during ventricular contraction.

The Left Ventricle

Even though the two ventricles hold equal amounts of blood, the left ventricle is much larger than the right ventricle because it has thicker walls. Its thick, muscular wall enables the left ventricle to develop pressure sufficient to push blood through the large systemic circuit, whereas the right ventricle needs to pump blood, at lower pressure, only about 15 cm (6 in.) to and from the lungs. The internal organization of the left ventricle generally resembles that of the right ventricle, except for the absence of a moderator band (see Figure 20–6a,c•). The trabeculae carneae are prominent, and a pair of large papillary muscles tense the chordae tendineae that anchor the cusps of the AV valve and prevent the backflow of blood into the left atrium.

Blood leaves the left ventricle by passing through the **aortic valve**, or *aortic semilunar valve*, into the **ascending aorta**. The arrangement of cusps in the aortic valve is the same as that in the pulmonary valve. Once the blood has been pumped out of the heart and into the systemic circuit, the aortic valve prevents backflow into the left ventricle. From the ascending aorta, blood flows through the **aortic arch** and into the **descending aorta** (see Figure 20–6a•). The pulmonary trunk is attached to the aortic arch by the *ligamentum arteriosum*, a fibrous band that is a remnant of an important fetal blood vessel that once linked the pulmonary and systemic circuits.

Structural Differences between the Left and Right Ventricles

The function of an atrium is to collect blood that is returning to the heart and convey it to the attached ventricle. The functional demands on the right and left atria are similar, and the two chambers look almost identical. The demands on the right and left ventricles, however, are very different, and the two have significant structural differences.

Anatomical differences between the left and right ventricles are best seen in a three-dimensional view (Figure 20–7a•). The lungs are close to the heart, and the pulmonary blood vessels are relatively short and wide. Thus, the right ventricle normally does not need to work very hard to push blood through the pulmonary circuit. Accordingly, the wall of the right ventricle is relatively thin. In sectional view, it resembles a pouch attached to the massive wall of the left ventricle. When it contracts, the right ventricle acts like a bellows, squeezing the blood against the thick wall of the left ventricle. This mechanism moves blood very efficiently with minimal effort, but it develops relatively low pressures.

A comparable pumping arrangement would not be suitable for the left ventricle, because four to six times as much pressure must be exerted to push blood around the systemic circuit as around the pulmonary circuit. The left ventricle has an extremely thick muscular wall and is round in cross section (Figure 20–7a•). When this ventricle contracts, (1) the distance between the base and apex decreases, and (2) the diameter of the ventricular chamber decreases. The effect is similar to simultaneously squeezing and rolling up the end of a toothpaste tube. The pressure generated is more than enough to open the aortic valve and eject blood into the ascending aorta.

As the powerful left ventricle contracts, it also bulges into the right ventricular cavity (Figure 20–7b•). This action improves the efficiency of the right ventricle’s efforts. Individuals whose right ventricular musculature has been severely damaged may survive, because the contraction of the left ventricle helps push blood into the pulmonary circuit. We will return to this topic in Chapter 21, where we consider the integrated functioning of the cardiovascular system. AM: The Cardiomyopathies

The Heart Valves

The heart has a series of one-way valves that prevent the backflow of blood as the chambers contract. We will now consider the structure and function of these heart valves.

The Atrioventricular Valves The atrioventricular (AV) valves prevent the backflow of blood from the ventricles to the atria when the ventricles are contracting. The chordae tendineae and papillary muscles play important roles in the normal function of the AV valves. When the ventricles are relaxed, the chordae tendineae are loose, and the AV valves offer no resistance to the flow of blood from the atria into the ventricles (Figure 20–8a•). When the ventricles contract, blood moving back toward the atria swings the cusps together, closing the valves (Figure 20–8b•). At the same time, the contraction of the papillary muscles tenses the chordae tendineae, stopping the cusps before they swing into the atria. If the chordae tendineae are cut or the papillary muscles are damaged, backflow **(regurgitation)** of blood into the atria occurs each time the ventricles contract.

The Semilunar Valves The pulmonary and aortic valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles, respectively. Unlike the AV valves, the semilunar valves do not require muscular braces, because the arterial walls do not contract and the relative positions of the cusps are stable. When the semilunar valves close, the three symmetrical cusps support one another like the legs of a tripod (Figure 20–8a,c•).

Saclike dilations of the base of the ascending aorta are adjacent to each cusp of the aortic valve. These sacs, called **aortic sinuses**, prevent the individual cusps from sticking to the wall of the aorta when the valve opens. The *right* and *left coronary arteries*, which deliver blood to the myocardium, originate at the aortic sinuses.

Serious valve problems can interfere with cardiac function. If valve function deteriorates to the point at which the heart cannot maintain adequate circulatory flow, symptoms of **valvular heart disease (VHD)** appear. Congenital malformations may be responsible, but in many cases the condition develops after **carditis**, an inflammation of the heart, occurs. One relatively common cause of carditis is **rheumatic** (roo-MAT-ik) **fever**, an acute childhood reaction to infection by streptococcal bacteria. AM: RHD and Valvular Stenosis

100 Keys | The heart has four chambers, two associated with the pulmonary circuit (right atrium and right ventricle) and two with the systemic circuit (left atrium and left ventricle). The left ventricle has a greater workload and is much more massive than the right ventricle, but the two chambers pump equal amounts of blood. AV valves prevent backflow from the ventricles into the atria, and semilunar valves prevent backflow from the aortic and pulmonary trunks into the ventricles.

Connective Tissues and the Fibrous Skeleton

The connective tissues of the heart include large numbers of collagen and elastic fibers. Each cardiac muscle cell is wrapped in a strong, but elastic, sheath, and adjacent cells are tied together by fibrous cross-links, or “struts.” These fibers are, in turn, interwoven into sheets that separate the superficial and deep muscle layers. The connective-tissue fibers (1) provide physical support for the cardiac muscle fibers, blood vessels, and nerves of the myocardium; (2) help distribute the forces of contraction; (3) add strength and prevent overexpansion of the heart; and (4) provide elasticity that helps return the heart to its original size and shape after a contraction.

The **fibrous skeleton** of the heart consists of four dense bands of tough elastic tissue that encircle the heart valves and the bases of the pulmonary trunk and aorta (see Figure 20–8•). These bands stabilize the positions of the heart valves and ventricular muscle cells and electrically insulate the ventricular cells from the atrial cells.

The Blood Supply to the Heart

The heart works continuously, so cardiac muscle cells require reliable supplies of oxygen and nutrients. Although a great volume of blood flows through the chambers of the heart, the myocardium needs its own, separate blood supply. The **coronary circulation** supplies blood to the muscle tissue of the heart. During maximum exertion, the demand for oxygen rises considerably. The blood flow to the myocardium may then increase to nine times that of resting levels. The coronary circulation includes an extensive network of coronary blood vessels (Figure 20–9•).

The Coronary Arteries

The left and right **coronary arteries** originate at the base of the ascending aorta, at the aortic sinuses (see Figure 20–9a•). Blood pressure here is the highest in the systemic circuit. Each time the left ventricle contracts, it forces blood into the aorta. The arrival of additional blood at elevated pressures stretches the elastic walls of the aorta. When the left ventricle relaxes, blood no longer flows into the aorta, pressure declines, and the walls of the aorta recoil. This recoil, called *elastic rebound*, pushes blood both forward, into the systemic circuit, and backward, through the aortic sinus and then into the coronary arteries. Thus, the combination of elevated blood pressure and elastic rebound ensures a continuous flow of blood to meet the demands of active cardiac muscle tissue. However, myocardial blood flow is not steady; it peaks while the heart muscle is relaxed, and almost ceases while it contracts.

The **right coronary artery**, which follows the coronary sulcus around the heart, supplies blood to (1) the right atrium, (2) portions of both ventricles, and (3) portions of the conducting system of the heart, including the *sinoatrial (SA)* and *atrioventricular (AV) nodes*. The cells of these nodes are essential to establishing the normal heart rate. We will focus on their functions and their part in regulating the heart rate in a later section.

Inferior to the right atrium, the right coronary artery generally gives rise to one or more **marginal arteries**, which extend across the surface of the right ventricle (see Figure 20–9a,b•). The right coronary artery then continues across the posterior surface of the heart, supplying the **posterior interventricular artery**, or *posterior descending artery,* which runs toward the apex within the posterior interventricular sulcus (see Figure 20–9b,c•). The posterior interventricular artery supplies blood to the interventricular septum and adjacent portions of the ventricles.

The **left coronary artery** supplies blood to the left ventricle, left atrium, and interventricular septum. As it reaches the anterior surface of the heart, it gives rise to a circumflex branch and an anterior interventricular branch. The **circumflex artery** curves to the left around the coronary sulcus, eventually meeting and fusing with small branches of the right coronary artery (see Figure 20–9a–c•). The much larger **anterior interventricular artery**, or *left anterior descending artery*, swings around the pulmonary trunk and runs along the surface within the anterior interventricular sulcus (see Figure 20–9a•).

The anterior interventricular artery supplies small tributaries continuous with those of the posterior interventricular artery.

Such interconnections between arteries are called **arterial anastomoses** (a-nas-t
¯o
-M

¯O

-s
¯e
z; *anastomosis*, outlet). Because the ar
teries are interconnected in this way, the blood supply to the cardiac muscle remains relatively constant despite pressure fluctuations in the left and right coronary arteries as the heart beats.

The Cardiac Veins

The various cardiac veins are shown in Figure 20–9•. The **great cardiac vein** begins on the anterior surface of the ventricles, along the interventricular sulcus. This vein drains blood from the region supplied by the anterior interventricular artery, a branch of the left coronary artery. The great cardiac vein reaches the level of the atria and then curves around the left side of the heart within the coronary sulcus. The vein empties into the coronary sinus, which lies in the posterior portion of the coronary sulcus. The coronary sinus opens into the right atrium near the base of the inferior vena cava.

Other cardiac veins that empty into the great cardiac vein or the coronary sinus include (1) the **posterior cardiac vein**, draining the area served by the circumflex artery, (2) the

middle cardiac vein, draining the area supplied by the posterior interventricular artery, and (3) the **small cardiac vein**, which receives blood from the posterior surfaces of the right atrium and ventricle. The **anterior cardiac veins**, which drain the anterior surface of the right ventricle, empty directly into the right atrium.

The Heartbeat

Objectives

- Describe the events of an action potential in cardiac muscle and explain the importance of calcium ions to the contractile process.
- Discuss the differences between nodal cells and conducting cells and describe the components and functions of the conducting system of the heart.
- Identify the electrical events associated with a normal electrocardiogram.
- Explain the events of the cardiac cycle, including atrial and ventricular systole and diastole, and relate the heart sounds to specific events in the cycle.

Cardiac Physiology

Figure 20–11• presents an overview of the aspects of cardiac physiology we will consider in this chapter. In a single cardiac contraction, or heartbeat, the entire heart contracts in series—first the atria and then the ventricles. Two types of cardiac muscle cells are involved in a normal heartbeat: (1) specialized muscle cells of the *conducting system*, which control and coordinate the heartbeat, and (2) *contractile cells*, which produce the powerful contractions that propel blood. Each heartbeat begins with an action potential generated at a pacemaker called the *SA node*, which is part of the conducting system. This electrical impulse is then propagated by the conducting system and distributed so that the stimulated contractile cells will push blood in the right direction at the proper time. The electrical events under way in the conducting system can be monitored from the surface of the body through a procedure known as *electrocardiography*; the printed record of the result is called an *electrocardiogram* (*ECG* or *EKG*).

The arrival of an impulse at a cardiac muscle cell membrane produces an action potential that is comparable to an action potential in a skeletal muscle fiber. As in a skeletal muscle fiber, this action potential triggers the contraction of the cardiac muscle cell. Thanks to the coordination provided by the conducting system, the atria contract first, driving blood into the ventricles through the AV valves, and the ventricles contract next, driving blood out of the heart through the semilunar valves.

The SA node generates impulses at regular intervals, and one heartbeat follows another throughout your life. After each heartbeat there is a brief pause—less than half a second—before the next heartbeat begins. The period between the start of one heartbeat and the start of the next is called the *cardiac cycle*.

A heartbeat lasts only about 370 msec. Although brief, it is a very busy period! We will begin our analysis of cardiac function by following the steps that produce a single heartbeat, from the generation of an action potential at the SA node through the contractions of the atria and ventricles.

The Conducting System

In contrast to skeletal muscle, cardiac muscle tissue contracts on its own, in the absence of neural or hormonal stimulation. This property is called **automaticity**, or *autorhythmicity*. The cells responsible for initiating and distributing the stimulus to contract are part of the heart's **conducting system**, also known as the *cardiac conduction system* or the *nodal system*. This system is a network of specialized cardiac muscle cells that initiates and distributes electrical impulses. The actual contraction lags behind the passage of an electrical impulse, with the delay representing the time it takes for calcium ions to enter the sarcoplasm and activate the contraction process, as described in Chapter 10. l**p. 302** The conducting system (Figure 20–12a•) includes the following elements:

- The *sinoatrial (SA) node,* located in the wall of the right atrium.
- The *atrioventricular (AV) node,* located at the junction between the atria and ventricles.
- *Conducting cells,* which interconnect the two nodes and distribute the contractile stimulus throughout the myocardium. In the atria, conducting cells are found in **internodal pathways**, which distribute the contractile stimulus to atrial muscle cells as the impulse travels from the SA node to the AV node. (The importance of these pathways in relaying the signal to the AV node remains in dispute, because an impulse can also spread from contractile cell to contractile cell, reaching the AV node at about the same time as an impulse that traverses an internodal pathway.) The ventricular conducting cells include those in the *AV bundle* and the *bundle branches,* as well as the *Purkinje* (pur-KIN-j) *fibers,* which distribute the stimulus to the ventricular myocardium.

e^{-}

Most of the cells of the conducting system are smaller than the contractile cells of the myocardium and contain very few myofibrils. Purkinje cells, however, are much larger in diameter than the contractile cells; as a result, they conduct action potentials more quickly than other conducting cells. Conducting cells of the SA and AV nodes share an important characteristic: Their excitable membranes cannot maintain a stable resting potential. After each repolarization, the membrane gradually drifts toward threshold. This gradual depolarization is called a **prepotential** or *pacemaker potential* (Figure 20–12b•).

The rate of spontaneous depolarization differs in various portions of the conducting system. It is fastest at the SA node, which in the absence of neural or hormonal stimulation generates action potentials at a rate of 80–100 per minute. Isolated cells of the AV node depolarize more slowly, generating 40–60 action potentials per minute. Because the SA node reaches threshold first, it establishes the heart rate—the impulse generated by the SA node brings the AV nodal cells to threshold faster than does the prepotential of the AV nodal cells. The normal resting heart rate is somewhat slower than 80–100 beats per minute, however, due to the effects of parasympathetic innervation. (The influence of autonomic innervation on heart rate is discussed in a later section.)

If any of the atrial pathways or the SA node becomes damaged, the heart will continue to beat, but at a slower rate, usually 40–60 beats per minute, as dictated by the AV node. Certain cells in the Purkinje fiber network depolarize spontaneously at an even slower rate, and if the rest of the conducting system is damaged, they can stimulate a heart rate of 20–40 beats per minute. Under normal conditions, cells of the AV bundle, the bundle branches, and most Purkinje fibers do not depolarize spontaneously. If, due to damage or disease, these cells *do* begin depolarizing spontaneously, the heart may no longer pump blood effectively, and death can result if the problem persists.

We will now trace the path of an impulse from its initiation at the SA node, examining its effects on the surrounding myocardium as we proceed.

The Sinoatrial (SA) Node

A¯

The **sinoatrial** (s

ı superior vena cava (Figure 20–13[STEP 1]•). The SA node contains **pacemaker cells**, which establish the heart rate. As a result, the SA node is also known as the *cardiac pacemaker* or the *natural pacemaker*. The SA node is connected to the larger AV node by the internodal pathways in the atrial walls. It takes roughly 50 msec for an action potential to travel from the SA node to the AV node along these pathways. Along the way, the conducting cells pass the stimulus to contractile cells of both atria. The action potential then spreads across the atrial surfaces by cell-to-cell contact (Figure 20–13 [STEP 2]•). The stimulus affects only the atria, because the fibrous skeleton isolates the atrial myocardium from the ventricular myocardium.

The Atrioventricular (AV) Node

The relatively large **atrioventricular (AV) node** (see 20–13 [STEP 2]•) sits within the floor of the right atrium near the opening of the coronary sinus. The rate of propagation of the impulse slows as it leaves the internodal pathways and enters the AV node, because the nodal cells are smaller in diameter than the conducting cells. (Chapter 12 discussed the relationship between diameter and propagation speed. l**p. 402**) In addition, the connections between nodal cells are less efficient than those between conducting cells at relaying the impulse from one cell to another. As a result, it takes about 100 msec for the impulse to pass through the AV node (Figure 20–13 [STEP 3]•). This delay is important because the atria must contract before the ventricles do. Otherwise, contraction of the powerful ventricles would close the AV valves and prevent blood flow from the atria into the ventricles.

After this brief delay, the impulse is conducted along the interventricular bundle and the bundle branches to the Purkinje fibers and the papillary muscles (Figure 20–13 [STEP 4]•). The Purkinje fibers then distribute the impulse to the ventricular myocardium, and ventricular contraction begins (Figure 20–13 [STEP 5]•).

The cells of the AV node can conduct impulses at a maximum rate of 230 per minute. Because each impulse results in a ventricular contraction, this value is the maximum normal heart rate. Even if the SA node generates impulses at a faster rate, the ventricles will still contract at 230 beats per minute (bpm). This limitation is important, because mechanical factors (discussed later) begin to decrease the pumping efficiency of the heart at rates above approximately 180 bpm. Rates above 230 bpm occur only when the heart or the conducting system has been damaged or stimulated by drugs. As ventricular rates increase toward their theoretical maximum limit of 300–400 bpm, pumping efficiency becomes dangerously, if not fatally, reduced.

-uh; *tachys*, swift) indicates a

faster-than-normal heart rate. These are relative terms, and in clinical practice the definitions vary with the normal resting heart rate of the individual. AM: Treating Problems with Pacemaker Function

The AV Bundle, Bundle Branches, and Purkinje Fibers

The connection between the AV node and the **AV bundle**, also called the *bundle of His* (hiss), is the only electrical connection between the atria and the ventricles. Once an impulse enters the AV bundle, it travels to the interventricular septum and enters the **right** and **left bundle branches**. The left bundle branch, which supplies the massive left ventricle, is much larger than the right bundle branch. Both branches extend toward the apex of the heart, turn, and fan out deep to the endocardial surface. As the branches diverge, they conduct the impulse to **Purkinje fibers** and, through the moderator band, to the papillary muscles of the right ventricle.

Purkinje fibers conduct action potentials very rapidly—as fast as small myelinated axons. Within about 75 msec, the signal to begin a contraction has reached all the ventricular cardiac muscle cells. The entire process, from the generation of an impulse at the SA node to the complete depolarization of the ventricular myocardium, normally takes around 225 msec. By this time, the atria have completed their contractions and ventricular contraction can safely occur.

Because the bundle branches deliver the impulse across the moderator band to the papillary muscles directly, rather than by way of Purkinje fibers, the papillary muscles begin contracting before the rest of the ventricular musculature does. Contraction of the papillary muscles applies tension to the chordae tendineae, bracing the AV valves. By limiting the movement of the cusps, tension in the chordae tendineae prevents the backflow of blood into the atria when the ventricles contract. The Purkinje fibers radiate from the apex toward the base of the heart. As a result, ventricular contraction proceeds in a wave that begins at the apex and spreads toward the base. Blood is therefore pushed toward the base of the heart, into the aorta and pulmonary trunk.

If the conducting pathways are damaged, the normal rhythm of the heart will be disturbed. The resulting problems are called *conduction deficits*. If the SA node or internodal pathways are damaged, the AV node will assume command. The heart will continue beating normally, although at a slower rate. If an abnormal conducting cell or ventricular muscle cell begins generating action potentials at a higher rate, the impulses can override those of the SA or AV node. The origin of these abnormal signals is called an **ectopic** (ek-TOP-ik; out of place) **pacemaker**. The activity of an ectopic pacemaker partially or completely bypasses the conducting system, disrupting the timing of ventricular contraction. The result is a dangerous reduction in the pumping efficiency of the heart. Such conditions are commonly diagnosed with the aid of an *electrocardiogram*. AM: Diagnosing Abnormal Heartbeats

The Electrocardiogram

The electrical events occurring in the heart are powerful enough to be detected by electrodes on the surface of the body. A record
ing of these events is an **electrocardiogram** (
¯e
-lek-tr
¯o
-KAR-d
¯e
-

¯o
-gram), also called an **ECG** or **EKG**. Each time the heart beats,
a wave of depolarization radiates through the atria, reaches the AV node, travels down the interventricular septum to the apex, turns, and spreads through the ventricular myocardium toward the base (see Figure 20–13•).

An ECG integrates electrical information obtained by placing electrodes at different locations on the body surface. Clinicians can use an ECG to assess the performance of specific nodal, conducting, and contractile components. When a portion of the heart has been damaged by a heart attack, for example, the ECG will reveal an abnormal pattern of impulse conduction.

The appearance of the ECG varies with the placement of the monitoring electrodes, or *leads*. Figure 20–14a• shows the leads in one of the standard configurations. Figure 20–14b• depicts the important features of an ECG obtained with that configuration. Note the following ECG features:

- The small **P wave**, which accompanies the depolarization of the atria. The atria begin contracting about 25 msec after the start of the P wave.

- The **QRS complex**, which appears as the ventricles depolarize. This is a relatively strong electrical signal, because the ventricular muscle is much more massive than that of the atria. It is also a complex signal, largely because of the complex pathway that the spread of depolarization takes through the ventricles. The ventricles begin contracting shortly after the peak of the **R wave**.
- The smaller **T wave**, which indicates ventricular repolarization. A deflection corresponding to atrial repolarization is not apparent, because it occurs while the ventricles are depolarizing, and the electrical events are masked by the QRS complex.

To analyze an ECG, you must measure the size of the voltage changes and determine the durations and temporal relationships of the various components. Of particular diagnostic importance is the amount of depolarization occurring during the P wave and the QRS complex. For example, an excessively large QRS complex often indicates that the heart has become enlarged. A smaller-than-normal electrical signal may mean that the mass of the heart muscle has decreased (although monitoring problems are more often responsible). The size and shape of the T wave may also be affected by any condition that slows ventricular repolarization. For example, starvation and low cardiac energy reserves, coronary ischemia, or abnormal ion concentrations will reduce the size of the T wave.

The times between waves are reported as *segments* or *intervals*. Segments generally extend from the end of one wave to the start of another; intervals are more variable, but always include at least one entire wave. Commonly used segments and intervals are indicated in Figure 20–14b•. The names, however, can be somewhat misleading. For example:

- The **P–R interval** extends from the start of atrial depolarization to the start of the QRS complex (ventricular depolarization) rather than to R, because in abnormal ECGs the peak at R can be difficult to determine. Extension of the P–R interval to more than 200 msec can indicate damage to the conducting pathways or AV node.
- The **Q–T interval** indicates the time required for the ventricles to undergo a single cycle of depolarization and repolarization. It is usually measured from the end of the P–R interval rather than from the bottom of the Q wave. The Q–T interval can be lengthened by

electrolyte disturbances, some medications, conduction problems, coronary ischemia, or myocardial damage. A congenital heart defect that can cause sudden death without warning may be detectable as a prolonged Q–T interval.

Despite the variety of sophisticated equipment available to assess or visualize cardiac function, in the majority of cases the ECG provides the most important diagnostic information. ECG analysis is especially useful in detecting and diagnosing **cardiac arrhythmias** (ā-RITH-mē-az)—abnormal patterns of cardiac electrical activity. Momentary arrhythmias are not inherently dangerous; about 5 percent of healthy individuals experience a few abnormal heartbeats each day. Clinical problems appear when arrhythmias reduce the pumping efficiency of the heart. Serious arrhythmias may indicate damage to the myocardium, injuries to the pacemakers or conduction pathways, exposure to drugs, or abnormalities in the electrolyte composition of extracellular fluids. AM: Diagnosing Abnormal Heartbeats; Examining the Heart

100 Keys | The heart rate is normally established by cells of the SA node, but that rate can be modified by autonomic activity, hormones, and other factors. From the SA node the stimulus is conducted to the AV node, the AV bundle, the bundle branches, and Purkinje fibers before reaching the ventricular muscle cells. The electrical events associated with the heartbeat can be monitored in an electrocardiogram (ECG).

Review the conducting system of the heart on the **IP CD-ROM: Cardiovascular System/Intrinsic Conduction System.**

Contractile Cells

The Purkinje fibers distribute the stimulus to the **contractile cells**, which form the bulk of the atrial and ventricular walls. In the discussions of cardiac muscle tissue in previous chapters, we considered only the structure of contractile cells, which account for roughly 99 percent of the muscle cells in the heart. In both cardiac muscle cells and skeletal muscle fibers, (1) an action potential quantity is called the **end-diastolic volume (EDV)**. In an adult who is standing at rest, the end-diastolic volume is typically about 130 ml.

Ventricular Systole As atrial systole ends, ventricular systole begins. This period lasts approximately 270 msec in a resting adult. As the pressures in the ventricles rise above those in the atria, the AV valves swing shut.

4. During this stage of ventricular systole, the ventricles are contracting. Blood flow has yet to occur, however, because ventricular pressures are not high enough to force open the semilunar valves and push blood into the pulmonary or aortic trunk. Over this period, the ventricles contract isometrically: They generate tension and ventricular pressures rise, but blood flow does not occur. The ventricles are now in the period of **isovolumetric contraction**: All the heart valves are closed, the volumes of the ventricles remain constant, and ventricular pressures rise.

5. Once pressure in the ventricles exceeds that in the arterial trunks, the semilunar valves open and blood flows into the pulmonary and aortic trunks. This point marks the beginning of the period of **ventricular ejection**. The ventricles now contract isotonically: The muscle cells shorten, and tension production remains relatively constant. (To review isotonic versus isometric contractions, see Figure 10–19•, p. 307.)

After reaching a peak, ventricular pressures gradually decline near the end of ventricular systole. Figure 20–17• shows values for the left ventricle and aorta. Although pressures in the right ventricle and pulmonary trunk are much lower, the right ventricle also goes through periods of isovolumetric contraction and ventricular ejection. During ventricular ejection, each ventricle will eject 70–80 ml of blood, the **stroke volume (SV)** of the heart. The stroke volume at rest is roughly 60 percent of the end-diastolic volume. This percentage, known as the *ejection fraction*, can vary in response to changing demands on the heart. (We will discuss the regulatory mechanisms involved in the next section.)

6. As the end of ventricular systole approaches, ventricular pressures fall rapidly. Blood in the aorta and pulmonary trunk now starts to flow back toward the ventricles, and this movement closes the semilunar valves. As the backflow begins, pressure decreases in the aorta. When the semilunar valves close, pressure rises again as the elastic arterial walls recoil. This small, temporary rise produces a valley in the pressure tracing, called a *dicrotic* (d -KROT-ik) *notch* (*dikrotos*, double beating). The amount

–

ı of blood remaining in the ventricle when the semilunar valve closes is the **end-systolic volume (ESV)**. At rest, the end-systolic volume is 50 ml, about 40 percent of the end-diastolic volume.

Ventricular Diastole The period of ventricular diastole lasts for the 430 msec remaining in the current cardiac cycle and continues through atrial systole in the next cycle.

7. All the heart valves are now closed, and the ventricular myocardium is relaxing. Because ventricular pressures are still higher than atrial pressures, blood cannot flow into the ventricles. This is the period of **isovolumetric relaxation**. Ventricular pressures drop rapidly over this period, because the elasticity of the connective tissues of the heart and fibrous skeleton helps re-expand the ventricles toward their resting dimensions.

8. When ventricular pressures fall below those of the atria, the atrial pressures force the AV valves open. Blood now flows from the atria into the ventricles. Both the atria and the ventricles are in diastole, but the ventricular pressures continue to fall as the ventricular chambers expand. Throughout this period, pressures in the ventricles are so far below those in the major veins that blood pours through the relaxed atria and on through the open AV valves into the ventricles. This passive mechanism is the primary method of ventricular filling. The ventricles will be nearly three-quarters full before the cardiac cycle ends.

The relatively minor contribution that atrial systole makes to ventricular volume explains why individuals can survive quite normally when their atria have been so severely damaged that they can no longer function. In contrast, damage to one or both ventricles can leave the heart unable to maintain adequate blood flow through peripheral tissues and organs. A condition of **heart failure** then exists. AM: Heart Failure

Heart Sounds

Listening to the heart, a technique called *auscultation,* is a simple and effective method of cardiac assessment. Physicians use an instrument called a **stethoscope** to listen for normal and abnormal heart sounds. Where the stethoscope is placed depends on which valve is under examination (Figure 20–18a•). Valve sounds must pass through the pericardium, surrounding tissues, and the chest wall, and some tissues muffle sounds more than others. As a result, the placement of the stethoscope differs somewhat from the position of the valve under review.

There are four heart sounds, designated as S1 through S4 (Figure 20–18b•). If you listen to your own heart with a stethoscope, you will clearly hear the *first* and *second heart sounds*. These sounds accompany the closing of your heart valves. The first heart sound, known as "lubb" (S1), lasts a little longer than the second, called "dupp" (S2). S1, which marks the start of ventricular contraction, is produced as the AV valves close; S2 occurs at the beginning of ventricular filling, when the semilunar valves close.

Third and *fourth heart sounds* are usually very faint and seldom are audible in healthy adults. These sounds are associated with blood flowing into the ventricles (S3) and atrial contraction (S4) rather than with valve action.

If the valve cusps are malformed or there are problems with the papillary muscles or chordae tendineae, the heart valves may not close properly. Regurgitation then occurs during ventricular systole. The surges, swirls, and eddies that accompany regurgitation create a rushing, gurgling sound known as a **heart murmur**. Minor heart murmurs are common and inconsequential.

diac muscle cell could reach 300–400 contractions per minute under maximum stimulation. This rate is not reached in a normal heart, due to limitations imposed by the conducting system.

Concept Check

If the cells of the SA node failed to function, how would the heart rate be affected?

Why is it important for impulses from the atria to be delayed at the AV node before they pass into the ventricles?

Answers begin on p. A–1

Review the cardiac action potential on the **IP CD-ROM: Cardiovascular System/Cardiac Action Potential.**

The Cardiac Cycle

Each heartbeat is followed by a brief resting phase, allowing time for the chambers to relax and prepare for the next heartbeat. The period between the start of one heartbeat and the beginning of the next is a single **cardiac cycle**. The cardiac cycle, therefore, includes alternating periods of contraction and relaxation. For any one chamber in the heart, the cardiac cycle can be divided into

two phases: (1) systole and (2) diastole. During **systole** (SIS-t
¯o
-l
¯e
), or contraction, the chamber contracts and pushes blood into
¯

an adjacent chamber or into an arterial trunk. Systole is followed by **diastole** (d -AS-t
ı chamber fills with blood and prepares for the next cardiac cycle.

Fluids move from an area of higher pressure to one of lower pressure. In the course of the cardiac cycle, the pressure within each chamber rises during systole and falls during diastole. Valves between adjacent chambers help ensure that blood flows in the required direction, but blood will flow from one chamber to another only if the pressure in the first chamber exceeds that in the second. This basic principle governs the movement of blood between atria and ventricles, between ventricles and arterial trunks, and between major veins and atria.

The correct pressure relationships are dependent on the careful timing of contractions. For example, blood could not move in the proper direction if an atrium and its attached ventricle contracted at precisely the same moment. The elaborate pacemaking and conducting systems normally provide the required spacing between atrial and ventricular systoles. At a representative heart rate of 75 bpm, a sequence of systole and diastole in either the atria or the ventricles lasts 800 msec. For convenience, we will assume that the cardiac cycle is determined by the atria, and that it includes one cycle of atrial systole and atrial diastole. This convention follows the previous description of the conducting system and the propagation of the stimulus for contraction.

Phases of the Cardiac Cycle

The phases of the cardiac cycle—atrial systole, atrial diastole, ventricular systole, and ventricular diastole—are diagrammed in Figure 20–16• for a heart rate of 75 bpm. When the cardiac cycle begins, all four chambers are relaxed, and the ventricles are partially filled with blood. During atrial systole, the atria contract, filling the ventricles completely with blood (Figure 20–16a,b•). Atrial systole lasts 100 msec. Over this period, blood cannot flow into the atria because atrial pressure exceeds venous pressure. Yet there is very little backflow into the veins, even though the connections with the venous system lack valves, because blood takes the path of least resistance. Resistance to blood flow through the broad AV connections and into the ventricles is less than that through the smaller, angled openings of the large veins.

The atria next enter atrial diastole, which continues until the start of the next cardiac cycle. Atrial diastole and ventricular systole begin at the same time. Ventricular systole lasts 270 msec. During this period, blood is pushed through the systemic and pulmonary circuits and toward the atria (Figure 20–16c,d•). The heart then enters ventricular diastole (Figure 20–16e,f•), which lasts 530 msec (the 430 msec remaining in this cardiac cycle, plus the first 100 msec of the next). For the rest of this cycle, filling occurs passively, and both the atria and the ventricles are relaxed. The next cardiac cycle begins with atrial systole and the completion of ventricular filling.

When the heart rate increases, all the phases of the cardiac cycle are shortened. The greatest reduction occurs in the length of time spent in diastole. When the heart rate climbs from 75 bpm to 200 bpm, the time spent in systole drops by less than 40 percent, but the duration of diastole is reduced by almost 75 percent.

Pressure and Volume Changes in the Cardiac Cycle

Figure 20–17• plots the pressure and volume changes during the cardiac cycle; the circled numbers in the figure correspond to numbered items in the text. The figure shows pressure and volume within the left atrium and left ventricle, but the discussion that follows applies to both sides of the heart. Although pressures are lower in the right atrium and right ventricle, both sides of the heart contract at the same time, and they eject equal volumes of blood.

Atrial Systole The cardiac cycle begins with atrial systole, which lasts about 100 msec in a resting adult:

1. As the atria contract, rising atrial pressures push blood into the ventricles through the open right and left AV valves.
2. At the start of atrial systole, the ventricles are already filled to about 70 percent of their normal capacity, due to passive blood flow during the end of the previous cardiac cycle. As the atria contract, rising atrial pressures provide the remaining 30 percent by pushing blood through the open AV valves. Atrial systole essentially “tops off” the ventricles.
3. At the end of atrial systole, each ventricle contains the maximum amount of blood that it will hold in this cardiac cycle. That

‾o

-l

‾e

), or relaxation. During diastole, the

quantity is called the **end-diastolic volume (EDV)**. In an adult who is standing at rest, the end-diastolic volume is typically about 130 ml.

Ventricular Systole As atrial systole ends, ventricular systole begins. This period lasts approximately 270 msec in a resting adult. As the pressures in the ventricles rise above those in the atria, the AV valves swing shut.

4. During this stage of ventricular systole, the ventricles are contracting. Blood flow has yet to occur, however, because ventricular pressures are not high enough to force open the semilunar valves and push blood into the pulmonary or aortic trunk. Over this period, the ventricles contract isometrically: They generate tension and ventricular pressures rise, but blood flow does not occur. The ventricles are now in the period of **isovolumetric contraction**: All the heart valves are closed, the volumes of the ventricles remain constant, and ventricular pressures rise.

5. Once pressure in the ventricles exceeds that in the arterial trunks, the semilunar valves open and blood flows into the pulmonary and aortic trunks. This point marks the beginning of the period of **ventricular ejection**. The ventricles now contract isotonically: The muscle cells shorten, and tension production remains relatively constant. (To review isotonic versus isometric contractions, see Figure 10–19•, p. 307.)

After reaching a peak, ventricular pressures gradually decline near the end of ventricular systole. Figure 20–17• shows values for the left ventricle and aorta. Although pressures in the right ventricle and pulmonary trunk are much lower, the right ventricle also goes through periods of isovolumetric contraction and ventricular ejection. During ventricular ejection, each ventricle will eject 70–80 ml of blood, the **stroke volume (SV)** of the heart. The stroke volume at rest is roughly 60 percent of the end-diastolic volume. This percentage, known as the *ejection fraction*, can vary in response to changing demands on the heart. (We will discuss the regulatory mechanisms involved in the next section.)

6. As the end of ventricular systole approaches, ventricular pressures fall rapidly. Blood in the aorta and pulmonary trunk now starts to flow back toward the ventricles, and this movement closes the semilunar valves. As the backflow begins, pressure decreases in the aorta. When the semilunar valves close, pressure rises again as the elastic arterial walls

recoil. This small, temporary rise produces a valley in the pressure tracing, called a *dicrotic* (d -KROT-ik) *notch* (*dikrotos*, double beating). The amount

–

ı of blood remaining in the ventricle when the semilunar valve closes is the **end-systolic volume (ESV)**. At rest, the end-systolic volume is 50 ml, about 40 percent of the end-diastolic volume.

Ventricular Diastole The period of ventricular diastole lasts for the 430 msec remaining in the current cardiac cycle and continues through atrial systole in the next cycle.

7. All the heart valves are now closed, and the ventricular myocardium is relaxing. Because ventricular pressures are still higher than atrial pressures, blood cannot flow into the ventricles. This is the period of **isovolumetric relaxation**. Ventricular pressures drop rapidly over this period, because the elasticity of the connective tissues of the heart and fibrous skeleton helps re-expand the ventricles toward their resting dimensions.
8. When ventricular pressures fall below those of the atria, the atrial pressures force the AV valves open. Blood now flows from the atria into the ventricles. Both the atria and the ventricles are in diastole, but the ventricular pressures continue to fall as the ventricular chambers expand. Throughout this period, pressures in the ventricles are so far below those in the major veins that blood pours through the relaxed atria and on through the open AV valves into the ventricles. This passive mechanism is the primary method of ventricular filling. The ventricles will be nearly three-quarters full before the cardiac cycle ends.

The relatively minor contribution that atrial systole makes to ventricular volume explains why individuals can survive quite normally when their atria have been so severely damaged that they can no longer function. In contrast, damage to one or both ventricles can leave the heart unable to maintain adequate blood flow through peripheral tissues and organs. A condition of **heart failure** then exists. AM: Heart Failure

Heart Sounds

Listening to the heart, a technique called *auscultation*, is a simple and effective method of cardiac assessment. Physicians use an instrument called a **stethoscope** to listen for normal and abnormal heart sounds. Where the stethoscope is placed depends on which valve is under examination (Figure 20–18a•). Valve sounds must pass through the pericardium, surrounding tissues, and the chest wall, and some tissues muffle sounds more than others. As a result, the placement of the stethoscope differs somewhat from the position of the valve under review.

There are four heart sounds, designated as S1 through S4 (Figure 20–18b•). If you listen to your own heart with a stethoscope, you will clearly hear the *first* and *second heart sounds*. These sounds accompany the closing of your heart valves. The first heart sound, known as “lubb” (S1), lasts a little longer than the second, called “dupp” (S2). S1, which marks the start of ventricular contraction, is produced as the AV valves close; S2 occurs at the beginning of ventricular filling, when the semilunar valves close.

Third and *fourth heart sounds* are usually very faint and seldom are audible in healthy adults. These sounds are associated with blood flowing into the ventricles (S3) and atrial contraction (S4) rather than with valve action.

If the valve cusps are malformed or there are problems with the papillary muscles or chordae tendineae, the heart valves may not close properly. Regurgitation then occurs during ventricular systole. The surges, swirls, and eddies that accompany regurgitation create a rushing, gurgling sound known as a **heart murmur**. Minor heart murmurs are common and inconsequential.

The Energy for Cardiac Contractions

When a normal heart is beating, the energy required is obtained by the mitochondrial breakdown of fatty acids (stored as lipid droplets) and glucose (stored as glycogen). These aerobic reactions can occur only when oxygen is readily available. l**p. 310**

In addition to obtaining oxygen from the coronary circulation, cardiac muscle cells maintain their own sizable reserves of oxygen. In these cells, oxygen molecules are bound to the heme units of myoglobin molecules. (We discussed this globular protein, which reversibly binds oxygen molecules, and its function in muscle fibers in Chapter 10.) l**p. 313** Normally, the combination of circulatory supplies plus myoglobin reserves is enough to meet the oxygen demands of the heart, even when it is working at maximum capacity.

Concept Check

Is the heart always pumping blood when pressure in the left ventricle is rising? Explain.

What factor or factors could cause an increase in the size of the QRS complex of an electrocardiogram recording?

Answers begin on p. A–1

Review the cardiac cycle on the **IP CD-ROM: Cardiovascular System/Cardiac Cycle.**

Cardiodynamics

Objectives

- Define cardiac output, and describe the factors that influence this variable.
- Describe the variables that influence heart rate.
- Describe the variables that influence stroke volume.
- Explain how adjustments in stroke volume and cardiac output are coordinated at different levels of activity.

The term **cardiodynamics** refers to the movements and forces generated during cardiac contractions. Each time the heart beats, the two ventricles eject equal amounts of blood. Earlier we introduced these terms:

- **End-Diastolic Volume (EDV):** The amount of blood in each ventricle at the end of ventricular diastole (the start of ventricular systole).
- **End-Systolic Volume (ESV):** The amount of blood remaining in each ventricle at the end of ventricular systole (the start of ventricular diastole).

- **Stroke Volume (SV):** The amount of blood pumped out of each ventricle during a single beat; it can be expressed as SV = EDV -ESV.
- **Ejection Fraction:** The percentage of the EDV represented by the SV.

Stroke volume is the most important factor in an examination of a single cardiac cycle. If the heart were an old-fashioned bicycle pump, the stroke volume would be the amount of air pumped in one up–down cycle of the handle (Figure 20–19•). Where you stop when you lift the handle determines how much air the pump contains—the end-diastolic volume. How far down you push the handle determines how much air remains in the pump at the end of the cycle—the end-systolic volume. You pump the maximum amount of air when the handle is pulled all the way to the top and then pushed all the way to the bottom (Figure 20–19b,d•). In other words, you get the largest stroke volume when the EDV is as large as it can be and the ESV is as small as it can be.

When considering cardiac function over time, physicians generally are most interested in the **cardiac output (CO)**, the amount of blood pumped by each ventricle in one minute. In essence, cardiac output is an indication of the blood flow through peripheral tissues—without adequate blood flow, homeostasis cannot be maintained. The cardiac output provides a useful indication of ventricular efficiency over time. We can calculate it by multiplying the heart rate (HR) by the average stroke volume (SV):

CO = HR * SV cardiac heart stroke output rate volume (ml> min) (beats> min) (ml> beat)

For example, if the heart rate is 75 bpm and the stroke volume is 80 ml per beat, the cardiac output will be

CO = 75 bpm * 80 ml> beat = 6000 ml> min (6 L> min)

The body precisely adjusts cardiac output such that peripheral tissues receive an adequate circulatory supply under a variety of conditions. When necessary, the heart rate can increase by 250 percent, and stroke volume in a normal heart can almost double.

Overview: The Control of Cardiac Output

Figure 20–20• summarizes the factors involved in the normal regulation of cardiac output. Cardiac output can be adjusted by changes in either heart rate or stroke volume. For convenience, we will consider these independently as we discuss the individual factors involved. However, changes in cardiac output generally reflect changes in both heart rate and stroke volume.

The heart rate can be adjusted by the activities of the autonomic nervous system or by circulating hormones. The stroke volume can be adjusted by changing the end-diastolic volume (how full the ventricles are when they start to contract), the end-systolic volume (how much blood remains in the ventricle after it contracts), or both. As Figure 20–19• shows, stroke volume peaks when EDV is highest and ESV is lowest. A variety of other factors can influence cardiac output under abnormal circumstances; we will consider several examples in a separate section.

Factors Affecting the Heart Rate

Under normal circumstances, autonomic activity and circulating hormones are responsible for making delicate adjustments to the heart rate as circulatory demands change. These factors act by modifying the natural rhythm of the heart. Even a heart removed for a heart transplant will continue to beat unless steps are taken to prevent it from doing so.

Autonomic Innervation

The sympathetic and parasympathetic divisions of the autonomic nervous system innervate the heart by means of the *cardiac plexus* (Figures 16–10, p. 534, and 20–21•). Postganglionic sympathetic neurons are located in the cervical and upper thoracic ganglia. The vagus nerves (X) carry parasympathetic preganglionic fibers to small ganglia in the cardiac plexus. Both ANS divisions innervate the SA and AV nodes and the atrial muscle cells. Although ventricular muscle cells are also innervated by both divisions, sympathetic fibers far outnumber parasympathetic fibers there.

The *cardiac centers* of the medulla oblongata contain the autonomic headquarters for cardiac control. l**p. 459** The **cardioacceleratory center** controls sympathetic neurons that increase the heart rate; the adjacent **cardioinhibitory center** controls the parasympathetic neurons that slow the heart rate. The activities of the cardiac centers are regulated by reflex pathways and through input from higher centers, especially from the parasympathetic and sympathetic headquarters in the hypothalamus.

Cardiac Reflexes Information about the status of the cardiovascular system arrives over visceral sensory fibers accompanying

the vagus nerve and the sympathetic nerves of the cardiac plexus. The cardiac centers monitor baroreceptors and chemoreceptors innervated by the glossopharyngeal (IX) and vagus (X) nerves. l**pp. 486, 487** On the basis of the information received, the centers adjust cardiac performance to maintain adequate circulation to vital organs, such as the brain. The centers respond to changes in blood pressure as reported by baroreceptors and in arterial concentrations of dissolved oxygen and carbon dioxide as reported by chemoreceptors. For example, a decline in blood pressure or oxygen concentrations or an increase in carbon dioxide levels generally indicates that the heart must work harder to meet the demands of peripheral tissues. The cardiac centers then call for an increase in cardiac activity. We will detail these reflexes and their effects on the heart and peripheral vessels in Chapter 21.

Autonomic Tone As is the case in other organs with dual innervation, the heart has a resting autonomic tone. Both autonomic divisions are normally active at a steady background level, releasing ACh and NE at the nodes and into the myocardium. Thus, cutting the vagus nerves increases the heart rate, and sympathetic blocking agents slow the heart rate.

In a healthy, resting individual, parasympathetic effects dominate. In the absence of autonomic innervation, the heart rate is established by the pacemaker cells of the SA node. Such a heart beats at a rate of 80–100 bpm. At rest, a typical adult heart with normal innervation beats at 70–80 bpm due to activity in the parasympathetic nerves innervating the SA node. If parasympathetic activity increases, the heart rate declines further. Conversely, the heart rate will increase if either parasympathetic activity decreases or sympathetic activation occurs. Through dual innervation and adjustments in autonomic tone, the ANS can make very delicate adjustments in cardiovascular function to meet the demands of other systems.

Effects on the SA Node The sympathetic and parasympathetic divisions alter the heart rate by changing the ionic permeabilities of cells in the conducting system. The most dramatic effects are seen at the SA node, where changes in the rate at which impulses are generated affect the heart rate.

Consider the SA node of a resting individual whose heart is beating at 75 bpm (Figure 20–22a•). Any factor that changes the rate of spontaneous depolarization or the duration of repolarization will alter the heart rate by changing the time required to reach threshold. Acetylcholine released by parasympathetic neurons opens chemically regulated K^+ channels in the cell membrane, thereby dramatically slowing the rate of spontaneous depolarization and also slightly extending the duration of repolarization (Figure 20–22b•). The result is a decline in heart rate.

NE released by sympathetic neurons binds to beta-1 receptors, leading to the opening of sodium-calcium ion channels. The subsequent influx of positively charged ions increases the rate of depolarization and shortens the period of repolarization. The nodal cells reach threshold more quickly, and the heart rate increases (Figure 20–22c•).

The Atrial Reflex The **atrial reflex**, or *Bainbridge reflex*, involves adjustments in heart rate in response to an increase in the venous return. When the walls of the right atrium are stretched, the stimulation of stretch receptors in the atrial walls triggers a reflexive increase in heart rate caused by increased sympathetic activity (see Figure 20–22•). Thus, when the rate of venous return to the heart increases, the heart rate, and hence the cardiac output, rises as well.

Hormones

Epinephrine, norepinephrine, and thyroid hormone increase the heart rate by their effect on the SA node. The effects of epinephrine on the SA node are similar to those of norepinephrine. Epinephrine also affects the contractile cells; after massive sympathetic stimulation of the adrenal medullae, the myocardium may become so excitable that abnormal contractions occur.

Venous Return

In addition to its indirect effect on heart rate via the atrial reflex, venous return also has direct effects on nodal cells. When venous return increases, the atria receive more blood and the walls are stretched. Stretching of the cells of the SA node leads to more rapid depolarization and an increase in the heart rate.

Concept Check

Caffeine has effects on conducting cells and contractile cells that are similar to those of NE. What effect would drinking large amounts of caffeinated drinks have on the heart?

If the cardioinhibitory center of the medulla oblongata were damaged, which part of the autonomic nervous system would be affected, and how would the heart be influenced?

How does a drug that increases the length of time required for the repolarization of pacemaker cells affect the heart rate?

Answers begin on p. A–1

Factors Affecting the Stroke Volume

The stroke volume is the difference between the end-diastolic volume and the end-systolic volume. Thus, changes in either EDV or ESV can change the stroke volume, and thus cardiac output. The factors involved in the regulation of stroke volume are indicated in Figure 20–23•.

The EDV

The EDV is the amount of blood a ventricle contains at the end of diastole, just before a contraction begins. This volume is affected by two factors: the filling time and the venous return. **Filling time** is the duration of ventricular diastole. As such, it depends entirely on the heart rate: The faster the heart rate, the shorter is the available filling time. **Venous return** is the rate of blood flow over this period. Venous return changes in response to alterations in cardiac output, blood volume, patterns of peripheral circulation, skeletal muscle activity, and other factors that affect the rate of blood flow through the venae cavae. (We will explore these factors in Chapter 21.)

Preload The degree of stretching experienced by ventricular muscle cells during ventricular diastole is called the **preload**. The preload is directly proportional to the EDV: The greater the EDV, the larger the preload. Preload is significant because it affects the ability of muscle cells to produce tension. As sarcomere length increases past resting length, the amount of force produced during systole increases.

The amount of preload, and hence the degree of myocardial stretching, varies with the demands on the heart. When you are standing at rest, your EDV is low; the ventricular muscle is stretched very little, and the sarcomeres are relatively short. During ventricular systole, the cardiac muscle cells develop little power, and the ESV (the amount of blood remaining in the ventricle after contraction) is relatively high because the muscle cells contract only a short distance. If you begin exercising, venous return increases and more blood flows into your heart. Your EDV increases, and the myocardium stretches further. As the sarcomeres approach optimal lengths, the ventricular muscle cells can contract more efficiently and produce more forceful contractions. They also shorten more, and more blood is pumped out of your heart.

The EDV and Stroke Volume In general, the greater the EDV, the larger the stroke volume. Stretching *past* the optimal length, which would reduce the force of contraction, does not normally occur, because ventricular expansion is limited by myocardial connective tissues, the fibrous skeleton, and the pericardial sac.

The relationship between the amount of ventricular stretching and the contractile force means that, within normal physiological limits, increasing the EDV results in a corresponding increase in the stroke volume. This general rule of “more in = more out” was first proposed by Ernest H. Starling based on his studies and research by Otto Frank. The relationship is therefore known as the **Frank–Starling principle**, or *Starling’s law of the heart*.

Autonomic adjustments to cardiac output make the effects of the Frank–Starling principle difficult to see. However, it can be demonstrated effectively in individuals who have received a heart transplant, because the implanted heart is not innervated by the ANS. The most obvious effect of the Frank–Starling principle in these hearts is that the outputs of the left and right ventricles remain balanced under a variety of conditions.

Consider, for example, an individual at rest, with the two ventricles ejecting equal volumes of blood. Although the ventricles contract together, they function in series: When the heart contracts, blood leaving the right ventricle heads to the lungs; during the next ventricular diastole, that volume of blood will pass through the left atrium, to be ejected by the left ventricle at the next contraction. If the venous return decreases, the EDV of the right ventricle will decline. During ventricular systole, it will then pump less blood into the pulmonary circuit. In the next cardiac cycle, the EDV of the left ventricle will be reduced, and that ventricle will eject a smaller volume of blood. The output of the two ventricles will again be in balance, but both will have smaller stroke volumes than they did initially.

The ESV

After the ventricle contracts and the stroke volume has been ejected, the amount of blood that remains in the ventricle at the end of ventricular systole is the ESV. Three factors that influence the ESV are the *preload* (discussed earlier), the *contractility* of the ventricle, and the *afterload*.

Contractility **Contractility** is the amount of force produced during a contraction, at a given preload. Under normal circumstances, contractility can be altered by autonomic innervation or circulating hormones. Under special circumstances, contractility can be altered by drugs or as a result of abnormal ion concentrations in the extracellular fluid.

Factors that increase contractility are said to have a *positive inotropic action*; those that decrease contractility have a *negative inotropic action*. Positive inotropic agents typically stimulate Ca^{2+} entry into cardiac muscle cells, thus increasing the force and duration of ventricular contractions. Negative inotropic agents may block Ca^{2+} movement or depress cardiac muscle metabolism.

Positive and negative inotropic factors include ANS activity, hormones, and changes in extracellular ion concentrations.

Effects of Autonomic Activity on Contractility Autonomic activity alters the degree of contraction and changes the ESV in the following ways:

- Sympathetic stimulation has a positive inotropic effect, causing the release of norepinephrine (NE) by postganglionic fibers of the cardiac nerves and the secretion of epinephrine (E) and NE by the adrenal medullae. In addition to their effects on heart rate, discussed shortly, these hormones stimulate cardiac muscle cell metabolism and increase the force and degree of contraction by stimulating alpha and beta receptors in cardiac muscle cell membranes. The net effect is that the ventricles contract more forcefully, increasing the ejection fraction and decreasing the ESV.
- Parasympathetic stimulation from the vagus nerves has a negative inotropic effect. The primary effect of acetylcholine (ACh) is at the membrane surface, where it produces hyperpolarization and inhibition. The force of cardiac contractions is reduced; because the ventricles are not extensively innervated by the parasympathetic division, the atria show the greatest changes in contractile force. However, under strong parasympathetic stimulation or after the administration of drugs that mimic the actions of ACh, the ventricles contract less forcefully, the ejection fraction decreases, and the ESV enlarges.

Hormones Many hormones affect the contractility of the heart. For example, epinephrine, norepinephrine, and thyroid hormones all have positive inotropic effects. Glucagon also has a positive inotropic effect. Before synthetic inotropic agents were available, glucagon was widely used to stimulate cardiac function. It is still used in cardiac emergencies and to treat some forms of heart disease.

The drugs *isoproterenol*, *dopamine*, and *dobutamine* mimic the action of E and NE by stimulating beta-1 receptors on cardiac muscle cells. l**p. 526** Dopamine (at high doses) and dobutamine also stimulate Ca^{2+} entry through alpha-1 receptor stimulation. *Digitalis* and related drugs elevate intracellular Ca^{2+} concentrations, but by a different mechanism: They interfere with the removal of Ca^{2+} from the sarcoplasm of cardiac muscle cells.

Many of the drugs used to treat hypertension (high blood pressure) have a negative inotropic action. Beta-blocking drugs such as *propranolol*, *timolol*, *metoprolol*, *atenolol*, and *labetalol* block beta receptors, alpha receptors, or both, and prevent sympathetic stimulation of the heart. Calcium channel blockers such as *nifedipine* or *verapamil* also have a negative inotropic effect.

Afterload The **afterload** is the amount of tension the contracting ventricle must produce to force open the semilunar valve and eject blood. The greater the afterload, the longer the period of isovolumetric contraction, the shorter the duration of ventricular ejection, and the larger the ESV. In other words, as the afterload increases, the stroke volume decreases.

Afterload is increased by any factor that restricts blood flow through the arterial system. For example, the constriction of peripheral blood vessels or a circulatory blockage will elevate arterial blood pressure and increase the afterload. If the afterload is too great, the ventricle cannot eject blood. Such a high afterload is rare in a normal heart, but damage to the heart muscle can weaken the myocardium enough that even a modest rise in arterial blood pressure can reduce stroke volume to dangerously low levels, producing symptoms of heart failure.

Concept Check

Why is it a potential problem if the heart beats too rapidly?

What effect would stimulating the acetylcholine receptors of the heart have on cardiac output?

What effect would an increase in venous return have on the stroke volume?

How would an increase in sympathetic stimulation of the heart affect the end-systolic volume?

Joe’s end-systolic volume is 40 ml, and his end-diastolic volume is 125 ml. What is Joe’s stroke volume?

Answers begin on p. A–1

Summary: The Control of Cardiac Output

Figure 20–24• summarizes the factors involved in the regulation of heart rate and stroke volume, the two factors that interact to determine cardiac output under normal conditions. The heart rate is influenced by the autonomic nervous system, circulating hormones, and the venous return.

- Sympathetic stimulation increases the heart rate; parasympathetic stimulation decreases it. Under resting conditions, parasympathetic tone dominates, and the heart rate is slightly slower than the intrinsic heart rate. When activity levels rise, venous return increases and triggers the atrial reflex. The result is an increase in sympathetic tone and an increase in heart rate.
- Circulating hormones, specifically E, NE, and T3, accelerate heart rate.
- An increase in venous return stretches the nodal cells and increases heart rate.
- The stroke volume is the difference between the end-diastolic volume (EDV) and the end-systolic volume (ESV).
- The EDV is determined by the available filling time and the rate of venous return.
- The ESV is determined by the amount of preload (the degree of myocardial stretching), the degree of contractility (adjusted by hormones and autonomic innervation), and the afterload (the amount of arterial resistance).

In most healthy people, increasing both the stroke volume and the heart rate, such as occurs during heavy exercise, can raise the cardiac output by 300–500 percent, to 18 – 30 L> min. The difference between resting and maximal cardiac outputs is the **cardiac reserve**. Trained athletes exercising at maximal levels may increase cardiac output by nearly 700 percent, to 40 L> min.

Cardiac output cannot increase indefinitely, primarily because the available filling time shortens as the heart rate increases. At heart rates up to 160–180 bpm, the combination of increased rate of venous return and increased contractility compensates for the reduction in filling time. Over this range, cardiac output and heart rate increase together. But if the heart rate continues to climb, the stroke volume begins to drop. Cardiac output first plateaus and then declines.

100 Keys | Cardiac output is the amount of blood pumped by the left ventricle each minute. It is adjusted on a moment-to-moment basis by the ANS, and in response to circulating hormones, changes in blood volume, and alterations in venous return. Most healthy people can increase cardiac output by 300–500 percent.

Review cardiac output on the **IP CD-ROM: Cardiovascular System/Cardiac Output.**

The Heart and the Cardiovascular System

The purpose of cardiovascular regulation is maintaining adequate blood flow to all body tissues. The heart cannot accomplish this by itself, and it does not work in isolation. For example, when blood pressure changes, the cardiovascular centers adjust not only the heart rate but also the diameters of peripheral blood vessels. These adjustments work together to keep the blood pressure within normal limits and to maintain circulation to vital tissues and organs. Chapter 21 will complete this story by detailing the cardiovascular responses to changing activity patterns and circulatory emergencies. We will then conclude our discussion of the cardiovascular system by examining the anatomy of the pulmonary and systemic circuits. AM: Abnormal Conditions Affecting Cardiac Output

Chapter Review

Selected Clinical Terminology

angina pectoris: A condition in which exertion or stress produces severe chest pain, resulting from temporary ischemia when the heart's workload increases. (p. 682) **balloon angioplasty:** A technique for reducing the size of a coronary plaque by compressing it against the arterial walls, using a catheter

with an inflatable collar. (p. 682) **bradycardia:** A heart rate that is slower than normal. (p. 686 and [AM]) **calcium channel blockers:** Drugs that reduce the contractility of the heart by slowing the influx of calcium ions during the plateau

phase of the cardiac muscle action potential. (p. 701) **cardiac arrhythmias:** Abnormal patterns of cardiac electrical activity, indicating abnormal contractions. (p. 688 and [AM])

cardiac tamponade: A condition, resulting from pericardial irritation and inflammation, in which fluid collects in the pericardial sac

and restricts cardiac output. (p. 672 and [AM]) **carditis:** A general term indicating inflammation of the heart. (p. 678 and [AM]) **conduction deficit:** An abnormality in the conducting system of the heart that affects the timing and pacing of cardiac contractions.

(p. 687 and [AM]) **coronary artery bypass graft (CABG):** The routing of blood around an obstructed coronary artery (or one of its branches) by a vessel

transplanted from another part of the body. (p. 682) **coronary artery disease (CAD):** The obstruction of coronary circulation. (p. 681) **coronary ischemia:** The restriction of the circulatory supply to the heart, potentially causing tissue damage and a reduction in cardiac efficiency. (p. 681) **coronary thrombosis:** A blockage due to the formation of a clot (thrombus) at a plaque in a coronary artery. (p. 691) **electrocardiogram (ECG** or **EKG):** A recording of the electrical activities of the heart over time. (p. 687) **heart failure:** A condition in which the heart weakens and peripheral tissues suffer from oxygen and nutrient deprivation. (p. 694 and

[AM]) **heart murmur:** The sound produced by regurgitation or turbulent flow through an incompletely closed heart valve. (p. 694) **mitral valve prolapse:** A condition in which the mitral valve cusps do not close properly and are pushed back toward the left atrium.

[AM]

myocardial infarction (MI): A condition in which the coronary circulation becomes blocked and cardiac muscle cells die from oxy

gen starvation; also called a *heart attack*. (p. 691) **pericarditis:** Inflammation of the pericardium. (p. 672) **rheumatic heart disease (RHD):** A disorder in which the heart valves become thickened and stiffen in a partially closed position, af

fecting the efficiency of the heart. [AM] **tachycardia:** A heart rate that is faster than normal. (p. 686 and [AM]) **valvular heart disease (VHD):** A condition caused by abnormal functioning of one of the cardiac valves. The severity of the condition

depends on the degree of damage and the valve involved. (p. 678 and [AM])

Study Outline

The Organization of the Cardiovascular System p. 670

1. The blood vessels can be subdivided into the **pulmonary circuit** (which carries blood to and from the lungs) and the **systemic circuit** (which transports blood to and from the rest of the body).

2. **Arteries** carry blood away from the heart; **veins** return blood to the heart. **Capillaries**, or *exchange vessels*, are thin-walled, narrow-diameter vessels that connect the smallest arteries and veins. *(Figure 20–1)*

3. The heart has four chambers: the **right atrium** and **right ventricle**, and the **left atrium** and **left ventricle**.

Anatomy of the Heart p. 670

1. The heart is surrounded by the **pericardial cavity** and lies within the anterior portion of the **mediastinum**, which separates the two pleural cavities. *(Figure 20–2)*

The Pericardium p. 671

2. The pericardial cavity is lined by the **pericardium**. The **visceral pericardium (epicardium)** covers the heart's outer surface, and the **parietal pericardium** lines the inner surface of the **pericardial sac**, which surrounds the heart. *(Figure 20–2)*

Superficial Anatomy of the Heart p. 672

3. The **coronary sulcus**, a deep groove, marks the boundary between the atria and the ventricles. Other surface markings also provide useful reference points in describing the heart and associated structures. *(Figure 20–3)*

The Heart Wall p. 673

4. The bulk of the heart consists of the muscular **myocardium**. The **endocardium** lines the inner surfaces of the heart, and the **epicardium** covers the outer surface. *(Figure 20–4)*

5. **Cardiac muscle cells** are interconnected by **intercalated discs**, which convey the force of contraction from cell to cell and conduct action potentials. *(Figure 20–5; Summary Table 20–1)*

Internal Anatomy and Organization p. 674

6. The atria are separated by the **interatrial septum**, and the ventricles are divided by the **interventricular septum**. The right atrium receives blood from the systemic circuit via two large veins, the **superior vena cava** and the **inferior vena cava**. (The atrial walls contain the **pectinate muscles**, prominent muscular ridges.) *(Figure 20–6)*

7. Blood flows from the right atrium into the right ventricle via the **right atrioventricular (AV) valve (tricuspid valve)**. This opening is bounded by three **cusps** of fibrous tissue braced by the **chordae tendineae**, which are connected to **papillary muscles**. *(Figure 20–6)*

8. Blood leaving the right ventricle enters the **pulmonary trunk** after passing through the **pulmonary valve**. The pulmonary trunk divides to form the **left** and **right pulmonary arteries**. The **left** and **right pulmonary veins** return blood from the lungs to the left atrium. Blood leaving the left atrium flows into the left ventricle via the **left atrioventricular (AV) valve** (**bicuspid**, or **mitral**, **valve**). Blood leaving the left ventricle passes through the **aortic valve** and into the systemic circuit via the **ascending aorta**. *(Figure 20–6)*

9. Anatomical differences between the ventricles reflect the functional demands placed on them. The wall of the right ventricle is relatively thin, whereas the left ventricle has a massive muscular wall. *(Figure 20–7)*

10. Valves normally permit blood flow in only one direction, preventing the **regurgitation** (backflow) of blood. *(Figure 20–8)*

100 Keys | p. 678

Connective Tissues and the Fibrous Skeleton p. 680

11. The connective tissues of the heart (mainly collagen and elastic fibers) and the **fibrous skeleton** support the heart's contractile cells and valves. *(Figure 20–8)*

The Blood Supply to the Heart p. 680

12. The **coronary circulation** meets the high oxygen and nutrient demands of cardiac muscle cells. The **coronary arteries** originate at the base of the ascending aorta. Interconnections between arteries, called **arterial anastomoses**, ensure a constant blood supply. The **great**, **posterior**, **small**, **anterior**, and **middle cardiac veins** carry blood from the coronary capillaries to the **coronary sinus**. *(Figure 20–9)*

13. In **coronary artery disease (CAD)**, portions of the coronary circulation undergo partial or complete blockage. *(Figure 20–10)*

Anatomy 360 | Cardiovascular System/Heart

Cardiovascular System/Anatomy Review: The Heart

The Heartbeat p. 684 Cardiac Physiology p. 684

1. Two general classes of cardiac muscle cells are involved in the normal **heartbeat: contractile cells** and cells of the **conducting system**. *(Figure 20–11)*

The Conducting System p. 684

2. The **conducting system** is composed of the *sinoatrial node*, the *atrioventricular node*, and *conducting cells*. The conducting system initiates and distributes electrical impulses within the heart. Nodal cells establish the rate of cardiac contraction, and conducting cells distribute the contractile stimulus from the SA node to the atrial myocardium and the AV node (along *internodal pathways*), and from the AV node to the ventricular myocardium. *(Figure 20–12)*

3. Unlike skeletal muscle, cardiac muscle contracts without neural or hormonal stimulation. **Pacemaker cells** in the **sinoatrial (SA) node** (*cardiac pacemaker*) normally establish the rate of contraction. From the SA node, the stimulus travels to the **atrioventricular (AV) node**, and then to the **AV bundle**, which divides into **bundle branches**. From there, **Purkinje fibers** convey the impulses to the ventricular myocardium. *(Figures 20–12, 20–13)*

The Electrocardiogram p. 687

4. A recording of electrical activities in the heart is an **electrocardiogram** (**ECG** or **EKG**). Important landmarks of an ECG include the **P wave** (atrial depolarization), the **QRS complex** (ventricular depolarization), and the **T wave** (ventricular repolarization).

(Figure 20–14)

100 Keys | p. 688

Cardiovascular System/Intrinsic Conduction System

Contractile Cells p. 688

5. **Contractile cells** form the bulk of the atrial and ventricular walls. Cardiac muscle cells have a long refractory period, so rapid stimulation produces twitches rather than tetanic contractions. *(Figure 20–15)*

Cardiovascular System/Cardiac Action Potential

The Cardiac Cycle p. 690

6. The **cardiac cycle** contains periods of **atrial** and **ventricular systole** (contraction) and **atrial** and **ventricular diastole** (relaxation).

(Figure 20–16)

7. When the heart beats, the two ventricles eject equal volumes of blood. *(Figure 20–17)*

8. The closing of valves and rushing of blood through the heart cause characteristic heart sounds, which can be heard during *auscultation*. *(Figure 20–18)*

Cardiovascular System/Cardiac Cycle

Cardiodynamics p. 695

1. The amount of blood ejected by a ventricle during a single beat is the **stroke volume (SV)**. The amount of blood pumped by a ventricle each minute is the **cardiac output (CO)**. *(Figure 20–19)*

2. Cardiac output can be adjusted by changes in either stroke volume or heart rate. *(Figure 20–20)*

Overview: The Control of Cardiac Output p. 697 Factors Affecting the Heart Rate p. 697

3. The **cardioacceleratory center** in the medulla oblongata activates sympathetic neurons; the **cardioinhibitory center** controls the parasympathetic neurons that slow the heart rate. These cardiac centers receive inputs from higher centers and from receptors monitoring blood pressure and the concentrations of dissolved gases. *(Figure 20–21)*

4. The basic heart rate is established by the pacemaker cells of the SA node, but it can be modified by the autonomic nervous system. The **atrial reflex** accelerates the heart rate when the walls of the right atrium are stretched. *(Figure 20–22)*

5. Sympathetic activity produces more powerful contractions that reduce the ESV. Parasympathetic stimulation slows the heart rate, reduces the contractile strength, and raises the ESV.

6. Cardiac output is affected by various factors, including autonomic innervation and hormones. *(Figure 20–22)*

Factors Affecting the Stroke Volume p. 699

7. The stroke volume is the difference between the **end-diastolic volume (EDV)** and the **end-systolic volume (ESV)**. The **filling time** and **venous return** interact to determine the EDV. Normally, the greater the EDV, the more powerful is the succeeding contraction (the **Frank–Starling principle**). *(Figure 20–23)*

Summary: The Control of Cardiac Output p. 702

8. The difference between resting and maximal cardiac outputs is the **cardiac reserve**. *(Figure 20–24)*

100 Keys | p. 703

Cardiovascular System/Cardiac Output

The Heart and the Cardiovascular System p. 703

1. The heart does not work in isolation in maintaining adequate blood flow to all tissues.

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The great cardiac vein drains blood from the heart muscle to the

(a) left ventricle **(b)** right ventricle

(c) right atrium **(d)** left atrium

2. The autonomic centers for cardiac function are located in the

(a) myocardial tissue of the heart

(b) cardiac centers of the medulla oblongata

(c) cerebral cortex

(d) a, b, and c are correct

3. The serous membrane covering the inner surface of the heart is the

(a) parietal pericardium

(b) endocardium

(c) myocardium

(d) visceral pericardium

4. The simple squamous epithelium covering the valves of the heart constitutes the

(a) epicardium **(b)** endocardium

(c) myocardium **(d)** fibrous skeleton

5. The heart lies in the

(a) pleural cavity

(b) peritoneal cavity

(c) abdominopelvic cavity

(d) mediastinum

(e) abdominal cavity

6. The fibrous skeleton of the heart functions in all of the following, *except* to

(a) physically isolate the muscle fibers of the atria from those of the ventricles

(b) maintain the normal shape of the heart

(c) help distribute the forces of cardiac contraction

(d) allow more rapid contraction of the ventricles

(e) strengthen and help prevent overexpansion of the heart

7. The cardiac output is equal to the

(a) difference between the end-diastolic volume and the end-systolic volume

(b) product of heart rate and stroke volume

(c) difference between the stroke volume at rest and the stroke volume during exercise

(d) stroke volume less the end-systolic volume

(e) product of heart rate and blood pressure

8. During diastole, a chamber of the heart

(a) relaxes and fills with blood

(b) contracts and pushes blood into an adjacent chamber

(c) experiences a sharp increase in pressure

(d) reaches a pressure of approximately 120 mm Hg

9. During the cardiac cycle, the amount of blood ejected from the left ventricle when the semilunar valve opens is the

(a) stroke volume (SV)

(b) end-diastolic volume (EDV)

(c) end-systolic volume (ESV)

(d) cardiac output (CO)

10. What role do the chordae tendineae and papillary muscles play in the normal function of the AV valves?

11. Describe the three distinct layers that make up the heart wall.

12. What are the valves in the heart, and what is the function of each?

13. Trace the normal pathway of an electrical impulse through the conducting system of the heart.

14. What is the cardiac cycle? What phases and events are necessary to complete the cardiac cycle?

15. What three factors regulate stroke volume to ensure that the left and right ventricles pump equal volumes of blood?

LEVEL 2 Reviewing Concepts

16. The cells of the conducting system differ from the contractile cells of the heart in that

(a) conducting cells are larger and contain more
myofibrils

(b) contractile cells exhibit prepotentials

(c) contractile cells do not normally exhibit automaticity

(d) both a and b are correct

17. Which of the following is *longer*?

(a) the refractory period of cardiac muscle

(b) the refractory period of skeletal muscle

18. If the papillary muscles fail to contract

(a) the ventricles will not pump blood

(b) the atria will not pump blood

(c) the semilunar valves will not open

(d) the AV valves will not close properly

(e) none of the above

19. The cardiac output cannot increase indefinitely because

(a) the available filling time becomes shorter as the heart rate increases

(b) the cardiovascular centers adjust the heart rate

(c) the rate of spontaneous depolarization decreases

(d) the ion concentrations of pacemaker cell membranes decrease

20. Describe the function of the SA node in the cardiac cycle. How does this differ from the function of the AV node?

21. What are the source and significance of heart sounds?

22. Differentiate between stroke volume and cardiac output. How is cardiac output calculated?

23. What factors influence cardiac output?

24. What effect does sympathetic stimulation have on the heart? What effect does parasympathetic stimulation have on the heart?

25. Describe the effects that epinephrine, norepinephrine, glucagon, and thyroid hormones have on the contractility of the heart.

LEVEL 3 Critical Thinking and Clinical Applications

26. Vern is brought into the emergency room of a hospital suffering from cardiac arrhythmias. In the emergency room he begins to exhibit tachycardia and as a result loses consciousness. His anxious wife asks you why he has lost consciousness. What would you tell her?

27. Harvey has a heart murmur in his left ventricle that produces a loud “gurgling” sound at the beginning of systole. Which valve is probably faulty?

28. The following measurements were made on two individuals (the values recorded remained stable for one hour): Person 1: heart rate, 75 bpm; stroke volume, 60 ml Person 2: heart rate, 90 bpm; stroke volume, 95 ml Which person has the greater venous return? Which person has the longer ventricular filling time?

29. Karen is taking the medication *verapamil*, a drug that blocks the calcium channels in cardiac muscle cells. What effect should this medication have on Karen’s stroke volume?

| SUMMARY TABLE 20–1 | STRUCTURAL AND FUNCTIONAL DIFFERENCES BETWEEN CARDIAC MUSCLE

CELLS AND SKELETAL MUSCLE FIBERS

Feature	Cardiac Muscle Cells	Skeletal Muscle Fibers
Size	10 – 20 mm * 50 –100 mm	100 mm * up to 40 cm
Nuclei	Typically 1 (rarely 2–5)	Multiple (hundreds)
Contractile proteins	Sarcomeres along myofibrils	Sarcomeres along myofibrils
Internal membranes	Short T tubules; no triads formed with sarcoplasmic reticulum	Lo
Mitochondria	Abundant (25% of cell volume)	Much less abundant
Inclusions	Myoglobin, lipids, glycogen	Little myoglobin, few lipids, but extensive glycogen reserves
Blood supply	Very extensive	More extensive than in most connective tissues, but sparse compared with supply to cardiac muscle cells
Metabolism (resting)	Not applicable	Aerobic, primarily lipid-based
Metabolism (active)	Aerobic, primarily using lipids and carbohydrates	A
Contractions	Twitches with brief relaxation periods; long refractory period prevents tetanic contractions	Usually sustained contractions
Stimulus for contraction	Autorhythmicity of pacemaker cells generates action potentials	Activity of somatic motor neuron generates action potentials in sarcolemma
Trigger for contraction	Calcium entry from the ECF and calcium release from the sarcoplasmic reticulum	Calcium release from the sarcoplasmic reticulum
Intercellular connections	Branching network with cell membranes locked together at intercalated discs; connective tissue fibers tie adjacent layers together	Adjacent fibers tied together by connective tissue fibers

Cardiovascular System

Can you describe the pathway of blood through the heart? Stop here to use the *Cardiovascular System* module of your InterActive Physiology (IP) CD-ROM. This module contains interactive exercises, quizzes, and study outlines that will help you understand the following topics:

- Anatomy Review: The Heart
- Intrinsic Conduction System
- Cardiac Action Potential
- Cardiac Cycle
- Cardiac Output
- Anatomy Review: Blood Vessel Structure and Function
- Measuring Blood Pressure
- Factors That Affect Blood Pressure
- Blood Pressure Regulation
- Autoregulation and Capillary Dynamics

At this point in the chapter, click on *Anatomy Review: The Heart*. Use **IP** to review the anatomy of the heart and quiz yourself before you continue reading. A Study Outline consisting of notes, diagrams, and study questions can also be printed from **IP**. To help ensure your success in anatomy and physiology, review the remaining cardiovascular topics as they appear in your text and each time you see the CD icon.

- **FIGURE 20–1** An Overview of the Cardiovascular System. Driven by the pumping of the heart, blood flows through the pulmonary and systemic circuits in sequence. Each circuit begins and ends at the heart and contains arteries, capillaries, and veins.
- **FIGURE 20–2** The Location of the Heart in the Thoracic Cavity. **(a)** An anterior view of the chest, showing the position of the heart and major vessels relative to the ribs, sternum, and lungs. **(b)** A superior view of the organs in the mediastinum; portions of the lungs have been removed to reveal the blood vessels and airways. The heart is situated in the anterior

part of the mediastinum, immediately posterior to the sternum. **(c)** The relationship between the heart and the pericardial cavity; compare with the fist-and-balloon example. ATLAS: Plates 47a,b

The Anatomy of Blood Vessels

Objectives

- Distinguish among the types of blood vessels on the basis of their structure and function.
- Describe how and where fluid and dissolved materials enter and leave the cardiovascular system.

There are five general classes of blood vessels in the cardiovascular system. **Arteries** carry blood away from the heart. As they enter peripheral tissues, arteries branch repeatedly, and the branches decrease in diameter. The smallest arterial branches are called **arterioles** (ar-T R

E

e

-

¯o

ls). From the arterioles, blood moves into the **capillaries**, where diffusion occurs between blood and inter

stitial fluid. From the capillaries, blood enters small **venules** (VEN-

¯u

ls), which unite to form larger **veins** that return blood to the

heart.

Blood leaves the heart through the pulmonary trunk, which originates at the right ventricle, and the aorta, which originates at the left ventricle. Each of these arterial trunks has an internal diameter of about 2.5 cm (1 in.). The pulmonary arteries that branch from the pulmonary trunk carry blood to the lungs. The systemic arteries that branch from the aorta distribute blood to all other organs. Within these organs, further branching occurs, creating several hundred million tiny arterioles that provide blood to more than 10 billion capillaries. These capillaries, barely the diameter of a single red blood cell, form extensive branching networks. If all the capillaries in your body were placed end to end, their combined length would exceed 25,000 miles, enough to circle the globe.

The vital functions of the cardiovascular system depend entirely on events at the capillary level: All chemical and gaseous exchange between blood and interstitial fluid takes place across capillary walls. Cells rely on capillary diffusion to obtain nutrients and oxygen and to remove metabolic wastes, such as carbon dioxide and urea. Diffusion occurs very rapidly, because the distances involved are very small; few cells lie farther than 125 mm (0.005 in.) from a capillary. Homeostatic mechanisms operating at the local, regional, and systemic levels adjust blood flow through the capillaries to meet the demands of peripheral tissues.

Blood vessels must be resilient enough to withstand changes in pressure, and flexible enough to move with underlying tissues and organs. The pressures experienced by vessels vary with distance from the heart, and their structures reflect this fact. Moreover, arteries, veins, and capillaries differ in function, and these functional differences are associated with distinctive anatomical features.

The Structure of Vessel Walls

The walls of arteries and veins contain three distinct layers—the tunica intima, tunica media, and tunica externa (Figure 21–1•):

1. The **tunica intima** (IN-ti-muh), or *tunica interna*, is the innermost layer of a blood vessel. This layer includes the endothelial lining and an underlying layer of connective tissue containing a variable number of elastic fibers. In arteries, the outer margin of the tunica intima contains a thick layer of elastic fibers called the **internal elastic membrane**.

2. The tunica media, the middle layer, contains concentric sheets of smooth muscle tissue in a framework of loose connective tissue. The collagen fibers bind the tunica media to the tunica intima and tunica externa. Commonly the thickest layer in the wall of a small artery, the tunica media is separated from the surrounding tunica externa by a thin band of elastic fibers called the external elastic membrane. The smooth muscle cells of the tunica media encircle the endothelium lining the lumen of the blood vessel. When these smooth muscles contract, the vessel decreases in diameter; when they relax, the diameter increases. Large arteries also contain layers of longitudinally arranged smooth muscle cells.

3. The **tunica externa** (eks-TER-nuh) or *tunica adventitia* (ad-ven-TISH-a), the outermost layer of a blood vessel, is a connective tissue sheath. In arteries, this layer contains collagen fibers with scattered bands of elastic fibers. In veins, it is generally thicker than the tunica media and contains networks of elastic fibers and bundles of smooth muscle cells. The connective-tissue fibers of the tunica externa typically blend into those of adjacent tissues, stabilizing and anchoring the blood vessel.

Their layered walls give arteries and veins considerable strength. The muscular and elastic components also permit controlled alterations in diameter as blood pressure or blood volume changes. However, the walls of arteries and veins are too thick to allow diffusion between the bloodstream and surrounding tissues, or even between the blood and the tissues of the vessel itself. For this reason, the walls of large vessels contain small arteries and veins that supply the smooth muscle cells and fibroblasts of the tunica media and tunica externa. These blood vessels are called the *vasa vasorum* (“vessels of vessels”).

Differences between Arteries and Veins

Arteries and veins servicing the same region typically lie side by side (see Figure 21–1•). In sectional view, arteries and veins may be distinguished by the following characteristics:

- In general, the walls of arteries are thicker than those of veins. The tunica media of an artery contains more smooth muscle and elastic fibers than does that of a vein. These contractile and elastic components resist the pressure generated by the heart as it forces blood into the circuit.
- When not opposed by blood pressure, the elastic fibers in the arterial walls recoil, constricting the lumen. Thus, seen on dissection or in sectional view, the lumen of an artery often looks smaller than that of the corresponding vein. Because the walls of arteries are relatively thick and strong, they retain their circular shape in section. Cut veins tend to collapse, and in section they often look flattened or grossly distorted.
- The endothelial lining of an artery cannot contract, so when an artery constricts, its endothelium is thrown into folds that give sectioned arteries a pleated appearance. The lining of a vein lacks these folds.

In gross dissection, arteries and veins can generally be distinguished because:

- The thicker walls of arteries can be felt if the vessels are compressed.
- Arteries usually retain their cylindrical shape, whereas veins often collapse.
- Arteries are more resilient: When stretched, they keep their shape and elongate, and when released, they snap back. A small vein cannot tolerate as much distortion without collapsing or tearing.
- Veins typically contain *valves*—internal structures that prevent the backflow of blood toward the capillaries. In an intact vein, the location of each valve is marked by a slight distension of the vessel wall. (We will consider valve structure in a later section.)

Arteries

Their relatively thick, muscular walls make arteries elastic and contractile. Elasticity permits passive changes in vessel diameter in response to changes in blood pressure. For example, it allows arteries to absorb the surging pressure waves that accompany the contractions of the ventricles.

The contractility of the arterial walls enables them to change in diameter actively, primarily under the control of the sympathetic division of the autonomic nervous system. When stimulated, arterial smooth muscles contract, thereby constricting the artery—a process called **vasoconstriction**. Relaxation of these smooth muscles increases the diameter of the lumen—a process called **vasodilation**. Vasoconstriction and vasodilation affect (1) the afterload on the heart, (2) peripheral blood pressure, and (3) capillary blood flow. We will explore these effects in a later section. Contractility is also important during the vascular phase of hemostasis, when the contraction of a damaged vessel wall helps reduce bleeding. l**p. 661**

In traveling from the heart to peripheral capillaries, blood passes through *elastic arteries, muscular arteries,* and *arterioles* (Figure 21–2•).

Elastic Arteries

Elastic arteries, or *conducting arteries*, are large vessels with diameters up to 2.5 cm (1 in.). These vessels transport large volumes of blood away from the heart. The pulmonary trunk and aorta, as well as their major arterial branches (the *pulmonary, common carotid, subclavian,* and *common iliac arteries*), are elastic arteries.

The walls of elastic arteries (see Figure 21–2•) are extremely resilient because the tunica media contains a high density of elastic fibers and relatively few smooth muscle cells. As a result, elastic arteries can tolerate the pressure changes that occur during the cardiac cycle. We have already considered the role played by elastic rebound in the aorta in maintaining blood flow in the coronary arteries. l**p. 681** However, elastic rebound occurs to some degree in all elastic arteries. During ventricular systole, pressures rise rapidly and the elastic arteries expand. During ventricular diastole, blood pressure within the arterial system falls and the elastic fibers recoil to their original dimensions. Their expansion cushions the sudden rise in pressure during ventricular systole, and their recoil slows the drop in pressure during ventricular diastole. This feature is important because blood pressure is the driving force behind blood flow: The greater the pressure oscillations, the greater the changes in blood flow. The elasticity of the arterial system dampens the pressure peaks and valleys that accompany the heartbeat. By the time blood reaches the arterioles, the pressure oscillations have disappeared, and blood flow is continuous.

Muscular Arteries

Muscular arteries, also known as *medium-sized arteries* or *distribution arteries,* distribute blood to the body's skeletal muscles and internal organs. Most of the vessels of the arterial system are muscular arteries. These arteries are characterized by a thick tunica media that contains more smooth muscle cells than does the tunica media of elastic arteries (see Figures 21–1 and 21–2•). A typical muscular artery has a lumen diameter of approximately 0.4 cm (0.16 in.), but some have diameters as small as 0.5 mm. The *external carotid arteries* of the neck, the *brachial arteries* of the arms, the *mesenteric arteries* of the abdomen, and the *femoral arteries* of the thighs are examples of muscular arteries. Superficial muscular arteries are important as *pressure points*—places in the body where muscular arteries can be forced against deeper bones to reduce blood flow and control severe bleeding.

Arterioles

Arterioles, with an internal diameter of 30 mm or less, are considerably smaller than muscular arteries. Arterioles have a poorly defined tunica externa, and the tunica media in the larger arterioles consists of one or two layers of smooth muscle cells (see Figure 21–2•). The tunica media of the smallest arterioles contains scattered smooth muscle cells that do not form a complete layer.

The diameters of smaller muscular arteries and arterioles change in response to local conditions or to sympathetic or endocrine stimulation. For example, arterioles in most tissues vasodilate when oxygen levels are low and, as we saw in Chapter 16, vaso-constrict under sympathetic stimulation. l**p. 526** Changes in their diameter affect the amount of force required to push blood around the cardiovascular system: More pressure is required to push blood through a constricted vessel than through a dilated one. The force opposing blood flow is called **resistance (R)**, so arterioles are also called **resistance vessels**.

Vessel characteristics change gradually with distance from the heart. Each type of vessel described here actually represents the midpoint in a portion of a continuum. Thus, the largest muscular arteries contain a considerable amount of elastic tissue, whereas the smallest resemble heavily muscled arterioles.

Arteries carry blood under great pressure, and their walls are adapted to handle that pressure. Occasionally, local arterial pressure exceeds the capacity of the elastic components of the tunics, producing an **aneurysm** (AN-u-rizm), or bulge in the weakened wall of an artery. The bulge resembles a bubble in the wall of a tire—and like a bad tire, the affected artery can suffer a catastrophic blowout. The most dangerous aneurysms occur in arteries of the brain (where they cause strokes) or in the aorta (where a rupture will cause fatal bleeding in a matter of minutes). AM: Aneurysms

Capillaries

When we think of the cardiovascular system, we think first of the heart or the great blood vessels connected to it. But the real work of the cardiovascular system is done in the microscopic capillaries that permeate most tissues. These delicate vessels weave throughout active tissues, forming intricate networks that surround muscle fibers, radiate through connective tissues, and branch beneath the basal laminae of epithelia.

Capillaries are the *only* blood vessels whose walls permit exchange between the blood and the surrounding interstitial fluids. Because capillary walls are thin, diffusion distances are small, so exchange can occur quickly. In addition, blood flows through capillaries relatively slowly, allowing sufficient time for the diffusion or active transport of materials across the capillary walls. Thus, the histological structure of capillaries permits a two-way exchange of substances between blood and interstitial fluid.

A typical capillary consists of an endothelial tube inside a delicate basal lamina; neither a tunica media nor a tunica externa is present (see Figure 21–2•). The average diameter of a capillary is a mere 8 mm, very close to that of a single red blood cell. There are two major types of capillaries: *continuous capillaries* and *fenestrated capillaries*.

Continuous Capillaries

Most regions of the body are supplied by continuous capillaries. In a **continuous capillary**, the endothelium is a complete lining. A cross section through a large continuous capillary cuts across several endothelial cells (Figure 21–4a•). In a small continuous capillary, a single endothelial cell may completely encircle the lumen.

Continuous capillaries are located in all tissues except epithelia and cartilage. Continuous capillaries permit the diffusion of water, small solutes, and lipid-soluble materials into the surrounding interstitial fluid, but prevent the loss of blood cells and plasma proteins. In addition, some exchange may occur between blood and interstitial fluid by bulk transport—the movement of vesicles that form through endocytosis at the inner endothelial surface. l**p. 93**

In specialized continuous capillaries throughout most of the central nervous system and in the thymus, the endothelial cells are bound together by tight junctions. These capillaries have very restricted permeability characteristics. We discussed one example—the capillaries responsible for the *blood–brain barrier*—in Chapters 12 and 14. l**pp. 386, 458**

Fenestrated Capillaries

Fenestrated (FEN-es-tr -ted) **capillaries** (*fenestra*, window) are capillaries that contain “windows,” or pores, that penetrate the

a endothelial lining (Figure 21–4b•). The pores permit the rapid exchange of water and solutes as large as small peptides between plasma and interstitial fluid. Examples of fenestrated capillaries include the *choroid plexus* of the brain and the blood vessels in a variety of endocrine organs, such as the hypothalamus and the pituitary, pineal, and thyroid glands. Fenestrated capillaries are also located along absorptive areas of the intestinal tract and at filtration sites in the kidneys. Both the number of pores and their permeability characteristics may vary from one region of the capillary to another.

Sinusoids (S -nuh-soydz) resemble fenestrated capillaries that are flattened and irregularly shaped. In contrast to fenestrated

I capillaries, sinusoids commonly have gaps between adjacent endothelial cells, and the basal lamina is either thinner or absent. As a result, sinusoids permit the free exchange of water and solutes as large as plasma proteins between blood and interstitial fluid.

Blood moves through sinusoids relatively slowly, maximizing the time available for exchange across the sinusoidal walls. Sinusoids occur in the liver, bone marrow, spleen, and many endocrine organs, including the pituitary and adrenal glands. At liver sinusoids, plasma proteins secreted by liver cells enter the bloodstream. Along sinusoids of the liver, spleen, and bone marrow, phagocytic cells monitor the passing blood, engulfing damaged red blood cells, pathogens, and cellular debris.

Capillary Beds

Capillaries do not function as individual units but as part of an interconnected network called a **capillary bed**, or **capillary plexus** (Figure 21–5•). A single arteriole generally gives rise to dozens of capillaries that empty into several *venules*, the smallest vessels of the venous system. The entrance to each capillary is guarded by a band of smooth muscle called a **precapillary sphincter**. Contraction of the smooth muscle cells narrows the diameter of the capillary entrance, thereby reducing the flow of blood. Relaxation of the sphincter dilates the opening, allowing blood to enter the capillary faster.

A capillary bed contains several relatively direct connections between arterioles and venules. The wall in the initial part of

such a passageway possesses smooth muscle capable of changing its diameter. This segment is called a **metarteriole** (met-ar-T

¯E

R-

¯e

-

¯o

l). The rest of the passageway, which resembles a typical capillary in structure, is called a **thoroughfare channel**.

A capillary bed may receive blood from more than one artery. The multiple arteries, called **collaterals**, enter the region and fuse before giving rise to arterioles. The fusion of two collateral arteries that supply a capillary bed is an example of an **arterial anastomosis**. (An *anastomosis* is the joining of two tubes.) The interconnections between the *anterior* and *posterior interventricu*

lar arteries of the heart are arterial anastomoses. l**p. 681** An arterial anastomosis acts like an insurance policy: If one artery is compressed or blocked, capillary circulation will continue.

Arteriovenous (ar-ter-e -o-VE¯-nus) **anastomoses** are direct connections between arterioles and venules. When an arteriovenous anastomosis is dilated, blood will bypass the capillary bed and flow directly into the venous circulation. The pattern of blood flow through an arteriovenous anastomosis is regulated primarily by sympathetic innervation under the control of the cardiovascular centers of the medulla oblongata.

Vasomotion

Although blood normally flows from arterioles to venules at a constant rate, the flow within each capillary is quite variable. Each precapillary sphincter alternately contracts and relaxes, perhaps a dozen times per minute. As a result, the blood flow within any capillary occurs in pulses rather than as a steady and constant stream. The net effect is that blood may reach the venules by one route now and by a different route later. The cycling of contraction and relaxation of smooth muscles that changes blood flow through capillary beds is called **vasomotion**.

Vasomotion is controlled locally by changes in the concentrations of chemicals and dissolved gases in the interstitial fluids. For example, when dissolved oxygen concentrations decline within a tissue, the capillary sphincters relax, so blood flow to the area increases. This process, an example of capillary *autoregulation*, will be the focus of a later section.

When you are at rest, blood flows through roughly 25 percent of the vessels within a typical capillary bed in your body. Your cardiovascular system does not contain enough blood to maintain adequate blood flow to all the capillaries in all the capillary beds in your body at the same time. As a result, when many tissues become active, the blood flow through capillary beds must be coordinated. We will describe the mechanisms by which the cardiovascular centers perform this coordination later in the chapter.

Veins

Veins collect blood from all tissues and organs and return it to the heart. The walls of veins can be thinner than those of corresponding arteries because the blood pressure in veins is lower than that in arteries. Veins are classified on the basis of their size. Even though their walls are thinner, in general veins are larger in diameter than their corresponding arteries. (Review Figure 21–2•,

p. 711, to compare typical arteries and veins.)

Venules

Venules, which collect blood from capillary beds, are the smallest venous vessels. They vary widely in size and structure. An average venule has an internal diameter of roughly 20 mm. Venules smaller than 50 mm lack a tunica media, and the smallest venules resemble expanded capillaries.

Medium-Sized Veins

Medium-sized veins range from 2 to 9 mm in internal diameter, comparable in size to muscular arteries. In these veins, the tunica media is thin and contains relatively few smooth muscle cells. The thickest layer of a medium-sized vein is the tunica externa, which contains longitudinal bundles of elastic and collagen fibers.

Large Veins

Large veins include the superior and inferior venae cavae and their tributaries within the abdominopelvic and thoracic cavities. All the tunica layers are present in all large veins.

The slender tunica media is surrounded by a thick tunica externa composed of a mixture of elastic and collagen fibers.

Venous Valves

The arterial system is a high-pressure system: Almost all the force developed by the heart is required to push blood along the network of arteries and through miles of capillaries. Blood pressure in a peripheral venule is only about 10 percent of that in the ascending aorta, and pressures continue to fall along the venous system.

The blood pressure in venules and medium-sized veins is so low that it cannot overcome the force of gravity. In the limbs, veins of this size contain **valves**, folds of the tunica intima that project from the vessel wall and point in the direction of blood flow. These valves, like those in the heart, permit blood flow in one direction only. Venous valves prevent the backflow of blood toward the capillaries (Figure 21–6•).

As long as the valves function normally, any movement that distorts or compresses a vein will push blood toward the heart. This effect improves *venous return*, the rate of blood flow to the heart. l**p. 699** The mechanism is particularly important when you are standing, because blood returning from your feet must overcome the pull of gravity to ascend to the heart. Valves compartmentalize the blood within the veins, thereby dividing the weight of the blood between the compartments. Any contraction of the surrounding skeletal muscles squeezes the blood toward the heart. Although you are probably not aware of it, when you stand, rapid cycles of contraction and relaxation are occurring within your leg muscles, helping to push blood toward the trunk. When you lie down, venous valves contribute less to venous return, because your heart and major vessels are at the same level.

If the walls of the veins near the valves weaken or become stretched and distorted, the valves may not work properly. Blood then pools in the veins, and the vessels become grossly distended. The effects range from mild discomfort and a cosmetic problem, as in superficial **varicose veins** in the thighs and legs, to painful distortion of adjacent tissues, as in **hemorrhoids**. AM: Problems with Venous Valve Function

The Distribution of Blood

The total blood volume is unevenly distributed among arteries, veins, and capillaries (Figure 21–7•). The heart, arteries, and capillaries in the pulmonary and systemic circuits normally contain 30–35 percent of the blood volume (roughly 1.5 liters of whole blood), and the venous system contains the rest (65–70 percent, or about 3.5 liters). Roughly one-third of the blood in the venous system (about a liter) is circulating within the liver, bone marrow, and skin. These organs have extensive venous networks that at any moment contain large volumes of blood.

Because their walls are thinner, with a lower proportion of smooth muscle, veins are much more distensible (expandable) than arteries. For a given rise in blood pressure, a typical vein will stretch about eight times as much as a corresponding artery. The *capacitance* of a blood vessel is the relationship between the volume of blood it contains and the blood pressure. If a vessel behaves like a child's balloon, expanding easily at low pressures, it has high capacitance. If it behaves more like a truck tire, expanding only at high pressures, it has low capacitance. Veins, which expand easily, are called **capacitance vessels**. Because veins have high capacitance, they can accommodate large changes in blood volume. If the blood volume rises or falls, the elastic walls stretch or recoil, changing the volume of blood in the venous system.

If serious hemorrhaging occurs, the *vasomotor centers* of the medulla oblongata stimulate sympathetic nerves that innervate smooth muscle cells in the walls of medium-sized veins. This activity has two major effects:

1. *Systemic Veins Constrict.* This process, called **venoconstriction** (ve-no-kon-STRIK-shun), reduces the amount of blood within the venous system, thereby increasing the volume within the arterial system and capillaries. Venoconstriction can keep the blood volume within the arteries and capillaries at near-normal levels despite a significant blood loss.

2. *The Constriction of Veins in the Liver, Skin, and Lungs Redistributes a Significant Proportion of the Total Blood Volume.* As a result, blood flow to delicate organs (such as the brain) and to active skeletal muscles can be increased or maintained after blood loss. The amount of blood that can be shifted from veins in the liver, skin, and lungs to the general circulation, called the **venous reserve**, is normally about 20 percent of total blood volume.

Concept Check

A cross section of tissue shows several small, thin-walled vessels with very little smooth muscle tissue in the tunica media.

Which type of vessel are these?

Why are valves located in veins, but not in arteries?

Where in the body would you find fenestrated capillaries?

Answers begin on p. A–1

Review blood vessel anatomy on the **IP CD-ROM: Cardiovascular System/Anatomy Review: Blood Vessel Structure and Function.**

Cardiovascular Physiology

Objectives

- Explain the mechanisms that regulate blood flow through arteries, capillaries, and veins.
- Describe the factors that influence blood pressure and how blood pressure is regulated.
- Discuss the mechanisms and various pressures involved in the movement of fluids between capillaries and interstitial spaces.

Figure 21–8• provides an overview of our discussion of cardiovascular physiology. The purpose of cardiovascular regulation is the maintenance of adequate blood flow through the capillaries in peripheral tissues and organs. Under normal circumstances, blood flow is equal to cardiac output. When cardiac output goes up, so does the blood flow through capillary beds; when cardiac output declines, capillary blood flow is reduced. Capillary blood flow is determined by the interplay between *pressure (P)* and *resistance*

(R) in the cardiovascular network. To keep blood moving, the heart must generate pressure sufficient to overcome the resistance to blood flow in the pulmonary and systemic circuits. In general terms, flow (*F*) is directly proportional to the pressure (increased pressure ¡ increased flow), and inversely proportional to resistance (increased resistance ¡ decreased flow). However, the absolute pressure is less important than the pressure *gradient*—the difference in pressure from one end of the vessel to the other. This relationship can be summarized as

R

where the symbol r means “is proportional to” and ¢ means “the difference in.” The largest pressure gradient is found between the base of the aorta and the proximal ends of peripheral capillary beds. Cardiovascular control centers can alter this pressure gradient, and thereby change the rate of capillary blood flow, by adjusting cardiac output and peripheral resistance.

Blood leaving the peripheral capillaries enters the venous system. Although the pressure gradient across the venous system is relatively small, venous resistance is very low. This low venous blood pressure—aided by valves, skeletal muscle contraction, gravity, and other factors—is sufficient to return the blood to the heart. When necessary, cardiovascular control centers can elevate venous pressure (through venoconstriction) to enhance venous return and maintain adequate cardiac output.

We will begin this section by examining blood pressure and resistance more closely. We will then consider the mechanisms of *capillary exchange*, the transfer of liquid and solutes between the blood and interstitial fluid. Capillary exchange provides tissues with oxygen and nutrients and removes the carbon dioxide and waste products generated by active cells.

Active tissues require more blood flow than inactive ones; even something as simple as a change in position—going from sitting to standing, for instance—triggers a number of cardiovascular changes. We will end this section with a discussion of what those changes are and how they are coordinated.

Pressure

When talking about cardiovascular pressures, three values are usually reported:

1. *Blood Pressure.* The term **blood pressure (BP)** refers to arterial pressure, usually reported in millimeters of mercury (mm Hg). Systemic arterial pressures range from an average of 100 mm Hg at the entrance to the aorta to roughly 35 mm Hg at the start of a capillary network.

2. *Capillary Hydrostatic Pressure.* **Capillary hydrostatic pressure (CHP)**, or *capillary pressure,* is the pressure within capillary beds. Along the length of a typical capillary, pressures decline from roughly 35 mm Hg to about 18 mm Hg.

3. *Venous Pressure.* **Venous pressure** is the pressure within the venous system. Venous pressure is quite low: The pressure gradient from the venules to the right atrium is only about 18 mm Hg.

The ¢*P* across the entire systemic circuit, sometimes called the *circulatory pressure,* averages about 100 mm Hg. For circulation to occur, the circulatory pressure must be sufficient to overcome the **total peripheral resistance—**the resistance of the entire cardiovascular system. The arterial network has by far the largest pressure gradient (65 mm Hg), and this primarily reflects the relatively high resistance of the arterioles.

Resistance

The total peripheral resistance of the cardiovascular system reflects a combination of *vascular resistance, viscosity,* and *turbulence.*

Vascular resistance

Vascular resistance, the resistance of the blood vessels, is the largest component. The most important factor in vascular resistance is friction between blood and the vessel walls. The amount of friction depends on the length and diameter of the vessel.

Vessel Length Increasing the length of a blood vessel increases friction: The longer the vessel, the larger the surface area in contact with blood. You can easily blow the water out of a snorkel that is 2.5 cm (1 in.) in diameter and 25 cm (10 in.) long, but you cannot blow the water out of a 15-m-long garden hose, because the total friction is too great. The most dramatic changes in blood vessel length occur between birth and maturity, as individuals grow to adult size. In adults, vessel length can increase or decrease gradually when individuals gain or lose weight, but on a day-to-day basis this component of vascular resistance can be considered constant.

Vessel Diameter The effects of friction on blood act primarily in a narrow zone closest to the vessel wall. In a small-diameter vessel, nearly all the blood is slowed down by friction with the walls. Resistance is therefore relatively high. Blood near the center of a large-diameter vessel does not encounter friction with the walls, so the resistance in large vessels is relatively low.

Differences in diameter have much more significant effects on resistance than do differences in length. If two vessels are equal in diameter but one is twice as long as the other, the longer vessel offers twice as much resistance to blood flow. But for two vessels of equal length, one twice the diameter of the other, the narrower one offers 16 times as much resistance to blood flow. This relationship, expressed in terms of the vessel radius r and resistance R, can be summarized as R r 1> r .

More significantly, there is no way to control vessel length, but vessel diameter can change quickly through vasoconstriction or vasodilation. Most of the peripheral resistance occurs in arterioles, the smallest vessels of the arterial system. As noted earlier in the chapter, arterioles are extremely muscular: The wall of an arteriole with a luminal diameter of 30 mm can have a 20-mm-thick layer of smooth muscle. When these smooth muscles contract or relax, peripheral resistance increases or decreases. Because a small change in diameter produces a large change in resistance, mechanisms that alter the diameters of arterioles provide control over peripheral resistance and blood flow.

Viscosity

Viscosity is the resistance to flow caused by interactions among molecules and suspended materials in a liquid. Liquids of low viscosity, such as water (viscosity 1.0), flow at low pressures; thick, syrupy fluids, such as molasses (viscosity 300), flow only under higher pressures. Whole blood has a viscosity about five times that of water, owing to the presence of plasma proteins and blood cells. Under normal conditions, the viscosity of blood remains stable, but anemia, polycythemia, and other disorders that affect the hematocrit also change blood viscosity, and thus peripheral resistance.

Turbulence

High flow rates, irregular surfaces, and sudden changes in vessel diameter upset the smooth flow of blood, creating eddies and swirls. This phenomenon, called **turbulence**, increases resistance and slows blood flow.

Turbulence normally occurs when blood flows between the atria and the ventricles, and between the ventricles and the aortic and pulmonary trunks. It also develops in large arteries, such as the aorta, when cardiac output and arterial flow rates are very high. However, turbulence seldom occurs in smaller vessels unless their walls are damaged. For example, the development of an atherosclerotic plaque creates abnormal turbulence and restricts blood flow. Because of the distinctive sound, or *bruit* (broo-E), produced by turbulence, the presence of plaques in large blood vessels can often be detected with a stethoscope. AM: Checking the Pulse and Blood Pressure

Table 21–1 provides a quick review of the terms and relationships discussed in this section.

An Overview of Cardiovascular Pressures

The graphs in Figure 21–9• provide an overview of the vessel diameters, areas, pressures, and velocity of blood flow in the systemic circuit.

- As you proceed from the aorta toward the capillaries, divergence occurs; the arteries branch repeatedly, and each branch is smaller in diameter than the preceding one (Figure 21–9a•). As you proceed from the capillaries toward the venae cavae, convergence occurs; vessel diameters increase as venules combine to form small and medium-sized veins.
- Although the arterioles, capillaries, and venules are small in diameter, the body has a great many of them. All the blood flowing through the aorta also flows through peripheral capillaries. Blood pressure and the speed of blood flow are proportional to the cross-sectional area of the vessels involved. What is important is not the cross-sectional area of each individual vessel, but the *combined* cross-sectional area of *all* the vessels (Figure 21–9b•). Even though the arterioles, capillaries, and venules are small in diameter, the body

has a great many of them. In effect, your blood moves from one big pipe (the aorta, with a cross-sectional area of 4.5 cm) into countless tiny ones (the peripheral capillaries, with a total cross-sectional area of 5000 cm), and then back to the heart through two large venae cavae.

- As arterial branching occurs, the cross-sectional area increases and blood pressure falls rapidly (Figure 21–9c•). Most of the decline occurs in the small arteries and arterioles of the arterial system; venous pressures are relatively low.
- As the total cross-sectional area of the vessels increases from the aorta toward the capillaries, the velocity of blood flow decreases (Figure 21–9d•). Blood flow velocity then rises as the cross-sectional area drops from the capillaries toward the venae cavae.

Figure 21–10• graphs the blood pressure throughout the cardiovascular system. Systemic pressures are highest in the aorta, peaking at about 120 mm Hg, and reach a minimum of 2 mm Hg at the entrance to the right atrium. Pressures in the pulmonary circuit are much lower than those in the systemic circuit. The right ventricle does not ordinarily develop high pressures because the pulmonary vessels are much shorter and more distensible than the systemic vessels, thus providing less resistance to blood flow.

Arterial Blood Pressure

Arterial pressure is important because it maintains blood flow through capillary beds. To do this, it must always be high enough to overcome the peripheral resistance. Arterial pressure is not constant; it rises during ventricular systole and falls during ventricular diastole. The peak blood pressure measured during ventricular systole is called **systolic pressure**, and the minimum blood pressure at the end of ventricular diastole is called **diastolic pressure**. In recording blood pressure, we separate systolic and diastolic pressures by a slash, as in “120> 80” (“one-twenty over eighty”) or “110> 75.”

A *pulse* is a rhythmic pressure oscillation that accompanies each heartbeat. The difference between the systolic and diastolic pressures is the **pulse pressure** (see Figure 21–10•). To report a single blood pressure value, we use the **mean arterial pressure (MAP)**, which is calculated by adding one-third of the pulse pressure to the diastolic pressure:

For a systolic pressure of 120 mm Hg and a diastolic pressure of 90 mm Hg, the MAP can be calculated as follows:

A normal range of systolic and diastolic pressures occurs in healthy individuals. When pressures shift outside of the normal range, clinical problems develop. Abnormally high blood pressure is termed **hypertension**; abnormally low blood pressure, **hypotension**. Hypertension is much more common, and in fact many cases of hypotension result from overly aggressive drug treatment for hypertension.

The usual criterion for hypertension in adults is a blood pressure greater than 140> 90. Hypertension significantly increases the workload on the heart, and the left ventricle gradually enlarges. More muscle mass means a greater oxygen demand. When the coronary circulation cannot keep pace, symptoms of coronary ischemia appear. l**p. 682** Increased arterial pressures also place a physical stress on the walls of blood vessels throughout the body. This stress promotes or accelerates the development of arteriosclerosis and increases the risk of aneurysms, heart attacks, and strokes. AM: Hypertension and Hypotension

Elastic Rebound

As systolic pressure climbs, the arterial walls stretch, just as an extra puff of air expands a partially inflated balloon. This expansion allows the arterial system to accommodate some of the blood provided by ventricular systole. When diastole begins and blood pressures fall, the arteries recoil to their original dimensions. This phenomenon is called **elastic rebound**. Some blood is forced back toward the left ventricle, closing the aortic valve and helping to drive additional blood into the coronary arteries. However, most of the push generated by elastic rebound forces blood toward the capillaries. This helps maintain blood flow along the arterial network while the left ventricle is in diastole.

Pressures in Small Arteries and Arterioles

The mean arterial pressure and the pulse pressure become smaller as the distance from the heart increases (see Figure 21–10•):

- The mean arterial pressure declines as the arterial branches become smaller and more numerous. In essence, the blood pressure decreases as it overcomes friction and produces blood flow.
- The pulse pressure lessens as a result of the cumulative effects of elastic rebound along the arterial system. The effect can be likened to a series of ever-softer echoes following a loud shout. Each time an echo is produced, the reflecting surface absorbs some of the sound energy. Eventually, the echo disappears. The pressure surge accompanying ventricular ejection is analogous to the shout, and it is reflected by the wall of the aorta, echoing down the arterial system until it finally disappears at the level of the small arterioles. By the time blood reaches a precapillary sphincter, no pressure oscillations remain, and the blood pressure remains steady at approximately 35 mm Hg. AM: Checking the Pulse and Blood Pressure

Venous Pressure and Venous Return

Venous pressure, although low, determines venous return—the amount of blood arriving at the right atrium each minute. Venous return has a direct impact on cardiac output. l**p. 699** Although blood pressure at the start of the venous system is only about one-tenth that at the start of the arterial system, the blood must still travel through a vascular network as complex as the arterial system before returning to the heart.

Pressures at the entrance to the right atrium fluctuate, but they average about 2 mm Hg. Thus, the effective pressure in the venous system is roughly 16 mm Hg (from 18 mm Hg in the venules to 2 mm Hg in the venae cavae), compared with 65 mm Hg in the arterial system (from 100 mm Hg at the aorta to 35 mm Hg at the capillaries). Yet, although venous pressures are low, veins offer comparatively little resistance, so pressure declines very slowly as blood moves through the venous system. As blood continues toward the heart, the veins become larger, resistance drops, and the velocity of blood flow increases (see Figure 21–9•,
p. 721).

When you stand, the venous blood returning from your body inferior to the heart must overcome gravity as it ascends within the inferior vena cava. Two factors assist the low venous pressures in propelling blood toward your heart: *muscular compression* of peripheral veins and the *respiratory pump*.

Muscular Compression The contractions of skeletal muscles near a vein compress it, helping to push blood toward the heart. The valves in small and medium-sized veins ensure that blood flows in one direction only (see Figure 21–6•, p. 717). When standing and walking, the cycles of contraction and relaxation that accompany normal movements assist venous return. If you stand at attention, with knees locked and leg muscles immobilized, that assistance is lost. The reduction in venous return then leads to a fall in cardiac output, which reduces the blood supply to the brain. This decline is sometimes enough to cause **fainting**, a temporary loss of consciousness. You would then collapse, but while you were in the horizontal position, both venous return and cardiac output would return to normal.

The Respiratory Pump As you inhale, your thoracic cavity expands, reducing the pressure within the pleural cavities. This drop in pressure pulls air into your lungs. At the same time, blood is pulled into the inferior vena cava and right atrium from the smaller veins of your abdominal cavity and lower body. The effect on venous return through the superior vena cava is less pronounced, as blood in that vessel is normally assisted by gravity. As you exhale, your thoracic cavity decreases in size. Internal pressure then rises, forcing air out of your lungs and pushing venous blood into the right atrium. This mechanism is called the **respiratory pump**, or *thoracoabdominal pump*. The importance of such pumping action increases during heavy exercise, when respirations are deep and frequent.

Review blood pressure regulation on the **IP CD-ROM: Cardiovascular System/Factors That Affect Blood Pressure.**

Capillary Pressures and Capillary Exchange

Because capillary exchange plays such an important role in homeostasis, we will now consider the factors and mechanisms involved. The most important processes that move materials across typical capillary walls are *diffusion*, *filtration*, and *reabsorption*.

Diffusion

As we saw in Chapter 3, *diffusion* is the net movement of ions or molecules from an area where their concentration is higher to an area where their concentration is lower. l**p. 85** The difference between the high and low concentrations represents a *concentration gradient*, and diffusion tends to eliminate that gradient. Diffusion occurs most rapidly when (1) the distances involved are small, (2) the concentration gradient is large, and (3) the ions or molecules involved are small.

Different substances diffuse across capillary walls by different routes:

1. Water, ions, and small organic molecules, such as glucose, amino acids, and urea, can usually enter or leave the bloodstream by diffusion between adjacent endothelial cells or through the pores of fenestrated capillaries.

2. Many ions, including sodium, potassium, calcium, and chloride, can diffuse across endothelial cells by passing through channels in cell membranes.

3. Large water-soluble compounds are unable to enter or leave the bloodstream except at fenestrated capillaries, such as those of the hypothalamus, the kidneys, many endocrine organs, and the intestinal tract.

4. Lipids, such as fatty acids and steroids, and lipid-soluble materials, including soluble gases such as oxygen and carbon dioxide, can cross capillary walls by diffusion through the endothelial cell membranes.

5. Plasma proteins are normally unable to cross the endothelial lining anywhere except in sinusoids, such as those of the liver, where plasma proteins enter the bloodstream.

Filtration

Filtration is the removal of solutes as a solution flows across a porous membrane; solutes too large to pass through the pores are filtered out of the solution. The driving force for filtration is hydrostatic pressure, which, as we saw earlier, pushes water from an area of higher pressure to an area of lower pressure.

In *capillary filtration*, water and small solutes are forced across a capillary wall, leaving larger solutes and suspended proteins in the bloodstream (Figure 21–11•). The solute molecules leaving the bloodstream are those small enough to pass between adjacent endothelial cells or through the pores in a fenestrated capillary. Filtration occurs primarily at the arterial end of a capillary, where CHP is highest.

Reabsorption

Reabsorption occurs as the result of osmosis. *Osmosis* is a special term used to refer to the diffusion of water across a selectively permeable membrane separating two solutions of differing solute concentrations. Water molecules tend to diffuse across a membrane toward the solution containing the higher solute concentration (see Figure 3–16•, p. 88).

The **osmotic pressure (OP)** of a solution is an indication of the force of osmotic water movement—in other words, the pressure that must be applied to prevent osmotic movement across a membrane. The higher the solute concentration of a solution, the greater the solution's osmotic pressure. The osmotic pressure of the blood is also called *blood colloid osmotic pressure (BCOP)*, because only the suspended proteins are unable to cross the capillary walls. Clinicians often use the term *oncotic pressure* (*onkos*, a swelling) when referring to the colloid osmotic pressure of body fluids. The two terms are equivalent. Osmotic water movement will continue until either the solute concentrations are equalized or the movement is prevented by an opposing hydrostatic pressure.

We will now consider the interplay between filtration and reabsorption along the length of a typical capillary. As the discussion proceeds, remember that hydrostatic pressure forces water *out of* a solution, whereas osmotic pressure draws water *into* a solution.

The Interplay between Filtration and Reabsorption

Capillary blood pressure declines as one travels from the arterial end to the venous end. As a result, the rates of filtration and reabsorption gradually change as blood passes along the length of a capillary. The factors involved are diagrammed in Figure 21–12•.

The *net hydrostatic pressure* tends to push water and solutes out of capillaries and into the interstitial fluid. The net hydrostatic pressure is the difference between

1. the *capillary hydrostatic pressure (CHP)*, which ranges from 35 mm Hg at the arterial end of a capillary to 18 mm Hg at the venous end, and

2. the *hydrostatic pressure of the interstitial fluid (IHP).* Measurements of IHP have yielded very small values that differ from tissue to tissue—from +6 mm Hg in the brain to -6 mm Hg in subcutaneous tissues. A positive IHP opposes CHP, and the tissue hydrostatic pressure must be overcome before fluid can move out of a capillary. A negative IHP assists CHP, and additional fluid will be pulled out of the capillary. However, under normal circumstances the average IHP is 0 mm Hg, and we can assume that the net hydrostatic pressure is equal to CHP. (For this reason, IHP is not included in Figure 21–12•.)

The *net colloid osmotic pressure* tends to pull water and solutes into a capillary from the interstitial fluid. The net colloid osmotic pressure is the difference between

1. the *blood colloid osmotic pressure (BCOP),* which is roughly 25 mm Hg, and

2. the *interstitial fluid colloid osmotic pressure (ICOP).* The ICOP is as variable and low as the IHP, because the interstitial fluid in most tissues contains negligible quantities of suspended proteins. Reported values of ICOP are from 0 to 5 mm Hg, within the range of pressures recorded for the IHP. It is thus safe to assume that under normal circumstances the net colloid osmotic pressure is equal to the BCOP. (For this reason, ICOP is not included in Figure 21–12•.)

The **net filtration pressure (NFP)** is the difference between the net hydrostatic pressure and the net osmotic pressure. In terms of the factors just listed, this means that

At the arterial end of a capillary, the net filtration pressure can be calculated as follows:

NFP =135 -02 -125 -02 =35 -25 =10 mm Hg

Because this value is positive, it indicates that fluid will tend to move *out of* the capillary and into the interstitial fluid. At the venous end of the capillary, the net filtration pressure will be:

NFP =118 -02 -125 -02 =18 -25 =-7 mm Hg

The minus sign indicates that fluid tends to move *into* the capillary; that is, reabsorption is occurring.

The transition between filtration and reabsorption occurs where the CHP is 25 mm Hg, because at that point the hydrostatic and osmotic forces are equal—that is, the NFP is 0 mm Hg. If the maximum filtration pressure at the arterial end of the capillary were equal to the maximum reabsorption pressure at the venous end, this transition point would lie midway along the length of the capillary. Under these circumstances, filtration would occur along the first half of the capillary, and an identical amount of reabsorption would occur along the second half. However, the maximum filtration pressure is higher than the maximum reabsorption pressure, so the transition point between filtration and reabsorption normally lies closer to the venous end of the capillary than to the arterial end. As a result, more filtration than reabsorption occurs along the capillary. Of the roughly 24 liters of fluid that moves out of the plasma and into the interstitial fluid each day, 20.4 liters (85 percent) is reabsorbed. The remainder (3.6 liters) flows through the tissues and into lymphatic vessels, for eventual return to the venous system.

This continuous movement of water out of the capillaries, through peripheral tissues, and then back to the bloodstream by way of the lymphatic system has four important functions:

1. It ensures that plasma and interstitial fluid, two major components of extracellular fluid, are in constant communication.

2. It accelerates the distribution of nutrients, hormones, and dissolved gases throughout tissues.

3. It assists in the transport of insoluble lipids and tissue proteins that cannot enter the bloodstream by crossing the capillary walls.

4. It has a flushing action that carries bacterial toxins and other chemical stimuli to lymphoid tissues and organs responsible for providing immunity to disease.

Any condition that affects hydrostatic or osmotic pressures in the blood or tissues will shift the balance between hydrostatic and osmotic forces. We can then predict the effects on the basis of an understanding of capillary dynamics. For example,

- If hemorrhaging occurs, both blood volume and blood pressure decline. This reduction in CHP lowers the NFP and increases the amount of reabsorption. The result is a reduction in the volume of interstitial fluid and an increase in the circulating plasma volume. This process is known as a *recall of fluids*.

- If dehydration occurs, the plasma volume decreases owing to water loss, and the concentration of plasma proteins increases. The increase in BCOP accelerates reabsorption and a recall of fluids that delays the onset and severity of clinical signs and symptoms.
- If the CHP rises or the BCOP declines, fluid moves out of the blood and builds up in peripheral tissues, a condition called *edema*.

AM: Edema

100 Keys | It is blood flow that's the goal, and total peripheral blood flow is equal to cardiac output. Blood pressure is
needed to overcome friction and elastic forces and sustain blood flow. If blood pressure is too low, vessels collapse, blood
flow stops, and tissue die; if blood pressure is too high, vessel walls stiffen and capillary beds may rupture.

Concept Check

In a healthy individual, where is blood pressure greater, at the aorta or at the inferior vena cava? Explain.

While standing in the hot sun, Sally begins to feel light-headed and faints. Explain.

Terry's blood pressure is 125> 70. What is his mean arterial pressure?

Answers begin on p. A–1

Review factors that influence blood pressure on the **IP CD-ROM: Cardiovascular System/Measuring Blood Pressure.**

Cardiovascular Regulation

Objectives

- Describe how central and local control mechanisms interact to regulate blood flow and pressure in tissues.
- Explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through the tissues.

Homeostatic mechanisms regulate cardiovascular activity to ensure that **tissue perfusion**, or blood flow through tissues, meets the demand for oxygen and nutrients. The factors that affect tissue perfusion are (1) cardiac output, (2) peripheral resistance, and

(3) blood pressure. We discussed cardiac output in Chapter 20 (p. 697) and considered peripheral resistance and blood pressure earlier in this chapter.

Most cells are relatively close to capillaries. When a group of cells becomes active, the circulation to that region must increase to deliver the necessary oxygen and nutrients, and to carry away the waste products and carbon dioxide they generate. The purpose of cardiovascular regulation is to ensure that these blood flow changes occur (1) at an appropriate time, (2) in the right area, and (3) without drastically changing blood pressure and blood flow to vital organs.

The regulatory mechanisms focus on controlling cardiac output and blood pressure to restore adequate blood flow after a fall in blood pressure. These mechanisms can be broadly categorized as follows:

- **Autoregulation.** Local factors change the pattern of blood flow within capillary beds in response to chemical changes in interstitial fluids. This is an example of autoregulation at the tissue level. Autoregulation causes immediate, localized homeostatic adjustments. If autoregulation fails to normalize conditions at the tissue level, neural mechanisms and endocrine factors are activated.
- **Neural Mechanisms.** Neural mechanisms respond to changes in arterial pressure or blood gas levels at specific sites. When those changes occur, the cardiovascular centers of the autonomic nervous system adjust cardiac output and peripheral resistance to maintain blood pressure and ensure adequate blood flow.

- **Endocrine Mechanisms.** The endocrine system releases hormones that enhance short-term adjustments and that direct long-term changes in cardiovascular performance.

We will next consider each of these regulatory mechanisms individually by examining regulatory responses to inadequate perfusion of skeletal muscles. The regulatory relationships are diagrammed in Figure 21–13•.

Autoregulation of Blood Flow within Tissues

Under normal resting conditions, cardiac output remains stable, and peripheral resistance within individual tissues is adjusted to control local blood flow.

Factors that promote the dilation of precapillary sphincters are called **vasodilators**. **Local vasodilators** act at the tissue level to accelerate blood flow through their tissue of origin. Examples of local vasodilators include the following:

- Decreased tissue oxygen levels or increased CO2 levels.
- Lactic acid or other acids generated by tissue cells.
- Nitric oxide (NO) released from endothelial cells.
- Rising concentrations of potassium ions or hydrogen ions in the interstitial fluid.
- Chemicals released during local inflammation, including histamine and NO. l**p. 136**
- Elevated local temperature.

These factors work by relaxing the smooth muscle cells of the precapillary sphincters. All of them indicate that tissue conditions are in some way abnormal. An increase in blood flow, which will bring oxygen, nutrients, and buffers, may be sufficient to restore homeostasis.

As noted in Chapter 19, aggregating platelets and damaged tissues produce compounds that stimulate the constriction of precapillary sphincters. These compounds are **local vasoconstrictors**. Examples include prostaglandins and thromboxanes released by activated platelets and white blood cells, and the endothelins released by damaged endothelial cells.

Local vasodilators and vasoconstrictors control blood flow within a single capillary bed (see Figure 21–5•, p. 715). In high concentrations, these factors also affect arterioles, increasing or decreasing blood flow to all the capillary beds in a given area.

Review capillary dynamics on the **IP CD-ROM: Cardiovascular System/Autoregulation and Capillary Dynamics.**

Neural Mechanisms

The nervous system is responsible for adjusting cardiac output and peripheral resistance in order to maintain adequate blood flow to vital tissues and organs. Centers responsible for these regulatory activities include the *cardiac centers* and the *vasomotor centers* of the medulla oblongata. l**p. 459** It is difficult to distinguish the cardiac and vasomotor centers anatomically, and they are often considered to form complex **cardiovascular (CV) centers**. In functional terms, however, the cardiac and vasomotor centers often act independently. As noted in Chapter 20, each cardiac center consists of a *cardioacceleratory center*, which increases cardiac output through sympathetic innervation, and a *cardioinhibitory center*, which reduces cardiac output through parasympathetic inner
vation. l**p. 697**

The vasomotor centers contain two populations of neurons: (1) a very large group responsible for widespread vasoconstriction and (2) a smaller group responsible for the vasodilation of arterioles in skeletal muscles and the brain. The vasomotor centers exert their effects by controlling the activity of sympathetic motor neurons:

1. *Control of Vasoconstriction.* The neurons innervating peripheral blood vessels in most tissues are *adrenergic*; that is, they release the neurotransmitter norepinephrine (NE). The response to NE release is the stimulation of smooth muscle in the walls of arterioles, producing vasoconstriction.

2. *Control of Vasodilation.* Vasodilator neurons innervate blood vessels in skeletal muscles and in the brain. The stimulation of these neurons relaxes smooth muscle cells in the walls of arterioles, producing vasodilation. The relaxation of smooth muscle cells is triggered by the appearance of NO in their surroundings. The vasomotor centers may control NO release indirectly or directly. The most common vasodilator synapses are *cholinergic*—their synaptic knobs release ACh. In turn, ACh stimulates endothelial cells in the area to release NO, which causes local vasodilation. Another population of vasodilator synapses is *nitroxidergic*—the synaptic knobs release NO as a neurotransmitter. Nitric oxide has an immediate and direct relaxing effect on the vascular smooth muscle cells in the area.

Vasomotor Tone

In Chapter 16, we discussed the significance of autonomic tone in setting a background level of neural activity that can increase or decrease on demand. l**p. 533** The sympathetic vasoconstrictor nerves are chronically active, producing a significant **vasomotor tone**. Vasoconstrictor activity is normally sufficient to keep the arterioles partially constricted. Under maximal stimulation, arterioles constrict to about half their resting diameter, whereas a fully dilated arteriole increases its resting diameter by roughly 1.5 times. Constriction has a significant effect on resistance, because, as we saw earlier (p. 719), resistance increases sharply as luminal diameter decreases. The resistance of a maximally constricted arteriole is roughly 80 *times* that of a fully dilated arteriole. Because blood pressure varies directly with peripheral resistance, the vasomotor centers can control arterial blood pressure very effectively by making modest adjustments in vessel diameters. Extreme stimulation of the vasomotor centers also produces venoconstriction and mobilization of the venous reserve.

Reflex Control of Cardiovascular Function

The cardiovascular centers detect changes in tissue demand by monitoring arterial blood, with particular attention to blood pressure, pH, and the concentrations of dissolved gases. The *baroreceptor reflexes* respond to changes in blood pressure, and the *chemoreceptor reflexes* monitor changes in the chemical composition of arterial blood. These reflexes are regulated through a negative feedback loop: The stimulation of a receptor by an abnormal condition leads to a response that counteracts the stimulus and restores normal conditions.

Baroreceptor Reflexes Baroreceptors are specialized receptors that monitor the degree of stretch in the walls of expandable organs. l**p. 502** The baroreceptors involved in cardiovascular regulation are located in the walls of (1) the **carotid sinuses**, expanded chambers near the bases of the *internal carotid arteries* of the neck (see Figure 21–22•, p. 740), (2) the **aortic sinuses**, pockets in the walls of the ascending aorta adjacent to the heart (see Figure 20–8b•, p. 681), and (3) the wall of the right atrium. These receptors are components of the **baroreceptor reflexes**, which adjust cardiac output and peripheral resistance to maintain normal arterial pressures.

Aortic baroreceptors monitor blood pressure within the ascending aorta. Any changes trigger the **aortic reflex**, which adjusts blood pressure to maintain adequate blood pressure and blood flow through the systemic circuit. In response to changes in blood pressure at the carotid sinus, carotid sinus baroreceptors trigger reflexes that maintain adequate blood flow to the brain. Because blood flow to the brain must remain constant, the carotid sinus receptors are extremely sensitive. Figure 21–14• presents the basic organization of the baroreceptor reflexes triggered by changes in blood pressure at the carotid and aortic sinuses.

When blood pressure climbs, the increased output from the baroreceptors alters activity in the CV centers and produces two major effects (Figure 21–14a•):

1. *A decrease in cardiac output*, due to parasympathetic stimulation and the inhibition of sympathetic activity.

2. *Widespread peripheral vasodilation*, due to the inhibition of excitatory neurons in the vasomotor centers.

The decrease in cardiac output reflects primarily a reduction in heart rate due to the release of acetylcholine at the sinoatrial (SA) node. l**p. 698** The widespread vasodilation lowers peripheral resistance, and this effect, combined with a reduction in cardiac output, leads to a decline in blood pressure to normal levels.

When blood pressure falls below normal, baroreceptor output is reduced accordingly (Figure 21–14b•). This change has two major effects:

1. *An increase in cardiac output*, through the stimulation of sympathetic innervation to the heart. This results from the stimulation of the cardioacceleratory centers and is accompanied by an inhibition of the cardioinhibitory centers.

2. *Widespread peripheral vasoconstriction*, caused by the stimulation of sympathetic vasoconstrictor neurons by the vasomotor centers.

The effects on the heart result from the release of NE by sympathetic neurons innervating the SA node, the atrioventricular (AV) node, and the general myocardium. In a crisis, sympathetic activation occurs, and its effects are enhanced by the release of both NE and epinephrine (E) from the adrenal medullae. The net effect is an immediate increase in heart rate and stroke volume, and a corresponding rise in cardiac output. The vasoconstriction, which also results from the release of NE by sympathetic neurons, increases peripheral resistance. These adjustments—increased cardiac output and increased peripheral resistance—work together to elevate blood pressure.

Atrial baroreceptors are receptors that monitor blood pressure at the end of the systemic circuit—at the venae cavae and the right atrium. The **atrial reflex** responds to a stretching of the wall of the right atrium. l**p. 698**

Under normal circumstances, the heart pumps blood into the aorta at the same rate at which blood arrives at the right atrium. When blood pressure rises at the right atrium, blood is arriving at the heart faster than it is being pumped out. The atrial baroreceptors correct the situation by stimulating the CV centers and increasing cardiac output until the backlog of venous blood is removed. Atrial pressure then returns to normal.

Exhaling forcefully against a closed glottis, a procedure known as the *Valsalva maneuver*, causes reflexive changes in blood pressure and cardiac output due to compression of the aorta and venae cavae. When internal pressures rise, the venae cavae collapse, and the venous return decreases. The resulting fall in cardiac output and blood pressure stimulates the aortic and carotid baroreceptors, causing reflexive increase in heart rate and peripheral vasoconstriction. When the glottis opens and pressures return to normal, venous return increases suddenly and so does cardiac output. Because vasoconstriction has occurred, blood pressure rises sharply, and this inhibits the baroreceptors. As a result, cardiac output, heart rate, and blood pressure quickly return to normal levels. The Valsalva maneuver is thus a simple way to check for normal cardiovascular responses to changes in arterial pressure and venous return.

Chemoreceptor Reflexes The **chemoreceptor reflexes** respond to changes in carbon dioxide, oxygen, or pH levels in blood and

cerebrospinal fluid (CSF) (Figure 21–15•). The chemoreceptors involved are sensory neurons located in the **carotid bodies**, situated in the neck near the carotid sinus, and the **aortic bodies**, near the arch of the aorta. l**p. 502** These receptors monitor the composition of arterial blood. Additional chemoreceptors located on the ventrolateral surfaces of the medulla oblongata monitor the composition of CSF.

When chemoreceptors in the carotid bodies or aortic bodies detect either a rise in the carbon dioxide content or a fall in the pH of the arterial blood, the cardioacceleratory and vasomotor centers are stimulated, and the cardioinhibitory centers are inhibited. This dual effect causes an increase in cardiac output, peripheral vasoconstriction, and an elevation in arterial blood pressure. A drop in the oxygen level at the aortic bodies has the same effects. Strong stimulation of the carotid or aortic chemoreceptors causes widespread sympathetic activation, with more dramatic increases in heart rate and cardiac output.

The chemoreceptors of the medulla oblongata are involved primarily with the control of respiratory function, and secondarily with regulating blood flow to the brain. For example, a steep rise in CSF carbon dioxide levels will trigger the vasodilation of cerebral vessels, but will produce vasoconstriction in most other organs. The result is increased blood flow—and hence increased oxygen delivery—to the brain.

Arterial CO2 levels can be reduced and O2 levels increased most effectively by coordinating cardiovascular and respiratory activities. Chemoreceptor stimulation also stimulates the respiratory centers, and the rise in cardiac output and blood pressure is associated with an increased respiratory rate. Coordination of cardiovascular and respiratory activities is vital, because accelerating blood flow in the tissues is useful only if the circulating blood contains an adequate amount of oxygen. In addition, a rise in the respiratory rate accelerates venous return through the action of the respiratory pump. (We will consider other aspects of chemoreceptor activity and respiratory control in Chapter 23.)

CNS Activities and the Cardiovascular Centers

The output of the cardiovascular centers can also be influenced by activities in other areas of the brain. For example, the activation of either division of the autonomic nervous system will affect output from the cardiovascular centers. The cardioacceleratory and vasomotor centers are stimulated when a general sympathetic activation occurs. The result is an increase in cardiac output and blood pressure. In contrast, when the parasympathetic division is activated, the cardioinhibitory centers are stimulated, producing a reduction in cardiac output. Parasympathetic activity does not directly affect the vasomotor centers, but vasodilation occurs as sympathetic activity declines.

The activities of higher brain centers can also affect blood pressure. Our thought processes and emotional states can produce significant changes in blood pressure by influencing cardiac output and vasomotor tone. For example, strong emotions of anxiety, fear, and rage are accompanied by an elevation in blood pressure, caused by cardiac stimulation and vasoconstriction.

Hormones and Cardiovascular Regulation

The endocrine system provides both short-term and long-term regulation of cardiovascular performance. As we have seen, E and NE from the adrenal medullae stimulate cardiac output and peripheral vasoconstriction. Other hormones important in regulating cardiovascular function include (1) antidiuretic hormone (ADH), (2) angiotensin II, (3) erythropoietin (EPO), and (4) the natri

uretic peptides (ANP and BNP). l**pp. 621–622** Although ADH and angiotensin II also affect blood pressure, all four are concerned primarily with the long-term regulation of blood volume (Figure 21–16•).

Antidiuretic Hormone

Antidiuretic hormone (ADH) is released at the posterior lobe of the pituitary gland in response to a decrease in blood volume, to an increase in the osmotic concentration of the plasma, or (secondarily) to circulating angiotensin II. The immediate result is a peripheral vasoconstriction that elevates blood pressure. This hormone also stimulates the conservation of water at the kidneys, thus preventing a reduction in blood volume that would further reduce blood pressure (Figure 21–16a•).

Angiotensin II

Angiotensin II appears in the blood after the release of the enzyme renin by *juxtaglomerular cells*, specialized kidney cells, in response to a fall in renal blood pressure (see Figure 21–16a•). Once in the bloodstream, renin starts an enzymatic chain reaction. In the first step, renin converts *angiotensinogen*, a plasma protein produced by the liver, to *angiotensin I*. In the capillaries of the lungs, *angiotensin-converting enzyme (ACE)* then modifies angiotensin I to angiotensin II, an active hormone with diverse effects.

Angiotensin II has four important functions: (1) It stimulates the adrenal production of aldosterone, causing Na retention and K loss at the kidneys; (2) it stimulates the secretion of ADH, in turn stimulating water reabsorption at the kidneys and complementing the effects of aldosterone; (3) it stimulates thirst, resulting in increased fluid consumption (the presence of ADH and aldosterone ensures that the additional water consumed will be retained, elevating blood volume); and (4) it stimulates cardiac output and triggers the constriction of arterioles, in turn elevating the systemic blood pressure. The effect of angiotensin II on blood pressure is four to eight times greater than that produced by norepinephrine.

Erythropoietin

Erythropoietin (EPO) is released at the kidneys if blood pressure falls or if the oxygen content of the blood becomes abnormally low (see Figure 21–16a•). EPO stimulates the production and maturation of red blood cells, thereby increasing the volume and viscosity of the blood and improving its oxygen-carrying capacity.

Natriuretic Peptides

Atrial natriuretic peptide (na-tre-u-RET-ik; *natrium*, sodium + *ouresis*, making water), or *ANP*, is produced by cardiac muscle cells in the wall of the right atrium in response to excessive stretching during diastole. A related hormone called *brain natriuretic peptide*, or *BNP*, is produced by ventricular muscle cells exposed to comparable stimuli. These peptide hormones reduce blood volume and blood pressure by (1) increasing sodium ion excretion at the kidneys, (2) promoting water losses by increasing the volume of urine produced; (3) reducing thirst; (4) blocking the release of ADH, aldosterone, epinephrine, and norepinephrine; and (5) stimulating peripheral vasodilation (Figure 21–16b•). As blood volume and blood pressure decline, the stresses on the walls of the heart are removed, and natriuretic peptide production ceases.

100 Keys | Cardiac output cannot increase indefinitely, and blood flow to active versus inactive tissues must be differentially controlled. This is accomplished by a combination of autoregulation, neural regulation, and hormone release.

Patterns of Cardiovascular Response

Objectives

- Explain how the cardiovascular system responds to the demands of exercise and hemorrhaging.
- Identify the principal blood vessels and the functional characteristics of the special circulation to the brain, heart, and lungs.

In this and the two previous chapters, we have considered the blood, the heart, and the cardiovascular system as individual entities. Yet in our day-to-day lives, the cardiovascular system operates as an integrated complex. The interactions are fascinating and of considerable importance when physical or physiological conditions are changing rapidly.

Two common stresses, exercise and blood loss, provide examples of the adaptability of the cardiovascular system in maintaining homeostasis. The homeostatic responses involve an interplay among the cardiovascular system, the endocrine system, and other systems, and the central mechanisms are aided by autoregulation at the tissue level.

Exercise and the Cardiovascular System

At rest, cardiac output averages about 5.8 liters per minute. That value changes dramatically during exercise. In addition, the pattern of blood distribution changes markedly, as detailed in Table 21–2.

Light Exercise

Before you begin to exercise, your heart rate increases slightly due to a general rise in sympathetic activity as you think about the workout ahead. As you begin light exercise, three interrelated changes take place:

- *Extensive vasodilation occurs* as the rate of oxygen consumption in skeletal muscles increases. Peripheral resistance drops, blood flow through the capillaries increases, and blood enters the venous system at an accelerated rate.
- *The venous return increases* as skeletal muscle contractions squeeze blood along the peripheral veins and an increased breathing rate pulls blood into the venae cavae via the respiratory pump.
- *Cardiac output rises*, primarily in response to (1) the rise in venous return (the Frank–Starling principle l**p. 700**) and (2) atrial stretching (the atrial reflex). Some sympathetic stimulation occurs, leading to increases in heart rate and contractility, but there is no massive sympathetic activation. The increased cardiac output keeps pace with the elevated demand, and arterial pressures are maintained despite the drop in peripheral resistance.

This regulation by venous feedback produces a gradual increase in cardiac output to about double resting levels. The increase supports accelerated blood flow to skeletal muscles, cardiac muscle, and the skin. The increased flow to skeletal and cardiac muscles reflects the dilation of arterioles and precapillary sphincters in response to local factors; the increased flow to the skin occurs in response to the rise in body temperature.

Heavy Exercise

At higher levels of exertion, other physiological adjustments occur as the cardiac and vasomotor centers call for the general activation of the sympathetic nervous system. Cardiac output increases toward maximal levels, and major changes in the peripheral distribution of blood occur, facilitating the blood flow to active skeletal muscles.

Under massive sympathetic stimulation, the cardioacceleratory centers can increase cardiac output to levels as high as 20–25 liters per minute. But that is still not enough to meet the demands of active skeletal muscles unless the vasomotor centers severely restrict the blood flow to “nonessential” organs, such as those of the digestive system. During exercise at maximal levels, your blood essentially races between the skeletal muscles and the lungs and heart. Although blood flow to most tissues is diminished, skin perfusion increases further, because the body temperature continues to climb. Only the blood supply to the brain remains unaffected.

Exercise, Cardiovascular Fitness, and Health

Cardiovascular performance improves significantly with training. Table 21–3 compares the cardiac performance of athletes with that of nonathletes. Trained athletes have bigger hearts and larger stroke volumes than do nonathletes, and these are important functional differences.

Recall that cardiac output is equal to the stroke volume times the heart rate; thus, for the same cardiac output, the person with a larger stroke volume has a slower heart rate. An athlete at rest can maintain normal blood flow to peripheral tissues at a heart rate as low as 32 bpm (beats per minute), and, when necessary, the athlete’s cardiac output can increase to levels 50 percent higher than those of nonathletes. Thus, a trained athlete can tolerate sustained levels of activity that are well beyond the capabilities of nonathletes.

Exercise and Cardiovascular Disease

Regular exercise has several beneficial effects. Even a moderate exercise routine (jogging 5 miles a week, for example) can lower total blood cholesterol levels. A high cholesterol level is one of the major risk factors for atherosclerosis, which leads to cardiovascular disease and strokes. In addition, a healthy lifestyle—regular exercise, a balanced diet, weight control, and not smoking— reduces stress, lowers blood pressure, and slows the formation of plaques.

Regular moderate exercise may cut the incidence of heart attacks almost in half. However, only an estimated 8 percent of adults in the United States currently exercise at recommended levels. Exercise is also beneficial in accelerating recovery after a heart attack. Regular light-to-moderate exercise (such as walking, jogging, or bicycling), coupled with a low-fat diet and a low-stress lifestyle, not only reduces symptoms of coronary artery disease (such as angina), but also improves one's mood and overall quality of life. However, exercise does not remove any underlying medical problem, and atherosclerotic plaques, described on p. 713, do not disappear and seldom grow smaller with exercise.

There is no evidence that *intense* athletic training lowers the incidence of cardiovascular disease. On the contrary, the strains placed on all physiological systems—including the cardiovascular system—during an ultramarathon, iron-man triathlon, or other extreme athletic event can be severe. Individuals with congenital aneurysms, cardiomyopathy, or cardiovascular disease risk fatal circulatory problems, such as an arrhythmia or heart attack, during severe exercise. Even healthy individuals can develop acute physiological disorders, such as kidney failure, after extreme exercise. We will discuss the effects of exercise on other systems in later chapters.

Cardiovascular Response to Hemorrhaging

In Chapter 19, we considered the local circulatory reaction to a break in the wall of a blood vessel. l**p. 661** When hemostasis fails to prevent significant blood loss, the entire cardiovascular system makes adjustments to maintain blood pressure and restore blood volume (Figure 21–17•). The immediate problem is the maintenance of adequate blood pressure and peripheral blood flow. The long-term problem is the restoration of normal blood volume.

Short-Term Elevation of Blood Pressure

Almost as soon as the pressures start to decline, several short-term responses appear:

- The initial neural response occurs as carotid and aortic reflexes increase cardiac output and cause peripheral vasoconstriction (pp.728–729). With blood volume reduced, cardiac output is maintained by increasing the heart rate, typically to 180–200 bpm.
- The combination of stress and anxiety stimulates the sympathetic nervous system headquarters in the hypothalamus, which in turn triggers a further increase in vasomotor tone, constricting the arterioles and elevating blood pressure. At the same time, venoconstriction mobilizes the venous reserve and quickly improves venous return (p. 718).
- Short-term hormonal effects also occur. For instance, sympathetic activation causes the secretion of E and NE by the adrenal medullae, increasing cardiac output and extending peripheral vasoconstriction. In addition, the release of ADH by the posterior lobe of the pituitary gland and the production of angiotensin II enhance vasoconstriction while participating in the long-term response.

This combination of short-term responses elevates blood pressure and improves peripheral blood flow, often restoring normal arterial pressures and peripheral circulation after blood losses of up to 20 percent of total blood volume. Such adjustments are more than sufficient to compensate for the blood loss experienced when you donate blood. (Most blood banks collect 500 ml of whole blood, roughly 10 percent of your total blood volume.) If compensatory mechanisms fail, the individual develops signs of *shock*, a condition considered in the *Applications Manual*. AM: Shock

Long-Term Restoration of Blood Volume

Short-term responses temporarily compensate for a reduction in blood volume. Long-term responses are geared to restoring normal blood volume, a process that can take several days after a serious hemorrhage. The steps include the following:

- The decline in capillary blood pressure triggers a recall of fluids from the interstitial spaces (p. 725).
- Aldosterone and ADH promote fluid retention and reabsorption at the kidneys, preventing further reductions in blood volume.

- Thirst increases, and additional water is obtained by absorption across the digestive tract. This intake of fluid elevates the plasma volume and ultimately replaces the interstitial fluids “borrowed” at the capillaries.
- Erythropoietin targets the bone marrow, stimulating the maturation of red blood cells, which increase blood volume and improve oxygen delivery to peripheral tissues.

Special Circulation

The vasoconstriction that occurs in response to a fall in blood pressure or a rise in CO2 levels affects multiple tissues and organs simultaneously. The term *special circulation* refers to the circulation through organs in which blood flow is controlled by separate mechanisms. We will consider three important examples: the circulation to the brain, the heart, and the lungs.

Circulation to the Brain

In Chapter 14, we noted the existence of the blood–brain barrier, which isolates most CNS tissue from the general circulation. l**p. 458** The brain has a very high demand for oxygen and receives a substantial supply of blood. Under a variety of conditions, blood flow to the brain remains steady at about 750 ml > min—roughly 12 percent of the cardiac output delivered to an organ that represents less than 2 percent of body weight. Neurons do not maintain significant energy reserves, and in functional terms most of the adjustments made by the cardiovascular system treat blood flow to the brain as the top priority. Even during a cardiovascular crisis, blood flow through the brain remains as near normal as possible: While the cardiovascular centers are calling for widespread peripheral vasoconstriction, the cerebral vessels are instructed to dilate.

Although total blood flow to the brain remains relatively constant, blood flow to specific regions of the brain changes from moment to moment. These changes occur in response to local changes in the composition of interstitial fluid that accompany neural activity. When you read, write, speak, or walk, specific regions of your brain become active. Blood flow to those regions increases almost instantaneously, ensuring that the active neurons will continue to receive the oxygen and nutrients they require.

The brain receives arterial blood through four arteries. Because these arteries form anastomoses inside the cranium, an interruption of flow in any one of these large vessels will not significantly reduce blood flow to the brain as a whole. However, a plaque or a blood clot may still block a small artery, and weakened arteries may rupture. Such incidents temporarily or permanently shut off blood flow to a localized area of the brain, damaging or killing the dependent neurons. Symptoms of a *stroke*, or *cerebrovascular accident (CVA)*, then appear. AM: The Causes and Treatment of Cerebrovascular Disease

Circulation to the Heart

The anatomy of the coronary circulation was described in Chapter 20. l**p. 680** The coronary arteries arise at the base of the ascending aorta, where systemic pressures are highest. Each time the heart contracts, it squeezes the coronary vessels, so blood flow is reduced. In the left ventricle, systolic pressures are high enough that blood can flow into the myocardium only during diastole; over this period, elastic rebound helps drive blood along the coronary vessels. Normal cardiac muscle cells can tolerate these brief circulatory interruptions because they have substantial oxygen reserves.

When you are at rest, coronary blood flow is about 250 ml > min. When the workload on your heart increases, local factors, such as reduced O2 levels and lactic acid production, dilate the coronary vessels and increase blood flow. Epinephrine released during sympathetic stimulation promotes the vasodilation of coronary vessels while increasing heart rate and the strength of cardiac contractions. As a result, coronary blood flow increases while vasoconstriction occurs in other tissues.

For unclear reasons, some individuals experience *coronary spasms*, which can temporarily restrict coronary circulation and produce symptoms of angina. A permanent restriction or blockage of coronary vessels (as in coronary artery disease) and tissue damage (as caused by a myocardial infarction) can limit the heart’s ability to increase its output, even under maximal stimulation. Individuals with these conditions experience signs and symptoms of heart failure when the cardiac workload increases much above resting levels. AM: Heart Failure

Circulation to the Lungs

The lungs contain roughly 300 million *alveoli* (al-VE-o-l ; *alveolus*, sac), delicate epithelial pockets where gas exchange occurs.

ı Each alveolus is surrounded by an extensive capillary network. Blood flow through the lungs is regulated primarily by local responses to oxygen levels within individual alveoli. When an alveolus contains oxygen in abundance, the associated vessels dilate, so blood flow increases, promoting the absorption of oxygen from the alveolar air. When the oxygen content of the air is very low, the vessels constrict, so blood is shunted to alveoli that still contain significant levels of oxygen. This mechanism maximizes the efficiency of the respiratory system, because the circulation of blood through the capillaries of an alveolus has no benefit unless that alveolus contains oxygen.

This mechanism is precisely the opposite of that in other tissues, where a decline in oxygen levels causes local vasodilation rather than vasoconstriction. The difference makes functional sense, but its physiological basis remains a mystery.

Blood pressure in pulmonary capillaries (average: 10 mm Hg) is lower than that in systemic capillaries. The BCOP (25 mm Hg) is the same as elsewhere in the bloodstream. As a result, reabsorption exceeds filtration in pulmonary capillaries. Fluid moves continuously into the pulmonary capillaries across the alveolar surfaces, thereby preventing a buildup of fluid in the alveoli that could interfere with the diffusion of respiratory gases. If the blood pressure in pulmonary capillaries rises above 25 mm Hg, fluid enters the alveoli, causing *pulmonary edema*.

Concept Check

Why does blood pressure increase during exercise?

How would applying a small pressure to the common carotid artery affect your heart rate?

What effect would the vasoconstriction of the renal artery have on blood pressure and blood volume?

Answers begin on p. A–1

Review cardiovascular regulation on the **IP CD-ROM: Cardiovascular System/Blood Pressure Regulation.**

The Distribution of Blood Vessels: An Overview

Objective

- Describe three general functional patterns seen in the pulmonary and systemic circuits of the cardiovascular system.

You already know that the cardiovascular system consists of the *pulmonary circuit* and the *systemic circuit*. The pulmonary circuit is composed of arteries and veins that transport blood between the heart and the lungs. This circuit begins at the right ventricle and ends at the left atrium. From the left ventricle, the arteries of the systemic circuit transport oxygenated blood and nutrients to all organs and tissues, ultimately returning deoxygenated blood to the right atrium. Figure 21–18• summarizes the primary distribution routes within the pulmonary and systemic circuits.

In the pages that follow, we will examine the vessels of the pulmonary and systemic circuits further. Three general functional patterns are worth noting at the outset:

1. The peripheral distributions of arteries and veins on the body’s left and right sides are generally identical, except near the heart, where the largest vessels connect to the atria or ventricles. Corresponding arteries and veins usually follow the same path. For example, the distributions of the left and right subclavian *arteries* parallel those of the left and right subclavian *veins*.

2. A single vessel may have several names as it crosses specific anatomical boundaries, making accurate anatomical descriptions possible when the vessel extends far into the periphery. For example, the *external iliac artery* becomes the *femoral artery* as it leaves the trunk and enters the lower limb.

3. Tissues and organs are usually serviced by several arteries and veins. Often, anastomoses between adjacent arteries or veins reduce the impact of a temporary or even permanent occlusion (blockage) of a single blood vessel.

The Pulmonary Circuit

Objective

- Identify the major arteries and veins of the pulmonary circuit and the areas they serve.

Blood entering the right atrium has just returned from the peripheral capillary beds, where oxygen was released and carbon dioxide absorbed. After traveling through the right atrium and ventricle, this deoxygenated blood enters the pulmonary trunk, the start of the pulmonary circuit (Figure 21–19•). At the lungs, oxygen is replenished, carbon dioxide is released, and the oxygenated blood is returned to the heart for distribution via the systemic circuit. Compared with the systemic circuit, the pulmonary circuit is short: The base of the pulmonary trunk and the lungs are only about 15 cm (6 in.) apart.

The arteries of the pulmonary circuit differ from those of the systemic circuit in that they carry deoxygenated blood. (For this reason, most color-coded diagrams show the pulmonary arteries in blue, the same color as systemic veins.) As the pulmonary trunk curves over the superior border of the heart, it gives rise to the **left** and **right pulmonary arteries**. These large arteries enter the lungs before branching repeatedly, giving rise to smaller and smaller arteries. The smallest branches, the *pulmonary arterioles*, provide blood to capillary networks that surround *alveoli*. The walls of these small air pockets are thin enough for gas to be exchanged between the capillary blood and inspired air. As it leaves the alveolar capillaries, oxygenated blood enters venules that in turn unite to form larger vessels carrying blood toward the **pulmonary veins**. These four veins, two from each lung, empty into the left atrium, completing the pulmonary circuit.

Anatomy 360 | Review the anatomy of the pulmonary circuit on the **Anatomy 360 CD-ROM: Cardiovascular System/Ar-teries and Veins of the Pulmonary Circuit.**

The Systemic Circuit

Objective

- Identify the major arteries and veins of the systemic circuit and the areas they serve.

The systemic circuit supplies the capillary beds in all parts of the body not serviced by the pulmonary circuit. The systemic circuit, which at any moment contains about 84 percent of total blood volume, begins at the left ventricle and ends at the right atrium.

Systemic Arteries

Figure 21–20• provides an overview of the systemic arterial system, indicating the relative locations of major systemic arteries. Figures 21–21 to 21–26• show the detailed distribution of these vessels and their branches. By convention, several large arteries are called *trunks*; examples are the *pulmonary*, *brachiocephalic*, *thyrocervical*, and *celiac trunks*. Because most of the major arteries are paired, with one artery of each pair on either side of the body, the terms *right* and *left* will appear in figures only when the arteries on both sides are labeled.

The Ascending Aorta

The **ascending aorta** (Figure 21–21•) begins at the aortic valve of the left ventricle. The left and right coronary arteries originate in the aortic sinus at the base of the ascending aorta, just superior to the aortic valve. The distribution of coronary vessels was described in Chapter 20 and illustrated in Figure 20–9•, p. 680.

The Aortic Arch

The **aortic arch** curves like the handle of a cane across the superior surface of the heart, connecting the ascending aorta with the *descending aorta* (see Figure 21–20•). Three elastic arteries originate along the aortic arch and deliver blood to the head, neck, shoulders, and upper limbs: (1) the **brachiocephalic** (bra-ke-o-se-FAL-ik) **trunk**, (2) the **left common carotid artery**, and

(3) the **left subclavian artery** (Figures 21–21 and 21–22•). The brachiocephalic trunk, also called the *innominate artery* (i-NOM-i-nat; unnamed), ascends for a short distance before branching to form the **right subclavian artery** and the **right common carotid artery**.

We have only one brachiocephalic trunk, with the left common carotid and left subclavian arteries arising separately from the aortic arch. However, in terms of their peripheral distribution, the vessels on the left side are mirror images of those on the right side. Figures 21–21 and 21–22• illustrate the major branches of these arteries.

The Subclavian Arteries The subclavian arteries supply blood to the arms, chest wall, shoulders, back, and CNS (see Figures 21–20 and 21–21•). Three major branches arise before a subclavian artery leaves the thoracic cavity: (1) the **internal thoracic artery**, supplying the pericardium and anterior wall of the chest; (2) the **vertebral artery**, which provides blood to the brain and spinal cord; and (3) the **thyrocervical trunk**, which provides blood to muscles and other tissues of the neck, shoulder, and upper back.

After leaving the thoracic cavity and passing across the superior border of the first rib, the subclavian is called the **axillary artery**. This artery crosses the axilla to enter the arm, where it gives rise to *humeral circumflex arteries*, which supply structures near the head of the humerus. Distally, it becomes the **brachial artery**, which supplies blood to the rest of the upper limb. The brachial artery gives rise to the *deep brachial artery*, which supplies deep structures on the posterior aspect of the arm, and the *ulnar collateral arteries*, which supply the area around the elbow. As it approaches the coronoid fossa of the humerus, the brachial artery divides into the **radial artery**, which follows the radius, and the **ulnar artery**, which follows the ulna to the wrist. These arteries supply blood to the forearm and, through the *ulnar recurrent arteries,* the region around the elbow. At the wrist, the radial and ulnar arteries fuse to form the **superficial** and **deep palmar arches**, which supply blood to the hand and to the **digital arteries** of the thumb and fingers.

The Carotid Artery and the Blood Supply to the Brain The common carotid arteries ascend deep in the tissues of the neck. You can usually locate the carotid artery by pressing gently along either side of the windpipe (trachea) until you feel a strong pulse.

Each common carotid artery divides into an **external carotid artery** and an **internal carotid artery** (see Figure 21–22•). The **carotid sinus**, located at the base of the internal carotid artery, may extend along a portion of the common carotid. The external carotid arteries supply blood to the structures of the neck, esophagus, pharynx, larynx, lower jaw, and face. The internal carotid arteries enter the skull through the carotid canals of the temporal bones, delivering blood to the brain. (See Figures 7–3 and 7–4•, pp. 210–211.)

The internal carotid arteries ascend to the level of the optic nerves, where each artery divides into three branches: (1) an **ophthalmic artery**, which supplies the eyes; (2) an **anterior cerebral artery**, which supplies the frontal and parietal lobes of the brain; and (3) a **middle cerebral artery**, which supplies the mesencephalon and lateral surfaces of the cerebral hemispheres (Figures 21–22 and 21–23•).

The brain is extremely sensitive to changes in blood supply. An interruption of blood flow for several seconds will produce unconsciousness, and after four minutes some permanent neural damage can occur. Such circulatory crises are rare, because blood reaches the brain through the vertebral arteries as well as by way of the internal carotid arteries. The left and right vertebral arteries arise from the subclavian arteries and ascend within the transverse foramina of the cervical vertebrae. (See Figure 7–18b,c•,

p. 227.) The vertebral arteries enter the cranium at the foramen magnum, where they fuse along the ventral surface of the medulla oblongata to form the **basilar artery**. The vertebral arteries and the basilar artery supply blood to the spinal cord, medulla oblongata, pons, and cerebellum before dividing into the **posterior cerebral arteries**, which in turn branch off into the **posterior communicating arteries** (see Figure 21–23•).

The internal carotid arteries normally supply the arteries of the anterior half of the cerebrum, and the rest of the brain receives blood from the vertebral arteries. But this circulatory pattern can easily change, because the internal carotid arteries and the basilar artery are interconnected in a ring-shaped anastomosis called the **cerebral arterial circle**, or *circle of Willis,* which encircles the infundibulum of the pituitary gland (see Figure 21–23•). With this arrangement, the brain can receive blood from either the carotid or the vertebral arteries, so the likelihood of a serious interruption of circulation is reduced.

Strokes, or *cerebrovascular accidents (CVAs)*, are interruptions of the vascular supply to a portion of the brain. The *middle cerebral artery,* a major branch of the cerebral arterial circle, is the most common site of a stroke. Superficial branches deliver blood to the temporal lobe and large portions of the frontal and parietal lobes; deep branches supply the basal nuclei and portions of the thalamus. If a stroke blocks the middle cerebral artery on the left side of the brain, aphasia and a sensory and motor paralysis of the right side of the body result. In a stroke affecting the middle cerebral artery on the right side, the individual experiences a loss of sensation and motor control over the left side of the body and has difficulty drawing or interpreting spatial relationships. Strokes affecting vessels that supply the brain stem also produce distinctive symptoms; those affecting the lower brain stem are commonly fatal.

The Descending Aorta

The **descending aorta** is continuous with the aortic arch. The diaphragm divides the descending aorta into a superior **thoracic aorta** and an inferior **abdominal aorta** (Figures 21–24 and 21–25•).

The Thoracic Aorta The thoracic aorta begins at the level of vertebra T5 and penetrates the diaphragm at the level of vertebra T12. It travels within the mediastinum, on the posterior thoracic wall, slightly to the left of the vertebral column. This vessel supplies blood to branches that service the tissues and organs of the mediastinum, the muscles of the chest and the diaphragm, and the thoracic spinal cord.

The branches of the thoracic aorta are anatomically grouped as either visceral or parietal:

- *Visceral branches* supply the organs of the chest: The **bronchial arteries** supply the tissues of the lungs not involved in gas exchange, the **pericardial arteries** supply the pericardium, the **esophageal arteries** supply the esophagus, and the **mediastinal arteries** supply the tissues of the mediastinum.
- *Parietal branches* supply the chest wall: The **intercostal arteries** supply the chest muscles and the vertebral column area, and the **superior phrenic** (FREN-ik) **arteries** deliver blood to the superior surface of the diaphragm, which separates the thoracic and abdominopelvic cavities.

The branches of the thoracic aorta are shown in Figure 21–24•.

The Abdominal Aorta The abdominal aorta, which begins immediately inferior to the diaphragm, is a continuation of the thoracic aorta (see Figure 21–24a•). Descending slightly to the left of the vertebral column but posterior to the peritoneal cavity, the abdominal aorta is commonly surrounded by a cushion of adipose tissue. At the level of vertebra L4, it splits into two major arteries—the *left* and *right common iliac arteries*—that supply deep pelvic structures and the lower limbs. The region where the abdominal aorta splits is called the *terminal segment of the aorta*.

The abdominal aorta delivers blood to all the abdominopelvic organs and structures. The major branches to visceral organs are unpaired; they arise on the anterior surface of the abdominal aorta and extend into the mesenteries. By contrast, branches to the body wall, the kidneys, the urinary bladder, and other structures outside the peritoneal cavity are paired, and originate along the lateral surfaces of the abdominal aorta. Figure 21–24a• shows the major arteries of the trunk after the removal of most thoracic and abdominal organs. Figure 21–25• shows the distribution of those arteries to abdominopelvic organs.

The abdominal aorta gives rise to three unpaired arteries (see Figures 21–24 and 21–25•).

1. The **celiac** (SE -le-ak) **trunk** delivers blood to the liver, stomach, and spleen. The celiac trunk divides into three branches:

(a) the **left gastric artery**, which supplies the stomach and the inferior portion of the esophagus, (b) the **splenic artery**, which supplies the spleen and arteries to the stomach (*left gastroepiploicartery*) and pancreas (*pancreatic arteries*), and (c) the **common hepatic artery**, which supplies arteries to the liver (*hepatic artery proper*), stomach (*right gastric artery*), gallbladder (*cystic artery*), and duodenal area (*gastroduodenal*, *right gastroepiploic*, and *superior pancreaticoduodenal arteries*).

2. The superior mesenteric (mez-en-TER-ik) **artery** arises about 2.5 cm (1 in.) inferior to the celiac trunk to supply arteries to the pancreas and duodenum (*inferior pancreaticoduodenal artery*), small intestine (*intestinal arteries*), and most of the large intestine (*right* and *middle colic* and the *ileocolic arteries*).

3. The **inferior mesenteric artery** arises about 5 cm (2 in.) superior to the terminal aorta and delivers blood to the terminal portions of the colon (*left colic* and *sigmoid arteries*) and the rectum (*rectal arteries*).

The abdominal aorta also gives rise to five paired arteries (see Figure 21–24•):

1. The **inferior phrenic arteries**, which supply the inferior surface of the diaphragm and the inferior portion of the esophagus.

2. The suprarenal arteries, which originate on either side of the aorta near the base of the superior mesenteric artery. Each suprarenal artery supplies one adrenal gland, which caps the superior part of a kidney.

3. The short (about 7.5 cm) renal arteries, which arise along the posterolateral surface of the abdominal aorta, about 2.5 cm (1 in.) inferior to the superior mesenteric artery, and travel posterior to the peritoneal lining to reach the adrenal glands and kidneys. We will consider the branches of the renal arteries in Chapter 26.

4. The gonadal (go-NAD-al) **arteries**, which originate between the superior and inferior mesenteric arteries. In males, they are called *testicular arteries* and are long, thin arteries that supply blood to the testes and scrotum. In females, they are termed *ovarian arteries* and supply blood to the ovaries, uterine tubes, and uterus. The distribution of gonadal vessels (both arteries and veins) differs by gender; we will describe the differences in Chapter 28.

5. Small **lumbar arteries**, which arise on the posterior surface of the aorta and supply the vertebrae, spinal cord, and abdominal wall.

Arteries of the Pelvis and Lower Limbs

Near the level of vertebra L4, the terminal segment of the abdominal aorta divides to form a pair of elastic arteries—the **right** and **left common iliac** (IL--ak) **arteries—**plus the small **middle sacral artery** (see Figure 21–24•). The common iliac arteries, which e carry blood to the pelvis and lower limbs, descend posterior to the cecum and sigmoid colon along the inner surface of the ilium. At the level of the lumbosacral joint, each common iliac divides to form an **internal iliac artery** and an **external iliac artery** (see Figure 21–25•). The internal iliac arteries enter the pelvic cavity to supply the urinary bladder, the internal and external walls of the pelvis, the external genitalia, the medial side of the thigh, and, in females, the uterus and vagina. The major tributaries of the internal iliac artery are the *gluteal*, *internal pudendal*, *obturator*, and *lateral sacral arteries*. The external iliac arteries supply blood to the lower limbs and are much larger in diameter than the internal iliac arteries.

Arteries of the Thigh and Leg Each external iliac artery crosses the surface of an iliopsoas muscle and penetrates the abdominal wall midway between the anterior superior iliac spine and the pubic symphysis on that side. It emerges on the anterior, medial surface of the thigh as the **femoral artery** (Figure 21–26a,b•). Roughly 5 cm (2 in.) distal to the emergence of the femoral artery, the **deep femoral artery** branches off its lateral surface. The deep femoral artery, which gives rise to the *femoral circumflex arteries*, supplies blood to the ventral and lateral regions of the skin and deep muscles of the thigh.

The femoral artery continues inferiorly and posterior to the femur. As it approaches the knee, it gives rise to the *descending genicular artery*, which supplies the area around the knee. At the popliteal fossa, posterior to the knee joint, the femoral artery becomes the **popliteal** (pop-LIT-e-al) **artery**, which then branches to form the **posterior** and **anterior tibial arteries**. The posterior tibial artery gives rise to the **fibular artery**, or *peroneal artery*, before continuing inferiorly along the posterior surface of the tibia. The anterior tibial artery passes between the tibia and fibula, emerging on the anterior surface of the tibia. As it descends toward the foot, the anterior tibial artery provides blood to the skin and muscles of the anterior portion of the leg.

Arteries of the Foot When it reaches the ankle, the anterior tibial artery becomes the **dorsalis pedis artery**, which then branches repeatedly, supplying the ankle and dorsal portion of the foot (see Figure 21–26a,b•).

As it reaches the ankle, the posterior tibial artery divides to form the **medial** and **lateral plantar arteries**, which supply blood to the plantar surface of the foot. These arteries are connected to the dorsalis pedis artery through a pair of anastomoses. The arrangement produces a **dorsal arch** (*arcuate arch*) and a **plantar arch**; small arteries branching off these arches supply the distal portions of the foot and the toes.

Concept Check

A blockage of which branch from the aortic arch would interfere with blood flow to the left arm?

Why would a compression of the common carotid arteries cause a person to lose consciousness?

Grace is in an automobile accident, and her celiac trunk is ruptured. Which organs will be affected most directly by this injury?

Answers begin on p. A–1

Anatomy 360 | Review the arteries of the systemic circuit on the **Anatomy 360 CD-ROM: Cardiovascular System/Major Arteries of the Systemic Circuit.**

Systemic Veins

Veins collect blood from each of the tissues and organs of the body by means of an elaborate venous network that drains into the right atrium of the heart via the superior and inferior venae cavae (Figure 21–27•). The branching pattern of peripheral veins is much more variable than is the branching pattern of arteries. The discussion that follows is based on the most common arrangement of veins. Complementary arteries and veins commonly run side by side, and in many cases they have comparable names.

One significant difference between the arterial and venous systems concerns the distribution of major veins in the neck and limbs. Arteries in these areas are located deep beneath the skin, protected by bones and surrounding soft tissues. In contrast, the neck and limbs generally have two sets of peripheral veins, one superficial and the other deep. This dual venous drainage is important for controlling body temperature. In hot weather, venous blood flows through superficial veins, where heat loss can occur; in cold weather, blood is routed to the deep veins to minimize heat loss.

The Superior Vena Cava

All the body’s systemic veins (except the cardiac veins) drain into either the superior vena cava or the inferior vena cava. The **superior vena cava (SVC)** receives blood from the tissues and organs of the head, neck, chest, shoulders, and upper limbs.

Venous Return from the Cranium Numerous veins drain the cerebral hemispheres. The *superficial cerebral veins* and small veins of the brain stem empty into a network of dural sinuses (Figure 21–28a•), including the *superior* and *inferior sagittal sinuses,* the *petrosal sinuses,* the *occipital sinus,* the *left* and *right transverse sinuses,* and the *straight sinus* (Figure 21–28b•). The largest, the **superior sagittal sinus**, is in the falx cerebri (see Figure 14–4•, p. 457). Most of the *inferior cerebral veins* converge within the brain to form the **great cerebral vein**, which delivers blood from the interior of the cerebral hemispheres and the choroid plexus to the **straight sinus**. Other cerebral veins drain into the **cavernous sinus** with numerous small veins from the orbit. Blood from the cavernous sinus reaches the internal jugular vein through the petrosal sinuses.

The venous sinuses converge within the dura mater in the region of the lambdoid suture. The left and right transverse sinuses begin at the confluence of the occipital, sagittal, and straight sinuses. Each transverse sinus drains into a **sigmoid sinus**, which penetrates the jugular foramen and leaves the skull as the **internal jugular vein**, descending parallel to the common carotid artery in the neck (p. 738).

Vertebral veins drain the cervical spinal cord and the posterior surface of the skull. These vessels descend within the transverse foramina of the cervical vertebrae, in company with the vertebral arteries. The vertebral veins empty into the *brachiocephalic veins* of the chest (discussed later in the chapter).

Superficial Veins of the Head and Neck The superficial veins of the head converge to form the **temporal**, **facial**, and **maxillary veins** (see Figure 21–28b•). The temporal vein and the maxillary vein drain into the **external jugular vein**. The facial vein drains into the internal jugular vein. A broad anastomosis between the external and internal jugular veins at the angle of the mandible provides dual venous drainage of the face, scalp, and cranium. The external jugular vein descends toward the chest just deep to the skin on the anterior surface of the sternocleidomastoid muscle. Posterior to the clavicle, the external jugular vein empties into the *subclavian vein*. In healthy individuals, the external jugular vein is easily palpable, and a *jugular venous pulse (JVP)* is sometimes detectable at the base of the neck.

Venous Return from the Upper Limbs The **digital veins** empty into the **superficial** and **deep palmar veins** of the hand, which are interconnected to form the **palmar venous arches** (Figure 21–29•). The superficial arch empties into the **cephalic vein**, which ascends along the radial side of the forearm; the **median antebrachial vein**; and the **basilic vein**, which ascends on the ulnar side. Anterior to the elbow is the superficial **median cubital vein**, which passes from the cephalic vein, medially and at an oblique angle, to connect to the basilic vein. (The median cubital is the vein from which venous blood samples are typically collected.) From the elbow, the basilic vein passes superiorly along the medial surface of the biceps brachii muscle.

The deep palmar veins drain into the **radial vein** and the **ulnar vein**. After crossing the elbow, these veins fuse to form the **brachial vein**, running parallel to the brachial artery. As the brachial vein continues toward the trunk, it merges with the basilic vein and becomes the **axillary vein**, which enters the axilla.

Formation of the Superior Vena Cava The cephalic vein joins the axillary vein on the lateral surface of the first rib, forming the **subclavian vein**, which continues into the chest. The subclavian vein passes superior to the first rib and along the superior margin of the clavicle, to merge with the external and internal jugular veins of that side. This fusion creates the **brachiocephalic vein**, or *innominate vein*, which penetrates the body wall and enters the thoracic cavity.

Each brachiocephalic vein receives blood from the **vertebral vein** of the same side, which drains the back of the skull and spinal cord. Near the heart, at the level of the first and second ribs, the left and right brachiocephalic veins combine, creating the superior vena cava. Close to the point of fusion, the **internal thoracic vein** empties into the brachiocephalic vein.

The **azygos** (AZ-i-gos) **vein** is the major tributary of the superior vena cava. This vein ascends from the lumbar region over the right side of the vertebral column to enter the thoracic cavity through the diaphragm. The azygos vein joins the superior vena cava at the level of vertebra T2. On the left side, the azygos receives blood from the smaller **hemiazygos vein**, which in many people also drains into the left brachiocephalic vein through the *highest intercostal vein*.

The azygos and hemiazygos veins are the chief collecting vessels of the thorax. They receive blood from (1) **intercostal veins**, which in turn receive blood from the chest muscles; (2) **esophageal veins**, which drain blood from the inferior portion of the esophagus; and (3) smaller veins draining other mediastinal structures.

Figure 21–30a• diagrams the venous tributaries of the superior vena cava.

The Inferior Vena Cava

The **inferior vena cava (IVC)** collects most of the venous blood from organs inferior to the diaphragm. (A small amount reaches the superior vena cava via the azygos and hemiazygos veins.)

Veins Draining the Lower Limbs Blood leaving capillaries in the sole of each foot collects into a network of **plantar veins**, which supply the **plantar venous arch** (Figure 21–31a•). The plantar network provides blood to the deep veins of the leg: the **anterior tibial vein**, the **posterior tibial vein**, and the **fibular vein**. The **dorsal venous arch** collects blood from capillaries on the superior surface of the foot and the **digital veins** of the toes. The plantar arch and the dorsal arch are extensively interconnected, and the path of blood flow can easily shift from superficial to deep veins.

The dorsal venous arch is drained by two superficial veins: the **great saphenous** (sa-FE-nus) **vein** (*saphenes*, prominent) and the **small saphenous vein**. The great saphenous vein ascends along the medial aspect of the leg and thigh, draining into the *femoral vein* near the hip joint. The small saphenous vein arises from the dorsal venous arch and ascends along the posterior and lateral aspect of the calf. This vein then enters the popliteal fossa, where it meets the **popliteal vein**, formed by the union of the fibular and both tibial veins (Figure 21–31b•). The popliteal vein is easily palpated in the popliteal fossa adjacent to the adductor mag-nus muscle. At the femur, the popliteal vein becomes the **femoral vein**, which ascends along the thigh, next to the femoral artery. Immediately before penetrating the abdominal wall, the femoral vein receives blood from (1) the great saphenous vein; (2)

the **deep femoral vein**, which collects blood from deeper structures in the thigh; and (3) the **femoral circumflex vein**, which drains the region around the neck and head of the femur. The femoral vein penetrates the body wall and emerges in the pelvic cavity as the **external iliac vein**.

Veins Draining the Pelvis The external iliac veins receive blood from the lower limbs, the pelvis, and the lower abdomen. As the left and right external iliac veins cross the inner surface of the ilium, they are joined by the **internal iliac veins**, which drain the pelvic organs (see Figure 21–30•). The internal iliac veins are formed by the fusion of the *gluteal*, *internal pudendal*, *obturator*, and *lateral sacral veins* (see Figure 21–31a•). The union of external and internal iliac veins forms the **common iliac vein**, the right and left branches of which ascend at an oblique angle. The left common iliac vein receives blood from the *middle sacral vein*, which drains the area supplied by the middle sacral artery (Figure 21–29•). Anterior to vertebra L5, the common iliac veins unite to form the inferior vena cava.

Veins Draining the Abdomen The inferior vena cava ascends posterior to the peritoneal cavity, parallel to the aorta. The abdominal portion of the inferior vena cava collects blood from six major veins (see Figures 21–29 and 21–30b•):

1. Lumbar veins drain the lumbar portion of the abdomen, including the spinal cord and body wall muscles. Superior branches of these veins are connected to the azygos vein (right side) and hemiazygos vein (left side), which empty into the superior vena cava.

2. Gonadal (*ovarian* or *testicular*) **veins** drain the ovaries or testes. The right gonadal vein empties into the inferior vena cava; the left gonadal vein generally drains into the left renal vein.

3. Hepatic veins from the liver empty into the inferior vena cava at the level of vertebra

T10.

4. Renal veins, the largest tributaries of the inferior vena cava, collect blood from the kidneys.

5. Suprarenal veins drain the adrenal glands. In most people, only the right suprarenal vein drains into the inferior vena cava; the left suprarenal vein drains into the left renal vein.

6. Phrenic veins drain the diaphragm. Only the right phrenic vein drains into the inferior vena cava; the left drains into the left renal vein.

Figure 21–30b• diagrams the tributaries of the inferior vena cava.

The Hepatic Portal System

The **hepatic portal system** (Figure 21–32•) begins in the capillaries of the digestive organs and ends in the liver sinusoids. (As you may recall from Chapter 18, a blood vessel connecting two capillary beds is called a *portal vessel*; the network is a *portal system*.) Blood flowing in the hepatic portal system is quite different from that in other systemic veins, because hepatic portal vessels contain substances absorbed by the stomach and intestines. For example, levels of blood glucose and amino acids in the hepatic portal vein often exceed those found anywhere else in the cardiovascular system. The hepatic portal system delivers these and other absorbed compounds directly to the liver for storage, metabolic conversion, or excretion.

The largest vessel of the hepatic portal system is the **hepatic portal vein** (see Figure 21–32•), which delivers venous blood to the liver. The hepatic portal vein receives blood from three large veins draining organs within the peritoneal cavity:

- The **inferior mesenteric vein**, which collects blood from capillaries along the inferior portion of the large intestine. Its tributaries include the *left colic vein* and the *superior rectal veins,* which drain the descending colon, sigmoid colon, and rectum.
- The **splenic vein**, formed by the union of the inferior mesenteric vein and veins from the spleen, the lateral border of the stomach (*left gastroepiploic vein*), and the pancreas (*pancreatic veins*).
- The **superior mesenteric vein**, which collects blood from veins draining the stomach (*right gastroepiploic vein*), the small intestine (*intestinal* and *pancreaticoduodenal veins*), and two-thirds of the large intestine (*ileocolic*, *right colic*, and *middle colic veins*).

The hepatic portal vein forms through the fusion of the superior mesenteric and splenic veins. The superior mesenteric vein normally contributes the greater volume of blood and most of the nutrients. As it proceeds, the hepatic portal vein receives blood from the left and right **gastric veins**, which drain the medial border of the stomach, and from the **cystic vein**, emanating from the gallbladder.

After passing through liver sinusoids, blood collects in the hepatic veins, which empty into the inferior vena cava. Because blood from the intestines goes to the liver first, and because the liver regulates the nutrient content of the blood before it enters the inferior vena cava, the composition of the blood in the systemic circuit is relatively stable despite changes in diet and digestive activity.

Anatomy 360 | Review the veins of the systemic circuit on the **Anatomy 360 CD-ROM: Cardiovascular System/Major Veins of the Systemic Circuit.**

Fetal Circulation

Objectives

- Identify the differences between fetal and adult circulation patterns.
- Describe the changes in the patterns of blood flow that occur at birth.

The fetal and adult cardiovascular systems exhibit significant differences, reflecting different sources of respiratory and nutritional support. Most strikingly, the embryonic lungs are collapsed and nonfunctional, and the digestive tract has nothing to digest. The nutritional and respiratory needs of the fetus are provided by diffusion across the placenta.

Placental Blood Supply

Fetal patterns of blood flow are diagrammed in Figure 21–33a•. Blood flow to the placenta is provided by a pair of **umbilical arteries**, which arise from the internal iliac arteries and enter the umbilical cord. Blood returns from the placenta in the single **umbilical vein**, bringing oxygen and nutrients to the developing fetus. The umbilical vein drains into the **ductus venosus**, a vascular connection to an intricate network of veins within the developing liver. The ductus venosus collects blood from the veins of the liver and from the umbilical vein, and empties into the inferior vena cava. When the placental connection is broken at birth, blood flow ceases along the umbilical vessels, and they soon degenerate. However, remnants of these vessels persist throughout life as fibrous cords.

Circulation in the Heart and Great Vessels

One of the most interesting aspects of circulatory development reflects the differences between the life of an embryo or fetus and that of an infant. Throughout embryonic and fetal life, the lungs are collapsed; yet after delivery, the newborn infant must be able to extract oxygen from inspired air rather than across the placenta. ATLAS: Embryology Summary 16: The Development of the Cardiovascular System

Although the interatrial and interventricular septa develop early in fetal life, the interatrial partition remains functionally incomplete until birth. The **foramen ovale**, or *interatrial opening*, is associated with a long flap that acts as a valve. Blood can flow freely from the right atrium to the left atrium, but any backflow will close the valve and isolate the two chambers from one another. Thus, blood entering the heart at the right atrium can bypass the pulmonary circuit. A second short-circuit exists between the pulmonary and aortic trunks. This connection, the **ductus arteriosus**, consists of a short, muscular vessel.

With the lungs collapsed, the capillaries are compressed and little blood flows through the lungs. During diastole, blood enters the right atrium and flows into the right ventricle, but it also passes into the left atrium through the foramen ovale. About 25 percent of the blood arriving at the right atrium bypasses the pulmonary circuit in this way. In addition, more than 90 percent of the blood leaving the right ventricle passes through the ductus arteriosus and enters the systemic circuit rather than continuing to the lungs.

Cardiovascular Changes at Birth

At birth, dramatic changes occur. When an infant takes the first breath, the lungs expand, and so do the pulmonary vessels. The resistance in the pulmonary circuit declines suddenly, and blood rushes into the pulmonary vessels. Within a few seconds, rising O2 levels stimulate the constriction of the ductus arteriosus, isolating the pulmonary and aortic trunks from one another. As pressures rise in the left atrium, the valvular flap closes the foramen ovale. In adults, the interatrial septum bears the *fossa ovalis*, a shallow depression that marks the site of the foramen ovale. (See Figure 20–6a,c•, p. 676.) The remnants of the ductus arteriosus persist throughout life as the *ligamentum arteriosum*, a fibrous cord.

If the proper circulatory changes do not occur at birth or shortly thereafter, problems will eventually develop. The severity of the problems depends on which connection remains open and on the size of the opening. Treatment may involve surgical closure of the foramen ovale, the ductus arteriosus, or both. Other forms of congenital heart defects result from abnormal cardiac development or inappropriate connections between the heart and major arteries and veins (see p. 755).

Aging and the Cardiovascular System

Objective

- Discuss the effects of aging on the cardiovascular system.

The capabilities of the cardiovascular system gradually decline. As you age, your cardiovascular system undergoes the following major changes:

- **Age-related changes in blood** may include (1) a decreased hematocrit; (2) constriction or blockage of peripheral veins by a *thrombus* (stationary blood clot), which can become detached, pass through the heart, and become wedged in a small artery (commonly in the lungs), causing *pulmonary embolism*; and (3) pooling of blood in the veins of the legs because valves are not working effectively.
- **Age-related changes in the heart** include (1) a reduction in maximum cardiac output, (2) changes in the activities of nodal and conducting cells, (3) a reduction in the

elasticity of the fibrous skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) replacement of damaged cardiac muscle cells by scar tissue.

- **Age-related changes in blood vessels** may be linked to arteriosclerosis: (1) The inelastic walls of arteries become less tolerant of sudden pressure increases, which can lead to an *aneurysm*, whose rupture may (depending on the vessel) cause a stroke, myocardial infarction, or massive blood loss; (2) calcium salts can be deposited on weakened vascular walls, increasing the risk of a stroke or myocardial infarction; and (3) thrombi can form at atherosclerotic plaques.

Integration with Other Systems

The cardiovascular system is both anatomically and functionally linked to all other systems. The section on vessel distribution demonstrated the extent of the anatomical connections. Figure 21–35• summarizes the physiological relationships between the cardiovascular system and other organ systems.

The most extensive communication occurs between the cardiovascular and lymphatic systems. Not only are the two systems physically interconnected, but cells of the lymphatic system move from one part of the body to another within the vessels of the cardiovascular system. We will examine the lymphatic system in detail, including its role in the immune response, in Chapter 22.

Clinical Patterns

Because the cardiovascular system plays a key role in supporting all other systems, cardiovascular disorders affect virtually every cell in the body. One method of organizing the many potential disorders involving the cardiovascular system is by the nature of the primary problem, and whether it affects the blood, the heart, or the vascular network. Some disorders are structural, such as congenital disorders that may affect blood formation, the structure of the heart, or the arrangement of vessels. Others are primarily functional disorders, such as heart failure or hypertension (p. 722). Cardiovascular disorders can also result from pathogenic infection, tumors, trauma, and degenerative disorders. For a review of the major categories of clinical disorders affecting the cardiovascular system, including an extended discussion of the causes and treatment of shock, see the related sections of the *Applications Manual*.

Concept Check

Whenever Tim gets angry, a large vein bulges in the lateral region of his neck. Which vein is this?

A thrombus that blocks the popliteal vein would interfere with blood flow in which other veins?

A blood sample taken from the umbilical cord contains a high concentration of oxygen and nutrients, and a low concentration of carbon dioxide and waste products. Is this sample from an umbilical artery or from the umbilical vein? Explain.

Answers begin on p. A–1

Chapter Review

Selected Clinical Terminology

aneurysm: A bulge in the weakened wall of a blood vessel, generally an artery. (p. 712 and [AM])

arteriosclerosis: A thickening and toughening of arterial walls. (p. 713)

atherosclerosis: A type of arteriosclerosis characterized by changes in the endothelial lining and by the formation of a plaque. (p. 713)

edema: An abnormal accumulation of fluid in peripheral tissues. (p. 725)

hemorrhoids: Varicose veins in the walls of the rectum, the anus, or both; commonly associated with frequent straining to force bowel

movements. (p. 717 and [AM]) **hypertension:** Abnormally high blood pressure; usually defined in adults as blood pressure higher than 140> 90. (p. 722 and [AM]) **hypotension:**

Blood pressure so low that circulation to vital organs may be impaired. (p. 722 and [AM]) **pressure points:** Locations where muscular arteries can be compressed against skeletal elements to restrict or stop the flow of blood in

an emergency. [AM] **pulmonary embolism:** Blockage of a pulmonary artery caused by an embolus (often a detached thrombus). (p. 756) **shock:** An acute cardiovascular crisis marked by hypotension and inadequate peripheral blood flow. [AM] **sounds of Korotkoff:** Distinctive sounds, caused by turbulent arterial blood flow, heard while measuring blood pressure. [AM] **sphygmomanometer:** A device that measures blood pressure using an inflatable cuff placed around a limb. [AM] **stroke,** or *cerebrovascular accident (CVA)***:** An interruption of the vascular supply to a portion of the brain. (p. 741 and [AM]) **thrombus:** A stationary blood clot within a blood vessel. (p. 756) **varicose veins:** Sagging, swollen veins distorted by gravity and by the failure of venous valves. (p. 717)

Study Outline

The Anatomy of Blood Vessels p. 709

1. Blood flows through a network of arteries, veins, and capillaries. All chemical and gaseous exchange between blood and interstitial fluid takes place across capillary walls.

2. **Arteries** and **veins** form an internal distribution system through which the heart propels blood. Arteries branch repeatedly, decreasing in size until they become **arterioles**. From the arterioles, blood enters **capillary** networks. Blood flowing from the capillaries enters small **venules** before entering larger veins.

The Structure of Vessel Walls p. 709

1. The walls of arteries and veins contain three layers: the innermost **tunica intima**, the **tunica media**, and the outermost **tunica externa**. *(Figure 21–1)*

Differences between Arteries and Veins p. 709

2. In general, the walls of arteries are thicker than those of veins. Arteries constrict when blood pressure does not distend them; veins constrict very little. The endothelial lining cannot contract, so when constriction occurs, the lining of an artery is thrown into folds.

(Figure 21–1)

Arteries p. 710

3. The arterial system includes the large **elastic arteries**, medium-sized **muscular arteries**, and smaller arterioles**.** As we proceed toward the capillaries, the number of vessels increases, but the diameter of the individual vessels decreases and the walls become thinner. *(Figure 21–2)*

4. **Atherosclerosis**, a type of **arteriosclerosis**, is associated with changes in the endothelial lining of arteries. Fatty masses of tissue called **plaques** typically develop during atherosclerosis. *(Figure 21–3)*

Capillaries p. 712

5. Capillaries are the only blood vessels whose walls permit an exchange between blood and interstitial fluid. Capillaries are **continuous** or **fenestrated**. **Sinusoids** have fenestrated walls and form elaborate networks that allow very slow blood flow. Sinusoids are located in the liver and in various endocrine organs. *(Figure 21–4)*

6. Capillaries form interconnected networks called **capillary beds (capillary plexuses)**. A **precapillary sphincter** (a band of smooth muscle) adjusts the blood flow into each capillary. Blood flow in a capillary changes as **vasomotion** occurs. The entire capillary bed may be bypassed by blood flow through **arteriovenous anastomoses**. *(Figure 21–5)*

Veins p. 716

7. Venules collect blood from the capillaries and merge into **medium-sized veins** and then **large veins**. The arterial system is a high-pressure system; blood pressure in veins is much lower. **Valves** in veins prevent the backflow of blood. *(Figures 21–1, 21–2, 21–6)*

The Distribution of Blood p. 717

8. Peripheral **venoconstriction** helps maintain adequate blood volume in the arterial system after a hemorrhage. The **venous reserve** normally accounts for about 20 percent of the total blood volume. *(Figure 21–7)*

Cardiovascular System/Anatomy Review: Blood Vessel Structure and Function

Cardiovascular Physiology p. 718

1. Cardiovascular regulation involves the manipulation of blood pressure and resistance to control the rates of blood flow and capillary exchange. *(Figure 21–8)*

Pressure p. 719

2. Flow is proportional to pressure difference; blood will flow from an area of higher pressure to one of lower pressure. The *circulatory pressure* is the pressure gradient across the systemic circuit. It is divided into three components: **blood pressure (BP)**, **capillary hydrostatic pressure (CHP)**, and **venous pressure**.

Resistance p. 719

3. The **resistance (R)** determines the rate of blood flow through the systemic circuit. The major determinant of blood flow rate is the **peripheral resistance**—the resistance of the arterial system. Neural and hormonal control mechanisms regulate blood pressure and peripheral resistance.

4. **Vascular resistance** is the resistance of blood vessels. It is the largest component of peripheral resistance and depends on vessel length and vessel diameter.

5. **Viscosity** and **turbulence** also contribute to peripheral resistance. *(Summary Table 21–1)*

An Overview of Cardiovascular Pressures p. 720

6. The high arterial pressures overcome peripheral resistance and maintain blood flow through peripheral tissues. Capillary pressures are normally low; small changes in capillary pressure determine the rate of movement of fluid into or out of the bloodstream. Venous pressure, normally low, determines *venous return* and affects cardiac output and peripheral blood flow. *(Figures 21–9, 21–10; Summary Table 21–1)*

7. Arterial blood pressure rises during ventricular systole and falls during ventricular diastole. The difference between these two blood pressures is the pulse pressure. Blood pressure is measured at the brachial artery with the use of a sphygmomanometer. *(Figures 21–9, 21–10)*

8. Valves, muscular compression, and the **respiratory pump** (*thoracoabdominal pump*) help the relatively low venous pressures propel blood toward the heart. *(Figures 21–6, 21–9)*

Cardiovascular System/Factors That Affect Blood Pressure

Capillary Pressures and Capillary Exchange p. 723

9. At the capillaries, blood pressure forces water and solutes out of the plasma, across capillary walls. Water moves out of the capillaries, through the peripheral tissues, and back to the bloodstream by way of the lymphatic system. Water movement across capillary walls is determined by the interplay between osmotic pressures and hydrostatic pressures. *(Figure 21–11)*

10. Osmotic pressure (OP) is a measure of the pressure that must be applied to prevent osmotic movement across a membrane. Osmotic water movement continues until either solute concentrations are equalized or the movement is prevented by an opposing hydrostatic pressure.

11. The rates of filtration and reabsorption gradually change as blood passes along the length of a capillary, as determined by the **net filtration pressure** (the difference between the net hydrostatic pressure and the net osmotic pressure). *(Figure 21–12)*

100 Keys | p. 725

Cardiovascular System/Measuring Blood Pressure

Cardiovascular Regulation p. 725

1. Homeostatic mechanisms ensure that **tissue perfusion** (blood flow) delivers adequate oxygen and nutrients.

2. Autoregulation, neural mechanisms, and endocrine mechanisms influence the coordinated regulation of cardiovascular function. Autoregulation involves local factors changing the pattern of blood flow within capillary beds in response to chemical changes in interstitial fluids. Neural mechanisms respond to changes in arterial pressure or blood gas levels. Hormones can assist in short-term adjustments (changes in cardiac output and peripheral resistance) and long-term adjustments (changes in blood volume that affect cardiac output and gas transport). *(Figure 21–13)*

Autoregulation of Blood Flow within Tissues p. 726

3. Peripheral resistance is adjusted at the tissues by local factors that result in the dilation or constriction of precapillary sphincters.

(Figure 21–5)

Cardiovascular System/Autoregulation and Capillary Dynamics

Neural Mechanisms p. 727

4. **Cardiovascular (CV) centers** of the medulla oblongata are responsible for adjusting cardiac output and peripheral resistance to maintain adequate blood flow. The vasomotor centers contain one group of neurons responsible for controlling vasoconstriction, and another group responsible for controlling vasodilation.

5. **Baroreceptor reflexes** monitor the degree of stretch within expandable organs. Baroreceptors are located in the **carotid sinuses**, the **aortic sinuses**, and the right atrium. *(Figure 21–14)*

6. **Chemoreceptor reflexes** respond to changes in the oxygen or CO2 levels in the blood. They are triggered by sensory neurons located in the **carotid bodies** and the **aortic bodies**. *(Figure 21–15)*

Hormones and Cardiovascular Regulation p. 730

7. The endocrine system provides short-term regulation of cardiac output and peripheral resistance with epinephrine and norepinephrine from the adrenal medullae. Hormones involved in the long-term regulation of blood pressure and volume are *antidiuretic hormone (ADH), angiotensin II, erythropoietin (EPO)*, and *natriuretic peptides (ANP and BNP). (Figure 21–16)*

100 Keys | p. 732

Patterns of Cardiovascular Response p. 732 Exercise and the Cardiovascular System p. 732

1. During exercise, blood flow to skeletal muscles increases at the expense of blood flow to nonessential organs, and cardiac output rises. Cardiovascular performance improves with training. Athletes have larger stroke volumes, slower resting heart rates, and larger cardiac reserves than do nonathletes. *(Tables 21–2, 21–3)*

Cardiovascular Response to Hemorrhaging p. 733

2. Blood loss lowers blood volume and venous return and decreases cardiac output. Compensatory mechanisms include an increase in cardiac output, a mobilization of venous reserves, peripheral vasoconstriction, and the release of hormones that promote the retention of fluids and the manufacture of erythrocytes. *(Figure 21–17)*

Special Circulation p. 735

3. The blood–brain barrier, the coronary circulation, and the circulation to alveolar capillaries in the lungs are examples of special circulation, in which cardiovascular dynamics and regulatory mechanisms differ from those in other tissues.

Cardiovascular System/Blood Pressure Regulation.

The Distribution of Blood Vessels: An Overview p. 736

1. The peripheral distributions of arteries and veins are generally identical on both sides of the body, except near the heart. *(Figure 21–18)*

The Pulmonary Circuit p. 737

1. The pulmonary circuit includes the pulmonary trunk, the **left** and **right pulmonary arteries**, and the **pulmonary veins**, which empty into the left atrium. *(Figure 21–19)*

Anatomy 360 | Cardiovascular System/Arteries and Veins of the Pulmonary Circuit

The Systemic Circuit p. 738 Systemic Arteries p. 738

1. The **ascending aorta** gives rise to the coronary circulation. The **aortic arch** communicates with the **descending aorta**. *(Figures 21–20 to 21–26)*

2. Three elastic arteries originate along the aortic arch: the **left common carotid artery**, the **left subclavian artery**, and the **brachiocephalic trunk**. *(Figures 21–21, 21–22, 21–23)*

3. The remaining major arteries of the body originate from the **descending aorta**. *(Figures 21–24, 21–25, 21–26)*

Anatomy 360 | Cardiovascular System/Major Arteries of the Systemic Circuit

Systemic Veins p. 745

4. Arteries in the neck and limbs are deep beneath the skin; in contrast, there are generally two sets of peripheral veins, one superficial and one deep. This dual venous drainage is important for controlling body temperature. *(Figure 21–27)*

5. The **superior vena cava** receives blood from the head, neck, chest, shoulders, and arms. *(Figures 21–27 to 21–30)*

6. The **inferior vena cava** collects most of the venous blood from organs inferior to the diaphragm. *(Figures 21–29 to 21–31)*

7. The **hepatic portal system** directs blood from the other digestive organs to the liver before the blood returns to the heart. *(Figure 21–32)*

Anatomy 360 | Cardiovascular System/Major Veins of the Systemic Circuit

Fetal Circulation p. 753 Placental Blood Supply p. 753

1. Blood flow to the placenta is provided by a pair of **umbilical arteries** and is drained by a single **umbilical vein**. *(Figure 21–33)*

Circulation in the Heart and Great Vessels p. 753

2. The interatrial partition remains functionally incomplete until birth. The **foramen ovale** allows blood to flow freely from the right to the left atrium, and the **ductus arteriosus** short-circuits the pulmonary trunk.

Cardiovascular Changes at Birth p. 754

3. The foramen ovale closes, leaving the fossa ovalis. The ductus arteriosus constricts, leaving the ligamentum arteriosum. *(Figure 21–33)*

4. Congenital cardiovascular problems generally reflect abnormalities of the heart or of interconnections between the heart and great vessels. *(Figure 21–34)*

Aging and the Cardiovascular System p. 756

1. Age-related changes in the blood include (1) a decreased hematocrit, (2) constriction or blockage of peripheral veins by a *thrombus* (stationary blood clot), and (3) pooling of blood in the veins of the legs because valves are not working effectively.

2. Age-related changes in the heart include (1) a reduction in the maximum cardiac output, (2) changes in the activities of nodal and conducting cells, (3) a reduction in the elasticity of the fibrous skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) the replacement of damaged cardiac muscle cells by scar tissue.

3. Age-related changes in blood vessels, commonly related to arteriosclerosis, include (1) a weakening in the walls of arteries, potentially leading to the formation of an *aneurysm*, (2) deposition of calcium salts on weakened vascular walls, increasing the risk of a stroke or myocardial infarction, and (3) the formation of a thrombus at atherosclerotic plaques.

Integration with Other Systems p. 756

1. The cardiovascular system is anatomically and functionally connected to all other body systems. *(Figure 21–35)*

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The blood vessels that play the most important role in the regulation of blood flow to a tissue and blood pressure are the

(a) arteries **(b)** arterioles

(c) veins **(d)** venules

(e) capillaries

2. Cardiovascular function is regulated by all of the following, *except*

(a) local factors **(b)** neural factors

(c) endocrine factors **(d)** venous return

(e) conscious control

3. Baroreceptors that function in the regulation of blood pressure are located in the

(a) left ventricle **(b)** brain stem

(c) carotid sinus **(d)** common iliac artery

(e) pulmonary trunk

4. The two-way exchange of substances between blood and body cells occurs only through

(a) arterioles **(b)** capillaries

(c) venules **(d)** a, b, and c are correct

5. Large molecules such as peptides and proteins move into and out of the bloodstream by way of

(a) continuous capillaries

(b) fenestrated capillaries

(c) thoroughfare channels

(d) metarterioles

6. The alteration of blood flow due to the action of precapillary sphincters is

(a) vasomotion **(b)** autoregulation

(c) selective resistance **(d)** turbulence

7. Blood is transported through the venous system by means of

(a) muscular contractions

(b) increasing blood pressure

(c) the respiratory pump

(d) a and c are correct

8. The most important factor in vascular resistance is

(a) the viscosity of the blood

(b) the diameter of blood vessel walls

(c) turbulence due to irregular surfaces of blood vessels

(d) the length of the blood vessels

9. Net hydrostatic pressure forces water ________________ a capillary; net osmotic pressure forces water ______________ a capillary.

(a) into, out of **(b)** out of, into

(c) out of, out of **(d)** a, b, and c are incorrect

10. The two arteries formed by the division of the brachiocephalic trunk are the

(a) aorta and internal carotid

(b) axillary and brachial

(c) external and internal carotid

(d) common carotid and subclavian

11. The unpaired arteries supplying blood to the visceral organs include the

(a) suprarenal, renal, lumbar

(b) iliac, gonadal, femoral

(c) celiac, superior and inferior mesenteric

(d) a, b, and c are correct

12. The paired arteries supplying blood to the body wall and other structures outside the abdominopelvic cavity include the

(a) left gastric, hepatic, splenic, phrenic

(b) suprarenals, colics, lumbars, gonadals

(c) iliacs, femorals, and lumbars

(d) celiac, left gastric, superior and inferior mesenteric

13. The vein that drains the dural sinuses of the brain is the

(a) cephalic **(b)** great saphenous

(c) internal jugular **(d)** superior vena cava

14. The vein that collects most of the venous blood from below the diaphragm is the

(a) superior vena cava **(b)** great saphenous

(c) inferior vena cava **(d)** azygos

15. What are the primary forces that cause fluid to move

(a) out of a capillary at its arterial end and into
the interstitial fluid?

(b) into a capillary at its venous end from the interstitial fluid?

16. What cardiovascular changes occur at birth?

LEVEL 2 Reviewing Concepts

17. A major difference between the arterial and venous systems is that

(a) arteries are usually more superficial than veins

(b) in the limbs there is dual venous drainage

(c) veins are usually less branched compared to arteries

(d) veins exhibit a much more orderly pattern of branching in the limbs

(e) veins are not found in the abdominal cavity

18. Which of the following conditions would have the *greatest* effect on peripheral resistance?

(a) doubling the length of a vessel

(b) doubling the diameter of a vessel

(c) doubling the viscosity of the blood

(d) doubling the turbulence of the blood

(e) doubling the number of white cells in the blood

19. Which of the following is *greater*?

(a) the osmotic pressure of the interstitial fluid during inflammation

(b) the osmotic pressure of the interstitial fluid during normal conditions

(c) neither is greater

20. Relate the anatomical differences between arteries and veins to their functions.

21. Why do capillaries permit the diffusion of materials whereas arteries and veins do not?

22. How is blood pressure maintained in veins to cope with the force of gravity?

23. How do pressure and resistance affect cardiac output and peripheral blood flow?

24. Why is blood flow to the brain relatively continuous and constant?

25. Compare the effects of the cardioacceleratory and cardioinhibitory centers on cardiac output and blood pressure.

LEVEL 3 Critical Thinking and Clinical Applications

26. Bob is sitting outside on a warm day and is sweating profusely. Mary wants to practice taking blood pressures, and he agrees to play patient. Mary finds that Bob’s blood pressure is elevated, even though he is resting and has lost fluid from sweating. (She reasons that fluid loss should lower blood volume and, thus, blood pressure.) Why is Bob’s blood pressure high instead of low?

27. Tom loves to soak in hot tubs and whirlpools. One day he decides to raise the temperature in his hot tub as high as it will go. After a few minutes in the very warm water, he feels faint, passes out, and nearly drowns. Luckily he is saved by an observant bystander. Explain what happened.

28. Jolene awakens suddenly to the sound of her alarm clock. Realizing that she is late for class, she jumps to her feet, feels light-headed, and falls back on her bed. What probably caused this reaction? Why doesn’t this happen all the time?

(continued)

Clinical Note

Arteriosclerosis

–

Arteriosclerosis (ar-t e¯-r e¯-o¯-skle-R O -sis) is a thickening and toughening of arterial walls. This condition may not sound life-threatening, but complications related to arteriosclerosis account for roughly half of all deaths in the United States. The effects of arteriosclerosis are varied; for example, arteriosclerosis of coronary vessels is responsible for *coronary artery disease (CAD)*, and arteriosclerosis of arteries supplying the brain can lead to strokes. l**p. 682** Arteriosclerosis takes two major forms:

1. Focal calcification is the deposition of calcium salts following the gradual degeneration of smooth muscle in the tunica media. Typically, the process involves arteries of the limbs

and genital organs. Some focal calcification occurs as part of the aging process, and it may develop in association with atherosclerosis (described next). Rapid and severe calcification may occur as a complication of diabetes mellitus, an endocrine disorder. l**p. 619**
–

2. Atherosclerosis (ath-er-o¯-skler-O -sis) is the formation of lipid deposits in the tunica media associated with damage to the endothelial lining. Atherosclerosis is the most common form of arteriosclerosis.

Many factors may be involved in the development of atherosclerosis. One major factor is lipid levels in the blood. Atherosclerosis tends to develop in people whose blood contains elevated levels of plasma lipids—specifically, cholesterol. Circulating cholesterol is transported to peripheral tissues in *lipoproteins,* which are protein–lipid complexes. (We will discuss the various types of lipoproteins in Chapter 25.)

When plasma cholesterol levels are chronically elevated, cholesterol-rich lipoproteins remain in circulation for an extended period. Circulating monocytes then begin removing them from the bloodstream. Eventually, the monocytes become filled with lipid droplets. Now called *foam cells*, they attach themselves to the endothelial walls of blood vessels, where they release cytokines. These growth factors stimulate the divisions of smooth muscle cells near the tunica intima, thickening the vessel wall.

Other monocytes then invade the area, migrating between the endothelial cells. As these changes occur, the monocytes, smooth muscle cells, and endothelial cells begin phagocytizing lipids as well. The result is an atherosclerotic **plaque**, a fatty mass of tissue that projects into the lumen of the vessel. At this point, the plaque has a relatively simple structure, and evidence suggests that the process can be reversed if appropriate dietary adjustments are made.

If the conditions persist, the endothelial cells become swollen with lipids, and gaps appear in the endothelial lining. Platelets now begin sticking to the exposed collagen fibers. The combination of platelet adhesion and aggregation leads to the formation of a localized blood clot, which further restricts blood flow through the artery. The structure of the plaque is now relatively complex.

A typical plaque is shown in Figure 21–3•. Elderly individuals—especially elderly men—are most likely to develop atherosclerotic plaques. Estrogens may slow plaque formation, which may account for the lower incidence of CAD, myocardial infarctions (MIs), and strokes in women. After menopause, when estrogen production declines, the risk of CAD, MIs, and strokes in women increases markedly.

In addition to advanced age and male gender, other important risk factors for atherosclerosis include high blood cholesterol levels, high blood pressure, and cigarette smoking. Roughly 20 percent of middle-aged men have all three of these risk factors; these individuals are four times as likely to experience an MI or a cardiac arrest as other men in their age group. Although fewer women develop atherosclerotic plaques, elderly female smokers with high blood cholesterol and high blood pressure are at much greater risk than other women. Factors that can promote the development of atherosclerosis in both men and women include diabetes mellitus, obesity, and stress. Evidence also indicates that at least some forms of atherosclerosis may be linked to chronic infection with *Chlamydia pneumoniae*, a bacterium responsible for several types of respiratory infections, including some forms of pneumonia.

We discussed potential treatments for atherosclerotic plaques, such as catheterization, balloon angioplasty, and bypass surgery, in Chapter 20. l**p. 682** In some cases in which dietary modifications do not lower circulating LDL levels sufficiently, drug therapies can bring them under control. Genetic engineering techniques have recently been used to treat an inherited form of *hypercholesterolemia* (high blood cholesterol) linked to extensive plaque formation. (Individuals with this condition are unable to absorb and recycle cholesterol in the liver.) In this experimental procedure, circulating cholesterol levels declined after copies of appropriate genes were inserted into some of the individual’s liver cells.

Without question, the best approach to atherosclerosis is avoiding it by eliminating or reducing associated risk factors. Suggestions include (1) reducing the intake of dietary cholesterol, saturated fats, and trans fatty acids by restricting consumption of fatty meats (such as beef, lamb, and pork), egg yolks, and cream; (2) not smoking; (3) checking your blood pressure and taking steps to lower it if necessary; (4) having your blood cholesterol levels checked annually; (5) controlling your weight; and (6) exercising regularly.

| SUMMARY TABLE 21–1 | KEY TERMS AND RELATIONSHIPS PERTAINING TO BLOOD CIRCULATION

Blood Flow (*F*): The volume of blood flowing per unit of time
through a vessel or a group of vessels; may refer
to circulation through a capillary, a tissue,
an organ, or the entire vascular network.
Total blood flow is equal to cardiac output.

Blood Pressure The hydrostatic pressure in the arterial system
(*BP*): that pushes blood through capillary beds.

Total Peripheral
Resistance: system.

Turbulence: A resistance due to the irregular, swirling
movement of blood at high flow rates or exposure
to irregular surfaces.

Vascular A resistance due to friction within a blood vessel,
Resistance: primarily between the blood and the vessel walls.
Increases with increasing length or decreasing
diameter; vessel length is constant, but vessel
diameter can change.

Venous Pressure:

Viscosity: A resistance to flow due to interactions among
molecules within a liquid.

RELATIONSHIPS AMONG THE PRECEDING TERMS:

F ˜ P (flow is proportional to the pressure gradient)

F ˜ $1/R$ (flow is inversely proportional to resistance)

F ˜ P/R (flow is directly proportional to the pressure gradient, and inversely proportional to resistance)

F ˜ BP/PR (flow is directly proportional to blood pressure, and inversely proportional to peripheral resistance)

R ˜ $1/r4$ (resistance is inversely proportional to the fourth power of the vessel radius)

TABLE 21–2

Tissue Blood Flow (ml min)/

Organ	**Rest**	**Light Exercise**	**Strenuous Exercise**
Skeletal muscles		1200	4500
Heart	250	350	750
Brain	750	750	750
Skin	500	1500	1900
Kidney	1100	900	600
Abdominal viscera	1400	1100	600
Miscellaneous	600	400	400
Total cardiac output	5800	9500	17,500

TABLE 21–3

Subject	**Heart Weight (g)**	**Stroke Volume (ml)**	**Heart Rate (bpm)**	**Cardiac Output (L min)/**	**Blood Pressure (systolic diastoli**
Nonathlete (rest)	300	60	83	5.0	120 80>
Nonathlete (maximum)			104	192	19.9
Trained athlete (rest)	500	100	53	5.3	120 > 80

Circulatory The pressure difference between the base of the

Pressure: ascending aorta and the entrance to the right atrium.

Hydrostatic A pressure exerted by a liquid in response
Pressure: to an applied force.

Peripheral The resistance of the arterial system; affected by
Resistance (*PR*): such factors as vascular resistance, viscosity,
and turbulence.

Resistance (*R*): A force that opposes movement
(in this case, blood flow).

Trained athlete (maximum) 167 182 30.4 200 > 90*

* Diastolic pressures in athletes during maximal activity have not been accurately measured.

• **FIGURE 21–34** Congenital Cardiovascular Problems

Clinical Note

Congenital Cardiovascular Problems

Minor individual variations in the vascular network are quite common. For example, very few individuals have identical patterns of venous distribution. Congenital cardiovascular problems serious enough to threaten homeostasis are relatively rare. They generally reflect abnormal formation of the heart or problems with the interconnections between the heart and the great vessels. Several examples of congenital cardiovascular defects are illustrated in Figure 21–34•. All these conditions can be surgically corrected, although multiple surgeries may be required.

The incomplete closure of the foramen ovale or ductus arteriosus results in similar types of problems. If the foramen ovale remains open, or *patent*, blood recirculates through the pulmonary circuit instead of entering the left ventricle (Figure 21–34a•). The movement, driven by the relatively high systemic pressure, is called a “left-to-right shunt.” Arterial oxygen content is normal, but the left ventricle must work much harder than usual to provide adequate blood flow through the systemic circuit. Hence, pressures rise in the pulmonary circuit. The abnormality may not be immediately apparent, but pulmonary hypertension, pulmonary edema, and cardiac enlargement are eventual results. If the ductus arteriosus remains open, the same basic problems develop as blood ejected by the left ventricle reenters the pulmonary circuit. If valve defects, constricted pulmonary vessels, or other abnormalities occur as well, pulmonary pressures can rise enough to force blood into the systemic circuit through the ductus arteriosus. This movement is called a “right-to-left shunt.” Because normal blood oxygenation does not occur, the circulating blood develops a deep red color. The skin then develops the blue tones typical of *cyanosis* and the infant is known as a “blue baby.”

Ventricular septal defects are openings in the interventricular septum (Figure 21–34b•). These are the most common congenital heart problems, affecting 0.12 percent of newborn infants. The opening between the left and right ventricles has a similar effect to a connection between the atria: When the more powerful left ventricle beats, it ejects blood into the right ventricle and pulmonary circuit. The end results are the same as for a patent foramen ovale: a left-to-right shunt, with eventual pulmonary hypertension, pulmonary edema, and cardiac enlargement.

The *tetralogy of Fallot* (fa-L O) is a complex group of heart and circulatory defects that affect 0.10 percent of newborn infants. In this
–

condition, (1) the pulmonary trunk is abnormally narrow (pulmonary *stenosis*), (2) the interventricular septum is incomplete, (3) the aorta originates where the interventricular septum normally ends, and (4) the right ventricle is enlarged and both ventricles are thickened owing to increased workloads (Figure 21–34c•).

In the *transposition of great vessels*, the aorta is connected to the right ventricle, and the pulmonary artery is connected to the left ventricle (Figure 21–34d•). This malformation affects 0.05 percent of newborn infants.

In an *atrioventricular septal defect*, both the atria and ventricles are incompletely separated (Figure 21–34e•). The results are quite variable, depending on the extent of the defect and the effects on the atrioventricular valves. This type of defect most commonly affects infants with *Down syndrome*, a disorder caused by the presence of an extra copy of chromosome 21.

Feature Typical Artery Typical Vein

GENERAL APPEARANCE Usually round, with relatively thick wall Usually flattened or collapsed, with

IN SECTIONAL VIEW relatively thin wall

TUNICA INTIMA

Endothelium Usually rippled, due to vessel constriction Often smooth

Internal elastic membrane Present Absent

TUNICA MEDIA Thick, dominated by smooth muscle cells Thin, dominated by smooth muscle cells

and elastic fibers and collagen fibers

External elastic membrane Present Absent

TUNICA EXTERNA Collagen and elastic fibers Collagen and elastic fibers and smooth muscle cells

• **FIGURE 21–2** Histological Structure of Blood Vessels. Representative diagrammatic cross-sectional views of the walls of arteries, capillaries, and veins. Notice the relative sizes of the layers in these vessels.

- **FIGURE 21–4** Capillary Structure. **(a)** A continuous capillary. The enlargement shows routes for the diffusion of water and solutes. **(b)** A fenestrated capillary. Note the pores, which facilitate diffusion across the endothelial lining.
- **FIGURE 21–5** The Organization of a Capillary Bed. **(a)** A typical capillary bed. Solid arrows indicate consistent blood flow; dashed arrows indicate variable or pulsating blood flow. **(b)** A micrograph of a number of capillary beds.
- **FIGURE 21–6** The Function of Valves in the Venous System. Valves in the walls of medium-sized veins prevent the backflow of blood. Venous compression caused by the contraction of adjacent skeletal muscles assists in maintaining venous blood flow.
- **FIGURE 21–7** The Distribution of Blood in the Cardiovascular System
- **FIGURE 21–8** An Overview of Cardiovascular Physiology. Neural and hormonal activities influence cardiac output, peripheral resistance, and venous pressure (through venoconstriction). Capillary pressure is the primary drive for exchange between blood and interstitial fluid.
- **FIGURE 21–9** Relationships among Vessel Diameter, Cross-Sectional Area, Blood Pressure, and Blood Velocity
- **FIGURE 21–10** Pressures within the Systemic Circuit. Notice the general reduction in circulatory pressure within the systemic circuit and the elimination of the pulse pressure within the arterioles.
- **FIGURE 21–11** Capillary Filtration. Capillary hydrostatic pressure forces water and solutes through the gaps between adjacent endothelial cells in continuous capillaries. The sizes of solutes that move across the capillary wall are determined primarily by the dimensions of the gaps.
- **FIGURE 21–12** Forces Acting across Capillary Walls. At the arterial end of the capillary, capillary hydrostatic pressure (CHP) is greater than blood colloid osmotic pressure (BCOP), so fluid moves out of the capillary (filtration). Near the venule, CHP is lower than BCOP, so fluid moves into the capillary (reabsorption). In this model, interstitial fluid colloid osmotic pressure (ICOP) and interstitial fluid hydrostatic pressure (IHP) are assumed to be 0 mm Hg and so are not shown.

An Overview of the Lymphatic System and Immunity

Objective

- Explain the difference between nonspecific and specific defense, and the role of lymphocytes in the immune response.

The world is not always kind to the human body. Accidental bumps, cuts, and scrapes; chemical and thermal burns; extreme cold; and ultraviolet radiation are just a few of the hazards in our physical environment. Making matters worse, the world around us contains an assortment of viruses, bacteria, fungi, and parasites capable of not only surviving but thriving inside our bodies—and potentially causing us great harm. These organisms, called **pathogens**, are responsible for many diseases in humans. Each pathogen has a different lifestyle and attacks the body in a specific way. For example, viruses spend most of their time hidden within cells, which they often eventually destroy, whereas some of the largest parasites actually burrow through internal organs. Many bacteria multiply in interstitial fluids, where they release foreign proteins—enzymes or toxins—that can damage cells, tissues, even entire organ systems. And as if that were not enough, we are constantly at risk from renegade body cells that have the potential to

produce lethal cancers. l**p. 100** AM: The Nature of Pathogens

Many organs and systems work together to keep us alive and healthy. In this ongoing struggle, the lymphatic system plays a central role. The **lymphatic system** includes the cells, tissues, and organs responsible for defending the body against both environmental hazards, such as various pathogens, and internal threats, such as cancer cells. *Lymphocytes*, the primary cells of the lymphatic system, were introduced in Chapters 4 and 19. l**pp. 125, 656** These cells are vital to the body’s ability to resist or overcome infection and disease. Lymphocytes respond to the presence of invading pathogens (such as bacteria or viruses), abnormal body cells (such as virus-infected cells or cancer cells), and foreign proteins (such as the toxins released by some bacteria). They act to eliminate these threats or render them harmless through a combination of physical and chemical attacks.

The body has several anatomical barriers and defense mechanisms that either prevent or slow the entry of infectious organisms, or attack them if they do succeed in gaining entry. These mechanisms are called *nonspecific defenses*, because they do not distinguish one potential threat from another. In contrast, lymphocytes respond specifically: If a bacterial pathogen invades peripheral tissues, lymphocytes organize a defense against that particular type of bacterium. For this reason, lymphocytes are said to provide a *specific defense*, known as the **immune response**. The ability to resist infection and disease through the activation of specific defenses constitutes **immunity**.

All the cells and tissues involved in the production of immunity are sometimes considered part of an *immune system*—a physiological system that includes not only the lymphatic system, but also components of the integumentary, cardiovascular, respiratory, digestive, and other systems. For example, interactions between lymphocytes and Langerhans cells of the skin are important in mobilizing specific defenses against skin infections.

We begin this chapter by examining the organization of the lymphatic system. We will then consider the body's nonspecific defenses. Finally, we will see how the lymphatic system interacts with cells and tissues of other systems to defend the body against infection and disease.

Organization of the Lymphatic System

Objectives

- Identify the major components of the lymphatic system and explain their functions.
- Discuss the importance of lymphocytes and describe their distribution in the body.
- Describe the structure of lymphoid tissues and organs and explain their functions.

The lymphatic system consists of (1) **lymph**, a fluid that resembles plasma but contains a much lower concentration of suspended proteins; (2) a network of **lymphatic vessels**, often called **lymphatics**, which begin in peripheral tissues and end at connections to veins; (3) an array of **lymphoid tissues** and **lymphoid organs** scattered throughout the body; and (4) lymphocytes and smaller numbers of phagocytes and other cells. Figure 22–1• provides a general overview of the primary lymphatic tissues, vessels, and organs of this system. ATLAS: Embryology Summary 17: The Development of the Lymphatic System

Functions of the Lymphatic System

The primary function of the lymphatic system is the production, maintenance, and distribution of lymphocytes that provide defense against infections and other environmental hazards. Most of the body’s lymphocytes are produced and stored within lymphoid tissues (such as the tonsils) and lymphoid organs (such as the spleen and thymus). However, lymphocytes are also produced in areas of red bone marrow, along with other defense cells, such as monocytes and macrophages.

To provide an effective defense, lymphocytes must be able to detect problems, and they must be able to reach the site of injury or infection. Lymphocytes, macrophages, and microphages circulate within the blood and are able to enter or leave the capillaries that supply most of the tissues of the body. As noted in Chapter 21, capillaries normally deliver more fluid to peripheral

tissues than they carry away. l**p. 725** The excess fluid returns to the bloodstream through lymphatic vessels. This continuous circulation of extracellular fluid helps transport lymphocytes and other defense cells from one organ to another. In the process, it maintains normal blood volume and eliminates local variations in the composition of the interstitial fluid by distributing hormones, nutrients, and waste products from their tissues of origin to the general circulation.

Lymphatic Vessels

Lymphatic vessels carry lymph from peripheral tissues to the venous system. The smallest lymphatic vessels are called *lymphatic capillaries*.

Lymphatic Capillaries

The lymphatic network begins with **lymphatic capillaries**, or *terminal lymphatics*, which branch through peripheral tissues. Lymphatic capillaries differ from blood capillaries in that they (1) originate as pockets rather than forming continuous tubes, (2) have larger diameters, (3) have thinner walls, and (4) typically have a flattened or irregular outline in sectional view (Figure 22–2•). Although lymphatic capillaries are lined by endothelial cells, the basal lamina is incomplete or absent. The endothelial cells of a lymphatic capillary are not tightly bound together, but they do overlap. The region of overlap acts as a one-way valve, permitting the entry of fluids and solutes (even those as large as proteins), as well as viruses, bacteria, and cell debris, but preventing their return to the intercellular spaces.

Lymphatic capillaries are present in almost every tissue and organ in the body. Prominent lymphatic capillaries in the small intestine called *lacteals* are important in the transport of lipids absorbed by the digestive tract. Lymphatic capillaries are absent in areas that lack a blood supply, such as the cornea of the eye. The bone marrow and the central nervous system also lack lymphatic vessels.

Small Lymphatic Vessels

From the lymphatic capillaries, lymph flows into larger lymphatic vessels that lead toward the body’s trunk. The walls of these vessels contain layers comparable to those of veins, and, like veins, the larger lymphatic vessels contain valves (Figure 22–3•). The valves are quite close together, and at each the lymphatic vessel bulges noticeably. As a result, large lymphatic vessels have a beaded appearance (Figure 22–3a•). The valves prevent the backflow of lymph within lymph vessels, especially those of the limbs. Pressures within the lymphatic system are minimal, and the valves are essential to maintaining normal lymph flow toward the thoracic cavity.

Lymphatic vessels commonly occur in association with blood vessels (see Figure 22–3a•). Differences in relative size, general appearance, and branching pattern distinguish lymphatic vessels from arteries and veins. Characteristic color differences are also apparent on examining living tissues. Most arteries are bright red, veins are dark red (although usually illustrated as blue to distinguish them from arteries), and lymphatic vessels are a pale golden color. In general, a tissue contains many more lymphatic vessels than veins, but the lymphatic vessels are much smaller.

Major Lymph-Collecting Vessels

Two sets of lymphatic vessels collect lymph from the lymphatic capillaries: superficial lymphatics and deep lymphatics. **Superficial lymphatics** are located in the subcutaneous layer deep to the skin; in the areolar tissues of the mucous membranes lining the digestive, respiratory, urinary, and reproductive tracts; and in the areolar tissues of the serous membranes lining the pleural, pericardial, and peritoneal cavities. **Deep lymphatics** are larger lymphatic vessels that accompany deep arteries and veins supplying skeletal muscles and other organs of the neck, limbs, and trunk, and the walls of visceral organs.

Superficial and deep lymphatics converge to form even larger vessels called *lymphatic trunks*, which in turn empty into two large collecting vessels: the thoracic duct and the right lymphatic duct. The *thoracic duct* collects lymph from the body inferior to the diaphragm and from the left side of the body superior to the diaphragm. The smaller *right lymphatic duct* collects lymph from the right side of the body superior to the diaphragm (Figure 22–4a•).

The **thoracic duct** begins inferior to the diaphragm at the level of vertebra L_2 (Figure 22–4b•). The base of the thoracic duct

is an expanded, saclike chamber called the **cisterna chyli** (K -l). The cisterna chyli receives lymph from the inferior part of the

I¯¯ı abdomen, the pelvis, and the lower limbs by way of the *right* and *left lumbar trunks* and the *intestinal trunk*.

The inferior segment of the thoracic duct lies anterior to the vertebral column. From the second lumbar vertebra, it passes posterior to the diaphragm alongside the aorta and ascends along the left side of the vertebral column to the level of the left clavicle. After collecting lymph from the *left bronchomediastinal trunk*, the *left subclavian trunk*, and the *left jugular trunk*, it empties into the left subclavian vein near the left internal jugular vein (see Figure 22–4b•). Lymph collected from the left side of the head, neck, and thorax, as well as lymph from the entire body inferior to the diaphragm, reenters the venous circulation in this way.

The **right lymphatic duct** is formed by the merging of the *right jugular*, *right subclavian*, and *right bronchomediastinal trunks* in the area near the right clavicle. This duct empties into the right subclavian vein, delivering lymph from the right side of the body superior to the diaphragm.

Blockage of the lymphatic drainage from a limb produces **lymphedema** (limf-e-DE¯-muh), a condition in which interstitial fluids accumulate and the limb gradually becomes swollen and grossly distended. If the condition persists, the connective tissues lose their elasticity and the swelling becomes permanent. Lymphedema by itself does not pose a major threat to life. The danger comes from the constant risk that an uncontrolled infection will develop in the affected area. Because the interstitial fluids are essentially stagnant, toxins and pathogens can accumulate and overwhelm local defenses without fully activating the immune system. AM: Lymphedema

Lymphocytes

Lymphocytes account for 20–30 percent of the circulating leukocyte population. However, circulating lymphocytes are only a small fraction of the total lymphocyte population. The body contains some 10^{12} lymphocytes, with a combined weight of more than a kilogram.

Types of Lymphocytes

Three classes of lymphocytes circulate in blood: (1) **T** (**t**hymus-dependent) **cells**, (2) **B** (**b**one marrow–derived) **cells**, and (3) **NK** (**n**atural **k**iller) **cells**. Each type has distinctive biochemical and functional characteristics.

Approximately 80 percent of circulating lymphocytes are classified as T cells. The primary types of T cells are the following:

- **Cytotoxic T cells,** which attack foreign cells or body cells infected by viruses. Their attack commonly involves direct contact. These lymphocytes are the primary cells involved in the production of *cell-mediated immunity*, or *cellular immunity*.
- **Helper T cells,** which stimulate the activation and function of both T cells and B cells.
- **Suppressor T cells,** which inhibit the activation and function of both T cells and B cells.

The interplay between suppressor and helper T cells helps establish and control the sensitivity of the immune response. For this reason, these cells are also known as *regulatory T cells*.

We will examine cytotoxic and regulatory T cells in the course of this chapter. Other types of T cells also participate in the immune response. For example, *inflammatory T cells* stimulate regional inflammation and local defenses in an injured tissue, and *suppressor/inducer T cells* suppress B cell activity but stimulate other T cells.

B cells account for 10–15 percent of circulating lymphocytes. When stimulated, B cells can differentiate into **plasma cells**, which are responsible for the production and secretion of *antibodies*—soluble proteins also known as *immunoglobulins*. l**p. 642** These proteins bind to specific chemical targets called **antigens**. Most antigens are pathogens, parts or products of pathogens, or other foreign compounds. Most antigens are proteins, but some lipids, polysaccharides, and nucleic acids can also stimulate antibody production. The binding of an antibody to its target antigen starts a chain reaction leading to the destruction of the target compound or organism. B cells are responsible for *antibody-mediated immunity*, which is also known as *humoral* ("liquid") *immunity* because antibodies occur in body fluids.

The remaining 5–10 percent of circulating lymphocytes are NK cells, also known as **large granular lymphocytes**. These lymphocytes attack foreign cells, normal cells infected with viruses, and cancer cells that appear in normal tissues. Their continuous "policing" of peripheral tissues has been called *immunological surveillance*.

Life Span and Circulation of Lymphocytes

Lymphocytes are not evenly distributed in the blood, bone marrow, spleen, thymus, and peripheral lymphoid tissues. The ratio of B cells to T cells varies among tissues or organs. For example, B cells are seldom found in the thymus, whereas in blood, T cells outnumber B cells by a ratio of 8:1.

The lymphocytes in these organs are visitors, not residents. All types of lymphocytes move throughout the body, wandering through tissues and then entering blood vessels or lymphatic vessels for transport.

T cells move relatively quickly. For example, a wandering T cell may spend about 30 minutes in the blood, 5–6 hours in the spleen, and 15–20 hours in a lymph node. B cells, which are responsible for antibody production, move more slowly. A typical B cell spends about 30 hours in a lymph node before moving on.

Lymphocytes have relatively long life spans. Roughly 80 percent survive 4 years, and some last 20 years or more. Throughout your life, you maintain normal lymphocyte populations by producing new lymphocytes in your bone marrow and lymphoid tissues.

Lymphocyte Production

In Chapter 19, we discussed *hemopoiesis*—the formation of the cellular elements of blood. l**pp. 648, 657** In adults, *erythropoiesis* (red blood cell formation) is normally confined to bone marrow, but lymphocyte production, or **lymphopoiesis** (lim-fo¯-poy-E¯-sis), involves the bone marrow, thymus, and peripheral lymphoid tissues (Figure 22–5•).

Bone marrow plays the primary role in the maintenance of normal lymphocyte populations. Hemocytoblast divisions in the bone marrow of adults generate the lymphoid stem cells that produce all types of lymphocytes. Two distinct populations of lymphoid stem cells are produced in the bone marrow.

One group of lymphoid stem cells remains in the bone marrow (Figure 22–5a•). Divisions of these cells produce immature B cells and NK cells. B cell development involves intimate contact with large **stromal cells** (*stroma*, a bed) in the bone marrow. The cytoplasmic extensions of stromal cells contact or even wrap around the developing B cells. Stromal cells produce an immune system hormone, or *cytokine*, called *interleukin-7*, that promotes the differentiation of B cells. (We will consider cytokines and their varied effects in a later section.)

As they mature, B cells and NK cells enter the bloodstream and migrate to peripheral tissues (Figure 22–5c•). Most of the B cells move into lymph nodes, the spleen, or other lymphoid tissues. The NK cells migrate throughout the body, moving through peripheral tissues in search of abnormal cells.

The second group of lymphoid stem cells migrates to the thymus (Figure 22–5b•). There, these cells and their descendants develop further in an environment that is isolated from the general circulation by the **blood–thymus barrier**. Under the influence of thymic hormones, the lymphoid stem cells divide repeatedly, producing the various kinds of T cells. At least seven thymic hormones have been identified, although their precise functions and interactions have yet to be determined.

When their development is nearing completion, T cells reenter the bloodstream and return to the bone marrow. They also travel to peripheral tissues, including lymphoid tissues and organs, such as the spleen (Figure 22–5c•).

The T cells and B cells that migrate from their sites of origin retain the ability to divide. Their divisions produce daughter cells of the same type; for example, a dividing B cell produces other B cells, not T cells or NK cells. As we will see, the ability of specific types of lymphocytes to increase in number is crucial to the success of the immune response.

Lymphoid Tissues

Lymphoid tissues are connective tissues dominated by lymphocytes. In a **lymphoid nodule**, or *lymphatic nodule*, the lymphocytes are densely packed in an area of areolar tissue. In many areas, lymphoid nodules form large clusters (Figure 22–6•). Lymphoid nodules occur in the connective tissue deep to the epithelia lining the respiratory tract, where they are known as *tonsils*, and along the digestive and urinary tracts. They are also found within more complex lymphoid organs, such as lymph nodes or the spleen. A single nodule averages about a millimeter in diameter, but the boundaries are not distinct, because no fibrous capsule surrounds them. Each nodule often has a central zone called a **germinal center**, which contains dividing lymphocytes (Figure 22–6b•).

MALT

The collection of lymphoid tissues linked with the digestive system is called the **mucosa-associated lymphoid tissue (MALT)**. Clusters of lymphoid nodules deep to the epithelial lining of the intestine are known as **aggregated lymphoid nodules**, or *Peyer's patches* (see Figure 22–6a•). In addition, the walls of the *appendix*, or *vermiform* ("worm-shaped") *appendix*—a blind pouch that originates near the junction between the small and large intestines—contain a mass of fused lymphoid nodules.

Tonsils

The **tonsils** are large lymphoid nodules in the walls of the pharynx (see Figure 22–6b•). Most people have five tonsils. Left and right **palatine tonsils** are located at the posterior, inferior margin of the oral cavity, along the boundary with the pharynx. A single **pharyngeal tonsil**, often called the *adenoid*, lies in the posterior superior wall of the nasopharynx, and a pair of **lingual tonsils** lie deep to the mucous epithelium covering the base (pharyngeal portion) of the tongue. Because of their location, the latter are usually not visible unless they become infected and swollen, a condition known as **tonsillitis**. AM: Infected Lymphoid Nodules

Anatomy 360 | Review the anatomy of the tonsils on the **Anatomy 360 CD-ROM: Lymphatic System/Tonsils**.

Lymphoid Organs

A fibrous connective-tissue capsule separates lymphoid organs—the *lymph nodes*, the *thymus*, and the *spleen*—from surrounding tissues.

Lymph Nodes

Lymph nodes are small lymphoid organs ranging in diameter from 1 mm to 25 mm (to about 1 in.). Figure 22–1•, p. 765, shows the general pattern of lymph node distribution in the body. Each lymph node is covered by a dense connective tissue capsule (Figure 22–7•). Bundles of collagen fibers extend from the capsule into the interior of the node. These fibrous partitions are called **trabeculae** (*trabecula*, a wall).

The shape of a typical lymph node resembles that of a kidney bean (see Figure 22–7•). Blood vessels and nerves reach the lymph node at the **hilus**, a shallow indentation. Two sets of lymphatic vessels, afferent lymphatics and efferent lymphatics, are connected to each lymph node. **Afferent lymphatics** carry lymph to the lymph node from peripheral tissues. The afferent lymphatics penetrate the capsule of the lymph node on the side opposite the hilus. **Efferent lymphatics** leave the lymph node at the hilus. These vessels carry lymph away from the lymph node and toward the venous circulation.

Lymph Flow Lymph delivered by the afferent lymphatics flows through the lymph node within a network of sinuses, open passageways with incomplete walls (see Figure 22–7•). Lymph first enters a *subcapsular sinus*, which contains a meshwork of branching reticular fibers, macrophages, and dendritic cells. **Dendritic cells** are involved in the initiation of the immune response; we will consider their role in a later section. After passing through the subcapsular sinus, lymph flows through the **outer cortex** of the node. The outer cortex contains B cells within germinal centers that resemble those of lymphoid nodules.

Lymph then continues through lymph sinuses in the **deep cortex** (*paracortical area*). Lymphocytes leave the bloodstream and enter the lymph node by crossing the walls of blood vessels within the deep cortex, which is dominated by T cells.

After flowing through the sinuses of the deep cortex, lymph continues into the core, or **medulla**, of the lymph node. The medulla contains B cells and plasma cells organized into elongate masses known as **medullary cords**. After passing through a network of sinuses in the medulla, lymph enters the efferent lymphatics at the hilus.

Lymph Node Function A lymph node functions like a kitchen water filter, purifying lymph before it reaches the venous circulation. As lymph flows through a lymph node, at least 99 percent of the antigens in the lymph are removed. Fixed macrophages in the walls of the lymphatic sinuses engulf debris or pathogens in lymph as it flows past. Antigens removed in this way are then processed by the macrophages and “presented” to nearby lymphocytes. Other antigens bind to receptors on the surfaces of dendritic cells, where they can stimulate lymphocyte activity. This process—*antigen presentation*—is generally the first step in the activation of the immune response.

In addition to filtering, lymph nodes provide an early-warning system. Any infection or other abnormality in a peripheral tissue will introduce abnormal antigens into the interstitial fluid, and thus into the lymph leaving the area. These antigens then stimulate macrophages and lymphocytes in nearby lymph nodes.

To protect a house against intrusion, you might guard all the entrances and exits or place traps by the windows and doors. The distribution of lymphoid tissues and lymph nodes follows such a pattern. The largest lymph nodes are located where peripheral lymphatics connect with the trunk, such as in the groin, the axillae, and the base of the neck. These nodes are often called *lymph glands*. Because lymph is monitored in the cervical, inguinal, or axillary lymph nodes, potential problems can be detected and dealt with before they affect the vital organs of the trunk. Aggregations of lymph nodes also exist in the mesenteries of the gut, near the trachea and passageways leading to the lungs, and in association with the thoracic duct. These lymph nodes protect against pathogens and other antigens within the digestive and respiratory systems.

A minor injury commonly produces a slight enlargement of the nodes along the lymphatic vessels draining the region. This sign, often called “swollen glands,” typically indicates inflammation in peripheral structures. The enlargement generally results from an increase in the number of lymphocytes and phagocytes in the node in response to a minor, localized infection. Chronic or excessive enlargement of lymph nodes constitutes **lymphadenopathy** (lim-fad-e-NOP-a-th), a condition that may occur in

e¯response to bacterial or viral infections, endocrine disorders, or cancer.

Clinical Note

Lymphatic vessels are located in almost all portions of the body except the central nervous system, and lymphatic capillaries offer

little resistance to the passage of cancer cells. As a result, metastasizing cancer cells commonly spread along lymphatic vessels.

Under these circumstances, the lymph nodes serve as “way stations” for migrating cancer cells. Thus, an analysis of lymph nodes

can provide information on the spread of the cancer cells, and such information helps determine the appropriate therapies. In

Chapter 29, we will discuss one example: identifying the stages of breast cancer by the degree of nodal involvement. *Lymphomas,*

one group of cancers originating in the lymphatic system, are discussed in the *Applications Manual*. AM: Lymphomas

The Thymus

The **thymus** is a pink, grainy organ located in the mediastinum, generally just posterior to the sternum (Figure 22–8a,b•). In newborn infants and young children, the thymus is relatively large, commonly extending from the base of the neck to the superior border of the heart. The thymus reaches its greatest size relative to body size in the first year or two after birth. (Although the organ continues to increase in mass throughout childhood, the body as a whole grows even faster, so the size of the thymus relative to that of the other organs in the mediastinum gradually decreases.) The thymus reaches its maximum absolute size, at a weight of about 40 g (1.4 oz), just before puberty. After puberty, it gradually diminishes in size and becomes increasingly fibrous, a process called *involution*. By the time an individual reaches age 50, the thymus may weigh less than 12 g (0.3 oz). The gradual decrease in the size and secretory abilities of the thymus may make elderly individuals more susceptible to disease.

The capsule that covers the thymus divides it into two **thymic lobes** (see Figure 22–8b•). Fibrous partitions called **septa** (singular, *septum*) originate at the capsule and divide the lobes into **lobules** averaging 2 mm in diameter (Figure 22–8b,c•). Each lobule consists of a densely packed outer **cortex** and a paler, central **medulla**. Lymphocytes in the cortex are dividing; as the T cells mature, they migrate into the medulla. After roughly three weeks, these T cells leave the thymus by entering one of the medullary blood vessels.

Lymphocytes in the cortex are arranged in clusters that are completely surrounded by **reticular epithelial cells**. These cells, which developed from epithelial cells of the embryo, also encircle the blood vessels of the cortex. The reticular epithelial cells maintain the blood–thymus barrier and secrete the thymic hormones that stimulate stem cell divisions and T cell differentiation.

As they mature, T cells leave the cortex and enter the medulla of the thymus. The medulla has no blood–thymus barrier. The reticular epithelial cells in the medulla cluster together in concentric layers, forming distinctive structures known as **Hassall's corpuscles** (Figure 22–8d•). Despite their imposing appearance, the function of Hassall's corpuscles remains unknown. T cells in the medulla can enter or leave the bloodstream across the walls of blood vessels in this region or within one of the efferent lymphatics that collect lymph from the thymus.

Hormones of the Thymus The thymus produces several hormones that are important to the development and maintenance of

normal immunological defenses. *Thymosin* (TH

¯I

-m

¯o

-sin) is the name originally given to an extract from the thymus that pro

motes the development and maturation of lymphocytes. This thymic extract actually contains several complementary hormones: *thymosin-a*, *thymosin-b*, *thymosin V*, *thymopoietin*, *thymulin*, and others. The term *thymosins* is now sometimes used to refer to all thymic hormones.

Anatomy 360 | Review the anatomy of the thymus on the **Anatomy 360 CD-ROM: Lymphatic System/Thymus.**

The Spleen

The adult **spleen** contains the largest collection of lymphoid tissue in the body. In essence, the spleen performs the same functions for blood that lymph nodes perform for lymph. Functions of the spleen can be summarized as (1) the removal of abnormal blood cells and other blood components by phagocytosis, (2) the storage of iron recycled from red blood cells, and (3) the initiation of immune responses by B cells and T cells in response to antigens in circulating blood.

Anatomy of the Spleen The spleen is about 12 cm (5 in.) long and weighs, on average, nearly 160 g (5.6 oz). In gross dissection, the spleen is deep red, owing to the blood it contains. The spleen lies along the curving lateral border of the stomach, extending between the 9th and 11th ribs on the left side. It is attached to the lateral border of the stomach by the **gastrosplenic ligament**, a broad band of mesentery (Figure 22–9a•).

The spleen has a soft consistency, so its shape primarily reflects its association with the structures around it. The spleen is in contact with the stomach, the left kidney, and the muscular diaphragm. The *diaphragmatic surface* is smooth and convex, conforming to the shape of the diaphragm and body wall. The *visceral surface* contains indentations that conform to the shape of the stomach (the *gastric area*) and the kidney (the *renal area*) (Figure 22–9b•). Splenic blood vessels (the *splenic artery* and *splenic vein*) and lymphatic vessels communicate with the spleen on the visceral surface at the **hilus**, a groove marking the border between the gastric and renal areas.

Histology of the Spleen The spleen is surrounded by a capsule containing collagen and elastic fibers.1 The cellular components within constitute the **pulp** of the spleen (Figure

22–9c•). **Red pulp** contains large quantities of red blood cells, whereas **white pulp** resembles lymphoid nodules.

The splenic artery enters at the hilus and branches to produce a number of arteries that radiate outward toward the capsule. These **trabecular arteries** in turn branch extensively, and their finer branches are surrounded by areas of white pulp. Capillaries then discharge the blood into the red pulp.

The cell population of the red pulp includes all the normal components of circulating blood, plus fixed and free macrophages. The structural framework of the red pulp consists of a network of reticular fibers. The blood passes through this meshwork and enters large sinusoids, also lined by fixed macrophages. The sinusoids empty into small veins, which ultimately collect into **trabecular veins** that continue toward the hilus.

This circulatory arrangement gives the phagocytes of the spleen an opportunity to identify and engulf any damaged or infected cells in circulating blood. Lymphocytes are scattered throughout the red pulp, and the area surrounding the white pulp has a high concentration of macrophages and dendritic cells. Thus, any microorganism or other antigen in the blood will quickly come to the attention of the splenic lymphocytes.

The spleen tears so easily that a seemingly minor blow to the left side of the abdomen can rupture the capsule. The result is serious internal bleeding and eventual circulatory shock. Such an injury is a known risk of contact sports (such as football and hockey) and of more solitary athletic activities, such as skiing and sledding.

Because the spleen is relatively fragile, it is very difficult to repair surgically. (Sutures typically tear out before they have been tensed enough to stop the bleeding.) A severely ruptured spleen is removed, a process called a **splenectomy** (sple-NEK-to-m).

e¯A person without a spleen survives but has a greater risk of bacterial infection (particularly involving pneumococcal bacteria) than do individuals with a functional spleen. AM: Disorders of the Spleen

Anatomy 360 | Review the anatomy of the spleen on the **Anatomy 360 CD-ROM: Lymphatic System/Spleen.**

The Lymphatic System and Body Defenses

The human body has multiple defense mechanisms that together provide resistance—the ability to fight infection, illness, and disease. Body defenses can be sorted into two general categories:

1. Nonspecific defenses do not distinguish one type of threat from another. Their response is the same, regardless of the type of invading agent. These defenses, which are present at birth, include *physical barriers*, *phagocytic cells, immunological surveillance, interferons, complement*, *inflammation*, and *fever*. They provide a defensive capability known as **nonspecific resistance**.

2. Specific defenses protect against particular threats. For example, a specific defense may protect against infection by one type of bacterium, but be ineffective against other bacteria and viruses. Many specific defenses develop after birth as a result of accidental or deliberate exposure to environmental hazards. *Specific defenses depend on the activities of lymphocytes*. The body's specific defenses produce a state of protection known as immunity, or **specific resistance**.

Nonspecific and specific resistances are complementary. Both must function normally to provide adequate resistance to infection and disease.

Concept Check

How would blockage of the thoracic duct affect the circulation of lymph?

If the thymus failed to produce thymic hormones, which population of lymphocytes would be affected?

Why do lymph nodes enlarge during some infections?

Answers begin on p. A–1

Nonspecific Defenses

Objectives

- List the body’s nonspecific defenses and explain the function of each.
- Describe the components and mechanisms of each nonspecific defense.

Nonspecific defenses prevent the approach, deny the entry, or limit the spread of microorganisms or other environmental hazards. Seven major categories of nonspecific defenses are summarized in Figure 22–10•.

1. *Physical barriers* keep hazardous organisms and materials outside the body. For example, a mosquito that lands on your head may be unable to reach the surface of the scalp if you have a full head of hair.

2. *Phagocytes* are cells that engulf pathogens and cell debris. Examples of phagocytes are the macrophages of peripheral tissues and the microphages of blood.

3. *Immunological surveillance* is the destruction of abnormal cells by NK cells in peripheral tissues.

4. *Interferons* are chemical messengers that coordinate the defenses against viral infections.

5. *Complement* is a system of circulating proteins that assist antibodies in the destruction of pathogens.

6. The *inflammatory response* is a local response to injury or infection that is directed at the tissue level. Inflammation tends to limit the spread of an injury as well as combat an infection.

7. *Fever* is an elevation of body temperature that accelerates tissue metabolism and defenses.

Physical Barriers

To cause trouble, an antigenic compound or pathogen must enter body tissues, which requires crossing an epithelium—either at the skin or across a mucous membrane. The epithelial covering of the skin has multiple layers, a keratin coating, and a network of desmosomes that lock adjacent cells together. l**pp. 156–157** These barriers provide very effective protection for underlying tissues. Even along the more delicate internal passageways of the respiratory, digestive, and urinary tracts, epithelial cells are tied together by tight junctions and generally are supported by a dense and fibrous basal lamina.

In addition to the barriers posed by the epithelial cells, most epithelia are protected by specialized accessory structures and secretions. The hairs on most areas of your body surface provide some protection against mechanical abrasion (especially on the scalp), and they often prevent hazardous materials or insects from contacting your skin surface. The epidermal surface also receives the secretions of sebaceous and sweat glands. These secretions, which flush the surface to wash away microorganisms and chemical agents, may also contain bactericidal chemicals, destructive enzymes (*lysozymes*), and antibodies.

The epithelia lining the digestive, respiratory, urinary, and reproductive tracts are more delicate, but they are equally well defended. Mucus bathes most surfaces of your digestive tract, and your stomach contains a powerful acid that can destroy many pathogens. Mucus moves across the respiratory tract lining, urine flushes the urinary passageways, and glandular secretions do the same for the reproductive tract. Special enzymes, antibodies, and an acidic pH add to the effectiveness of these secretions.

Phagocytes

Phagocytes perform janitorial and police services in peripheral tissues, removing cellular debris and responding to invasion by foreign compounds or pathogens. Phagocytes represent the “first line of cellular defense” against pathogenic invasion. Many phagocytes attack and remove microorganisms even before lymphocytes detect their presence. The human body has two general classes of phagocytic cells: *microphages* and *macrophages*.

Microphages

Microphages are the neutrophils and eosinophils that normally circulate in the blood. These phagocytic cells leave the bloodstream and enter peripheral tissues that have been subjected to injury or infection. As noted in Chapter 19, neutrophils are abundant, mobile, and quick to phagocytize cellular debris or invading bacteria. l**p. 655** Eosinophils, which are less abundant, target foreign compounds or pathogens that have been coated with antibodies.

Macrophages

Macrophages are large, actively phagocytic cells. Your body contains several types of macrophages, and most are derived from the monocytes of the circulating blood. Typically, macrophages are either fixed in position or freely mobile, and they are usually classified as fixed macrophages or free macrophages as a result. The distinction is not absolute, however; during an infection, fixed macrophages may lose their attachments and begin roaming around the damaged tissue.

Although no organs or tissues are dominated by phagocytes, almost every tissue in the body shelters resident or visiting macrophages. This relatively diffuse collection of phagocytic cells has been called the **monocyte–macrophage system**, or the *reticuloendothelial system*.

An activated macrophage may respond to a pathogen in several ways:

- It may engulf a pathogen or other foreign object and destroy it with lysosomal enzymes.
- It may bind to or remove a pathogen from the interstitial fluid, but be unable to destroy the invader until assisted by other cells.
- It may destroy its target by releasing toxic chemicals, such as *tumor necrosis factor*, nitric oxide, or hydrogen peroxide, into the interstitial fluid.

We will consider those responses further in a later section.

Fixed Macrophages **Fixed macrophages**, or *histiocytes*, are permanent residents of specific tissues and organs. These cells are normally incapable of movement, so their targets must diffuse or otherwise move through the surrounding tissue until they are within range. Fixed macrophages are scattered among connective tissues, usually in close association with collagen or reticular fibers. Their presence has already been noted in the papillary and reticular layers of the dermis, in the subarachnoid space of the meninges, and in bone marrow. In some organs, the fixed macrophages have special names: **Microglia** are macrophages in the central nervous system, and **Kupffer cells** are macrophages located in and around the liver sinusoids.

Free Macrophages **Free macrophages**, or *mobile macrophages*, travel throughout the body, arriving at the site of an injury by migrating through adjacent tissues or by recruitment from the circulating blood. Some tissues contain free macrophages with distinctive characteristics; for example, the exchange surfaces of the lungs are monitored by **alveolar macrophages**, also known as *phagocytic dust cells*.

Movement and Phagocytosis

Free macrophages and microphages share a number of functional characteristics:

- Both can move through capillary walls by squeezing between adjacent endothelial cells, a process known as *emigration*, or *diapedesis*. l**p. 655** The endothelial cells in an injured area develop membrane "markers" that signal passing blood cells that something is wrong. The cells then attach to the endothelial lining and migrate into the surrounding tissues.
- Both may be attracted to or repelled by chemicals in the surrounding fluids, a phenomenon called **chemotaxis**. They are particularly sensitive to cytokines released by other body cells and to chemicals released by pathogens.
- For both, phagocytosis begins with **adhesion**, the attachment of the phagocyte to its target. In adhesion, receptors on the cell membrane of the phagocyte bind to the surface of the target. Adhesion is followed by the formation of a vesicle containing the bound target (see Figure 3–22•, p. 93). The contents of the vesicle are digested once the vesicle fuses with lysosomes or peroxisomes.

All phagocytic cells function in much the same way, although the target of phagocytosis may differ from one type of phagocyte to another. The life span of an actively phagocytic cell can be rather brief. For example, most neutrophils die before they have engulfed more than 25 bacteria, and in an infection a neutrophil may attack that many in an hour.

Immunological Surveillance

The immune system generally ignores the body's own cells unless they become abnormal in some way. Natural killer (NK) cells are responsible for recognizing and destroying abnormal cells when they appear in peripheral tissues. The constant monitoring of normal tissues by NK cells is called **immunological surveillance**.

The cell membrane of an abnormal cell generally contains antigens that are not found on the membranes of normal cells. NK cells recognize an abnormal cell by detecting the presence of those antigens. NK cells are much less selective about their targets than are other lymphocytes: They respond to a *variety* of abnormal antigens that may appear anywhere on a cell membrane, and *any* membrane containing abnormal antigens will be attacked. As a result, NK cells are highly versatile: A single NK cell can attack bacteria in the interstitial fluid, body cells infected with viruses, or cancer cells.

NK cells also respond much more rapidly than T cells or B cells. The activation of T cells and B cells involves a relatively complex and time-consuming sequence of events; NK cells respond immediately on contact with an abnormal cell.

NK Cell Activation

Activated NK cells react in a predictable way (Figure 22–11•):

Step 1 If a cell has unusual components in its cell membrane, an NK cell recognizes that other cell as abnormal. Such recognition activates the NK cell, which then adheres to its target cell.

Step 2 The Golgi apparatus moves around the nucleus until the maturing face points directly toward the abnormal cell. The process might be compared to the rotation of a tank turret to point the cannon toward the enemy. A flood of secretory vesicles is then produced at the Golgi apparatus. These vesicles, which contain proteins called **perforins**, travel through the cytoplasm toward the cell surface.

Step 3 The perforins are released at the cell surface by exocytosis and diffuse across the narrow gap separating the NK cell from its target.

Step 4 On reaching the opposing cell membrane, perforin molecules interact with one another and with the membrane to create a network of pores in it. These pores are large enough to permit the free passage of ions, proteins, and other intracellular materials. As a result, the target cell can no longer maintain its internal environment, and it quickly disintegrates.

It is not clear why perforin does not affect the membrane of the NK cell itself. NK cell membranes contain a second protein, called *protectin*, which may be responsible for binding and inactivating perforin.

NK cells attack cancer cells and cells infected with viruses. Cancer cells probably appear throughout life, but their cell membranes generally contain unusual proteins called **tumor-specific antigens**, which NK cells recognize as abnormal. The affected cells are then destroyed, preserving tissue integrity. Unfortunately, some cancer cells avoid detection, perhaps because they lack tumor-specific antigens or because these antigens are covered in some way. Other cancer cells are able to destroy the NK cells that detect them. This process of avoiding detection or neutralizing body defenses is called **immunological escape**. Once immunological escape has occurred, cancer cells can multiply and spread without interference by NK cells.

In viral infections, the viruses replicate inside cells, beyond the reach of circulating antibodies. However, infected cells incorporate viral antigens into their cell membranes, and NK cells recognize these infected cells as abnormal. By destroying them, NK cells can slow or prevent the spread of a viral infection.

Interferons

Interferons (in-ter-F
¯E

R-onz) are small proteins released by activated lymphocytes and macrophages, and by tissue cells infected
with viruses. On reaching the membrane of a normal cell, an interferon binds to surface receptors on the cell and, via second messengers, triggers the production of **antiviral proteins** in the cytoplasm. Antiviral proteins do not interfere with the entry of viruses, but

they do interfere with viral replication inside the cell. In addition to their role in slowing the spread of viral infections, interferons stimulate the activities of macrophages and NK cells.

At least three types of interferons exist, each of which has additional specialized functions: (1) **Alpha**-(a) **interferons**, produced by several types of leukocytes, attract and stimulate NK cells; (2) **beta**-(b) **interferons**, secreted by fibroblasts, slow inflammation in a damaged area; and (3) **gamma**-(g) **interferons**, secreted by T cells and NK cells, stimulate macrophage activity. Most cells other than lymphocytes and macrophages respond to viral infection by secreting beta-interferon.

Interferons are examples of **cytokines** (S

¯I

–

-t -k nz)—chemical messengers released by tissue cells to coordinate local activ-

ı

¯o

ities. Cytokines produced by most cells are used only for paracrine communication—that is, cell-to-cell communication within one tissue. However, cytokines released by defense cells also act as hormones, affecting cells and tissues throughout the body. We will discuss their role in the regulation of specific defenses in a later section.

Complement

Plasma contains 11 special **complement (C) proteins** that form the **complement system**. The term *complement* refers to the fact that this system complements the action of antibodies.

The complement proteins interact with one another in chain reactions, or *cascades*, reminiscent of those of the clotting system. Figure 22–12• provides an overview of the complement system. AM: The Complement System: A Closer Look

The activation of complement can occur by two different routes: the *classical pathway* and the *alternative pathway*.

Complement Activation: The Classical Pathway

The most rapid and effective activation of the complement system occurs through the **classical pathway** (Figure 22–12•). The process begins when one of the complement proteins (*C1*) binds to an antibody molecule already attached to its specific antigen— in this case, a bacterial cell wall. The bound complement protein then acts as an enzyme, catalyzing a series of reactions involving other complement proteins. The classical pathway ends with the conversion of an inactive complement protein, *C3*, to an active form, *C3b*.

Complement Activation: The Alternative Pathway

A less effective, slower activation of the complement system occurs in the absence of antibody molecules. This **alternative pathway**, or *properdin pathway*, is important in the defense against bacteria, some parasites, and virus-infected cells. The pathway begins when several complement proteins—including **properdin** (or *factor P*), *factor B*, and *factor D*—interact in the plasma (see Figure 22–12•). This interaction can be triggered by exposure to foreign materials, such as the capsule of a bacterium. As does the classical pathway, the alternative pathway ends with the conversion of C3 to C3b.

Effects of Complement Activation

Known effects of complement activation include the following:

- **Stimulation of Inflammation.** Activated complement proteins enhance the release of histamine by mast cells and basophils. Histamine increases the degree of local inflammation and accelerates blood flow to the region.
- **Attraction of Phagocytes.** Activated complement proteins attract neutrophils and macrophages to the area, improving the likelihood that phagocytic cells will be able to cope with the injury or infection.
- **Enhancement of Phagocytosis.** A coating of complement proteins and antibodies both attracts phagocytes and makes the target easier to engulf. Macrophage membranes contain receptors that can detect and bind to complement proteins and bound antibodies. After binding, the pathogens are easily engulfed. The antibodies involved are called **opsonins**, and the effect is called **opsonization**.

- **Destruction of Target Cell Membranes.** In the presence of C3b, five of the interacting complement proteins (C5–C9) bind to the cell membrane, forming a functional unit called a **membrane attack complex (MAC)**. The MACs create pores in the membrane that are comparable to those produced by perforin and have the same effect: The target cell is soon destroyed.

Inflammation

Inflammation, or the *inflammatory response*, is a localized tissue response to injury. l**p. 135** Inflammation produces local swelling (*tumor*), redness (*rubor*), heat (*calor*), and pain (*dolor*); these are known as the *cardinal signs and symptoms*. Many stimuli, including impact, abrasion, distortion, chemical irritation, infection by pathogens, and extreme temperatures (hot or cold), can produce inflammation. Each of these stimuli kills cells, damages connective-tissue fibers, or injures the tissue in some other way. The changes alter the chemical composition of the interstitial fluid. Damaged cells release prostaglandins, proteins, and potassium ions, and the injury itself may have introduced foreign proteins or pathogens. The changes in the interstitial environment trigger the complex process of inflammation.

Inflammation has several effects:

- The injury is temporarily repaired, and additional pathogens are prevented from entering the wound.
- The spread of pathogens away from the injury is slowed.
- Local, regional, and systemic defenses are mobilized to overcome the pathogens and facilitate permanent repairs. This repair process is called *regeneration*.

The Response to Injury

Mast cells play a pivotal role in the inflammatory response. Figure 22–13• summarizes the events of inflammation in the skin; comparable events take place in almost any tissue subjected to physical damage or infection.

When stimulated by mechanical stress or chemical changes in the local environment, mast cells release histamine, heparin, prostaglandins, and other chemicals into interstitial fluid. The released histamine increases capillary permeability and accelerates blood flow through the area. The combination of abnormal tissue conditions and chemicals released by mast cells stimulates local sensory neurons, producing sensations of pain. The individual then becomes aware of these sensations and may take steps to limit the damage they signal, such as removing a splinter or cleaning a wound.

The increased blood flow reddens the area and elevates the local temperature, increasing the rate of enzymatic reactions and accelerating the activity of phagocytes. The rise in temperature may also denature foreign proteins or vital enzymes of invading microorganisms.

Because vessel permeability has increased, clotting factors and complement proteins can leave the bloodstream and enter the injured or infected area. Clotting does not occur at the actual site of injury, due to the presence of heparin. However, a clot soon forms around the damaged area, both isolating the region and slowing the spread of the chemical or pathogen into healthy tissues. Meanwhile, complement activation through the alternative pathway breaks down bacterial cell walls and attracts phagocytes.

Debris and bacteria are attacked by neutrophils drawn to the area by chemotaxis. As they circulate through a blood vessel in an injured area, neutrophils undergo *activation*, a process in which (1) they stick to the side of the vessel and move into the tissue by diapedesis; (2) their metabolic rate goes up dramatically, and while this *respiratory burst* continues, they generate reactive compounds, such as nitric oxide and hydrogen peroxide, that can destroy engulfed pathogens; and (3) they secrete cytokines that attract other neutrophils and macrophages to the area. As inflammation proceeds, the foreign proteins, toxins, microorganisms, and active phagocytes in the area activate the body’s specific defenses.

Fixed and free macrophages engulf pathogens and cell debris. At first, these cells are outnumbered by neutrophils, but as the macrophages and neutrophils continue to secrete cytokines, the number of macrophages increases rapidly. Eosinophils may get involved if the foreign materials become coated with antibodies.

The cytokines released by active phagocytes stimulate fibroblasts in the area. The fibroblasts then begin forming scar tissue that reinforces the clot and slows the invasion of adjacent tissues are. Over time, the clot is broken down and the injured tissues are either repaired or replaced by scar tissue. Although subsequent remodeling may occur over a period of years, the process is essentially complete.

After an injury, tissue conditions generally become even more abnormal before they begin to improve. The tissue destruction

that occurs after cells have been injured or destroyed is called **necrosis** (ne-KR

¯O

-sis). The process begins several hours after the

initial event, and the damage is caused by lysosomal enzymes. Lysosomes break down by autolysis, releasing digestive enzymes that first destroy the injured cells and then attack surrounding tissues. l**p. 75** As local inflammation continues, debris, fluid, dead and dying cells, and necrotic tissue components accumulate at the injury site. This viscous fluid mixture is known as **pus**. An accumulation of pus in an enclosed tissue space is called an **abscess**. AM: Complications of Inflammation

Fever

Fever is the maintenance of body temperature greater than 37.2°C (99°F). The presence of a temperature-regulating center in the

preoptic area of the hypothalamus was described in Chapter 14. l**p. 468** Circulating proteins called **pyrogens** (P

¯I

-r

¯o

-jenz;

pyro-, fever or heat + *-gen*, substance) can reset this thermostat and raise body temperature. A variety of stimuli, including pathogens, bacterial toxins, and antigen-antibody complexes, either act as pyrogens themselves or stimulate the release of pyro-gens by macrophages. The pyrogen released by active macrophages is a cytokine called **endogenous pyrogen**, or **interleukin-1** (in-ter-LOO-kin), abbreviated **IL-1**.

Within limits, a fever can be beneficial. High body temperatures may inhibit some viruses and bacteria, but the most likely beneficial effect is on body metabolism. For each 1°C rise in body temperature, metabolic rate jumps by 10 percent. Cells can move faster, and enzymatic reactions occur faster. The net results may be the quicker mobilization of tissue defenses and an accelerated repair process.

Concept Check

What types of cells would be affected by a decrease in the number of monocyte-forming cells in bone marrow?

A rise in the level of interferon in the body suggests what kind of infection?

What effects do pyrogens have in the body?

Answers begin on p. A–1

Specific Defenses: An Overview of the Immune Response

Objectives

- Define specific resistance and identify the forms and properties of immunity.
- Distinguish between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity and identify the cells responsible for each.

Specific resistance, or immunity, is provided by the coordinated activities of T cells and B cells, which respond to the presence of specific antigens. In general, T cells are responsible for **cell-mediated immunity** (or *cellular immunity*), which defends against abnormal cells and pathogens inside cells, and B cells provide **antibody-mediated immunity** (or *humoral immunity*), which defends against antigens and pathogens in body fluids.

Both mechanisms are important, because they come into play under different circumstances. Activated T cells do not respond to antigenic materials in solution, and antibodies (produced by activated B cells) cannot cross cell membranes. Moreover, helper T cells play a crucial role in antibody-mediated immunity by stimulating the activity of B cells.

Our understanding of immunity has greatly improved in the past two decades, and a comprehensive discussion would involve hundreds of pages and thousands of details. The discussion that follows emphasizes important patterns and introduces general principles that will provide a foundation for future courses in microbiology and immunology.

Forms of Immunity

Immunity is either *innate* or *acquired* (Figure 22–14•).

Innate immunity is genetically determined; it is present at birth and has no relationship to previous exposure to the antigen involved. For example, people do not get the same diseases that goldfish do. Innate immunity breaks down only in the case of *AIDS* or other conditions that depress all aspects of specific resistance.

Acquired immunity is not present at birth; you acquire immunity to a specific antigen only when you have been exposed to that antigen. Acquired immunity can be *active* or *passive*.

Active immunity develops after exposure to an antigen, as a consequence of the immune response. The immune system is *capable* of defending against a huge number of antigens. However, the appropriate defenses are mobilized only after you encounter a particular antigen. Active immunity can develop as a result of natural exposure to an antigen in the environment (*naturally acquired active immunity*) or from deliberate exposure to an antigen (*induced active immunity*).

- **Naturally acquired active immunity** normally begins to develop after birth, and it is continually enhanced as you encounter “new” pathogens or other antigens. You might compare this process to the development of a child’s vocabulary: The child begins with a few basic common words and learns new ones as they are encountered.
- The purpose of **induced active immunity** is to stimulate the production of antibodies under controlled conditions so that you will be able to overcome natural exposure to the pathogen some time in the future. This is the basic principle behind *immunization*, or *vaccination*, to prevent disease. A **vaccine** is a preparation designed to induce an immune response. It contains either a dead or an inactive pathogen, or antigens derived from that pathogen.

Passive immunity is produced by the transfer of antibodies from another source.

- In **naturally acquired passive immunity**, a mother’s antibodies protect her baby against infections, either during gestation (by crossing the placenta) or in early infancy (through breast milk).
- In **induced passive immunity**, antibodies are administered to fight infection or prevent disease. For example, antibodies against the rabies virus are injected into a person bitten by a rabid animal.

Properties of Immunity

Regardless of the form, immunity exhibits four general properties: (1) *specificity*, (2) *versatility*, (3) *memory*, and (4) *tolerance*.

Specificity

A specific defense is activated by a specific antigen, and the immune response targets that particular antigen and no others. **Specificity** results from the activation of appropriate lymphocytes and the production of antibodies with targeted effects. Specificity occurs because T cells and B cells respond to the molecular structure of an antigen. The shape and size of the antigen determine which lymphocytes will respond to its presence. Each T cell or B cell has receptors that will bind to one specific antigen, ignoring all others. The response of an activated T cell or B cell is equally specific. Either lymphocyte will destroy or inactivate that antigen without affecting other antigens or normal tissues.

Versatility

Millions of antigens in the environment can pose a threat to health. Over a normal lifetime, an individual encounters only a fraction of that number—perhaps tens of thousands of antigens. Your immune system, however, has no way of anticipating which antigens it will encounter. It must be ready to confront *any* antigen at *any* time. **Versatility** results in part from the large diversity of lymphocytes present in the body, and in part from variability in the structure of synthesized antibodies.

During development, differentiation of cells in the lymphatic system produces an enormous number of lymphocytes with varied antigen sensitivities. The trillion or more T cells and B cells in the human body include millions of different lymphocyte populations, distributed throughout the body. Each population consists of several thousand cells with receptors in their membranes that differ from those of other lymphocyte populations. As a result, each population of lymphocytes will respond to the presence of a different antigen.

Several thousand lymphocytes are not enough to overcome a pathogenic invasion. However, when activated in the presence of an appropriate antigen, a lymphocyte begins to divide, producing more lymphocytes with the same specificity. All the cells produced by the division of an activated lymphocyte constitute a **clone**, and all the members of that clone are sensitive to the same specific antigen.

To understand how this system works, think about running a commercial kitchen with only samples on display. You can display a wide selection because the samples don’t take up much space and you don’t have to expend energy preparing food that might never be eaten. When a customer selects one of your samples and places an order for several dozen, you prepare them on the spot.

The same principle applies to the lymphatic system: Your body contains a small number of many different kinds of lymphocytes. When an antigen arrives, lymphocytes sensitive to its presence are “selected,” and these lymphocytes divide to generate a large number of additional lymphocytes of the same type.

Memory

As we saw in the last section, during the initial response to an antigen, lymphocytes that are sensitive to its presence undergo repeated cycles of cell division. Immunologic **memory** exists because those cell divisions produce two groups of cells: One group that attacks the invader immediately, and another that remains inactive unless it is exposed to the same antigen at a later date. These inactive *memory cells* enable your immune system to “remember” antigens it has previously encountered, and to launch a faster, stronger, and longer-lasting counterattack if such an antigen reappears.

Tolerance

The immune system does not respond to all antigens. All cells and tissues in the body, for example, contain antigens that normally do not stimulate an immune response. The immune system is said to exhibit **tolerance** toward such antigens.

The immune response targets foreign cells and compounds, but it generally ignores normal tissues. During their differentiation in the bone marrow (B cells) and thymus (T cells), cells that react to antigens that are normally present in the body are destroyed. As a result, mature B cells and T cells will ignore normal (or *self*) antigens, and attack foreign (or *nonself*) antigens. Tolerance can also develop over time in response to chronic exposure to an antigen in the environment. Such tolerance lasts only as long as the exposure continues.

An Introduction to the Immune Response

Figure 22–15• provides an overview of the immune response. When an antigen triggers an immune response, it usually activates both T cells and B cells. The activation of T cells generally occurs first, but only after phagocytes have been exposed to the antigen. Once activated, T cells attack the antigen and stimulate the activation of B cells. Activated B cells mature into cells that produce antibodies; antibodies distributed in the bloodstream bind to and attack the antigen. We will examine each of these processes more closely in the sections that follow.

T Cells and Cell-Mediated Immunity

Objectives

- Discuss the types of T cells and the role played by each in the immune response.
- Describe the mechanisms of T cell activation and the differentiation of the major classes of T cells.

T cells play a key role in the initiation, maintenance, and control of the immune response. We have already noted three major types of T cells:

1. *Cytotoxic T cells* (T_C cells) are responsible for cell-mediated immunity. These cells enter peripheral tissues and directly attack antigens physically and chemically.

2. *Helper T cells* (T_H cells) stimulate the responses of both T cells and B cells. Helper T cells are absolutely vital to the immune response, because B cells must be activated by helper T cells before the B cells can produce antibodies. The reduction in the helper T cell population that occurs in AIDS is largely responsible for the loss of immunity. (We will discuss AIDS on p. 803.)

3. *Suppressor T cells* (T_S cells) inhibit T cell and B cell activities and moderate the immune response.

Before an immune response can begin, T cells must be activated by exposure to an antigen. This activation seldom occurs through direct lymphocyte–antigen interaction, and foreign compounds or pathogens entering a tissue commonly fail to stimulate an immediate immune response.

Antigen Presentation

T cells recognize antigens when the antigens are bound to glycoproteins in cell membranes. Glycoproteins are integral membrane components. l**p. 67 Antigen presentation** occurs when an antigen–glycoprotein combination capable of activating T cells appears in a cell membrane. The structure of these glycoproteins is genetically determined. The genes controlling their synthesis are located along one portion of chromosome 6, in a region called the **major histocompatibility complex (MHC)**. These membrane glycoproteins are called **MHC proteins**, or *human leukocyte antigens (HLAs).*

The amino acid sequences and the shapes of MHC proteins differ among individuals. Each MHC molecule has a distinct three-dimensional shape with a relatively narrow central groove. An antigen that fits into this groove can be held in position by hydrogen bonding.

Two major classes of MHC proteins are known: *Class I* and *Class II*. An antigen bound to a Class I MHC protein acts like a red flag that in effect tells the immune system "Hey, I'm an abnormal cell—kill me!" An antigen bound to a Class II MHC protein tells the immune system "Hey, this antigen is dangerous—get rid of it!"

Class I MHC proteins are in the membranes of all nucleated cells. These proteins are continuously synthesized and exported to the cell membrane in vesicles created at the Golgi apparatus. As they form, Class I proteins pick up small peptides from the surrounding cytoplasm and carry them to the cell surface. If the cell is healthy and the peptides are normal, T cells will ignore them. If the cytoplasm contains abnormal (nonself) peptides or viral proteins (Figure 22–16a•), they will soon appear in the cell membrane, and T cells will be activated. Ultimately, their activation leads to the destruction of the abnormal cells. This is the primary reason that donated organs are commonly rejected by the recipient; despite preliminary cross-match testing, the recipient's T cells recognize the transplanted tissue as foreign.

Class II MHC proteins are present only in the membranes of antigen-presenting cells and lymphocytes. **Antigen-presenting cells (APCs)** are specialized cells responsible for activating T cell defenses against foreign cells (including bacteria) and foreign proteins. Antigen-presenting cells include all the phagocytic cells of the monocyte–macrophage group discussed in other chapters, including (1) free and fixed macrophages in connective tissues, (2) the Kupffer cells of the liver, and (3) the microglia in the

central nervous system (Chapter 12). l**pp. 119, 387** The Langerhans cells of the skin and the dendritic cells of the lymph nodes and spleen are APCs that are not phagocytic. l**p. 157**

Phagocytic APCs engulf and break down pathogens or foreign antigens. Such **antigen processing** creates antigenic fragments, which are then bound to Class II MHC proteins and inserted into the cell membrane (Figure 22–16b•). *Class II MHC proteins appear in the cell membrane only when the cell is processing antigens*. Exposure to an APC membrane containing processed antigen can stimulate appropriate T cells.

The Langerhans cells and dendritic cells remove antigenic materials from their surroundings via pinocytosis rather than phagocytosis. However, their cell membranes still present antigens bound to Class II MHC proteins.

Antigen Recognition

Inactive T cells have receptors that recognize Class I or Class II MHC proteins. The receptors also have binding sites that detect the presence of specific bound antigens. If an MHC protein contains any antigen other than the specific target of a particular kind of T cell, the T cell remains inactive. If the MHC protein contains the antigen that the T cell is programmed to detect, binding will occur. This process is called **antigen recognition**, because the T cell recognizes that it has found an appropriate target.

Some T cells can recognize antigens bound to Class I MHC proteins, whereas others can recognize antigens bound to Class II MHC proteins. Whether a T cell responds to antigens held by Class I or Class II proteins depends on the structure of the T cell membrane. The membrane proteins involved are members of a larger class of proteins called **CD** (***c****luster of* ***d****ifferentiation*) **markers**.

Lymphocytes, macrophages, and other, related cells have CD markers. Each of the more than 70 types of CD markers is designated by an identifying number. All T cells have a **CD3 receptor complex** in their membranes. Two other CD markers are of particular importance in specific groups of T cells:

1. CD8 markers are found on cytotoxic T cells and suppressor T cells, which together are often called *CD8 T cells* or *CD8 + T cells*. CD8 T cells respond to antigens presented by Class I MHC proteins.

2. CD4 markers are found on helper T cells, often called *CD4 T cells* or *CD4 + T cells*. CD4 T cells respond to antigens presented by Class II MHC proteins.

Costimulation

CD8 or CD4 markers are bound to the CD3 receptor complex, which ultimately activates the T cell. However, such activation usually does not occur upon the first encounter with the antigen. Antigen recognition simply prepares the cell for activation. Before activation can occur, a T cell must bind to the stimulating cell at a second site. This vital secondary binding process, called *costimulation*, essentially confirms the initial activation signal. Appropriate costimulation proteins appear in the presenting cell only if that cell has engulfed antigens or is infected by viruses. Many costimulation proteins are structurally related to the cytokines released by activated lymphocytes. The effects of these proteins on the exposed T cell vary, but they typically include the stimulation of transcription at the nucleus and the promotion of cell division and differentiation.

Costimulation is like the safety on a gun: It helps prevent T cells from mistakenly attacking normal (self) tissues. If a cell displays an unusual antigen but does not display the “I am an active phagocyte” or “I am infected” signal, T cell activation will not occur. Costimulation is important only in determining whether a T cell will become activated. Once activation has occurred, the “safety” is off and the T cell will attack any cells that carry the target antigens.

Activation of CD8 T Cells

Two different classes of CD8 T cells are activated by exposure to antigens bound to Class I MHC proteins. One type of CD8 T cell responds quickly, giving rise to large numbers of *cytotoxic T cells* and *memory T cells* (Figure 22–17•). The other type of CD8 T cell responds more slowly and produces relatively small numbers of *suppressor T cells*.

Cytotoxic T Cells

Cytotoxic T cells, also called *TC cells* or *killer T cells*, seek out and destroy abnormal and infected cells. Killer T cells are highly mobile cells that roam throughout injured tissues. When a cytotoxic T cell encounters its target antigens bound to Class I MHC proteins of another cell, it immediately destroys the target cell (see Figure 22–17•). The T cell may (1) destroy the antigenic cell membrane through the release of perforin, (2) kill the target cell by secreting a poisonous **lymphotoxin** (lim-fo¯-TOK-sin), or

(3) activate genes in the target cell's nucleus that tell that cell to die. (We introduced genetically programmed cell death, called *apoptosis*, in Chapter 3.) l**p. 95**

The entire sequence of events, from the appearance of the antigen in a tissue to cell destruction by cytotoxic T cells, takes a significant amount of time. After the first exposure to an antigen, two days or more may pass before the concentration of cytotoxic T cells reaches effective levels at the site of injury or infection. Over this period, the damage or infection may spread, making it more difficult to control.

Memory T_C Cells

Memory TC cells are produced by the same cell divisions that produce cytotoxic T cells. Thousands of these cells are produced, but they do not differentiate further the first time the antigen triggers an immune response. However, if the same antigen appears a second time, memory T cells will *immediately* differentiate into cytotoxic T cells, producing a prompt, effective cellular response that can overwhelm an invading organism before it becomes well established in the tissues.

Suppressor T Cells

Suppressor T cells (*TS cells*) suppress the responses of other T cells and of B cells by secreting *suppression factors*—inhibitory cytokines of unknown structure. Suppression does not occur immediately, because suppressor T cell activation takes much longer than the activation of other types of T cells. In addition, upon activation, most of the CD8 T cells in the bloodstream produce cytotoxic T cells rather than suppressor T cells. As a result, suppressor T cells act *after* the initial immune response. In effect, these cells limit the degree of immune system activation from a single stimulus.

Activation of CD4 T Cells

Upon activation, CD4 T cells undergo a series of divisions that produce active helper T cells (*TH cells*) and **memory TH cells** (Figure 22–18•). The memory TH cells remain in reserve, whereas the helper T cells secrete a variety of cytokines that coordinate specific and nonspecific defenses and stimulate cell-mediated and antibody-mediated immunities. Activated helper T cells secrete cytokines that do the following:

1. stimulate the T cell divisions that produce memory T cells and accelerate the maturation of cytotoxic T cells;

2. enhance nonspecific defenses by attracting macrophages to the affected area, preventing their departure, and stimulating their phagocytic activity and effectiveness;

3. attract and stimulate the activity of NK cells, providing another mechanism for the destruction of abnormal cells and pathogens; and

4. promote the activation of B cells, leading to B cell division, plasma cell maturation, and antibody production.

Figure 22–19• provides a review of the methods of antigen presentation and T cell stimulation. The cell membranes of infected or otherwise abnormal cells trigger an immune response when CD8 T cells recognize antigens bound to Class I MHC proteins. Extracellular pathogens or foreign proteins trigger an immune response when CD4 T cells recognize antigens displayed by Class II MHC proteins. In the next section, we will consider how the TH cells derived from activated CD4 T cells in turn activate B cells that are sensitive to the specific antigen involved.

Graft Rejection and Immunosuppression

Organ transplantation may be a treatment option for patients with severe disorders of the kidneys, liver, heart, lungs, or pancreas. Finding a suitable donor is the first major problem. In the United States, many people die each day while awaiting an organ transplant, and dozens are added to the transplant waiting list. After surgery has been performed, the major problem is **graft rejection**. In graft rejection, T cells are activated by contact with MHC proteins on cell membranes in the donated tissues. The cytotoxic T cells that develop then attack and destroy the foreign cells. AM: Transplants and Immunosuppressive Drugs

100 Keys | Cell-mediated immunity involves close physical contact between activated T_C cells and foreign, abnormal, or infected cells. T cell activation usually involves (1) antigen presentation by a phagocytic cell and (2) costimulation by cytokines released by active phagocytes. T_C cells may destroy target cells through the local release of cytokines, lymphotoxins, or perforin.

B Cells and Antibody-Mediated Immunity

Objectives

- Describe the mechanisms of B cell activation and the differentiation of plasma cells and memory B cells.
- Describe the structure of an antibody and discuss the types of antibodies in body fluids and secretions.
- Explain the functions of antibodies and how they perform those functions.
- Discuss the primary and secondary responses to antigen exposure.

B cells are responsible for launching a chemical attack on antigens by producing appropriate, specific *antibodies*.

B Cell Sensitization and Activation

As noted earlier, the body has millions of B cell populations. Each kind of B cell carries its own particular antibody molecules in its cell membrane. If corresponding antigens appear in the interstitial fluid, they will interact with these superficial antibodies. When binding occurs, the B cell prepares to undergo activation. This preparatory process is called **sensitization**. Because B cells migrate throughout the body, pausing briefly in one lymphoid tissue or another, sensitization typically occurs at the lymph node nearest the site of infection or injury.

As noted earlier, B cell membranes contain Class II MHC proteins. During sensitization, antigens are brought into the cell by endocytosis. The antigens subsequently appear on the surface of the B cell, bound to Class II MHC proteins. (The mechanism is comparable to that shown in Figure 22–16b•, p. 786). Once this happens, the sensitized B cell is on “standby” but generally will not undergo activation unless it receives the “OK” from a helper T cell (Figure 22–20•). The need for activation by a helper T cell helps prevent inappropriate activation, the same way that costimulation acts as a “safety” for cell-mediated immunity.

When a sensitized B cell encounters a helper T cell already activated by antigen presentation, the helper T cell binds to the MHC complex, recognizes the presence of an antigen, and begins secreting cytokines that promote B cell activation. After activation has occurred, these same cytokines stimulate B cell division, accelerate plasma cell formation, and enhance antibody production.

The activated B cell typically divides several times, producing daughter cells that differentiate into plasma cells and *memory B cells*. The plasma cells begin synthesizing and secreting large quantities of antibodies into the interstitial fluid. These antibodies have the same target as the antibodies on the surface of the sensitized B cell. When stimulated by cytokines from helper T cells, a plasma cell can secrete up to 100 million antibody molecules each hour.

Memory B cells perform the same role in antibody-mediated immunity that memory T cells perform in cell-mediated immunity. Memory B cells do not respond to a threat on first exposure. Instead, they remain in reserve to deal with subsequent injuries or infections that involve the same antigens. On subsequent exposure, the memory B cells respond by dividing and differentiating into plasma cells that secrete antibodies in massive quantities.

Antibody Structure

An antibody molecule consists of two parallel pairs of polypeptide chains: one pair of **heavy chains** and one pair of **light chains** (Figure 22–21•). Each chain contains both *constant segments* and *variable segments*.

The constant segments of the heavy chains form the base of the antibody molecule (Figure 22–21a,b•). B cells produce only five types of constant segments. These form the basis of a classification scheme that identifies antibodies as *IgG, IgE, IgD, IgM,* or *IgA,* as we will discuss in the next section. The structure of the constant segments of the heavy chains determines the way the antibody is secreted and how it is distributed within the body. For example, antibodies in one class circulate in body fluids, whereas those of another class bind to the membranes of basophils and mast cells.

The heavy-chain constant segments, which are bound to constant segments of the light chains, also contain binding sites that can activate the complement system. These binding sites are covered when the antibody is secreted but become exposed when the antibody binds to an antigen.

The specificity of an antibody molecule depends on the structure of the variable segments of the light and heavy chains. The free tips of the two variable segments form the **antigen binding sites** of the antibody molecule (see Figure 22–21a•). These sites can interact with an antigen in the same way that the active site of an enzyme interacts with a substrate molecule. l**p. 52**

Small differences in the amino acid sequence of the variable segments affect the precise shape of the antigen binding site. These differences account for differences in specificity among the antibodies produced by different B cells. The distinctions are the result of minor genetic variations that occur during the production, division, and differentiation of B cells. A normal adult body contains roughly 10 trillion B cells, which can produce an estimated 100 million types of antibodies, each with a different specificity.

The Antigen–Antibody Complex

When an antibody molecule binds to its corresponding antigen molecule, an **antigen–antibody complex** is formed. Once the two molecules are in position, hydrogen bonding and other weak chemical forces lock them together.

Antibodies bind not to the entire antigen, but to specific portions of its exposed surface—regions called **antigenic determinant sites** (Figure 22–21c•). The specificity of the binding depends initially on the three-dimensional “fit” between the variable segments of the antibody molecule and the corresponding antigenic determinant sites. A **complete antigen** is an antigen with at least two antigenic determinant sites, one for each of the antigen binding sites on an antibody molecule. Exposure to a complete antigen can lead to B cell sensitization and a subsequent immune response. Most environmental antigens have multiple antigenic determinant sites; entire microorganisms may have thousands.

Haptens, or *partial antigens,* do not ordinarily cause B cell activation and antibody production. Haptens include short peptide chains, steroids and other lipids, and several drugs, including antibiotics such as *penicillin*. However, haptens may become attached to carrier molecules, forming combinations that can function as complete antigens (Figure 22–21d•). In some cases, the carrier contributes an antigenic determinant site. The antibodies produced will attack both the hapten and the carrier molecule. If the carrier molecule is normally present in the tissues, the antibodies may begin attacking and destroying normal cells. This process is the basis for several drug reactions, including allergies to penicillin.

Classes and Actions of Antibodies

Body fluids have five classes of antibodies, or **immunoglobulins (Igs)**: *IgG*, *IgE*, *IgD*, *IgM*, and *IgA* (Table 22–1). The classes are determined by variations in the structure of the heavy-chain constant segments and so have no effect on the antibody's specificity, which is determined by the antigen binding sites. The formation of an antigen–antibody complex may cause the elimination of the antigen in seven ways:

1. *Neutralization.* Both viruses and bacterial toxins have specific sites that must bind to target regions on body cells before they can enter or injure those cells. Antibodies may bind to those sites, making the virus or toxin incapable of attaching itself to a cell. This mechanism is known as **neutralization**.

2. *Precipitation and Agglutination.* Each antibody molecule has two antigen binding sites, and most antigens have many antigenic determinant sites. If separate antigens (such as macromolecules or bacterial cells) are far apart, an antibody molecule will necessarily bind to two antigenic sites on the same antigen. However, if antigens are close together, an antibody can bind to antigenic determinant sites on two different antigens. In this way, antibodies can form extensive "bridges" that tie large numbers of antigens together. The three-dimensional structure created by such binding is known as an **immune complex**. When the antigen is a soluble molecule, such as a toxin, this process may create complexes that are too large to remain in solution. The formation of insoluble immune complexes is called **precipitation**. When the target antigen is on the surface of a cell or virus, the formation of large complexes is called **agglutination**. The clumping of erythrocytes that occurs when incompatible blood types are mixed is an agglutination reaction. l**p. 652**

3. *Activation of Complement.* On binding to an antigen, portions of the antibody molecule change shape, exposing areas that bind complement proteins. The bound complement molecules then activate the complement system, destroying the antigen (as discussed previously).

4. *Attraction of Phagocytes.* Antigens covered with antibodies attract eosinophils, neutrophils, and macrophages—cells that phagocytize pathogens and destroy foreign or abnormal cell membranes.

5. *Opsonization.* A coating of antibodies and complement proteins increases the effectiveness of phagocytosis. This effect is called *opsonization* (p. 781). Some bacteria have slick cell membranes or capsules, and phagocytes must be able to hang onto their prey before they can engulf it. Phagocytes can bind more easily to antibodies and complement proteins on the surface of a pathogen than they can to the bare surface.

6. *Stimulation of Inflammation.* Antibodies may promote inflammation through the stimulation of basophils and mast cells.

7. *Prevention of Bacterial and Viral Adhesion.* Antibodies dissolved in saliva, mucus, and perspiration coat epithelia, providing an additional layer of defense. A covering of antibodies makes it difficult for pathogens to attach to and penetrate body surfaces.

100 Keys | Antibody-mediated immunity involves the production of specific antibodies by plasma cells derived from activated B cells. B cell activation usually involves (1) antigen recognition, through binding to surface antibodies, and (2) costimulation by a T_H cell. The antibodies produced by active plasma cells bind to the target antigen and either inhibit its ac tivity, destroy it, remove it from solution, or promote its phagocytosis by other defense cells.

Concept Check

How can the presence of an abnormal peptide in the cytoplasm of a cell initiate an immune response?

A decrease in the number of cytotoxic T cells would affect which type of immunity?

How would a lack of helper T cells affect the antibody-mediated immune response?

A sample of lymph contains an elevated number of plasma cells. Would you expect the number of antibodies in the blood to be increasing or decreasing? Why?

Answers begin on p. A–1

Primary and Secondary Responses to Antigen Exposure

The initial response to exposure to an antigen is called the **primary response**. When the antigen appears again, it triggers a more extensive and prolonged **secondary response**. This response reflects the presence of large numbers of memory cells that are primed for the arrival of the antigen. Primary and secondary responses are characteristic of both cell-mediated and antibody-mediated immunities. The differences between the responses are most easily demonstrated by following the production of antibodies over time.

The Primary Response

Because the antigen must activate the appropriate B cells, which must then differentiate into plasma cells, the primary response takes time to develop (Figure 22–22a•). As plasma cells differentiate and begin secreting, the concentration of circulating antibodies undergoes a gradual, sustained rise.

During the primary response, the **antibody titer**, or level of antibody activity, in the plasma does not peak until one to two weeks after the initial exposure. If the individual is no longer exposed to the antigen, the antibody concentration declines thereafter. This reduction in antibody production occurs because (1) plasma cells have very high metabolic rates and survive for only a short time, and (2) further production of plasma cells is inhibited by suppression factors released by suppressor T cells. However, suppressor T cell activity does not begin immediately after antigen exposure, and under normal conditions helper cells outnumber suppressors by more than 3 to 1. As a result, many B cells are activated before suppressor T cell activity has a noticeable effect.

Activated B cells start dividing immediately. At each cycle of division, some of the daughter cells differentiate into plasma cells, while others continue to divide. Molecules of *immunoglobulin M*, or *IgM*, are the first to appear in the bloodstream. The plasma cells responsible for IgM production differentiate after only a few cycles of B cell division. Levels of *immunoglobulin G*, or *IgG*, rise more slowly, because the plasma cells responsible differentiate only after repeated cell divisions that also generate large numbers of memory B cells. In general, IgM is less effective as a defense mechanism than IgG. However, IgM provides an immediate defense that can fight the infection until massive quantities of IgG can be produced.

The Secondary Response

Unless they are exposed to the same antigen a second time, memory B cells do not differentiate into plasma cells. If and when that exposure occurs, the memory B cells respond immediately—faster than the B cells stimulated during the initial exposure. This response is immediate in part because memory B cells are activated at relatively low antigen concentrations, and in part because they synthesize more effective and destructive antibodies. Activated memory B cells divide and differentiate into plasma cells that secrete these antibodies in massive quantities. This secretion is the secondary response to antigen exposure.

During the secondary response, antibody titers increase more rapidly and reach levels many times higher than they did in the primary response (Figure 22–22b•). The secondary response appears even if the second exposure occurs years after the first, because memory cells may survive for 20 years or more.

Because the primary response develops slowly and antibodies are not produced in massive quantities, it may not prevent an infection the first time a pathogen appears in the body. However, a person who survives that first infection will probably be resistant to that pathogen in the future, because the secondary response will be so rapid and overwhelming that the pathogens won’t be able to survive in body tissues. The effectiveness of the secondary response is one of the basic principles behind the use of immunization to prevent disease. AM: Immunization

100 Keys | Immunization produces a primary response to a specific antigen under controlled conditions. If the same anti
gen is encountered at a later date, it triggers a powerful secondary response that is usually sufficient to prevent infection
and disease.

Summary of the Immune Response

We have now examined the basic cellular and chemical interactions that follow the appearance of a foreign antigen in the body. Figure 22–23• presents an integrated view of the immune response and its relationship to nonspecific defenses.

Figure 22–24• provides an overview of the course of events responsible for overcoming a bacterial infection. In the early stages of infection, before antigen processing has occurred, neutrophils and NK cells migrate into the threatened area and destroy bacteria. Over time, cytokines draw increasing numbers of phagocytes into the region. Cytotoxic T cells appear as arriving T cells are activated by antigen presentation. Last of all, the population of plasma cells rises as activated B cells differentiate. This rise is followed by a gradual, sustained increase in the level of circulating antibodies.

The basic sequence of events is similar when a viral infection occurs. The initial steps are different, however, because cytotoxic T cells and NK cells can be activated by contact with virus-infected cells. Figure 22–25• contrasts the events involved in defending against bacterial infection with those involved in defending against viral infection. Table 22–2 reviews the cells that participate in tissue defenses.

100 Keys | Viruses replicate inside cells, whereas bacteria may live independently. Antibodies (and administered antibi

otics) work outside cells, so they are primarily effective against bacteria rather than viruses. (That's why antibiotics can't
fight the common cold or flu.) T cells, NK cells, and interferons are the primary defenses against viral infection.

Normal and Abnormal Resistance

Objectives

- Describe the origin, development, activation, and regulation of normal resistance to disease.
- Explain the origin of autoimmune disorders, immunodeficiency diseases, and allergies and list important examples of each type of disorder.
- Discuss the effects of stress on the immune function.

The ability to produce an immune response after exposure to an antigen is called **immunological competence**. Cell-mediated immunity can be demonstrated as early as the third month of fetal development, and active antibody-mediated immunity roughly one month later.

The Development of Immunological Competence

The first cells that leave the fetal thymus migrate to the skin and into the epithelia lining the mouth, the digestive tract, and the uterus and vagina in females. These cells take up residence in these tissues as antigen-presenting cells, such as the Langerhans cells of the skin, whose primary function will be the activation of T cells. T cells that leave the thymus later in development populate lymphoid organs throughout the body.

The cell membranes of the first B cells produced in the liver and bone marrow carry IgM antibodies. Sometime after the fourth month in utero the fetus may, if exposed to specific pathogens, produce IgM antibodies. Fetal antibody production is uncommon, however, because the developing fetus has naturally acquired passive immunity due to the transfer of

IgG antibodies from the maternal bloodstream. These are the only antibodies that can cross the placenta, and they include the antibodies responsible for the

clinical problems that accompany fetal–maternal Rh incompatibility, discussed in Chapter 19. l**p. 653** Because the anti-A and anti-B antibodies are IgM antibodies, which cannot cross the placenta, problems with maternal–fetal incompatibilities involving the ABO blood groups rarely occur.

The natural immunity provided by maternal IgG may not be enough to protect the fetus if the maternal defenses are overwhelmed by a bacterial or viral infection. For example, the microorganisms responsible for syphilis and rubella ("German measles") can cross from the maternal to the fetal bloodstream, producing a congenital infection that leads to the production of fetal antibodies. IgM provides only a partial defense, and these infections can result in severe developmental problems for the fetus. AM: Fetal Infections

Delivery eliminates the maternal supply of IgG. Although the mother provides IgA antibodies in breast milk, the infant gradually loses its passive immunity. The amount of maternal IgG in the infant's bloodstream declines rapidly over the first two months after birth. During this period, the infant becomes vulnerable to infection by bacteria or viruses that were previously overcome by maternal antibodies. The infant also begins producing its own IgG, as its immune system begins to respond to infections, environmental antigens, and vaccinations. It has been estimated that, from birth to age 12, children encounter a "new" antigen every six weeks. (This fact explains why most parents, exposed to the same antigens when they were children, remain healthy while their children develop runny noses and colds.) Over this period, the concentration of circulating antibodies gradually rises toward normal adult levels, and the populations of memory B cells and T cells continue to increase.

Skin tests can sometimes determine whether an individual has been exposed to a particular antigen. In this procedure, small quantities of antigen are injected into the skin, generally on the anterior surface of the forearm. If resistance has developed, the region will become inflamed over the next two to four days. Many states require a tuberculosis test, called a *tuberculin skin test,* before children enter public school, and when adults apply for a food-service or health-service job. If the test is positive, further tests must then be performed to determine whether an infection is currently under way. Skin tests are also used to check for allergies to environmental antigens. AM: Delayed Hypersensitivity and Skin Tests

Immune Disorders

Because the immune response is so complex, many opportunities exist for things to go wrong. A variety of clinical conditions result from disorders of the immune function. **Autoimmune disorders** develop when the immune response inappropriately targets normal body cells and tissues. In an **immunodeficiency disease**, either the immune system fails to develop normally or the immune response is blocked in some way. Autoimmune disorders and immunodeficiency diseases are relatively rare—clear evidence of the effectiveness of the immune system's control mechanisms. A far more common (and generally far less dangerous) class of immune disorders is the **allergies**. We next consider examples of each type of immune disorder. AM: Immune Complex Disorders; Systemic Lupus Erythematosus

Autoimmune Disorders

Autoimmune disorders affect an estimated 5 percent of adults in North America and Europe. Previous chapters cited many examples of the effects of autoimmune disorders on the function of major systems. AM: Autoimmune Disorders

The immune system usually recognizes but ignores antigens normally found in the body—self-antigens. When the recognition system malfunctions, however, activated B cells make antibodies against other body cells and tissues. These "misguided" antibodies are called **autoantibodies**. The trigger may be a reduction in suppressor T cell activity, the excessive stimulation of helper T cells, tissue damage that releases large quantities of antigenic fragments, haptens bound to compounds normally ignored, viral or bacterial toxins, or a combination of factors.

The condition produced depends on the specific antigen attacked by autoantibodies. For example,

- The inflammation of *thyroiditis* results from the release of autoantibodies against thyroglobulin;
- *Rheumatoid arthritis* occurs when autoantibodies form immune complexes within connective tissues around the joints; and
- *Insulin-dependent diabetes mellitus (IDDM)* is generally caused by autoantibodies that attack cells in the pancreatic islets.

Many autoimmune disorders appear to be cases of mistaken identity. For example, proteins associated with the measles, Epstein–Barr, influenza, and other viruses contain amino acid sequences that are similar to those of myelin proteins. As a result, antibodies that target these viruses may also attack myelin sheaths. This mechanism accounts for the neurological complications that sometimes follow a vaccination or a viral infection. It is also the mechanism that is likely responsible for *multiple sclerosis*.

For unknown reasons, the risk of autoimmune problems increases if an individual has an unusual type of MHC protein. At least 50 clinical conditions have been linked to specific variations in MHC structure.

Immunodeficiency Diseases

Immunodeficiency diseases result from (1) problems with the embryological development of lymphoid organs and tissues; (2) an infection with a virus, such as HIV, that depresses immune function; or (3) treatment with, or exposure to, immunosuppressive agents, such as radiation or drugs.

Individuals born with **severe combined immunodeficiency disease (SCID)** fail to develop either cell- or antibody-mediated immunity. Their lymphocyte populations are low, and normal B and T cells are absent. Such infants cannot produce an immune response, so even a mild infection can prove fatal. Total isolation offers protection but at great cost—extreme restrictions on lifestyle. Bone marrow transplants from compatible donors, normally a close relative, have been used to colonize lymphoid tissues with functional lymphocytes. Gene-splicing techniques have led to therapies that can treat at least one form of SCID. AM: Genetic Engineering and Gene Therapy

AIDS, an immunodeficiency disease that we consider on page 803, is the result of a viral infection that targets primarily helper T cells. As the number of T cells declines, the normal immune control mechanism breaks down. When a subsequent infection occurs, suppressor factors released by suppressor T cells inhibit an immune response before the few surviving helper T cells can stimulate the formation of cytotoxic T cells or plasma cells in adequate numbers.

Immunosuppressive drugs have been used for many years to prevent graft rejection after transplant surgery. But immunosuppressive agents can destroy stem cells and lymphocytes, leading to a complete immunological failure. This outcome is one of the potentially fatal consequences of radiation exposure.

Allergies

Allergies are inappropriate or excessive immune responses to antigens. The sudden increase in cellular activity or antibody titers can have several unpleasant side effects. For example, neutrophils or cytotoxic T cells may destroy normal cells while attacking the antigen, or the antigen–antibody complex may trigger a massive inflammatory response. Antigens that trigger allergic reactions are often called **allergens**.

There are several types of allergies. A complete classification recognizes four categories: *immediate hypersensitivity (Type I), cytotoxic reactions (Type II), immune complex disorders (Type III)*, and *delayed hypersensitivity (Type IV)*. Here we will consider only immediate (Type I) hypersensitivity, probably the most common type of allergy. One form, *allergic rhinitis*, includes hay fever and environmental allergies that may affect 15 percent of the U.S. population. In Chapter 19 we discussed one example of a cytotoxic (Type II) reaction: the cross-reaction that follows the transfusion of an incompatible blood type. l**p. 652** Other types of allergies are discussed in the *Applications Manual*. AM: Immune Complex Disorders; Delayed Hypersensitivity and Skin Tests

Immediate Hypersensitivity **Immediate hypersensitivity** is a rapid and especially severe response to the presence of an antigen. Sensitization to an allergen during the initial exposure leads to the production of large quantities of IgE. The tendency to produce IgE antibodies in response to specific allergens may be genetically determined.

Due to the lag time needed to activate B cells, produce plasma cells, and synthesize antibodies, the first exposure to an allergen does not produce symptoms, but merely sets the stage for the next encounter. After sensitization, the IgE molecules become attached to the cell membranes of basophils and mast cells throughout the body. When the individual is subsequently exposed to the same allergen, the bound antibodies stimulate these cells to release histamine, heparin, several cytokines, prostaglandins, and other chemicals into the surrounding tissues. A sudden, massive inflammation of the affected tissues results.

The cytokines and other mast cell secretions draw basophils, eosinophils, T cells, and macrophages into the area. These cells release their own chemicals, extending and intensifying the responses initiated by mast cells. The severity of the allergic reaction depends on the individual’s sensitivity and on the location involved. If allergen exposure occurs at the body surface, the response may be restricted to that area. If the allergen enters the bloodstream, the response could be lethal.

In **anaphylaxis** (an-a-fi-LAK-sis; *ana*-, again + *phylaxis*, protection), a circulating allergen affects mast cells throughout the body (Figure 22–26•). (In drug reactions, such as allergies to penicillin, IgE antibodies are produced in response to a hapten <partial antigen> bound to a larger molecule that is widely distributed within the body; the combination acts as an allergen.) A wide range of signs and symptoms can develop within minutes. Changes in capillary permeabilities produce swelling and edema in the dermis, and raised welts, or *hives*, appear on the surface of the skin. Smooth muscles along the respiratory passageways contract; the narrowed passages make breathing extremely difficult. In severe cases, an extensive peripheral vasodilation occurs, producing a fall in blood pressure that can lead to a circulatory collapse. This response is **anaphylactic shock**.

Many of the signs and symptoms of immediate hypersensitivity can be prevented by the prompt administration of **antihista**

mines (an-t

¯e

-HIS-ta-m

¯e

nz)—drugs that block the action of histamine. *Benadryl* (*diphenhydramine hydrochloride*) is a popular an
tihistamine that is available over the counter. The treatment of severe anaphylaxis involves antihistamine, corticosteroid, and epinephrine injections.

Stress and the Immune Response

One of the normal effects of interleukin-1 secretion is the stimulation of adrenocorticotropic hormone (ACTH) production by the anterior lobe of the pituitary gland. The production of ACTH in turn leads to the secretion of glucocorticoids by the adrenal cortex. l**p. 615** The anti-inflammatory effects of the glucocorticoids may help control the extent of the immune response. However, the long-term secretion of glucocorticoids, as in the resistance phase of the *general adaptation syndrome*, can inhibit the immune response and lower resistance to disease. l**p. 626** The effects of glucocorticoids that alter the effectiveness of specific and nonspecific defenses include the following:

- **Depression of the Inflammatory Response.** Glucocorticoids inhibit mast cells and reduce the permeability of capillaries. Inflammation is therefore less likely. When it does occur, the reduced permeability of the capillaries slows the entry of fibrinogen, complement proteins, and cellular defenders into tissues.
- **Reduction in the Abundance and Activity of Phagocytes in Peripheral Tissues.** This reduction further impairs nonspecific defense mechanisms and interferes with the processing and presentation of antigens to lymphocytes.
- **Inhibition of Interleukin Secretion**. A reduction in interleukin production depresses the response of lymphocytes, even to antigens bound to MHC proteins.

The mechanisms responsible for these changes are still under investigation. It is clear, however, that depression of the immune system due to chronic stress can be a serious threat to health.

Aging and the Immune Response

Objective

- Describe the effects of aging on the lymphatic system and the immune response.

With advancing age, the immune system becomes less effective at combating disease. T cells become less responsive to antigens, so fewer cytotoxic T cells respond to an infection. This effect may, at least in part, be associated with the gradual involution of the thymus and a reduction in circulating levels of thymic hormones. Because the number of helper T cells is also reduced, B cells are less responsive, so antibody levels do not rise as quickly after antigen exposure. The net result is an increased susceptibility to viral and bacterial infections. For this reason, vaccinations for acute viral diseases, such as the flu (influenza), and pneumococcal pneumonia are strongly recommended for elderly individuals. The increased incidence of cancer in the elderly reflects the fact that immune surveillance declines, so tumor cells are not eliminated as effectively.

Concept Check

Would the primary response or the secondary response be more affected by a lack of memory B cells for a particular antigen?

Which kind of immunity protects a developing fetus, and how is that immunity produced?

How does increased stress decrease the effectiveness of the immune response?

Answers begin on p. A–1

Integration with Other Systems

Figure 22–27• summarizes the interactions between the lymphatic system and other physiological systems. The following relationships among elements of the immune response and the nervous and endocrine systems are now the focus of intense research.

- The thymus secretes oxytocin, ADH, and endorphins as well as thymic hormones. The effects on the CNS are not known, but removal of the thymus lowers brain endorphin levels.
- Both thymic hormones and cytokines help establish the normal levels of CRH and TRH produced by the hypothalamus.
- Other thymic hormones affect the anterior lobe of the pituitary gland directly, stimulating the secretion of prolactin and GH. Conversely, the nervous system can apparently adjust the sensitivity of the immune response:
- The CNS innervates dendritic cells in the lymph nodes and spleen, Langerhans cells in the skin, and other antigen-presenting cells. The nerve endings release neurotransmitters that heighten local immune responses. For this reason, some skin conditions, such as *psoriasis*, worsen when a person is under stress.
- Neuroglia in the CNS produce cytokines that promote an immune response.
- A sudden decline in immune function can occur after even a brief period of emotional distress.

Clinical Patterns

Disorders of the lymphatic system that affect the immune response can be sorted into three general categories:

1. *Disorders Resulting from an Insufficient Immune Response.* This category includes immunodeficiency disorders, such as AIDS
(p. 803) and SCID (p. 800). Individuals with depressed immune defenses can develop life-threatening diseases caused by microorganisms that are harmless to other individuals.

2. *Disorders Resulting from an Inappropriate Immune Response.* Autoimmune disorders result when normal tissues are attacked by T cells or antibodies produced by activated B cells (p. 800). For instance, in *thrombocytopenic purpura*, the body forms antibodies against its own platelets.

3. *Disorders Resulting from an Excessive Immune Response.* Conditions such as allergies (p. 800) can result from an immune response that is out of proportion with the size of the stimulus.

The *Applications Manual* discusses representative disorders from each of these categories.

Chapter Review

Selected Clinical Terminology

acquired immune deficiency syndrome (AIDS): A disorder that develops following HIV infection and is characterized by reduced circulating antibody levels and depressed cell-mediated immunity. (p. 803 and [AM])

allergen: An antigen capable of triggering an allergic reaction. (p. 800)

allergy: An inappropriate or excessive immune response to antigens, triggered by the stimulation of mast cells bound to IgE. (p. 800 and [AM])

anaphylactic shock: A drop in blood pressure that may lead to circulatory collapse, resulting from a severe case of anaphylaxis. (p. 801)

anaphylaxis: A type of allergy in which a circulating allergen affects mast cells throughout the body, producing numerous signs and symptoms very quickly. (p. 801)

appendicitis: An infection and inflammation of the aggregated lymphoid nodules in the appendix. [AM]

autoimmune disorder: A disorder that develops when the immune response inappropriately targets normal body cells and tissues.

(p. 800) **bacteria:** Prokaryotic cells (cells lacking nuclei and other membranous organelles) that may be extracellular or intracellular pathogens.

[AM]

filariasis: An infection by parasitic roundworms; the adult worms may scar and block lymphatic vessels, causing acute lymphedema, commonly in the external genitalia and lower limbs (**elephantiasis**). [AM]

fungi (singular, *fungus*): Eukaryotic organisms that absorb organic materials from the remains of dead cells; some fungi are pathogenic. [AM]

human immunodeficiency virus (HIV): The virus responsible for AIDS and related immunodeficiency disorders. (p. 803 and [AM])

immune complex disorder: A disorder caused by the precipitation of immune complexes at sites such as the kidneys, where their presence disrupts normal tissue function. (p. 792 and [AM])

immunodeficiency disease: A disease in which either the immune system fails to develop normally or the immune response is blocked.

(p. 800) **immunosuppression:** A reduction in the sensitivity of the immune system. (p. 788) **immunosuppressive drugs:** Drugs administered to inhibit the immune response; examples include prednisone, cyclophosphamide, aza

thioprine, cyclosporin, and FK506. (p. 800 and [AM])

lymphadenopathy: A chronic or excessive enlargement of lymph nodes. (p. 772)

lymphedema: An accumulation of lymph in a region whose lymphatic drainage has been blocked. (p. 767)

lymphomas: Cancers consisting of abnormal lymphocytes or lymphoid stem cells; examples include *Hodgkin's disease* and *non-Hodgkin's lymphoma*. (p. 772 and [AM])

severe combined immunodeficiency disease (SCID): A congenital disorder resulting from the failure of both cell-mediated and antibody-mediated immunity to develop. (p. 800 and [AM])

tonsillitis: An infection of one or more tonsils; signs and symptoms include a sore throat, high fever, and leukocytosis (an abnormally

high white blood cell count). (p. 770 and [AM]) **vaccine:** A preparation of antigens derived from a specific pathogen; administered during *immunization*, or *vaccination*. (p. 783) **viruses:** Noncellular pathogens that replicate by directing the synthesis of virus-specific proteins and nucleic acids inside tissue cells.

[AM]

Study Outline

An Overview of the Lymphatic System and Immunity p. 764

1. The cells, tissues, and organs of the **lymphatic system** play a central role in the body's defenses against a variety of **pathogens**, or disease-causing organisms.

2. *Lymphocytes*, the primary cells of the lymphatic system, are central to an **immune response** against specific threats to the body. **Immunity** is the ability to resist infection and disease through the activation of specific defenses.

Organization of the Lymphatic System p. 764

1. The lymphatic system includes a network of **lymphatic vessels**, or **lymphatics**, that carries **lymph** (a fluid similar to plasma, but with a lower concentration of proteins). An array of **lymphoid tissues** and **lymphoid organs** is connected to the lymphatic vessels. *(Figure 22–1)*

Functions of the Lymphatic System p. 764

2. The lymphatic system produces, maintains, and distributes lymphocytes (which attack invading organisms, abnormal cells, and foreign proteins); it also helps maintain blood volume and eliminate local variations in the composition of interstitial fluid.

Lymphatic Vessels p. 765

3. Lymph flows along a network of lymphatic vessels, the smallest of which are the **lymphatic capillaries** (*terminal lymphatics*). The lymphatic vessels empty into the **thoracic duct** and the **right lymphatic duct**. *(Figures 22–2 to 22–4)*

Lymphocytes p. 768

4. The three classes of lymphocytes are **T** (**t**hymus-dependent) **cells**, **B** (**b**one marrow–derived) **cells**, and **NK** (**n**atural **k**iller) **cells**.

5. **Cytotoxic T cells** attack foreign cells or body cells infected by viruses and provide **cell-mediated (cellular) immunity**. *Regulatory T cells* (**helper T cells** and **suppressor T cells**) regulate and coordinate the immune response.

6. B cells can differentiate into **plasma cells**, which produce and secrete *antibodies* that react with specific chemical targets called **antigens**. Antibodies in body fluids are called *immunoglobulins*. B cells are responsible for **antibody-mediated (humoral) immunity**.

7. NK cells (also called **large granular lymphocytes**) attack foreign cells, normal cells infected with viruses, and cancer cells. NK cells provide *immunological surveillance*.

8. Lymphocytes continuously migrate into and out of the blood through the lymphoid tissues and organs. **Lymphopoiesis** (lymphocyte production) involves the bone marrow, thymus, and peripheral lymphoid tissues. *(Figure 22–5)*

Lymphoid Tissues p. 769

9. **Lymphoid tissues** are connective tissues dominated by lymphocytes. In a **lymphoid nodule**, the lymphocytes are densely packed in an area of loose connective tissue. The lymphoid tissue embedded within the organs of the digestive system is called **mucosa-as-sociated lymphoid tissue (MALT)**. *(Figure 22–6)*

Anatomy 360 | Lymphatic System/Tonsils

Lymphoid Organs p. 770

10. Important lymphoid organs include the **lymph nodes**, the **thymus**, and the **spleen**. Lymphoid tissues and organs are distributed in areas that are especially vulnerable to injury or invasion.

11. Lymph nodes are encapsulated masses of lymphoid tissue. The **deep cortex** is dominated by T cells; the **outer cortex** and **medulla** contain B cells. *(Figure 22–7)*

12. The thymus lies behind the sternum, in the anterior mediastinum. **Reticular epithelial cells** scattered among the lymphocytes maintain the blood–thymus barrier and secrete thymic hormones. *(Figure 22–8)*

Anatomy 360 | Lymphatic System/Thymus

13. The adult spleen contains the largest mass of lymphoid tissue in the body. The cellular components form the **pulp** of the spleen. **Red pulp** contains large numbers of red blood cells, and **white pulp** resembles lymphoid nodules. *(Figure 22–9)*

Anatomy 360 | Lymphatic System/Spleen

The Lymphatic System and Body Defenses p. 775

14. The lymphatic system is a major component of the body's defenses, which are classified as either (1) **nonspecific defenses**, which protect without distinguishing one threat from another, or (2) **specific defenses**, which protect against particular threats only.

Nonspecific Defenses p. 775

1. Nonspecific defenses prevent the approach, deny the entry, or limit the spread of living or nonliving hazards. *(Figure 22–10)*

Physical Barriers p. 775

2. Physical barriers include skin, mucous membranes, hair, epithelia, and various secretions of the integumentary and digestive systems.

Phagocytes p. 777

3. The two types of phagocytic cells are **microphages** and **macrophages** (cells of the **monocyte–macrophage system**). Microphages are neutrophils and eosinophils in circulating blood.

4. **Phagocytes** move among cells by *emigration*, or *diapedesis* (migration between adjacent endothelial cells), and exhibit **chemotaxis** (sensitivity and orientation to chemical stimuli).

Immunological Surveillance p. 778

5. **Immunological surveillance** involves constant monitoring of normal tissues by NK cells that are sensitive to abnormal antigens on the surfaces of otherwise normal cells. Cancer cells with **tumor-specific antigens** on their surfaces are killed. *(Figure 22–11)*

Interferons p. 779

6. **Interferons**—small proteins released by cells infected with viruses—trigger the production of **antiviral proteins**, which interfere with viral replication inside the cell. Interferons are **cytokines**—chemical messengers released by tissue cells to coordinate local activities.

Complement p. 779

7. At least 11 **complement proteins** make up the **complement system**. These proteins interact with each other in cascades to destroy target cell membranes, stimulate inflammation, attract phagocytes, or enhance phagocytosis. The complement system can be activated by either the **classical pathway** or the **alternative pathway**. *(Figure 22–12)*

Inflammation p. 781

8. **Inflammation** is a localized tissue response to injury. *(Figure 22–13)*

Fever p. 782

9. A **fever** (body temperature greater than 37.2°C [99°F]) can inhibit pathogens and accelerate metabolic processes. **Pyrogens** can reset the body's thermostat and raise the temperature.

Specific Defenses: An Overview of the Immune Response p. 782

1. T cells are responsible for **cell-mediated (cellular) immunity**. B cells provide **antibody-mediated (humoral) immunity**.

Forms of Immunity p. 782

2. Specific resistance or immunity involves **innate immunity** (genetically determined and present at birth) or **acquired immunity**. The two types of acquired immunity are **active immunity** (which appears after exposure to an antigen) and **passive immunity** (produced by the transfer of antibodies from another source). *(Figure 22–14)*

Properties of Immunity p. 783

3. Immunity exhibits four general properties: **specificity**, **versatility**, **memory**, and **tolerance**. *Memory cells* enable the immune system to "remember" previous target antigens. Tolerance is the ability of the immune system to ignore some antigens, such as those of normal body cells.

An Introduction to the Immune Response p. 784

4. The immune response is triggered by the presence of an antigen and includes cell-mediated and antibody-mediated defenses. *(Figure -22–15)*

T Cells and Cell-Mediated Immunity p. 784 Antigen Presentation p. 784

1. **Antigen presentation** occurs when an antigen–glycoprotein combination appears in a cell membrane (typically, that of a macrophage). T cells sensitive to this antigen are activated if they contact the membrane of the antigen-presenting cell.

2. All body cells have membrane glycoproteins. The genes controlling their synthesis make up a chromosomal region called the **major histocompatibility complex (MHC)**. The membrane glycoproteins are called **MHC proteins**. **APCs (antigen-presenting cells)** are involved in antigen stimulation.

Antigen Recognition p. 786

3. Lymphocytes are not activated by lone antigens, but will respond to an antigen bound to either a **Class I** or a **Class II** MHC protein in a process called **antigen recognition**. *(Figure 22–16)*

4. Class I MHC proteins are in all nucleated body cells. Class II MHC proteins are only in antigen-presenting cells (APCs) and lymphocytes.

5. Whether a T cell responds to antigens held in Class I or Class II MHC proteins depends on the structure of the T cell membrane. T cell membranes contain proteins called **CD** (**c***luster of* **d***ifferentiation*) **markers**. **CD3 markers** are present on all T cells. **CD8 markers** are on cytotoxic and suppressor T cells. **CD4 markers** are on all helper T cells.

Activation of CD8 T Cells p. 787

6. One type of CD8 cell responds quickly, giving rise to large numbers of cytotoxic T cells and memory cells. The other type of CD8 cell responds more slowly, giving rise to small numbers of suppressor T cells.

7. Cytotoxic T cells seek out and destroy abnormal and infected cells, using three different methods, including the secretion of **lymphotoxin**. *(Figure 22–17)*

8. Cell-mediated immunity (cellular immunity) results from the activation of CD8 T cells by antigens bound to Class I MHCs. When

activated, most of these T cells divide to generate cytotoxic T cells and **memory T_C cells**, which remain in reserve to guard against future such attacks. Suppressor T cells depress the responses of other T cells and of B cells. *(Figures 22–17, 22–19)*

Activation of CD4 T Cells p. 788

9. Helper, or CD4, T cells respond to antigens presented by Class II MHC proteins. When activated, helper T cells secrete lymphokines that aid in coordinating specific and nonspecific defenses, and regulate cell-mediated and antibody-mediated immunity. *(Figures 22–18, 22–19)*

100 Keys | p. 789

B Cells and Antibody-Mediated Immunity p. 789 B Cell Sensitization and Activation p. 789

1. B cells become **sensitized** when antibody molecules in their membranes bind antigens. The antigens are then displayed on the Class II MHC proteins of the B cells, which become activated by helper T cells activated by the same antigen. *(Figure 22–20)*

2. An active B cell may differentiate into a plasma cell or produce daughter cells that differentiate into plasma cells and **memory B cells**. Antibodies are produced by plasma cells. *(Figure 22–20)*

Antibody Structure p. 790

3. An antibody molecule consists of two parallel pairs of polypeptide chains containing *constant* and *variable segments*. *(Figure 22–21)*

4. When antibody molecules bind to an antigen, they form an **antigen–antibody complex**. Effects that appear after binding include **neutralization** (antibody binding such that viruses or bacterial toxins cannot bind to body cells); **precipitation** (formation of an insoluble **immune complex**) and **agglutination** (formation of large complexes); *opsonization* (coating of pathogens with antibodies and complement proteins to enhance phagocytosis); stimulation of inflammation; and prevention of bacterial or viral adhesion.

(Figure 22–21)

5. The five classes of antibodies **(immunoglobulins, Ig)** in body fluids are (1) **IgG**, responsible for resistance against many viruses, bacteria, and bacterial toxins; (2) **IgE**, which releases chemicals that accelerate local inflammation; (3) **IgD**, located on the surfaces of B cells; (4) **IgM**, the first type of antibody secreted after an antigen arrives; and (5) **IgA**, found in glandular secretions. *(Table 22–1)*

100 Keys | p. 792

Primary and Secondary Responses to Antigen Exposure p. 793

6. In humoral immunity, the antibodies first produced by plasma cells are the agents of the **primary response**. The maximum **antibody titer** appears during the **secondary response** to antigen exposure. *(Figure 22–22)*

100 Keys | p. 794

Summary of the Immune Response p. 795

7. The initial steps in the immune response to viral and bacterial infections differ. *(Figures 22–23 to 22–25; Summary Table 22–2)*

100 Keys | p. 795

FOCUS: Hormones of the Immune System p. 798

8. **Interleukins** increase T cell sensitivity to antigens exposed on macrophage membranes; stimulate B cell activity, plasma cell formation, and antibody production; enhance nonspecific defenses; and moderate the immune response. *(Summary Table 22–2)*

9. Interferons slow the spread of a virus by making the synthesizing cell and its neighbors resistant to viral infections. *(Summary Table 22–2)*

10. Tumor necrosis factors (TNFs) slow tumor growth and kill tumor cells. *(Summary Table 22–2)*

11. Several cytokines adjust the activities of phagocytic cells to coordinate specific and nonspecific defenses. *(Summary Table 22–2)*

12. Colony-stimulating factors (CSFs) are factors produced by active T cells, cells of the monocyte-macrophage group, endothelial cells, and fibroblasts. *(Summary Table 22–2)*

Normal and Abnormal Resistance p. 796 The Development of Immunological Competence p. 796

1. **Immunological competence** is the ability to produce an immune response after exposure to an antigen. A developing fetus receives passive immunity from the maternal bloodstream. After delivery, the infant begins developing active immunity following exposure to environmental antigens.

Immune Disorders p. 800

2. **Autoimmune disorders** develop when the immune response inappropriately targets normal body cells and tissues.

3. In an **immunodeficiency disease**, either the immune system does not develop normally or the immune response is blocked.

4. **Allergies** are inappropriate or excessive immune responses to **allergens** (antigens that trigger allergic reactions). The four types of allergies are *immediate hypersensitivity (Type I), cytotoxic reactions (Type II), immune complex disorders (Type III),* and *delayed hypersensitivity (Type IV).*

5. In **anaphylaxis**, a circulating allergen affects mast cells throughout the body. *(Figure 22–26)*

6. Interleukin-1 released by active macrophages triggers the release of ACTH by the anterior lobe of the pituitary gland. Glucocorti

Stress and the Immune Response p. 801

coids produced by the adrenal cortex moderate the immune response, but their long-term secretion can lower a person's resistance to disease.

Aging and the Immune Response p. 802

1. With aging, the immune system becomes less effective at combating disease.

Integration with Other Systems p. 802

1. The lymphatic system has extensive interactions with the neural and endocrine systems *(Figure 22–27)*.

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive
Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. Lymph from the right arm, the right half of the head, and the right chest is received by the

(a) cisterna chyli **(b)** right lymphatic duct

(c) right thoracic duct **(d)** aorta

2. Anatomically, lymph vessels resemble

(a) elastic arteries **(b)** muscular arteries

(c) arterioles **(d)** medium veins

(e) the venae cavae

3. The specificity of an antibody is determined by the

(a) fixed segment

(b) antigenic determinants

(c) variable region

(d) size of the antibody

(e) antibody class

4. The major histocompatibility complex (MHC)

(a) is responsible for forming lymphocytes

(b) produces antibodies in lymph glands

(c) is a group of genes that codes for human leukocyte antigens

(d) is a membrane protein that can recognize foreign antigens

(e) is the antigen found on bacteria that stimulates an immune response

5. Red blood cells that are damaged or defective are removed from the bloodstream by the

(a) thymus **(b)** lymph nodes

(c) spleen **(d)** tonsils

6. Phagocytes move through capillary walls by squeezing between adjacent endothelial cells, a process known as

(a) diapedesis

(b) chemotaxis

(c) adhesion

(d) perforation

7. Perforins are proteins associated with the activity of

(a) T cells **(b)** B cells

(c) NK cells **(d)** plasma cells

8. Complement activation

(a) stimulates inflammation

(b) attracts phagocytes

(c) enhances phagocytosis

(d) a, b, and c are correct

9. The most beneficial effect of fever is that it

(a) inhibits the spread of some bacteria and viruses

(b) increases the metabolic rate by up to 10 percent

(c) stimulates the release of pyrogens

(d) a and b are correct

10. CD4 markers are associated with

(a) cytotoxic T cells

(b) suppressor T cells

(c) helper T cells

(d) a, b, and c are correct

11. List the lymphoid tissues and organs of the body. What are the specific functions of each?

12. Give a function for each of the following:

(a) cytotoxic T cells

(b) helper T cells

(c) suppressor T cells

(d) plasma cells

(e) NK cells

(f) stromal cells

(g) reticular epithelial cells

(h) interferons

(i) pyrogens

(j) T cells

(k) B cells

(l) interleukins

(m) tumor necrosis factor

(n) colony-stimulating factors

13. What are the three classes of lymphocytes, and where does each class originate?

14. What seven defenses, present at birth, provide the body with the defensive capability known as nonspecific resistance?

LEVEL 2 Reviewing Concepts

15. Compared with nonspecific defenses, specific defenses

(a) do not distinguish between one threat and another

(b) are always present at birth

(c) protect against threats on an individual basis

(d) deny the entry of pathogens to the body

16. Blocking the antigen receptors on the surface of lymphocytes would interfere with

(a) phagocytosis of the antigen

(b) that lymphocyte's ability to produce antibodies

(c) antigen recognition

(d) the ability of the lymphocyte to present antigen

(e) opsonization of the antigen

17. A *decrease* in which population of lymphocytes would impair all aspects of an immune response?

18. Skin tests are used to determine if a person

(a) has an active infection

(b) has been exposed to a particular antigen

(c) carries a particular antigen

(d) has measles

(e) can produce antibodies

19. Compare and contrast the effects of complement with those of interferon.

20. How does a cytotoxic T cell destroy another cell displaying antigens bound to Class I MHC proteins?

21. How does the formation of an antigen–antibody complex cause the elimination of an antigen?

22. Give one example of each type of immunity: innate immunity, naturally acquired immunity, induced active immunity, induced passive immunity, and natural passive immunity.

23. An anesthesia technician is advised that she should be vaccinated against hepatitis B, which is caused by a virus. She is given one injection and is told to come back for a second injection in a month and a third injection after six months. Why is this series of injections necessary?

(a) cytoxic T cells **(b)** helper T cells
(c) suppressor T cells **(d)** B cells
(e) plasma cells

LEVEL 3 Critical Thinking and Clinical Applications

24. An investigator at a crime scene discovers some body fluid on the victim's clothing. The investigator carefully takes a sample and sends it to the crime lab for analysis. On the basis of the analysis of antibodies, could the crime lab determine whether the sample is blood plasma or semen? Explain.

25. Ted finds out that he has been exposed to the measles. He is concerned that he might have contracted the disease, so he goes to see his physician. The physician takes a blood sample and sends it to a lab for antibody titers. The results show an elevated level of IgM antibodies to rubella (measles) virus but very few IgG antibodies to the virus. Has Ted contracted the disease?

26. While walking along the street, you and your friend see an elderly woman whose left arm appears to be swollen to several times its normal size. Your friend remarks that the woman must have been in the tropics and contracted a form of filariasis that produces elephantiasis. You disagree, saying that it is more likely that the woman had a radical mastectomy (the removal of a breast because of cancer). Explain the rationale behind your answer.

27. Paula's grandfather is diagnosed as having lung cancer. His physician orders biopsies of several lymph nodes from neighboring regions of the body, and Paula wonders why, since his cancer is in the lungs. What would you tell her?

28. Willy is allergic to ragweed pollen and tells you that he read about a medication that can help his condition by blocking certain an

tibodies. Do you think that this treatment could help Willy? Explain. 1The spleens of dogs, cats, and other mammals of the order *Carnivora* have extensive layers of smooth muscle that can contract to eject blood into the bloodstream. The human spleen lacks those muscle layers and cannot contract.

TABLE 22–1 Classes of Antibodies

Structure Description

IgG is the largest and most diverse class of antibodies. There are several types of IgG, but each type occurs as an individual molecule. Together, they account for 80 percent of all antibodies. IgG antibodies are responsible for resistance against many viruses, bacteria, and bacterial toxins. These antibodies can cross the placenta, and maternal IgG provides passive immunity to the fetus during embryological development. However, the anti-Rh (anti-D) antibodies produced by Rh-negative mothers sensitized to Rh surface antigens are also IgG antibodies that can cross the placenta and attack fetal Rh-positive red blood cells, producing *hemolytic disease of the newborn*. lp. 653

IgE IgE attaches as an individual molecule to the exposed surfaces of basophils and mast cells. When a suitable antigen is bound by IgE molecules, the cell is stimulated to release histamine and other chemicals that accelerate inflammation in the immediate area. IgE is also important in the allergic response.

IgD IgD is an individual molecule on the surfaces of B cells, where it can bind antigens in the extracellular fluid. This binding can play a role in the activation of the B cell involved.

IgM IgM is the first class of antibody secreted after an antigen arrives. The concentration of IgM declines as IgG production accelerates. Although plasma cells secrete individual IgM molecules, IgM circulates as a five-antibody starburst. This configuration makes these antibodies particularly effective in forming immune complexes. The anti-A and anti-B antibodies responsible for the agglutination of incompatible blood types are IgM antibodies. lp. 652 IgM antibodies may also attack bacteria that are insensitive to IgG.

IgA IgA is found primarily in glandular secretions such as mucus, tears, and saliva. These antibodies attack pathogens before they gain access to internal tissues. IgA antibodies circulate in blood as individual molecules or in pairs. Epithelial cells absorb them from the blood and attach a *secretory piece*, which confers solubility, before secreting the IgA molecules onto the epithelial surface.

| SUMMARY TABLE 22–2 | CELLS THAT PARTICIPATE IN TISSUE DEFENSES

Cell Functions

Neutrophils Phagocytosis; stimulation of inflammation **Eosinophils** Phagocytosis of antigen–antibody complexes; suppression of inflammation; participation in allergic response **Mast cells and basophils** Stimulation and coordination of inflammation by release of histamine, heparin, leukotrienes, prostaglandins

ANTIGEN-PRESENTING CELLS Macrophages (free and fixed macrophages, Phagocytosis; antigen processing; antigen presentation with Class II **Kupffer cells, microglia, etc.)** MHC proteins; secretion of cytokines, especially interleukins and interferons **Dendritic cells, Langerhans cells** Antigen presentation bound to Class II MHC proteins

LYMPHOCYTES NK cells Destruction of cell membranes containing abnormal antigens **Cytotoxic T cells (T_C, CD8 marker)** Lysis of cell membranes containing antigens bound to Class I MHC proteins;

secretion of perforins, defensins, lymphotoxins, and other cytokines **Helper T cells (T_H, CD4 marker)** Secretion of cytokines that stimulate cell-mediated and antibody-mediated immunity; activation of sensitized B cells **B cells** Differentiation into plasma cells, which secrete antibodies and provide antibody

mediated immunity

Suppressor T cells (TS, CD8 marker) Secretion

Memory cells (TS, TH, B) Produced during the activation of T cells and B cells; remain in tissues awaiting

rearrival of antigens

Hormones of the Immune System

- Discuss important hormones of the immune response and explain their significance.

The specific and nonspecific defenses of the body are coordinated by both physical interaction and the release of chemical messengers. One example of physical interaction is antigen presentation by activated macrophages and helper T cells. An example of the release of chemical messengers is the secretion of cytokines by many cell types involved in the immune response. Cytokines are often classified according to their origins:

Lymphokines are produced by lymphocytes, *monokines* by active macrophages and other antigen-presenting cells. These terms are misleading, however, because lymphocytes and macrophages may secrete the same cytokines, and cytokines can also be secreted by cells involved in nonspecific defenses and tissue repair.

Table 22–3 summarizes the cytokines identified to date. Six subgroups merit special attention: (1) *interleukins,* (2) interferons, (3) *tumor necrosis factors,* (4) chemicals that regulate phagocytic activities, (5) *colony-stimulating factors,* and (6) miscellaneous cytokines.

Interleukins

Interleukins may be the most diverse and important chemical messengers in the immune system. Nearly 20 types of interleukins have been identified; several are listed in Table 22–3. Lymphocytes and macrophages are the primary sources of interleukins, but certain interleukins, such as interleukin-1 (IL-1), are also produced by endothelial cells, fibroblasts, and astrocytes. Interleukins have the following general functions:

1. Increasing T Cell Sensitivity to Antigens Exposed on Macrophage Membranes. Heightened sensitivity accelerates the production of cytotoxic and regulatory T cells.

2. Stimulating B Cell Activity, Plasma Cell Formation, and Antibody Production. These events promote the production of antibodies and the development of antibody-mediated immunity.

3. Enhancing Nonspecific Defenses. Known effects of interleukin production include (1) stimulation of inflammation, (2) formation of scar tissue by fibroblasts, (3) elevation of body temperature via the preoptic nucleus of the central nervous system, (4) stimulation of mast cell formation, and (5) promotion of adrenocorticotropic hormone (ACTH) secretion by the anterior lobe of the pituitary gland.

4. Moderating the Immune Response. Some interleukins help suppress immune function and shorten the duration of an immune response.

Two interleukins, IL-1 and IL-2, are important in stimulation and maintenance of the immune response. When released by activated macrophages and lymphocytes, these cytokines not only stimulate the activities of other immune cells but also further stimulate the secreting cell. The result is a positive feedback loop that promotes the recruitment of additional immune cells. Although mechanisms exist to control the degree of stimulation, the regulatory process sometimes breaks down, and massive production of interleukins can cause problems at least as severe as those of the primary infection. For example, in *Lyme disease* the release of IL-1 by activated macrophages in response to a localized bacterial infection produces fever, pain, skin rash, and arthritis throughout the entire body. AM: Lyme Disease

Some interleukins enhance the immune response, whereas others suppress it. The relative quantities secreted at any moment therefore have significant effects on the nature and intensity of the response to an antigen. In the course of a typical infection, the pattern of interleukin secretion is constantly changing. Whether the individual succeeds in overcoming the infection is determined in part by whether stimulatory or suppressive interleukins predominate. As a result, interleukins and their interactions are now the focus of an intensive research effort.

Interferons

Interferons make the cell that synthesizes them, and that cell’s neighbors, resistant to viral infection, thereby slowing the spread of the virus. These compounds may have other beneficial effects in addition to their antiviral activity. For example, alpha-interferons and gamma-interferons attract and stimulate NK cells, and beta-interferons slow the progress of inflammation associated with viral infection. Gamma-interferons also stimulate macrophages, making them more effective at killing bacterial or fungal pathogens.

Because they stimulate NK cell activity, interferons can be used to fight some cancers. For example, alpha-interferons have been used in the treatment of malignant melanoma, bladder cancer, ovarian cancer, and two forms of leukemia. Alpha- or gamma-interferons may be used to treat Kaposi’s sarcoma, a cancer that typically develops in individuals with AIDS. AM: AIDS

Tumor Necrosis Factors

Tumor necrosis factors (TNFs) slow the growth of a tumor and kill sensitive tumor cells. Activated macrophages secrete one type of TNF and carry the molecules in their cell membranes. Cytotoxic T cells produce a different type of TNF. In addition to their effects on tumor cells, tumor necrosis factors stimulate granular leukocyte production, promote eosinophil activity, cause fever, and increase T cell sensitivity to interleukins.

Chemicals Regulating Phagocytic Activities

Several cytokines coordinate immune defenses by adjusting the activities of phagocytic cells. These cytokines include factors that attract free macrophages and microphages and prevent their premature departure from the site of an injury.

Colony-Stimulating Factors

Colony-stimulating factors (CSFs) were introduced in Chapter 19. l**p. 657** These factors are produced by active T cells, cells of the monocyte–macrophage group, endothelial cells, and fibroblasts. CSFs stimulate the production of blood cells in bone marrow and lymphocytes in lymphoid tissues and organs. AM: Technology, Immunity, and Disease

Miscellaneous Cytokines

This general category includes many chemicals that have been discussed in earlier chapters. Examples include leukotrienes, lymphotoxins, perforin, hemopoiesis-stimulating factor, and suppression factors.

Clinical Note

AIDS

Acquired immune deficiency syndrome (AIDS), or *late-stage HIV disease*, is caused by the **human immunodeficiency virus (HIV)**. This virus is a *retrovirus*: It carries its genetic information in RNA rather than in DNA. The virus enters human leukocytes by receptor-mediated endocytosis. l**p. 92** Specifically, the virus binds to CD4, the membrane protein characteristic of helper T cells. Several types of antigen-presenting cells, including those of the monocyte– macrophage line, also are infected by HIV, but it is the infection of helper T cells that leads to clinical problems.

Once the virus is inside a cell, the viral enzyme *reverse transcriptase* synthesizes a complementary strand of DNA, which is then incorporated into the cell's genetic material. When these inserted viral genes are activated, the infected cell begins synthesizing viral proteins. In effect, the introduced viral genes take over the cell's synthetic machinery and force the cell to produce additional viruses. These new viruses are then shed at the cell surface. AM: The Nature of Pathogens

Cells infected with HIV are ultimately destroyed by (1) formation of pores in the cell membrane as the viruses are shed, (2) cessation of cell maintenance due to the continuing synthesis of viral components, (3) autolysis, or (4) stimulation of apoptosis.

The gradual destruction of helper T cells impairs the immune response, because these cells play a central role in coordinating cell-mediated and antibody-mediated responses to antigens. To make matters worse, suppressor T cells are relatively unaffected by the virus, and over time the excess of suppressing factors “turns off” the normal immune response. Circulating antibody levels decline, cell-mediated immunity is reduced, and the body is left with impaired defenses against a wide variety of microbial invaders. With the affected person’s immune function reduced, ordinarily harmless microorganisms can initiate lethal *opportunistic infections*. Because immune surveillance is also depressed, the risk of cancer increases.

Infection with HIV occurs through intimate contact with the body fluids of infected individuals. Although all body fluids may contain the virus, the major routes of transmission involve contact with blood, semen, or vaginal secretions. Worldwide, most individuals with AIDS become infected through sexual contact with an HIV-infected person (who may *not* necessarily be exhibiting the clinical signs of AIDS). The next largest group of infected individuals consists of intravenous drug users who shared contaminated needles. Relatively few individuals have become infected with the virus after receiving a transfusion of contaminated blood or blood products. Finally, an increasing number of infants are born with AIDS, having acquired it from infected mothers.

AIDS is a public health problem of massive proportions. Nearly half a million people have already died of AIDS in the United States alone. The estimated number of individuals infected with HIV in the United States as of 2003 was 877,000. In 2003, an estimated 13,000 of these people died, and more than 43,000 new cases of AIDS were diagnosed. The numbers worldwide are even more frightening. The World Health Organization (WHO) estimates that, as of 2003, 40 million individuals were infected. Every 6 seconds another person becomes infected with the HIV virus, resulting in 5 million new cases in 2003.

Every 11 seconds someone dies of AIDS, and the total death toll for 2003 was estimated to be 3 million people, including 500,000 children under age 15.

The best defense against AIDS is abstinence and the avoidance of needle sharing. All forms of sexual intercourse carry the risk of viral transmission. The use of synthetic condoms greatly reduces (but does not eliminate) the chance of infection. Condoms that are not made of synthetic materials prevent pregnancy but do not block the passage of viruses.

Clinical signs and symptoms of AIDS may not appear until 5–10 years or more after infection. When they do appear, they are commonly mild, consisting of lymphadenopathy and chronic, but nonfatal, infections. So far as is known, however, AIDS is almost always fatal, and most people who carry the virus will eventually die from complications of the disease. (A handful of infected individuals have been able to tolerate the virus without apparent illness for many years; for details, see the *Applications Manual*.)

Despite intensive efforts, a vaccine has yet to be developed that prevents HIV infection in an uninfected person exposed to the virus. While efforts to prevent the spread of HIV continue, the survival rate for AIDS patients has been steadily increasing, because new drugs and drug combinations that slow the progression of the disease are available, and because improved antibiotic therapies help combat secondary infections. This combination is extending the life expectancy of patients while the search for more effective treatment continues. For more information on the distribution of HIV infection, current and future drug therapies, and additional details on HIV disease, consult the *Applications Manual*. AM: AIDS

Environmental Exchange

Chapter 23, The Respiratory System, describes how air enters and leaves the lungs as a result of the actions of respiratory muscles, and how oxygen and carbon dioxide are exchanged across delicate epithelial surfaces within the lungs.

Chapter 24, The Digestive System, discusses the structure and function of the elongate digestive tract and several digestive glands (notably the liver and pancreas), how the process of digestion breaks down large and complex organic molecules to smaller fragments that can be absorbed by the digestive epithelium, and how a few organic wastes are removed from the body.

Chapter 25, Metabolism and Energetics, examines how the body obtains energy released by the breakdown of organic molecules, stores it as ATP, and uses it to support intracellular operations such as the construction of new organic molecules.

Chapter 26, The Urinary System, relates how the kidneys remove metabolic waste products from the circulation to produce urine, which is transported to the urinary bladder and released from the body through urinary tract passageways.

Chapter 27, Fluid, Electrolyte, and Acid–Base Balance, discusses the homeostatic mechanisms that regulate ion concentrations, volume, and pH in the fluid surrounding cells.

The End of Chapter questions within this unit include critical thinking questions about both normal and abnormal functions. For comprehensive exercises covering material in the unit as a whole, see the Clinical Problems at the end of the corresponding unit in the *Applications Manual* [AM].

The Respiratory System: An Introduction

Objectives

- Describe the primary functions of the respiratory system.
- Explain how the delicate respiratory exchange surfaces are protected from pathogens, debris, and other hazards.

When we think of the respiratory system, we generally think of the mechanics of breathing—pulling air into and out of our bodies. However, the requirements for an efficient respiratory system go beyond merely moving air. Cells need energy for maintenance, growth, defense, and division. Our cells obtain that energy primarily through aerobic mechanisms that require oxygen and produce carbon dioxide.

Many aquatic organisms can obtain oxygen and excrete carbon dioxide through diffusion across the surface of the skin or in specialized structures, such as the gills of a fish. But such arrangements are poorly suited for life on land, because the exchange surfaces must be very thin and relatively delicate to permit rapid diffusion. In air, the exposed membranes collapse, evaporation and dehydration reduce blood volume, and the delicate surfaces become vulnerable to attack by pathogens. The respiratory exchange surfaces of humans are just as delicate as those of an aquatic organism, but they are confined to the inside of the *lungs*—a warm, moist, protected environment. Under these conditions, diffusion can occur between the air and the blood. The cardiovascular system provides the link between the interstitial fluids and the exchange surfaces of your lungs. Circulating blood carries oxygen from the lungs to peripheral tissues; it also accepts and transports the carbon dioxide generated by those tissues, delivering it to the lungs.

Functions of the Respiratory System

The **respiratory system** has five basic functions:

1. Providing an extensive surface area for gas exchange between air and circulating blood.

2. Moving air to and from the exchange surfaces of the lungs along the respiratory passageways.

3. Protecting respiratory surfaces from dehydration, temperature changes, or other environmental variations, and defending the respiratory system and other tissues from invasion by pathogens.

4. Producing sounds involved in speaking, singing, and other forms of communication.

5. Facilitating the detection of olfactory stimuli by olfactory receptors in the superior portions of the nasal cavity.

In addition, the capillaries of the lungs indirectly assist in the regulation of blood volume and blood pressure, through the conversion of angiotensin I to angiotensin II. l**p. 621**

Organization of the Respiratory System

We can divide the components of the respiratory system into the upper respiratory system and the lower respiratory system (Figure 23–1•). The **upper respiratory system** consists of the nose, nasal cavity, paranasal sinuses, and pharynx. These passageways filter, warm, and humidify incoming air—protecting the more delicate surfaces of the lower respiratory system—and cool and dehumidify outgoing air. The **lower respiratory system** includes the larynx (voice box), trachea (windpipe), bronchi, bronchioles, and alveoli of the lungs.

Your **respiratory tract** consists of the airways that carry air to and from the exchange surfaces of your lungs. The respiratory tract consists of a *conducting portion* and a *respiratory portion*. The conducting portion begins at the entrance to the nasal cavity and extends through many passageways (the pharynx and larynx, and along the trachea, bronchi, and bronchioles to the *terminal*

¯E

bronchioles). The respiratory portion of the tract includes the delicate *respiratory bronchioles* and the **alveoli** (al-V

–

-l), air-filled

ı pockets within the lungs where all gas exchange between air and blood occurs.

Gas exchange can occur quickly and efficiently because the distance between the blood in an alveolar capillary and the air inside an alveolus is generally less than 1 mm, and in some cases as small as 0.1 mm. To meet the metabolic requirements of peripheral tissues, the surface area devoted to gas exchange in the lungs must be very large; it is roughly 35 times the surface area of the body. Estimates of the surface area involved in gas exchange range from 70 m^2 to 140 m^2 (753 ft^2 to 1506 ft^2).

Filtering, warming, and humidification of the inhaled air begin at the entrance to the upper respiratory system and continue throughout the rest of the conducting system. By the time air reaches the alveoli, most foreign particles and pathogens have been removed, and the humidity and temperature are within acceptable limits. The success of this “conditioning process” is due primarily to the properties of the respiratory mucosa.

The Respiratory Mucosa

¯o

-

The **respiratory mucosa** (m

¯u

-K

¯O

-suh) lines the conducting portion of the respiratory system. A *mucosa* is a *mucous membrane*, one of the four types of membranes introduced in Chapter 4. It consists of an epithelium and an underlying layer of areolar tis

¯

sue. l**p. 129** The **lamina propria** (LAM-i-nuh PRO

-pr

¯e

-uh) is the underlying layer of areolar tissue that supports the respiratory epithelium. In the upper respiratory system, trachea, and bronchi, the lamina propria contains mucous glands that discharge their secretions onto the epithelial surface. The lamina propria in the conducting portions of the lower respiratory system contains bundles of smooth muscle cells. At the bronchioles, the smooth muscles form relatively thick bands that encircle or spiral around the lumen.

The structure of the respiratory epithelium changes along the respiratory tract. A pseudostratified ciliated columnar epithelium with numerous goblet cells lines the nasal cavity and the superior portion of the pharynx. l**p. 114** The epithelium lining inferior portions of the pharynx is a stratified squamous epithelium similar to that of the oral cavity. These portions of the pharynx, which conduct air to the larynx, also convey food to the esophagus. The pharyngeal epithelium must therefore protect against abrasion and chemical attack.

A pseudostratified ciliated columnar epithelium comparable to that of the nasal cavity lines the superior portion of the lower respiratory system. In the smaller bronchioles, this pseudostratified epithelium is replaced by a cuboidal epithelium with scattered cilia. The exchange surfaces of the alveoli are lined by a very delicate simple squamous epithelium. Other, more specialized cells are scattered among the squamous cells; together they form the *alveolar epithelium*.

The Respiratory Defense System

The delicate exchange surfaces of the respiratory system can be severely damaged if inhaled air becomes contaminated with debris or pathogens. Such contamination is prevented by a series of filtration mechanisms that constitute the **respiratory defense system**.

Along much of the length of the respiratory tract, goblet cells in the epithelium and mucous glands in the lamina propria produce a sticky mucus that bathes exposed surfaces. In the nasal cavity, cilia sweep that mucus and any trapped debris or microorganisms toward the pharynx, where it will be swallowed and exposed to the acids and enzymes of the stomach. In the lower respiratory system, the cilia also beat toward the pharynx, moving a carpet of mucus in that direction and cleaning the respiratory surfaces. This process is often described as a *mucus escalator* (Figure 23–2c•).

Filtration in the nasal cavity removes from the inhaled air virtually all particles larger than about 10 mm. Smaller particles may be trapped by the mucus of the nasopharynx or by secretions of the pharynx before proceeding along the conducting system. Exposure to unpleasant stimuli, such as noxious vapors, large quantities of dust and debris, allergens, or pathogens, generally causes a rapid increase in the rate of mucus production in the nasal cavity and paranasal sinuses. (The familiar symptoms of the "common cold" result from the invasion of the respiratory epithelium by any of more than 200 types of viruses.)

Most particles

1

–

5 mm

in diameter are trapped in the mucus coating the respiratory bronchioles or in the liquid covering the

alveolar surfaces. These areas are outside the boundaries of the mucus escalator, but the foreign particles can be engulfed by alveolar macrophages. Most particles smaller than about 0.5 mm remain suspended in the air.

The Upper Respiratory System

Objective

- Identify the organs of the upper respiratory system and describe their functions.

As previously noted, the upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx (Figures 23–1 and 23–3•).

The Nose and Nasal Cavity

The nose is the primary passageway for air entering the respiratory system. Air normally enters through the paired **external nares**

(N

¯A

-r

¯e

z), or *nostrils* (Figure 23–3a•), which open into the *nasal cavity*. The **nasal vestibule** is the space contained within the

flexible tissues of the nose (Figure 23–3c•). The epithelium of the vestibule contains coarse hairs that extend across the external nares. Large airborne particles, such as sand, sawdust, or even insects, are trapped in these hairs and are thereby prevented from entering the nasal cavity.

The **nasal septum** divides the nasal cavity into left and right portions (Figure 23–3b•). The bony portion of the nasal septum is formed by the fusion of the perpendicular plate of the ethmoid bone and the plate of the vomer (see Figure 7–3d•, p. 210). The anterior portion of the nasal septum is formed of hyaline cartilage. This cartilaginous plate supports the *dorsum nasi* (DOR-sum

NA¯

ı

The maxillary, nasal, frontal, ethmoid, and sphenoid bones form the lateral and superior walls of the nasal cavity. The mucous secretions produced in the associated *paranasal sinuses* (see Figure 7–14•, p. 222), aided by the tears draining through the nasolacrimal ducts, help keep the surfaces of the nasal cavity moist and clean. The *olfactory region*, or superior portion of the nasal cavity, includes the areas lined by olfactory epithelium: (1) the inferior surface of the cribriform plate, (2) the superior portion of the

nasal septum, and (3) the superior nasal conchae. Receptors in the olfactory epithelium provide your sense of smell. l**p. 550**

The *superior*, *middle*, and *inferior nasal conchae* project toward the nasal septum from the lateral walls of the nasal cavity. l**pp. 216, 218** To pass from the vestibule to the internal nares, air tends to flow between adjacent conchae, through the **super**

–

-z

), or bridge, and *apex* (tip) of the nose.

ior, **middle**, and **inferior meatuses** (m

¯e

-

¯A

-tus-ez; *meatus*, a passage) (see Figure 23–3b•). These are narrow grooves rather than open passageways; the incoming air bounces off the conchal surfaces and churns like a stream flowing over rocks. This turbulence serves several purposes: As the air swirls, small airborne particles are likely to come into contact with the mucus that coats the lining of the nasal cavity. In addition, the turbulence provides extra time for warming and humidifying incoming air, and it creates eddy currents that bring olfactory stimuli to the olfactory receptors.

A bony **hard palate**, made up of portions of the maxillary and palatine bones, forms the floor of the nasal cavity and separates it from the oral cavity. A fleshy **soft palate** extends posterior to the hard palate, marking the boundary between the superior

nasopharynx (n

¯a

-z

¯o

-FAR-inks) and the rest of the pharynx. The nasal cavity opens into the nasopharynx through a connection known as the **internal nares**.

The Nasal Mucosa

The mucosa of the nasal cavity prepares inhaled air for arrival at the lower respiratory system. Throughout much of the nasal cavity, the lamina propria contains an abundance of arteries, veins, and capillaries that bring nutrients and water to the secretory cells. The lamina propria of the nasal conchae also contains an extensive network of large and highly expandable veins. This vascularization provides a mechanism for warming and humidifying the incoming air (as well as for cooling and dehumidifying the outgoing air). As cool, dry air passes inward over the exposed surfaces of the nasal cavity, the warm epithelium radiates heat, and water in the mucus evaporates. Air moving from your nasal cavity to your lungs is thus heated almost to body temperature, and it is nearly saturated with water vapor. This mechanism protects more delicate respiratory surfaces from chilling or drying out— two potentially disastrous events. Breathing through your mouth eliminates much of the preliminary filtration, heating, and humidifying of the inhaled air. To avoid alveolar damage, patients breathing on a respirator (mechanical ventilator), which utilizes a tube to conduct air directly into the trachea, must receive air that has been externally filtered and humidified.

As air moves out of the respiratory tract, it again passes over the epithelium of the nasal cavity. This air is warmer and more humid than the air that enters; it warms the nasal mucosa, and moisture condenses on the epithelial surfaces. Thus, breathing through your nose also helps prevent heat loss and water loss.

The extensive vascularization of the nasal cavity and the relatively vulnerable position of the nose make a nosebleed, or *epistaxis* (ep-i-STAK-sis), a fairly common event. This bleeding generally involves vessels of the mucosa covering the cartilaginous portion of the septum. A variety of factors may be responsible, including trauma (such as a punch in the nose), drying, infections, allergies, or clotting disorders. Hypertension can also provoke epistaxis by rupturing small vessels of the lamina propria.

The Pharynx

The **pharynx** (FAR-inks) is a chamber shared by the digestive and respiratory systems. It extends between the internal nares and the entrances to the larynx and esophagus. The curving superior and posterior walls of the pharynx are closely bound to the axial skeleton, but the lateral walls are flexible and muscular.

The pharynx is divided into the nasopharynx, the oropharynx, and the laryngopharynx (see Figure 23–3c•):

1. The **nasopharynx** is the superior portion of the pharynx. It is connected to the posterior portion of the nasal cavity through the internal nares and is separated from the oral cavity by the soft palate. The nasopharynx is lined by the same pseudostratified ciliated columnar epithelium as that in the nasal cavity. The *pharyngeal tonsil* is located on the posterior wall of the nasopharynx; the left and right *auditory tubes* open into the nasopharynx on either side of this tonsil. l**pp. 573, 770**

2. The **oropharynx** (*oris*, mouth) extends between the soft palate and the base of the tongue at the level of the hyoid bone. The posterior portion of the oral cavity communicates directly with the oropharynx, as does the posterior inferior portion of the nasopharynx. At the boundary between the nasopharynx and the oropharynx, the epithelium changes from pseudostratified columnar to stratified squamous.

3. The narrow **laryngopharynx** (la-rin-gō-FAR-inks), the inferior part of the pharynx, includes that portion of the pharynx between the hyoid bone and the entrance to the larynx and esophagus. Like the oropharynx, the laryngopharynx is lined with a stratified squamous epithelium that resists abrasion, chemical attack, and invasion by pathogens.

Anatomy 360 | Review the anatomy of the pharynx on the **Anatomy 360 CD-ROM: Respiratory System/Pharynx.**

The Larynx

Objective

- Describe the structure of the larynx and discuss its role in normal breathing and in the production of sound.

Inhaled air leaves the pharynx and enters the larynx through a narrow opening called the **glottis** (GLOT-is). The **larynx** (LARinks) is a cartilaginous structure that surrounds and protects the glottis. The larynx begins at the level of vertebra C4 or C5 and ends at the level of vertebra C6. Essentially a cylinder, the larynx has incomplete cartilaginous walls that are stabilized by ligaments and skeletal muscles (Figure 23–4•).

Cartilages and Ligaments of the Larynx

Three large, unpaired cartilages form the larynx: (1) the thyroid cartilage, (2) the cricoid cartilage, and (3) the epiglottis (see Figure 23–4•). The **thyroid cartilage** (*thyroid*, shield shaped) is the largest laryngeal cartilage. Consisting of hyaline cartilage, it forms most of the anterior and lateral walls of the larynx. In section, this cartilage is U-shaped; posteriorly, it is incomplete. The prominent anterior surface of the thyroid cartilage, which you can easily see and feel, is called the *laryngeal prominence* or *Adam's apple*. The inferior surface articulates with the cricoid cartilage. The superior surface has ligamentous attachments to the hyoid bone and to the epiglottis and smaller laryngeal cartilages.

¯I

The thyroid cartilage sits superior to the **cricoid** (KR -koyd; ring shaped) **cartilage**, another hyaline cartilage. The posterior portion of the cricoid is greatly expanded, providing support in the absence of the thyroid cartilage. The cricoid and thyroid cartilages protect the glottis and the entrance to the trachea, and their broad surfaces provide sites for the attachment of important laryngeal muscles and ligaments. Ligaments attach the inferior surface of the cricoid cartilage to the first tracheal cartilage. The superior surface of the cricoid cartilage articulates with the small, paired *arytenoid cartilages*.

The shoehorn-shaped **epiglottis** (ep-i-GLOT-is) projects superior to the glottis and forms a lid over it. Composed of elastic cartilage, the epiglottis has ligamentous attachments to the anterior and superior borders of the thyroid cartilage and the hyoid bone. During swallowing, the larynx is elevated and the epiglottis folds back over the glottis, preventing the entry of both liquids and solid food into the respiratory tract.

The larynx also contains three pairs of smaller hyaline cartilages: (1) The **arytenoid** (ar-i-T
¯E

-noyd; ladle shaped) **cartilages**
articulate with the superior border of the enlarged portion of the cricoid cartilage. (2) The **corniculate** (kor-NIK-
¯u
-l
¯a
t; horn
shaped) **cartilages** articulate with the arytenoid cartilages. The corniculate and arytenoid cartilages function in the opening and
closing of the glottis and the production of sound. (3) Elongate, curving **cuneiform** (k
¯u
-N

¯E

-i-form; wedge shaped) **cartilages**
lie within folds of tissue (the *aryepiglottic folds*) that extend between the lateral surface of each arytenoid cartilage and the epiglottis (see Figures 23–4c and 23–5•).

The various laryngeal cartilages are bound together by ligaments; additional ligaments attach the thyroid cartilage to the hyoid bone and the cricoid cartilage to the trachea (see

Figure 23–4a,b•). The **vestibular ligaments** and the **vocal ligaments** extend between the thyroid cartilage and the arytenoid cartilages.

The vestibular and vocal ligaments are covered by folds of laryngeal epithelium that project into the glottis. The vestibular ligaments lie within the superior pair of folds, known as the **vestibular folds** (see Figure 23–5•). These folds, which are relatively inelastic, help prevent foreign objects from entering the glottis and protect the more delicate **vocal folds**.

The vocal folds, inferior to the vestibular folds, guard the entrance to the glottis. The vocal folds are highly elastic, because the vocal ligaments consist of elastic tissue. The vocal folds are involved with the production of sound, and for this reason they are known as the **vocal cords**.

Sound Production

Air passing through the glottis vibrates the vocal folds and produces sound waves. The pitch of the sound produced depends on the diameter, length, and tension in the vocal folds. The diameter and length are directly related to the size of the larynx. The tension is controlled by the contraction of voluntary muscles that reposition the arytenoid cartilages relative to the thyroid cartilage. When the distance increases, the vocal folds tense and the pitch rises; when the distance decreases, the vocal folds relax and the pitch falls.

Children have slender, short vocal folds; their voices tend to be high-pitched. At puberty, the larynx of males enlarges much more than does that of females. The vocal cords of an adult male are thicker and longer, and produce lower tones, than those of an adult female.

¯o

-N

¯A

-shun; *phone*, voice). Phonation is one component of speech pro-

Sound production at the larynx is called *phonation* (f duction. However, clear speech also requires *articulation*, the modification of those sounds by other structures. In a stringed instrument, such as a guitar, the quality of the sound produced does not depend solely on the nature of the vibrating string. Rather, the entire instrument becomes involved as the walls vibrate and the composite sound echoes within the hollow body. Similar amplification and resonance occur within your pharynx, oral cavity, nasal cavity, and paranasal sinuses. The combination determines the particular and distinctive sound of your voice.

When the nasal cavity and paranasal sinuses are filled with mucus rather than air, as in sinus infections, the sound changes. The final production of distinct words depends further on voluntary movements of the tongue, lips, and cheeks. An infection or inflammation of the larynx is known as *laryngitis* (lar-in-J -tis). It commonly affects the vibrational qualities of the vocal folds;

Ī¯hoarseness is the most familiar manifestation. Mild cases are temporary and seldom serious. However, bacterial or viral infections of the epiglottis can be very dangerous; the resulting swelling may close the glottis and cause suffocation. This condition, *acute epiglottitis* (ep-i-glot-T -tis), can develop rapidly after a bacterial infection of the throat. Young children are most likely to be af-

Ī¯fected.

The Laryngeal Musculature

The larynx is associated with (1) muscles of the neck and pharynx, which position and stabilize the larynx (l**pp. 341–343**), and (2) smaller intrinsic muscles that control tension in the vocal folds or open and close the glottis. These latter muscles insert on the thyroid, arytenoid, and corniculate cartilages. The opening or closing of the glottis involves rotational movements of the arytenoid cartilages that move the vocal folds.

When you swallow, both sets of muscles cooperate to prevent food or drink from entering the glottis. Before food is swallowed, it is crushed and chewed into a pasty mass known as a *bolus*. Muscles of the neck and pharynx then elevate the larynx, bending the epiglottis over the glottis, so that the bolus can glide across the epiglottis rather than falling into the larynx. While this movement is under way, the glottis is closed.

Food or liquids that touch the vestibular or vocal folds trigger the *coughing reflex*. In a cough, the glottis is kept closed while the chest and abdominal muscles contract, compressing the lungs. When the glottis is opened suddenly, the resulting blast of air from the trachea ejects material that blocks the entrance to the glottis.

Concept Check

☐ Why is the vascularization of the nasal cavity important?

☐ Why is the lining of the nasopharynx different from that of the oropharynx and the laryngopharynx?

☐ When the tension in your vocal folds increases, what happens to the pitch of your voice?

Answers begin on p. A–1

The Trachea and Primary Bronchi

Objective

- Discuss the structure of the airways outside the lungs.

The Trachea

The epithelium of the larynx is continuous with that of the **trachea** (TR
¯A

-k
¯e
-uh), or windpipe, a tough, flexible tube with a diC6

ameter of about 2.5 cm (1 in.) and a length of about 11 cm (4.33 in.) (Figure 23–6•). The trachea begins anterior to vertebra
in a ligamentous attachment to the cricoid cartilage. It ends in the mediastinum, at the level of vertebra T5, where it branches to form the *right* and *left primary bronchi*.

The mucosa of the trachea resembles that of the nasal cavity and nasopharynx (see Figure 23–2a•, p. 816). The **submucosa**
(sub-m
¯u
-K

¯O

-suh), a thick layer of connective tissue, surrounds the mucosa. The submucosa contains mucous glands that com
municate with the epithelial surface through a number of secretory ducts. The trachea contains 15–20 **tracheal cartilages** (Figure 23–6a•), which serve to stiffen the tracheal walls and protect the airway. They also prevent its collapse or overexpansion as pressures change in the respiratory system.

Each tracheal cartilage is C-shaped. The closed portion of the C protects the anterior and lateral surfaces of the trachea. The open portion of the C faces posteriorly, toward the esophagus (Figure 23–6b•). Because these cartilages are not continuous, the posterior tracheal wall can easily distort when you swallow, permitting large masses of food to pass through the esophagus.

An elastic ligament and the **trachealis muscle**, a band of smooth muscle, connect the ends of each tracheal cartilage (Figure 23–6b•). Contraction of the trachealis muscle reduces the diameter of the trachea, increasing the vessel’s resistance to airflow. The normal diameter of the trachea changes from moment to moment, primarily under the control of the sympathetic division of the ANS. Sympathetic stimulation increases the diameter of the

trachea and makes it easier to move large volumes of air along the respiratory passageways.
AM: Tracheal Blockage

Anatomy 360 | Review the anatomy of the conducting system on the **Anatomy 360 CD-ROM: Respiratory System/ Trachea**.

The Primary Bronchi

The trachea branches within the mediastinum, giving rise to the **right** and **left primary bronchi** (BRONG-k ; singular, *bronchus*).
–

ı An internal ridge called the **carina** (ka-R -nuh) separates the two bronchi (see Figure 23–6a•). Like the trachea, the primary
Ī bronchi have cartilaginous C-shaped supporting rings. The right primary bronchus supplies the right lung, and the left supplies the left lung. The right primary bronchus is larger in diameter than the left, and descends toward the lung at a steeper angle. Thus, most foreign objects that enter the trachea find their way into the right bronchus rather than the left.

Before branching further, each primary bronchus travels to a groove along the medial surface of its lung. This groove, the **hilus** of the lung, also provides access for entry to pulmonary vessels, nerves, and lymphatics (Figure 23–7•). The entire array is firmly anchored in a meshwork of dense connective tissue. This complex, the **root** of the lung (see Figure 23–6a•), attaches to the mediastinum and fixes the positions of the major nerves, vessels, and lymphatic vessels. The roots of the lungs are anterior to vertebrae T5 (right) and T6 (left).

The Lungs

Objective

• Describe the superficial anatomy of the lungs, the structure of a pulmonary lobule, and the functional anatomy of the alveoli.

The left and right lungs (see Figure 23–7•) are in the left and right pleural cavities, respectively. Each lung is a blunt cone, the tip (or apex) of which points superiorly. The apex on each side extends superior to the first rib. The broad concave inferior portion (or base) of each lung rests on the superior surface of the diaphragm.

Lobes and Surfaces of the Lungs

The lungs have distinct **lobes** that are separated by deep fissures (see Figure 23–7•). The right lung has three lobes—*superior*, *middle*, and *inferior*—separated by the *horizontal* and *oblique fissures*. The left lung has only two lobes—*superior* and *inferior*— separated by the *oblique fissure*. The right lung is broader than the left, because most of the heart and great vessels project into the left thoracic cavity. However, the left lung is longer than the right lung, because the diaphragm rises on the right side to accommodate the mass of the liver.

The curving anterior and lateral surfaces of each lung follow the inner contours of the rib cage. The medial surface, which contains the hilus, has a more irregular shape. The medial surfaces of both lungs bear grooves that mark the positions of the great vessels and the heart (see Figures 23–7 and 23–8•). The heart is located to the left of the midline, so the corresponding impression is larger in the left lung than in the right. In anterior view, the medial edge of the right lung forms a vertical line, whereas the medial margin of the left lung is indented at the **cardiac notch** (see Figure 23–7•).

The Bronchi

The primary bronchi and their branches form the **bronchial tree**. Because the left and right primary bronchi are outside the lungs, they are called *extrapulmonary bronchi*. As the primary bronchi enter the lungs, they divide to form smaller passageways (see Figure 23–6a•). The branches within the lungs are collectively called the *intrapulmonary bronchi*.

Each primary bronchus divides to form **secondary bronchi**, also known as *lobar bronchi*. In each lung, one secondary bronchus goes to each lobe, so the right lung has three secondary bronchi, and the left lung has two.

Figure 23–9• depicts the branching pattern of the left primary bronchus as it enters the lung. (The number of branches has been reduced for clarity.) In each lung, the secondary bronchi branch to form **tertiary bronchi**, or *segmental bronchi*. The branching pattern differs between the two lungs, but each tertiary bronchus ultimately supplies air to a single **bronchopulmonary segment**, a specific region of one lung (see Figure 23–9a•). The right lung has 10 bronchopulmonary segments. During development, the left lung also has 10 segments, but subsequent fusion of adjacent tertiary bronchi generally reduces that number to eight or nine.

The walls of the primary, secondary, and tertiary bronchi contain progressively less cartilage. In the secondary and tertiary bronchi, the cartilages form plates arranged around the lumen. These cartilages serve the same purpose as the rings of cartilage in the trachea and primary bronchi. As the amount of cartilage decreases, the relative amount of smooth muscle increases. With less cartilaginous support, the amount of tension in those smooth muscles has a greater effect on bronchial diameter and the resistance to airflow. During a respiratory infection, the bronchi and bronchioles can become inflamed and constricted, increasing resistance. In this condition, called **bronchitis**, the individual has difficulty breathing. AM: Bronchoscopy

Anatomy 360 | Review the anatomy of the bronchial tree on the **Anatomy 360 CD-ROM: Respiratory System/ Bronchial Tree**.

The Bronchioles

Each tertiary bronchus branches several times within the bronchopulmonary segment, giving rise to multiple **bronchioles**. These passageways further branch into the finest conducting branches, called **terminal bronchioles**. Roughly 6500 terminal bronchioles arise from each tertiary bronchus. The lumen of each terminal bronchiole has a diameter of 0.3–0.5 mm.

The walls of bronchioles, which lack cartilaginous supports, are dominated by smooth muscle tissue (see Figure 23–9b•). In functional terms, bronchioles are to the respiratory system what arterioles are to the cardiovascular system. Varying the diameter of the bronchioles controls the resistance to airflow and the distribution of air in the lungs.

The autonomic nervous system regulates the activity in this smooth muscle layer and thereby controls the diameter of the bronchioles. Sympathetic activation leads to **bronchodilation**, the enlargement of airway diameter. Parasympathetic stimulation leads to **bronchoconstriction**, a reduction in the diameter of the airway. Bronchoconstriction also occurs during allergic reactions

such as anaphylaxis, in response to histamine released by activated mast cells and basophils. l**p. 801**

By adjusting the resistance to airflow, bronchodilation and bronchoconstriction direct airflow toward or away from specific portions of the respiratory exchange surfaces. Tension in the smooth muscles commonly throws the bronchiolar mucosa into a series of folds, limiting airflow; excessive stimulation, as in **asthma** (AZ-muh), can almost completely prevent airflow along the terminal bronchioles. AM: COPD: Asthma, Bronchitis, and Emphysema

Pulmonary Lobules

The connective tissues of the root of each lung extend into the lung's parenchyma. These fibrous partitions, or *trabeculae*, contain elastic fibers, smooth muscles, and lymphatic vessels. The trabeculae branch repeatedly, dividing the lobes into ever-smaller compartments. The branches of the conducting passageways, pulmonary vessels, and nerves of the lungs follow these trabeculae. The finest partitions, or **interlobular septa** (*septum*, a wall), divide the lung into **pulmonary lobules** (LOB-u¯lz), each of which is supplied by branches of the pulmonary arteries, pulmonary veins, and respiratory passageways (see Figure 23–9b•). The connective tissues of the septa are, in turn, continuous with those of the *visceral pleura*, the serous membrane covering the lungs.

Each terminal bronchiole delivers air to a single pulmonary lobule. Within the lobule, the terminal bronchiole branches to form several **respiratory bronchioles**. The thinnest and most delicate branches of the bronchial tree, the respiratory bronchioles deliver air to the gas exchange surfaces of the lungs.

The preliminary filtration and humidification of incoming air are completed before the air moves beyond the terminal bronchioles. A cuboidal epithelium lines the terminal bronchioles and respiratory bronchioles. There are only scattered cilia, and no goblet cells or underlying mucous glands are present. If particulate matter or pathogens reach this part of the respiratory tract, there is little to prevent them from damaging the delicate exchange surfaces of the lungs.

Alveolar Ducts and Alveoli

Respiratory bronchioles are connected to individual alveoli and to multiple alveoli along regions called **alveolar ducts** (see Figures 23–9b and 23–10•). Alveolar ducts end at **alveolar sacs**, common chambers connected to multiple individual alveoli. Each lung contains about 150 million alveoli, and their abundance gives the lung an open, spongy appearance. An extensive network of capillaries is associated with each alveolus (Figure 23–11a•). The capillaries are surrounded by a network of elastic fibers, which help maintain the relative positions of the alveoli and respiratory bronchioles. Recoil of these fibers during exhalation reduces the size of the alveoli and helps push air out of the lungs.

The alveolar epithelium consists primarily of simple squamous epithelium (Figure 23–11b•). The squamous epithelial cells, called *Type I cells*, are unusually thin and delicate. Roaming **alveolar macrophages** (*dust cells*) patrol the epithelial surface, phagocytizing any particulate matter that has eluded other respiratory defenses and reached the alveolar surfaces. **Septal cells**, also called *Type II cells*, are scattered among the squamous cells. The large septal cells produce **surfactant** (sur-FAK-tant), an oily secretion containing a mixture of phospholipids and proteins. Surfactant is secreted onto the alveolar surfaces, where it forms a superficial coating over a thin layer of water.

Surfactant reduces surface tension in the liquid coating the alveolar surface. Recall from Chapter 2 that *surface tension* results from the attraction between water molecules at an air–water boundary. l**p. 33** Surface tension creates a barrier that keeps small objects from entering the water, but it also tends to collapse small bubbles. Alveolar walls, like air bubbles, are very delicate; without surfactant, the surface tension would be so high that the alveoli would collapse. Surfactant forms a thin surface layer that interacts with the water molecules, reducing the surface tension and keeping the alveoli open.

If septal cells produce inadequate amounts of surfactant due to injury or genetic abnormalities, the alveoli will collapse after each exhalation, and respiration will become difficult. On each breath, the inhalation must be forceful enough to pop open the alveoli. A person who does not produce enough surfactant is soon exhausted by the effort required to keep inflating and deflating the lungs. This condition is called *respiratory distress syndrome*. AM: Respiratory Distress Syndrome (RDS)

Gas exchange occurs across the **respiratory membrane** of the alveoli. The respiratory membrane is a composite structure consisting of three parts (Figure 23–11c•): (1) the squamous epithelial cells lining the alveolus, (2) the endothelial cells lining an adjacent capillary, and (3) the fused basal laminae that lie between the alveolar and endothelial cells. At the respiratory membrane, the total distance separating alveolar air from blood can be as little as 0.1 mm; it averages about 0.5 mm. Diffusion across the respiratory membrane proceeds very rapidly, because the distance is small and both oxygen and carbon dioxide are lipid soluble. The membranes of the epithelial and endothelial cells thus do not pose a barrier to the movement of oxygen and carbon dioxide between blood and alveolar air spaces.

In certain disease states, function of the respiratory membrane can be compromised. **Pneumonia** (noo-MŌ-nē-uh) develops from an infection or any other stimulus that causes inflammation of the lobules of the lung. As inflammation occurs, fluids leak into the alveoli and the respiratory bronchioles swell and constrict. Respiratory function deteriorates as a result. When bacteria are involved, they are generally types that normally inhabit the mouth and pharynx, but have managed to evade the respiratory defenses. Pneumonia becomes more likely when the respiratory defenses have already been compromised by other factors, such as epithelial damage from smoking or the breakdown of the immune system in AIDS. The most common pneumonia that develops in individuals with AIDS results from infection by the fungus *Pneumocystis carinii*. The respiratory defenses of healthy individuals are able to prevent infection and tissue damage, but the breakdown of those defenses in AIDS can result in a massive, potentially fatal lung infection.

Concept Check

- Why are the cartilages that reinforce the trachea C-shaped?
- What would happen to the alveoli if surfactant were not produced?
- What path does air take in flowing from the glottis to the respiratory membrane?

Answers begin on p. A–1

The Blood Supply to the Lungs

The respiratory exchange surfaces receive blood from arteries of the pulmonary circuit. The pulmonary arteries enter the lungs at the hilus and branch with the bronchi as they approach the lobules. Each lobule receives an arteriole and a venule, and a network of capillaries surrounds each alveolus as part of the respiratory membrane. In addition to providing a mechanism for gas exchange, the endothelial cells of the alveolar capillaries are the primary source of *angiotensin-converting enzyme (ACE)*, which converts circulating angiotensin I to angiotensin II. This enzyme plays an important role in the regulation of blood volume and blood pressure. l**p. 731**

Blood from the alveolar capillaries passes through the pulmonary venules and then enters the pulmonary veins, which deliver it to the left atrium. The conducting portions of the respiratory tract receive blood from the *external carotid arteries* (the nasal passages and larynx), the *thyrocervical trunks* (the inferior larynx and trachea), and the *bronchial arteries* (the bronchi and bronchi oles). l**pp. 740, 741, 743** The capillaries supplied by the bronchial arteries provide oxygen and nutrients to the tissues of conducting passageways of your lungs. The venous blood from these bronchial capillaries ultimately flows into the pulmonary veins, bypassing the rest of the systemic circuit and diluting the oxygenated blood leaving the alveoli.

Blood pressure in the pulmonary circuit is usually relatively low, with systemic pressures of 30 mm Hg or less. With such pressures, pulmonary vessels can easily become blocked by small blood clots, fat masses, or air bubbles in the pulmonary arteries. Because the lungs receive the entire cardiac output, any such objects drifting in blood are likely to cause problems almost at once. The blockage of a branch of a pulmonary artery will stop blood flow to a group of lobules or alveoli. This condition is called **pulmonary embolism**. If a pulmonary embolus is in place for several hours, the alveoli will permanently collapse. If the blockage occurs in a major pulmonary vessel rather than a minor tributary, pulmonary resistance increases. The resistance places extra strain on the right ventricle, which may be unable to maintain cardiac output, and congestive heart failure can result.

The Pleural Cavities and Pleural Membranes

The thoracic cavity has the shape of a broad cone. Its walls are the rib cage, and the muscular diaphragm forms its floor. The two **pleural cavities** are separated by the mediastinum (see Figure 23–8•, p. 824). Each lung occupies a single pleural cavity, which is lined by a serous membrane called the **pleura** (PLOOR-uh; plural, *pleurae*). The pleura consists of two layers: the parietal pleura and the visceral pleura. The **parietal pleura** covers the inner surface of the thoracic wall and extends over the diaphragm and mediastinum. The **visceral pleura** covers the outer surfaces of the lungs, extending into the fissures between the lobes. Each pleural cavity actually represents a potential space rather than an open chamber, because the parietal and visceral pleurae are usually in close contact.

Both pleurae secrete a small amount of transudate referred to as **pleural fluid**. Pleural fluid forms a moist, slippery coating that provides lubrication, thereby reducing friction between the parietal and visceral surfaces as you breathe. Samples of pleural fluid, obtained through

a long needle inserted between the ribs, are sometimes obtained for diagnostic purposes. This sampling
procedure is called *thoracentesis* (th
¯o
r-a-sen-T E¯
-sis; *thora*-, thoracic +
centesis, puncture). The extracted fluid is examined for
the presence of bacteria, blood cells, or other abnormal components.

In some disease states, the normal coating of pleural fluid is unable to prevent friction between the opposing pleural surfaces. The result is pain and pleural inflammation, a condition called *pleurisy*. When pleurisy develops, the secretion of pleural fluid may be excessive, or the inflamed pleurae may adhere to one another, limiting relative movement. In either case, breathing becomes difficult, and prompt medical attention is required.

Concept Check

 Which arteries supply blood to the conducting portions and respiratory exchange surfaces of the lungs?

 List the functions of the pleura. What does it secrete?

Answers begin on p. A–1

An Overview of Respiratory Physiology

Objectives

- Define and compare the processes of external respiration and internal respiration.
- Describe the major steps involved in external respiration.

The general term *respiration* refers to two integrated processes: *external respiration* and *internal respiration*. The precise definitions of these terms vary among references. In this discussion, **external respiration** includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. The purpose of external respiration, and the primary function of the respiratory system, is meeting the respiratory demands of cells. **Internal respiration** is the absorption of oxygen and the release of carbon dioxide by those cells. We will consider the biochemical pathways responsible for oxygen consumption and for the generation of carbon dioxide by mitochondria—pathways known collectively as *cellular respiration*—in Chapter 25.

Our discussion here focuses on three integrated steps involved in external respiration (Figure 23–12•):

1. *Pulmonary ventilation*, or breathing, which involves the physical movement of air into and out of the lungs.

2. *Gas diffusion* across the respiratory membrane between alveolar air spaces and alveolar capillaries, and across capillary walls between blood and other tissues.

3. *The transport of oxygen and carbon dioxide* between alveolar capillaries and capillary beds in other tissues. Abnormalities affecting any of the steps involved in external respiration will ultimately affect the gas concentrations of interstitial fluids, and thus cellular activities as well. If the oxygen content declines, the affected tissues will become starved for oxygen. **Hypoxia**, or low tissue oxygen levels, places severe limits on the metabolic activities of the affected area. For example, the effects of coronary ischemia result from chronic hypoxia affecting cardiac muscle cells. l**p. 682** If the supply of oxygen is cut off

completely, the condition called **anoxia** (an-ok-SE-a; *a*-, without + *ox*-, oxygen) results. Anoxia kills cells very quickly. Much of the damage caused by strokes and heart attacks is the result of localized anoxia.

Pulmonary Ventilation

Objectives

- Summarize the physical principles governing the movement of air into the lungs.
- Describe the origins and actions of the respiratory muscles responsible for respiratory movements.

Pulmonary ventilation is the physical movement of air into and out of the respiratory tract. The primary function of pulmonary ventilation is to maintain adequate *alveolar ventilation*—movement of air into and out of the alveoli. Alveolar ventilation prevents the buildup of carbon dioxide in the alveoli and ensures a continuous supply of oxygen that keeps pace with absorption by the bloodstream.

The Movement of Air

To understand this mechanical process, we need to grasp some basic physical principles governing the movement of air. One of the most basic is that our bodies and everything around us are compressed by the weight of Earth's atmosphere. Although we are seldom aware of it, this **atmospheric pressure** has several important physiological effects. For example, air moves into and out of the respiratory tract as the air pressure in the lungs cycles between below atmospheric pressure and above atmospheric pressure.

Gas Pressure and Volume (Boyle's Law)

The primary differences between liquids and gases reflect the interactions among individual molecules. Although the molecules in a liquid are in constant motion, they are held closely together by weak interactions, such as the hydrogen bonding between adjacent water molecules. l**p. 33** Yet because the electrons of adjacent atoms tend to repel one another, liquids tend to resist compression. If you squeeze a balloon filled with water, it will distort into a different shape, but the volumes of the two shapes will be the same.

In a gas, such as air, the molecules bounce around as independent entities. At normal atmospheric pressures, gas molecules are much farther apart than the molecules in a liquid, so the density of air is relatively low. The forces acting between gas molecules are minimal (the molecules are too far apart for weak interactions to occur), so an applied pressure can push them closer together. Consider a sealed container of air at atmospheric pressure. The pressure exerted by the enclosed gas results from the collision of gas molecules with the walls of the container. The greater the number of collisions, the higher the pressure.

You can change the gas pressure within a sealed container by changing the volume of the container, thereby giving the gas molecules more or less room in which to bounce around. If you decrease the volume of the container, collisions occur more frequently over a given period, elevating the pressure of the gas (Figure 23–13a•). If you increase the volume, fewer collisions occur per unit time, because it takes longer for a gas molecule to travel from one wall to another. As a result, the gas pressure inside the container declines (Figure 23–13b•).

For a gas in a closed container and at a constant temperature, pressure (P) is inversely proportional to volume (V). That is, *if you decrease the volume of a gas, its pressure will rise; if you increase the volume of a gas, its pressure will fall*. In particular, the relationship between pressure and volume is reciprocal: If you double the external pressure on a flexible container, its volume will

drop by half; if you reduce the external pressure by half, the volume of the container will double. This relationship, $P = 1> V$, first recognized by Robert Boyle in the 1600s, is called **Boyle's law**. AM: Boyle's Law and Air Overexpansion Syndrome

Pressure and Airflow to the Lungs

Air will flow from an area of higher pressure to an area of lower pressure. This tendency for directed airflow, plus the pressure–volume relationship of Boyle's law, provides the basis for pulmonary ventilation. A single respiratory cycle consists of an *inspiration*, or inhalation, and an *expiration*, or exhalation. Inhalation and exhalation involve changes in the volume of the lungs. These volume changes create pressure gradients that move air into or out of the respiratory tract.

Each lung lies within a pleural cavity. The parietal and visceral pleurae are separated by only a thin film of pleural fluid. The two membranes can slide across one another, but they are held together by that fluid film. You encounter the same principle when you set a wet glass on a smooth tabletop. You can slide the glass easily, but when you try to lift it, you experience considerable resistance. As you pull the glass away from the tabletop, you create a powerful suction. The only way to overcome it is to tilt the glass so that air is pulled between the glass and the table, breaking the fluid bond.

A comparable fluid bond exists between the parietal pleura and the visceral pleura covering the lungs. As a result, the surface of each lung sticks to the inner wall of the chest and to the superior surface of the diaphragm. As a result, movements of the diaphragm or rib cage that change the volume of the thoracic cavity also change the volume of the lungs.

Changes in the volume of the thoracic cavity result from movements of the diaphragm or rib cage (Figure 23–14a•):

- The diaphragm forms the floor of the thoracic cavity. The relaxed diaphragm has the shape of a dome that projects superiorly into the thoracic cavity. When the diaphragm contracts, it tenses and moves inferiorly. This movement increases the volume of the thoracic cavity, reducing the pressure within it. When the diaphragm relaxes, it returns to its original position, and the volume of the thoracic cavity decreases.
- Owing to the nature of the articulations between the ribs and the vertebrae, superior movement of the rib cage increases the depth and width of the thoracic cavity, increasing its volume. Inferior movement of the rib cage reverses the process, reducing the volume of the thoracic cavity.

At the start of a breath, pressures inside and outside the thoracic cavity are identical, and no air moves into or out of the lungs (Figure 23–14b•). When the thoracic cavity enlarges, the pleural cavities and lungs expand to fill the additional space (Figure 23–14c•). This increase in volume lowers the pressure inside the lungs. Air then enters the respiratory passageways, be cause the pressure inside the lungs (*P*inside) is lower than atmospheric pressure (*P*outside). Air continues to enter the lungs until their volume stops increasing and the internal pressure is the same as that outside. When the thoracic cavity decreases in volume, pressures rise inside the lungs, forcing air out of the respiratory tract (Figure 23–14d•).

Compliance

The **compliance** of the lungs is an indication of their expandability, how easily the lungs expand and contract. The lower the compliance, the greater the force required to fill and empty the lungs. The greater the compliance, the easier it is to fill and empty the lungs. Factors affecting compliance include the following:

- **The Connective-Tissue Structure of the Lungs.** The loss of supporting tissues resulting from alveolar damage, as in *emphysema*, increases compliance.
- **The Level of Surfactant Production.** On exhalation, the collapse of alveoli as a result of inadequate surfactant, as in respiratory distress syndrome, reduces the lungs' compliance.
- **The Mobility of the Thoracic Cage.** Arthritis or other skeletal disorders that affect the articulations of the ribs or spinal column also reduce compliance.

At rest, the muscular activity involved in pulmonary ventilation accounts for 3–5 percent of the resting energy demand. If compliance is reduced, that figure climbs dramatically, and an individual may become exhausted simply trying to continue breathing.

Pressure Changes during Inhalation and Exhalation

To understand the mechanics of respiration and the principles of gas exchange, we must know the pressures existing inside and outside the respiratory tract. We can report pressure readings in several ways (Table 23–1); in this text, we will use millimeters of mercury (mm Hg), as we did for blood pressure. Atmospheric pressure is also measured in *atmospheres*; one atmosphere of pressure (1 *atm*) is equivalent to 760 mm Hg.

The Intrapulmonary Pressure

The direction of airflow is determined by the relationship between atmospheric pressure and intrapulmonary pressure. **Intrap-**

E¯

ulmonary (in-tra-PUL-mo-ner-) **pressure**, or **intra-alveolar** (in-tra-al-V tory tract, at the alveoli.

When you are relaxed and breathing quietly, the difference between atmospheric pressure and intrapulmonary pressure is relatively small. On inhalation, your lungs expand, and the intrapulmonary pressure drops to about 759 mm Hg. Because the intrapulmonary pressure is 1 mm Hg below atmospheric pressure, it is generally reported as -1 mm Hg. On exhalation, your lungs recoil, and intrapulmonary pressure rises to 761 mm Hg, or + 1 mm Hg (Figure 23–15a•).

The size of the pressure gradient increases when you breathe heavily. When a trained athlete breathes at maximum capacity, the pressure differentials can reach -30 mm Hg during inhalation and + 100 mm Hg if the individual is straining with the glottis kept closed. This is one reason you are told to exhale while lifting weights; exhaling keeps your intrapulmonary pressures and peritoneal pressure from climbing so high that an alveolar rupture or hernia could occur.

The Intrapleural Pressure

Intrapleural pressure is the pressure in the space between the parietal and visceral pleurae. Intrapleural pressure averages about

-4 mm Hg (Figure 23–15b•), but can reach -18 mm Hg during a powerful inhalation. This pressure is below atmospheric pressure, due to the relationship between the lungs and the body wall. Earlier, we noted that the lungs are highly elastic. In fact, they would collapse to about 5 percent of their normal resting volume if the elastic fibers could recoil completely. The elastic fibers cannot recoil significantly, however, because they are not strong enough to overcome the fluid bond between the parietal and visceral pleurae.

The elastic fibers continuously oppose that fluid bond and pull the lungs away from the chest wall and diaphragm, lowering the intrapleural pressure slightly. Because the elastic fibers remain stretched even after a full exhalation, intrapleural pressure remains below atmospheric pressure throughout normal cycles of inhalation and exhalation. The cyclical changes in the intrapleural pressure are responsible for the *respiratory pump*—the mechanism that assists the venous return to the heart. l**p. 722**

The Respiratory Cycle

A **respiratory cycle** is a single cycle of inhalation and exhalation. The curves in Figure 23–15a,b• indicate the intrapulmonary and intrapleural pressures during a single respiratory cycle of an individual at rest. The graph in Figure 23–15c• plots the **tidal**

¯e

volume, the amount of air you move into or out of your lungs during a single respiratory cycle.

At the start of the respiratory cycle, the intrapulmonary and atmospheric pressures are equal, and no air is moving. Inhalation begins with the fall of intrapleural pressure that accompanies the expansion of the thoracic cavity. This pressure gradually falls to approximately -6 mm Hg. Over the period, intrapulmonary pressure drops to just under -1 mm Hg; it then begins to rise as air flows into the lungs. When exhalation begins, intrapleural and intrapulmonary pressures rise rapidly, forcing air out of the lungs. At the end of exhalation, air movement again ceases when the difference between intrapulmonary and atmospheric pressures has been eliminated. The amount of air moved into the lungs during inhalation is equal to the amount moved out of the lungs during exhalation. That amount is the tidal volume.

An injury to the chest wall that penetrates the parietal pleura, or a rupture of the alveoli that breaks through the visceral pleura,

¯o

-lar) **pressure**, is the pressure inside the respira-

can allow air into the pleural cavity. This condition, called **pneumothorax** (noo-m

¯o

-THO-raks; *pneumo*-, air), breaks the fluid

bond between the pleurae and allows the elastic fibers to recoil, resulting in a “collapsed lung,” or **atelectasis** (at-e-LEK-ta-sis; *atel*-, imperfect or incomplete + *ectasia*, distention). The opposite lung would not be affected due to compartmentalization. The treatment for a collapsed lung involves the removal of as much of the air as possible from the affected pleural cavity before the opening is sealed. This treatment lowers the intrapleural pressure and reinflates the lung.

The Mechanics of Breathing

As we have just seen, you move air into and out of the respiratory system by changing the volume of the lungs. Those changes alter the pressure relationships, producing air movement. The changes of volume in the lungs occur through the contraction of skeletal muscles—specifically, those that insert on the rib cage—and the *diaphragm*, which separates the thoracic and abdominopelvic cavities. Because of the nature of their articulations with the vertebrae, when the ribs are elevated they swing out
ward, increasing the depth of the thoracic cavity. l**p. 234** This movement can be compared to the elevation of a bucket handle (Figure 23–16a•).

The Respiratory Muscles

The skeletal muscles involved in respiratory movements were introduced in Chapter 11. Of those muscles, the most important are the *diaphragm* and the *external intercostal muscles*. l**pp. 347, 348** These muscles are active during normal breathing at rest. The **accessory respiratory muscles** become active when the depth and frequency of respiration must be increased markedly. These muscles include the *internal intercostal*, *sternocleidomastoid*, *serratus anterior*, *pectoralis minor*, *scalene*, *transversus thoracis*, *transversus abdominis*, *external* and *internal oblique*, and *rectus abdominis muscles* (Figure 23–16b–d•). l**pp. 343, 347, 352, 355**

AM: Artificial Respiration

Muscles Used in Inhalation Inhalation is an active process involving one or more of the following muscles:

- Contraction of the diaphragm flattens the floor of the thoracic cavity, increasing its volume and drawing air into the lungs. Diaphragmatic contraction is responsible for roughly 75 percent of the air movement in normal breathing at rest.

- Contraction of the external intercostal muscles assists in inhalation by elevating the ribs. This action contributes roughly 25 percent to the volume of air in the lungs at rest.
- Contraction of accessory muscles, including the sternocleidomastoid, serratus anterior, pectoralis minor, and scalene muscles, can assist the external intercostal muscles in elevating the ribs. These muscles increase the speed and amount of rib movement.

Muscles Used in Exhalation Exhalation is either passive or active, depending on the level of respiratory activity. When exhalation is active, it may involve one or more of the following muscles:

- The internal intercostal and transversus thoracis muscles depress the ribs and reduce the width and depth of the thoracic cavity.
- The abdominal muscles, including the external and internal oblique, transversus abdominis, and rectus abdominis muscles, can assist the internal intercostal muscles in exhalation by compressing the abdomen and forcing the diaphragm upward.

Modes of Breathing

The respiratory muscles are used in various combinations, depending on the volume of air that must be moved into or out of the system. Respiratory movements are usually classified as *quiet breathing* or *forced breathing* according to the pattern of muscle activity during a single respiratory cycle.

Quiet Breathing In **quiet breathing**, or **eupnea** (
¯U

P-n
¯e
-uh; *eu*-, true or normal + -*pnea*, respiration), inhalation involves mus
cular contractions, but exhalation is a passive process. Inhalation usually involves the contraction of both the diaphragm and the external intercostal muscles. The relative contributions of these muscles can vary:

- During **diaphragmatic breathing**, or **deep breathing**, contraction of the diaphragm provides the necessary change in thoracic volume. Air is drawn into the lungs as the diaphragm contracts, and is exhaled passively when the diaphragm relaxes.
- In **costal breathing**, or **shallow breathing**, the thoracic volume changes because the rib cage alters its shape. Inhalation occurs when contractions of the external intercostal muscles elevate the ribs and enlarge the thoracic cavity. Exhalation occurs passively when these muscles relax.

During quiet breathing, expansion of the lungs stretches their elastic fibers. In addition, elevation of the rib cage stretches opposing skeletal muscles and elastic fibers in the connective tissues of the body wall. When the muscles of inhalation relax, these elastic components recoil, returning the diaphragm, the rib cage, or both to their original positions. This phenomenon is called **elastic rebound**.

Diaphragmatic breathing typically occurs at minimal levels of activity. As increased volumes of air are required, inspiratory movements become larger and the contribution of rib movement increases. Even when you are at rest, costal breathing can predominate when abdominal pressures, fluids, or masses restrict diaphragmatic movements. For example, pregnant women increasingly rely on costal breathing as the enlarging uterus pushes the abdominal viscera against the diaphragm.

Forced Breathing

–

Forced breathing, or **hyperpnea** (h -perp-N

ı Forced breathing calls on the accessory muscles to assist with inhalation, and exhalation involves contraction of the internal intercostal muscles. At absolute maximum levels of forced breathing, the abdominal muscles are involved in exhalation. Their contraction compresses the abdominal contents, pushing them up against the diaphragm and further reducing the volume of the thoracic cavity.

Respiratory Rates and Volumes

Your respiratory system is extremely adaptable. You can be breathing slowly and quietly one moment, rapidly and deeply the next. The respiratory system adapts to meet the oxygen demands of the body by varying both the number of breaths per minute and the amount of air moved per breath. When you are exercising at peak levels, the amount of air moving into and out of the respiratory tract can be 50 times the amount moved at rest.

Respiratory Rate

Your **respiratory rate** is the number of breaths you take each minute. As you read this, you are probably breathing quietly, with a low respiratory rate. The normal respiratory rate of a resting adult ranges from 12 to 18 breaths each minute, roughly one for every four heartbeats. Children breathe more rapidly, at rates of about 18–20 breaths per minute.

¯E

-uh), involves active inspiratory and expiratory movements.

The Respiratory Minute Volume

#

We can calculate the amount of air moved each minute, symbolized *V*E, by multiplying the respiratory rate *f* by the tidal volume

*V*T. This value is called the **respiratory minute volume**. The respiratory rate at rest averages 12 breaths per minute, and the tidal volume at rest averages around 500 ml per breath. On that basis, we can calculate the respiratory minute volume as follows:

= 12 * 500 ml per minute = 6000 ml per minute = 6.0 liters per minute

In other words, the respiratory minute volume at rest is approximately 6 liters per minute.

Alveolar Ventilation

The respiratory minute volume measures pulmonary ventilation and provides an indication of how much air is moving into and out of the respiratory tract. However, only some of the inhaled air reaches the alveolar exchange surfaces. A typical inhalation pulls about 500 ml of air into the respiratory system. The first 350 ml inhaled travels along the conducting passageways and enters the alveolar spaces. The last 150 ml of inhaled air never gets farther than the conducting passageways and thus does not participate in gas exchange with blood. The volume of air in the conducting passages is known as the **anatomic dead space**, denoted V*D*.

#

Alveolar ventilation, symbolized *V*A, is the amount of air reaching the alveoli each minute. The alveolar ventilation is less than the respiratory minute volume, because some of the air never reaches the alveoli, but remains in the dead space of the lungs. We can calculate alveolar ventilation by subtracting the dead space from the tidal volume:

At rest, alveolar ventilation rates are approximately 4.2 liters per minute (12 * 350 ml). However, the gas arriving in the alveoli is significantly different from that of the surrounding atmosphere, because inhaled air always mixes with “used” air in the conducting passageways (the anatomic dead space) on its way to the exchange surfaces. The air in alveoli thus contains less oxygen and more carbon dioxide than does atmospheric air.

##

Relationships among V_T, V_E, and V_A

The respiratory minute volume can be increased by increasing either the tidal volume or the respiratory rate. Under maximum stimulation, the tidal volume can increase to roughly 4.8 liters. At peak respiratory rates of 40–50 breaths per minute and maximum cycles of inhalation and exhalation, the respiratory minute volume can approach 200 liters (about 55 gal) per minute.

In functional terms, the alveolar ventilation rate is more important than the respiratory minute volume, because it determines the rate of delivery of oxygen to the alveoli. The respiratory rate and the tidal volume together determine the alveolar ventilation rate:

- For a given respiratory rate, increasing the tidal volume increases the alveolar ventilation rate.
- For a given tidal volume, increasing the respiratory rate increases the alveolar ventilation rate.

The alveolar ventilation rate can change independently of the respiratory minute volume. In our previous example, the respiratory minute volume at rest was 6 liters and the alveolar ventilation rate was 4.2 L> min. If the respiratory rate rises to 20 breaths per minute but the tidal volume drops to 300 ml, the respiratory minute volume remains the same 120 * 300 = 60002. However, the alveolar ventilation rate drops to only 3 L>min 120 * 3300 -1504 = 30002. Thus, whenever the demand for oxygen increases, both the tidal volume *and* the respiratory rate must be regulated closely. (The mechanisms involved are the focus of a later section.)

Respiratory Performance and Volume Relationships

Only a small proportion of the air in the lungs is exchanged during a single quiet respiratory cycle; the tidal volume can be increased by inhaling more vigorously and exhaling more completely. We can divide the total volume of the lungs into a series of *volumes* and *capacities* (each the sum of various volumes), as indicated in Figure 23–17•. The values obtained are useful in diagnosing problems with pulmonary ventilation. Adult females, on average, have smaller bodies and thus smaller lung volumes than do males. As a result, there are sex-related differences in respiratory volumes and capacities. Representative values for both sexes are indicated in the figure.

Pulmonary volumes include the following:

- The **resting tidal volume** is the amount of air you move into or out of your lungs during a single respiratory cycle under resting conditions. The resting tidal volume averages about 500 ml in both males and females.
- The **expiratory reserve volume (ERV)** is the amount of air that you can voluntarily expel after you have completed a normal, quiet respiratory cycle. As an example, if, with maximum use of the accessory muscles, you can expel an additional 1000 ml of air, your expiratory reserve volume is 1000 ml.
- The **residual volume** is the amount of air that remains in your lungs even after a maximal exhalation—typically about 1200 ml in males and 1100 ml in females. The **minimal volume**, a component of the residual volume, is the amount of air that would

remain in your lungs if they were allowed to collapse. The minimal volume ranges from 30 to 120 ml, but, unlike other volumes, it cannot be measured in a healthy person. The minimal volume and the residual volume are very different, because the fluid bond between the lungs and the chest wall prevents the recoil of the elastic fibers. Some air remains in the lungs, even at minimal volume, because the surfactant coating the alveolar surfaces prevents their collapse.

- The **inspiratory reserve volume (IRV)** is the amount of air that you can take in over and above the tidal volume. On average, the lungs of males are larger than those of females, and as a result the inspiratory reserve volume of males averages 3300 ml, compared with 1900 ml in females.

We can calculate respiratory capacities by adding the values of various volumes. Examples include the following:

- The **inspiratory capacity** is the amount of air that you can draw into your lungs after you have completed a quiet respiratory cycle. The inspiratory capacity is the sum of the tidal volume and the inspiratory reserve volume.
- The **functional residual capacity (FRC)** is the amount of air remaining in your lungs after you have completed a quiet respiratory cycle. The FRC is the sum of the expiratory reserve volume and the residual volume.
- The **vital capacity** is the maximum amount of air that you can move into or out of your lungs in a single respiratory cycle. The vital capacity is the sum of the expiratory reserve volume, the tidal volume, and the inspiratory reserve volume and averages around 4800 ml in males and 3400 ml in females.
- The **total lung capacity** is the total volume of your lungs, calculated by adding the vital capacity and the residual volume. The total lung capacity averages around 6000 ml in males and 4500 ml in females.

Pulmonary function tests monitor several aspects of respiratory function by measuring rates and volumes of air movement.

Gas Exchange

Objectives

- Summarize the physical principles governing the diffusion of gases into and out of the blood.
- Explain the important structural features of the respiratory membrane.
- Describe the partial pressures of oxygen and carbon dioxide in alveolar air, blood, and the systemic circuit.

Pulmonary ventilation both ensures that your alveoli are supplied with oxygen and removes the carbon dioxide arriving from your bloodstream. The actual process of gas exchange occurs between blood and alveolar air across the respiratory membrane. To understand these events, we will first consider (1) the *partial pressures* of the gases involved and (2) the diffusion of molecules between a gas and a liquid. We can then proceed to discuss the movement of oxygen and carbon dioxide across the respiratory membrane.

The Gas Laws

Gases are exchanged between the alveolar air and the blood through diffusion, which occurs in response to concentration gradi ents. As we saw in Chapter 3, the rate of diffusion varies in response to a variety of factors, including the size of the concentration gradient and the temperature. l**p. 86** The principles that govern the movement and diffusion of gas molecules, such as those in the atmosphere, are relatively straightforward. These principles, known as *gas laws*, have been understood for roughly 250 years. You have already heard about Boyle's law, which determines the direction of air movement in pulmonary ventilation. In this section, you will learn about gas laws and other factors that determine the rate of oxygen and carbon dioxide diffusion across the respiratory membrane.

Dalton's Law and Partial Pressures

The air we breathe is not a single gas but a mixture of gases. Nitrogen molecules (N_2) are the most abundant, accounting for about 78.6 percent of atmospheric gas molecules. Oxygen molecules (O_2), the second most abundant, make up roughly 20.9 percent of air. Most of the remaining 0.5 percent consists of water molecules, with carbon dioxide (CO_2) contributing a mere 0.04 percent. Atmospheric pressure, 760 mm Hg, represents the combined effects of collisions involving each type of molecule in air. At any moment, 78.6 percent of those collisions will involve nitrogen molecules, 20.9 percent oxygen molecules, and so on. Thus, each of the gases contributes to the total pressure in proportion to its relative abundance. This relationship is known as **Dalton's law**. The **partial pressure** of a gas is the pressure contributed by a single gas in a mixture of gases. The partial pressure is abbreviated by the symbol P or p. All the partial pressures added together equal the total pressure exerted by the gas mixture. For the atmosphere, this relationship can be summarized as follows:

$$PN_2 + PO_2 + PH_2O + PCO_2 = 760 \text{ mm Hg}$$

Because we know the individual percentages in air, we can easily calculate the partial pressure of each gas. For example, the partial pressure of oxygen, PO_2, is 20.9 percent of 760 mm Hg, or roughly 159 mm Hg. The partial pressures for other atmospheric gases are included in Table 23–2.

Diffusion between Liquids and Gases (Henry's Law)

Differences in pressure, which move gas molecules from one place to another, also affect the movement of gas molecules into and out of solution. At a given temperature, the amount of a particular gas in solution is directly proportional to the partial pressure of that gas. This principle is known as **Henry's law**.

When a gas under pressure contacts a liquid, the pressure tends to force gas molecules into solution. At a given pressure, the number of dissolved gas molecules will rise until an equilibrium is established. At equilibrium, gas molecules diffuse out of the liquid as quickly as they enter it, so the total number of gas molecules in solution remains constant. If the partial pressure goes up, more gas molecules will go into solution; if the partial pressure goes down, gas molecules will come out of solution.

You see Henry's law in action whenever you open a can of soda. The soda was put into the can under pressure, and the gas (carbon dioxide) is in solution (Figure 23–18a•). When you open the can, the pressure falls and the gas molecules begin coming out of solution (Figure 23–18b•). Theoretically, the process will continue until an equilibrium develops between the surrounding air and the gas in solution. In fact, the volume of the can is so small, and the volume of the atmosphere so great, that within a half hour or so virtually all the carbon dioxide comes out of solution. You are then left with "flat" soda.

The actual *amount* of a gas in solution at a given partial pressure and temperature depends on the solubility of the gas in that particular liquid. In body fluids, carbon dioxide is highly soluble, oxygen is somewhat less soluble, and nitrogen has very limited solubility. The dissolved gas content is usually reported in milliliters of gas per 100 ml (1 dl) of solution. To see the differences in relative solubility, we can compare the gas content of blood in the pulmonary veins with the partial pressure of each gas in the

alveoli. In a pulmonary vein, plasma generally contains 2.62 ml> dl of dissolved CO_2 (PCO_2 = 40 mm Hg), 0.29 ml> dl of dissolved

O_2 (PO_2 = 100 mm Hg), and 1.25 ml> dl of dissolved N_2 (PN_2 = 573 mm Hg).

Clinical Note

Decompression sickness is a painful condition that develops when a person is exposed to a sudden drop in atmospheric pressure. Ni trogen is the gas responsible for the problems experienced, owing to its high partial pressure in air. When the pressure drops, nitrogen comes out of solution, forming bubbles like those in a shaken can of soda. The bubbles may form in joint cavities, in the bloodstream, and in the cerebrospinal fluid. Individuals with decompression sickness typically curl up from the pain in affected joints; this reaction accounts for the condition's common name: *the bends*. Decompression sickness most commonly affects scuba divers who return to the surface too quickly after breathing air under greater-than-normal pressure while submerged. It can also develop in airline passengers subject to sudden losses of cabin pressure. AM: Decompression Sickness

Diffusion and Respiratory Function

The gas laws apply to the diffusion of oxygen, carbon dioxide, and nitrogen between a gas and a liquid. We will now consider how differing partial pressures and solubilities determine the direction and rate of diffusion across the respiratory membrane that separates the air within the alveoli from the blood in alveolar capillaries.

The Composition of Alveolar Air

As soon as air enters the respiratory tract, its characteristics begin to change. In passing through the nasal cavity, inhaled air becomes warmer, and the amount of water vapor increases. Humidification and filtration continue as the air travels through the pharynx, trachea, and bronchial passageways. On reaching the alveoli, the incoming air mixes with air remaining in the alveoli from the previous respiratory cycle. Alveolar air thus contains more carbon dioxide and less oxygen than does atmospheric air.

The last 150 ml of inhaled air never gets farther than the conducting passageways and remains in the anatomic dead space of the lungs. During the subsequent exhalation, the departing alveolar air mixes with air in the dead space, producing yet another mixture that differs from both atmospheric and alveolar samples. The differences in composition between atmospheric (inhaled) and alveolar air are given in Table 23–2.

Efficiency of Diffusion at the Respiratory Membrane

Gas exchange at the respiratory membrane is efficient for the following five reasons:

1. *The Differences in Partial Pressure across the Respiratory Membrane Are Substantial.* This fact is important, because the greater the difference in partial pressure, the faster the rate of gas diffusion. Conversely, if PO_2 in alveoli decreases, the rate of oxygen diffusion into blood will drop. This is why many people feel light-headed at altitudes of 3000 m or more; the partial pressure of oxygen in their alveoli has dropped low enough that the rate of oxygen absorption is significantly reduced.

2. *The Distances Involved in Gas Exchange Are Small.* The fusion of capillary and alveolar basal laminae reduces the distance for gas exchange to an average of 0.5 mm. Inflammation of the lung tissue or a buildup of fluid in alveoli increases the diffusion distance and impairs alveolar gas exchange.

3. *The Gases Are Lipid Soluble.* Both oxygen and carbon dioxide diffuse readily through the surfactant layer and the alveolar and endothelial cell membranes.

4. *The Total Surface Area Is Large.* The combined alveolar surface area at peak inhalation may approach 140 m^2 (1506 ft^2). Damage to alveolar surfaces, which occurs in emphysema, reduces the available surface area and the efficiency of gas transfer.

5. *Blood Flow and Airflow Are Coordinated.* This arrangement improves the efficiency of both pulmonary ventilation and pulmonary circulation. For example, blood flow is greatest around alveoli with the highest PO_2 values, where oxygen uptake can proceed with maximum efficiency. If the normal blood flow is impaired (as it is in *pulmonary embolism*), or if the normal airflow is interrupted (as it is in various forms of *pulmonary obstruction*), this coordination is lost and respiratory efficiency decreases. AM: COPD: Asthma, Bronchitis, and Emphysema

Partial Pressures in Alveolar Air and Alveolar Capillaries

Figure 23–19• illustrates the partial pressures of oxygen and carbon dioxide in the pulmonary and systemic circuits. Blood arriving in the pulmonary arteries has a lower PO_2 and a higher PCO_2 than does alveolar air (Figure 23–19a•). Diffusion between the alveolar mixture and the pulmonary capillaries thus elevates the PO_2 of blood while lowering its PCO_2. By the time the blood enters the pulmonary venules, it has reached equilibrium with the alveolar air. Hence, blood departs the alveoli with a PO_2 of about 100 mm Hg and a PCO_2 of roughly 40 mm Hg.

Diffusion between alveolar air and blood in the pulmonary capillaries occurs very rapidly. When you are at rest, a red blood cell moves through one of your pulmonary capillaries in about 0.75 second; when you exercise, the passage takes less than 0.3 second. This amount of time is usually sufficient to reach an equilibrium between the alveolar air and the blood.

Partial Pressures in the Systemic Circuit

The oxygenated blood now leaves the alveolar capillaries and returns to the heart, to be discharged into the systemic circuit. As this blood enters the pulmonary veins, it mixes with blood that flowed through capillaries around conducting passageways. Because gas exchange occurs only at alveoli, the blood leaving the conducting passageways carries relatively little oxygen. The partial pressure of oxygen in the pulmonary veins therefore drops to about 95 mm Hg. This is the PO_2 in the blood that enters the systemic circuit, and no further changes in partial pressure occur until the blood reaches the peripheral capillaries (Figure 23–19b•).

Normal interstitial fluid has a PO_2 of 40 mm Hg. As a result, oxygen diffuses out of the capillaries and carbon dioxide diffuses in, until the capillary partial pressures are the same as those in the adjacent tissues. Inactive peripheral tissues normally have a PCO_2 of about 45 mm Hg, whereas blood entering peripheral capillaries normally has a PCO_2 of 40 mm Hg. As a result, carbon dioxide diffuses into the blood as oxygen diffuses out (see Figure 23–19b•).

Clinical Note

Blood samples can be analyzed to determine their concentrations of dissolved gases. The usual tests include the determination of pH, P_{CO_2}, and in an arterial sample. Such samples provide information about the degree of oxygenation in peripheral tissues. For $^{P}O_2$
example, if the arterial is very high and the is very low, tissues are not receiving adequate oxygen. This
$^{P}CO_2$ $^{P}O_2$
problem may be solved by providing a gas mixture that has a high (or even pure oxygen, with a of 760 mm Hg). Blood gas measurements also provide information on the efficiency of gas $^{P}O_2$ $^{P}O_2$
exchange at the lungs. If the arterial remains low despite the administration of oxygen,
$^{P}O_2$
or if the P_{CO_2} is very high, pulmonary exchange problems, such as pulmonary edema, asthma, or pneumonia, must exist.

Gas Pickup and Delivery

Objectives

- Describe how oxygen is picked up, transported, and released in the blood.
- Discuss the structure and function of hemoglobin.
- Describe how carbon dioxide is transported in the blood.

Oxygen and carbon dioxide have limited solubilities in blood plasma. For example, at the normal PO_2 of alveoli, 100 ml of plasma will absorb only about 0.3 ml of oxygen. The limited solubilities of these gases are a problem, because peripheral tissues need more oxygen and generate more carbon dioxide than the plasma can absorb and transport.

The problem is solved by red blood cells (RBCs), which remove dissolved oxygen and CO_2 molecules from plasma and bind them (in the case of oxygen) or use them to manufacture soluble compounds (in the case of carbon dioxide). Because these reactions remove dissolved gases from blood plasma, gases continue to diffuse into the blood, but never reach equilibrium.

The important thing about these reactions is that they are both temporary and completely reversible. When plasma oxygen or carbon dioxide concentrations are high, the excess molecules are removed by RBCs. When plasma concentrations are falling, the RBCs release their stored reserves.

Oxygen Transport

Each 100 ml of blood leaving the alveolar capillaries carries away roughly 20 ml of oxygen. Of this amount, only about 0.3 ml (1.5 percent) consists of oxygen molecules in solution. The rest of the oxygen molecules are bound to *hemoglobin* (*Hb*) *molecules*—specifically, to the iron ions in the center of heme units. l**p. 645** Recall that the hemoglobin molecule consists of four globular protein subunits, each containing a heme unit. Thus, each hemoglobin molecule can bind four molecules of oxygen, forming oxy
hemoglobin (HbO2). This is a reversible reaction that can be summarized as
Hb + O2 Δ HbO2.

Each red blood cell has approximately 280 million molecules of hemoglobin. Because a hemoglobin molecule contains four heme units, each RBC potentially can carry more than a billion molecules of oxygen.

The percentage of heme units containing bound oxygen at any given moment is called the **hemoglobin saturation**. If all the Hb molecules in the blood are fully loaded with oxygen, saturation is 100 percent. If, on average, each Hb molecule carries two O_2 molecules, saturation is 50 percent.

In Chapter 2, we saw that the shape and functional properties of a protein change in response to changes in its environment. l**p. 52** Hemoglobin is no exception: Any changes in shape that occur can affect oxygen binding. Under normal conditions, the most important environmental factors affecting hemoglobin are (1) the PO_2 of blood, (2) blood pH, (3) temperature, and (4) ongoing metabolic activity within RBCs.

Hemoglobin and P_{O_2}

An **oxygen–hemoglobin saturation curve**, or *oxygen– hemoglobin dissociation curve*, is a graph that relates the saturation of hemoglobin to the partial pressure of oxygen (Figure 23–20•). The binding and dissociation of oxygen to hemoglobin is a typical reversible reaction. At equilibrium, oxygen molecules bind to heme at the same rate that other oxygen molecules are being released. If the PO_2 increases, the reaction shifts to the right, and more oxygen gets bound to hemoglobin. If the PO_2 decreases, the reaction shifts

to the left, and more oxygen is released by hemoglobin. The graph of this relationship is a curve rather than a straight line, because the shape of the Hb molecule changes slightly each time it binds an oxygen molecule, in a way that enhances its ability to bind *another* oxygen molecule. In other words, the attachment of the first oxygen molecule makes it easier to bind the second; binding the second promotes binding of the third; and binding of the third enhances binding of the fourth.

Because each arriving oxygen molecule increases the affinity of hemoglobin for the *next* oxygen molecule, the saturation curve takes the form shown in Figure 23–20•. Once the first oxygen molecule binds to the hemoglobin, the slope rises rapidly until reaching a plateau near 100 percent saturation. While the slope is steep, a very small change in plasma PO_2 will result in a large change in the amount of oxygen bound to Hb or released from HbO2. Because the curve rises quickly, hemoglobin will be more than 90 percent saturated if exposed to an alveolar PO_2 above 60 mm Hg. Thus, near-normal oxygen transport can continue despite a decrease in the oxygen content of alveolar air. Without this ability, you could not survive at high altitudes, and conditions significantly reducing pulmonary ventilation would be immediately fatal.

At normal alveolar pressures (PO_2 = 100 mm Hg) the hemoglobin saturation is very high (97.5 percent), although complete saturation does not occur until the PO_2 reaches excessively high levels (about 250 mm Hg). In functional terms, the maximum saturation is not as important as the ability of hemoglobin to provide oxygen over the normal PO_2 range in body tissues. Over that range—from 100 mm Hg at the alveoli to perhaps 15 mm Hg in active tissues—the saturation drops from 97.5 percent to less than 20 percent, and a small change in PO_2 makes a big difference in terms of the amount of oxygen bound to hemoglobin.

Note that the relationship between PO_2 and hemoglobin saturation remains valid whether the PO_2 is rising or falling. If the PO_2 increases, the saturation goes up and hemoglobin stores oxygen. If the PO_2 decreases, hemoglobin releases oxygen into its surroundings. When oxygenated blood arrives in the peripheral capillaries, the blood PO_2 declines rapidly as a result of gas exchange with the interstitial fluid. As the PO_2 falls, hemoglobin gives up its oxygen.

The relationship between the PO_2 and hemoglobin saturation provides a mechanism for automatic regulation of oxygen delivery. Inactive tissues have little demand for oxygen, and the local PO_2 is usually about 40 mm Hg. Under these conditions, hemoglobin will not release much oxygen. As it passes through the capillaries, it will go from 97 percent saturation (PO_2 = 95 mm Hg) to 75 percent saturation (PO_2 = 40 mm Hg). Because it still retains three-quarters of its oxygen, venous blood has a relatively large oxygen reserve. This reserve is important, because it can be mobilized if tissue oxygen demands increase.

Active tissues consume oxygen at an accelerated rate, so the PO_2 may drop to 15–20 mm Hg. Hemoglobin passing through these capillaries will then go from 97 percent saturation to about 20 percent saturation. In practical terms, this means that as blood circulates through peripheral capillaries, active tissues will receive 3.5 times as much oxygen as will inactive tissues.

The exhaust of automobiles and other petroleum-burning engines, of oil lamps, and of fuel-fired space heaters contains *carbon monoxide* (CO), and each winter entire families die from *carbon monoxide poisoning*. Carbon monoxide competes with oxygen molecules for the binding sites on heme units. Unfortunately, the carbon monoxide usually wins the competition, because at very low partial pressures it has a much stronger affinity for hemoglobin than does oxygen. The bond formed between CO and heme is extremely durable, so the attachment of a CO molecule essentially makes that heme unit inactive for respiratory purposes.

Hemoglobin and pH

The oxygen–hemoglobin saturation curve in Figure 23–20• was determined in normal blood, with a pH of 7.4 and a temperature of 37°C. In addition to consuming oxygen, active tissues generate acids that lower the pH of the interstitial fluid. When the pH drops, the shape of hemoglobin molecules changes. As a result of this change, the molecules release their oxygen reserves more readily, so the slope of the hemoglobin saturation curve changes (Figure 23–21a•). In other words, as pH drops, the saturation declines. At a tissue PO_2 of 40 mm Hg, for example, a pH drop from 7.4 to 7.2 changes hemoglobin saturation from 75 percent to 60 percent. This means that hemoglobin molecules will release 20 percent more oxygen in peripheral tissues at a pH of 7.2 than they will at a pH of 7.4. This effect of pH on the hemoglobin saturation curve is called the **Bohr effect**. Carbon dioxide is the primary compound responsible for the Bohr effect. When CO_2 diffuses into the blood, it rapidly diffuses into red blood cells. There, an enzyme called **carbonic anhydrase** catalyzes the reaction of CO_2 with water molecules:

The product of this enzymatic reaction, $H2CO3$, is called *carbonic acid*, because it dissociates into a hydrogen ion (H^+) and a bicarbonate ion ($HCO3^-$). The rate of carbonic acid formation depends on the amount of carbon dioxide in solution, which, as noted earlier, depends on the PCO_2. When the PCO_2 rises, the reaction proceeds from left to right, and the rate of carbonic acid formation accelerates. The hydrogen ions that are generated diffuse out of the RBCs, and the pH of the plasma drops. When the PCO_2 declines, the reaction proceeds from right to left; hydrogen ions then diffuse into the RBCs, so the pH of the plasma rises.

Hemoglobin and Temperature

Changes in temperature also affect the slope of the hemoglobin saturation curve (Figure 23–21b•). As the temperature rises, hemoglobin releases more oxygen; as the temperature declines, hemoglobin holds oxygen more tightly. Temperature effects are significant only in active tissues in which large amounts of heat are being generated. For example, active skeletal muscles generate heat, and the heat warms blood that flows through these organs. As the blood warms, the Hb molecules release more oxygen than can be used by the active muscle fibers.

Hemoglobin and BPG

Red blood cells, which lack mitochondria, produce adenosine triphosphate (ATP) only by glycolysis, in which, as we saw in Chapter 10, lactic acid is formed. l**p. 310** The metabolic pathways involved in glycolysis in an RBC also generate the compound

2,3-bisphosphoglycerate (biz-fos-f
ō
-GLIS-er-
ā
t), or **BPG**. Normal RBCs always contain BPG, which has a direct effect on oxygen binding and release. For any partial pressure of oxygen, the higher the concentration of BPG, the more oxygen will be released by Hb molecules.

The concentration of BPG can be increased by thyroid hormones, growth hormone, epinephrine, androgens, and high blood pH. These factors improve oxygen delivery to the tissues, because when BPG levels are elevated, hemoglobin releases about 10 percent more oxygen at a given PO_2 than it would otherwise. Both BPG synthesis and the Bohr effect improve oxygen delivery when the pH changes: BPG levels rise when the pH increases, and the Bohr effect appears when the pH decreases.

The production of BPG decreases as RBCs age. Thus, the level of BPG can determine how long a blood bank can store fresh whole blood. When BPG levels get too low, hemoglobin becomes firmly bound to the available oxygen. The blood is then useless for transfusions, because the RBCs will no longer release oxygen to peripheral tissues, even at a disastrously low PO_2.

Fetal Hemoglobin

The RBCs of a developing fetus contain **fetal hemoglobin**. The structure of fetal hemoglobin differs from that of adult hemoglobin, giving it a much higher affinity for oxygen. At the same PO_2, fetal hemoglobin binds more oxygen than does adult hemoglobin (Figure 23–22•). This trait is important in transferring oxygen across the placenta.

A fetus obtains oxygen from the maternal bloodstream. At the placenta, maternal blood has a relatively low PO_2, ranging from 35 to 50 mm Hg. If maternal blood arrives at the placenta with a PO_2 of 40 mm Hg, hemoglobin saturation will be roughly 75 percent. The fetal blood arriving at the placenta has a PO_2 close to 20 mm Hg. However, because fetal hemoglobin has a higher affinity for oxygen, it is still 58 percent saturated.

As diffusion occurs between fetal blood and maternal blood, oxygen enters the fetal bloodstream until the PO_2 equilibrates at 30 mm Hg. At this PO_2, the maternal hemoglobin is less than 60 percent saturated, but the fetal hemoglobin is over 80 percent saturated. The steep slope of the saturation curve for fetal hemoglobin means that when fetal RBCs reach peripheral tissues, the Hb molecules will release a large amount of oxygen in response to a very small change in PO_2.

100 Keys | Hemoglobin within RBCs carries most of the oxygen in the bloodstream, and it releases it in response to changes in the oxygen partial pressure in the surrounding plasma. If the PO_2 increases, hemoglobin binds oxygen; if the PO_2 decreases, hemoglobin releases oxygen. At a given PO_2, hemoglobin will release additional oxygen if the pH decreases or the temperature increases.

Carbon Dioxide Transport

Carbon dioxide is generated by aerobic metabolism in peripheral tissues. After entering the bloodstream, a CO_2 molecule is either

(1) converted to a molecule of carbonic acid, (2) bound to the protein portion of hemoglobin molecules within red blood cells, or

(3) dissolved in plasma. All three reactions are completely reversible. We will consider the events that occur as blood enters peripheral tissues in which the PCO_2 is 45 mm Hg.

Carbonic Acid Formation

Most of the carbon dioxide absorbed by blood (roughly 70 percent of the total) is transported as molecules of carbonic acid. Carbon dioxide is converted to carbonic acid through the activity of the enzyme carbonic anhydrase in RBCs. The carbonic acid molecules immediately dissociate into a hydrogen ion and a bicarbonate ion, as described earlier (p. 845). Hence, we can ignore the intermediate steps in this sequence and summarize the reaction as

carbonic anhydrase $CO_2 + H_2O$ ERF $H^+ + HCO_3^-$.

This reaction is completely reversible. In peripheral capillaries, it proceeds vigorously, tying up large numbers of CO_2 molecules. The reaction continues as carbon dioxide diffuses out of the interstitial fluids.

The hydrogen ions and bicarbonate ions have different fates. Most of the hydrogen ions bind to hemoglobin molecules, forming HbH^+ . The Hb molecules thus function as pH buffers, tying up the released hydrogen ions before the ions can leave the RBCs and lower the plasma pH. The bicarbonate ions move into the surrounding plasma with the aid of a countertransport mechanism that exchanges intracellular bicarbonate ions ($HCO3^-$) for extracellular chloride ions (Cl^-). This exchange, which trades one anion for another, does not require ATP. The result is a mass movement of chloride ions into the RBCs, an event known as the **chloride shift**.

Binding to Hemoglobin

Roughly 23 percent of the carbon dioxide carried by blood is bound to the globular protein portions of Hb molecules inside RBCs. These CO_2 molecules are attached to exposed amino groups (¬ NH2) of the Hb molecules. The resulting compound is called **carbaminohemoglobin** (kar-bam-i-no-he-mo-glo-bin), $HbCO_2$. The reversible reaction is summarized as follows:

CO2 + HbNH2 Δ HbNHCOOH

This reaction can be abbreviated without the amino groups as

CO2 + Hb Δ HbCO2.

Transport in Plasma

Plasma becomes saturated with carbon dioxide quite rapidly, and only about 7 percent of the carbon dioxide absorbed by peripheral capillaries is transported as dissolved gas molecules. The rest is absorbed by the RBCs for conversion by carbonic anhydrase or storage as carbaminohemoglobin.

Mechanisms of carbon dioxide transport are summarized in Figure 23–23•.

Note that the relationship between PO_2 and hemoglobin saturation remains valid whether the PO_2 is rising or falling. If the

PO_2 increases, the saturation goes up and hemoglobin

stores oxygen. If the PO_2 decreases, hemoglobin releases oxygen into its surroundings. When oxygenated blood arrives in the peripheral capillaries, the blood PO_2 declines rapidly as a result of gas exchange with the interstitial fluid. As the PO_2 falls, hemoglobin gives up its

oxygen.

The relationship between the PO_2 and hemoglobin saturation provides a mechanism for automatic regulation of oxygen de livery. Inactive tissues have little demand for oxygen, and the local PO_2 is usually about 40 mm Hg. Under these conditions, hemoglobin will not release much oxygen. As it passes through the capillaries, it will go from 97 percent saturation (PO_2 = 95 mm Hg) to 75 percent saturation (PO_2 = 40 mm Hg). Because it still retains three-quarters of its oxygen, venous blood has a relatively large oxygen reserve. This reserve is important, because it can be mobilized if tissue oxygen demands increase.

Active tissues consume oxygen at an accelerated rate, so the PO_2 may drop to 15–20 mm Hg. Hemoglobin passing through these capillaries will then go from 97 percent saturation to about 20 percent saturation. In practical terms, this means that as blood circulates through peripheral capillaries, active tissues will receive 3.5 times as much oxygen as will inactive tissues.

The exhaust of automobiles and other petroleum-burning engines, of oil lamps, and of fuel-fired space heaters contains *carbon monoxide* (CO), and each winter entire families die from *carbon monoxide poisoning*. Carbon monoxide competes with oxygen molecules for the binding sites on heme units. Unfortunately, the carbon monoxide usually wins the competition, because at very low partial pressures it has a much stronger affinity for hemoglobin than does oxygen. The bond formed between CO and heme is extremely durable, so the attachment of a CO molecule essentially makes that heme unit inactive for respiratory purposes.

Hemoglobin and pH

The oxygen–hemoglobin saturation curve in Figure 23–20• was determined in normal blood, with a pH of 7.4 and a temperature of 37°C. In addition to consuming oxygen, active tissues generate acids that lower the pH of the interstitial fluid. When the pH drops, the shape of hemoglobin molecules changes. As a result of this change, the molecules release their oxygen reserves more readily, so the slope of the hemoglobin saturation curve changes (Figure 23–21a•). In other words, as pH drops, the saturation declines. At a tissue PO_2 of 40 mm Hg, for example, a pH drop from 7.4 to 7.2 changes hemoglobin saturation from 75 percent to 60 percent. This means that hemoglobin molecules will release 20 percent more oxygen in peripheral tissues at a pH of 7.2 than they will at a pH of 7.4. This effect of pH on the hemoglobin saturation curve is called the **Bohr effect**. Carbon dioxide is the primary compound responsible for the Bohr effect. When CO_2 diffuses into the blood, it rapidly diffuses into red blood cells. There, an enzyme called **carbonic anhydrase** catalyzes the reaction of CO_2 with water molecules:

carbonic anhydrase $CO_2 + H_2O$ ERF $H_2CO_3 \Delta H^+ + HCO_3$

The product of this enzymatic reaction, H2CO3, is called *carbonic acid*, because it dissociates into a hydrogen ion (H^+) and a bicarbonate ion ($HCO3^-$). The rate of carbonic acid formation depends on the amount of carbon dioxide in solution, which, as noted earlier, depends on the PCO_2. When the PCO_2 rises, the reaction proceeds from left to right, and the rate of carbonic acid forma

tion accelerates. The hydrogen ions that are generated diffuse out of the RBCs, and the pH of the plasma drops. When the PCO_2 declines, the reaction proceeds from right to left; hydrogen ions then diffuse into the RBCs, so the pH of the plasma rises.

Hemoglobin and Temperature

Changes in temperature also affect the slope of the hemoglobin saturation curve (Figure 23–21b•). As the temperature rises, hemoglobin releases more oxygen; as the temperature declines, hemoglobin holds oxygen more tightly. Temperature effects are significant only in active tissues in which large amounts of heat are being generated. For example, active skeletal muscles generate heat, and the heat warms blood that flows through these organs. As the blood warms, the Hb molecules release more oxygen than can be used by the active muscle fibers.

Hemoglobin and BPG

Red blood cells, which lack mitochondria, produce adenosine triphosphate (ATP) only by glycolysis, in which, as we saw in Chapter 10, lactic acid is formed. l**p. 310** The metabolic pathways involved in glycolysis in an RBC also generate the compound

2,3-bisphosphoglycerate (biz-fos-f

‾o

-GLIS-er-

‾a

t), or **BPG**. Normal RBCs always contain BPG, which has a direct effect on oxy

gen binding and release. For any partial pressure of oxygen, the higher the concentration of BPG, the more oxygen will be released by Hb molecules.

The concentration of BPG can be increased by thyroid hormones, growth hormone, epinephrine, androgens, and high blood pH. These factors improve oxygen delivery to the tissues, because when BPG levels are elevated, hemoglobin releases about 10 percent more oxygen at a given PO_2 than it would otherwise. Both BPG synthesis and the Bohr effect improve oxygen delivery

when the pH changes: BPG levels rise when the pH increases, and the Bohr effect appears when the pH decreases.

and respiratory rates increase under neural control, but the adjustments in alveolar blood flow and bronchiole diameter occur automatically.

Review gas exchange on the **IP CD-ROM: Respiratory System/Gas Exchange.**

The Respiratory Centers of the Brain

Respiratory control has both involuntary and voluntary components. Your brain’s involuntary centers regulate the activities of the respiratory muscles and control the respiratory minute volume by adjusting the frequency and depth of pulmonary ventilation. They do so in response to sensory information arriving from your lungs and other portions of the respiratory tract, as well as from a variety of other sites.

The voluntary control of respiration reflects activity in the cerebral cortex that affects either the output of the respiratory centers in the medulla oblongata and pons or of motor neurons in the spinal cord that control respiratory muscles. The **respiratory centers** are three pairs of nuclei in the reticular formation of the medulla oblongata and pons. The motor neurons in the spinal cord are generally controlled by *respiratory reflexes*, but they can also be controlled voluntarily through commands delivered by the corticospinal pathway. l**p. 509**

Respiratory Centers in the Medulla Oblongata

The *respiratory rhythmicity centers* of the medulla oblongata were introduced in Chapter 14. l**p. 459** These paired centers set the pace of respiration. Each center can be subdivided into a **dorsal respiratory group (DRG)** and a **ventral respiratory group (VRG)**. The DRG's *inspiratory center* contains neurons that control lower motor neurons innervating the external intercostal muscles and the diaphragm. The DRG functions in every respiratory cycle, whether quiet or forced. The VRG functions only during forced breathing. It includes neurons that innervate lower motor neurons controlling accessory respiratory muscles involved in active exhalation (an *expiratory center*) and maximal inhalation (an *inspiratory center*).

Reciprocal inhibition occurs between the neurons involved with inhalation and exhalation. l**p. 443** When the inspiratory neurons are active, the expiratory neurons are inhibited, and vice versa. The pattern of interaction between these groups differs between quiet breathing and forced breathing. During quiet breathing (Figure 23–25a•):

- Activity in the DRG increases over a period of about 2 seconds, providing stimulation to the inspiratory muscles. Over this period, inhalation occurs.
- After 2 seconds, the DRG neurons become inactive. They remain quiet for the next 3 seconds and allow the inspiratory muscles to relax. Over this period, passive exhalation occurs.

During forced breathing (Figure 23–25b•):

- Increases in the level of activity in the DRG stimulate neurons of the VRG that activate the accessory muscles involved in inhalation.
- After each inhalation, active exhalation occurs as the neurons of the expiratory center stimulate the appropriate accessory muscles.

The basic pattern of respiration thus reflects a cyclic interaction between the DRG and the VRG. The pace of this interaction is thought to be established by pacemaker cells that spontaneously undergo rhythmic patterns of activity. Attempts to locate the pacemaker, however, have been unsuccessful.

Central nervous system stimulants, such as amphetamines or even caffeine, increase the respiratory rate by facilitating the respiratory centers. These actions are opposed by CNS depressants, such as barbiturates or opiates.

The Apneustic and Pneumotaxic Centers of the Pons

The **apneustic** (ap-NOO-stik) **centers** and the **pneumotaxic** (noo-mo¯-TAKS-ik) **centers** of the pons are paired nuclei that adjust the output of the respiratory rhythmicity centers. Their activities regulate the respiratory rate and the depth of respiration in response to sensory stimuli or input from other centers in the brain. Each apneustic center provides continuous stimulation to the DRG on that side of the brain stem. During quiet breathing, stimulation from the apneustic center helps increase the intensity of inhalation over the next 2 seconds. Under normal conditions, after 2 seconds the apneustic center is inhibited by signals from the pneumotaxic center on that side. During forced breathing, the apneustic centers also respond to sensory input from the vagus nerves regarding the amount of lung inflation.

The pneumotaxic centers inhibit the apneustic centers and promote passive or active exhalation. Centers in the hypothalamus and cerebrum can alter the activity of the pneumotaxic centers, as well as the respiratory rate and depth. However, essentially normal respiratory cycles continue even if the brain stem superior to the pons has been severely damaged. If the inhibitory output of the pneumotaxic centers is cut off by a stroke or other damage to the brain stem, and if sensory innervation from the lungs is eliminated due to damage to the vagus nerves, the person inhales to maximum capacity and maintains that state for 10–20 seconds at a time. Intervening exhalations are brief, and little pulmonary ventilation occurs.

The CNS regions involved with respiratory control are diagrammed in Figure 23–26•. Interactions between the DRG and the VRG establish the basic pace and depth of respiration. The pneumotaxic centers modify that pace: An increase in pneumotaxic output quickens the pace of respiration by shortening the duration of each inhalation; a decrease in pneumotaxic output slows the respiratory pace, but increases the depth of respiration, because the apneustic centers are more active.

Sudden infant death syndrome (SIDS), also known as *crib death*, kills an estimated 10,000 infants each year in the United States alone. Most crib deaths occur between midnight and 9:00 A.M., in the late fall or winter, and involve infants 2 to 4 months old. Eyewitness accounts indicate that the sleeping infant suddenly stops breathing, turns blue, and relaxes. Genetic factors appear to be involved, but controversy remains as to the relative importance of other factors. The age at the time of death corresponds with a period when the pacemaker complex and respiratory centers are establishing connections with other portions of the brain. It has been suggested that SIDS results from a problem in the interconnection process that disrupts the reflexive respiratory pattern.

Respiratory Reflexes

The activities of the respiratory centers are modified by sensory information from several sources:

- Chemoreceptors sensitive to the PCO_2, pH, or PO_2 of the blood or cerebrospinal fluid.
- Baroreceptors in the aortic or carotid sinuses sensitive to changes in blood pressure.
- Stretch receptors that respond to changes in the volume of the lungs.
- Irritating physical or chemical stimuli in the nasal cavity, larynx, or bronchial tree.
- Other sensations, including pain, changes in body temperature, and abnormal visceral sensations. Information from these receptors alters the pattern of respiration. The induced changes have been called *respiratory reflexes*.

The Chemoreceptor Reflexes

The respiratory centers are strongly influenced by chemoreceptor inputs from cranial nerves IX and X, and from receptors that monitor the composition of the cerebrospinal fluid (CSF):

- The glossopharyngeal nerve (IX) carries chemoreceptive information from the carotid bodies, adjacent to the carotid sinus.

l**pp. 502, 741** The carotid bodies are stimulated by a decrease in the pH or PO_2 of blood. Because changes in PCO_2 affect pH, these receptors are indirectly stimulated by a rise in the PCO_2.

- The vagus nerve (X) monitors chemoreceptors in the aortic bodies, near the aortic arch. l**pp. 502, 738** These receptors are sensitive to the same stimuli as the carotid bodies. Carotid and aortic body receptors are often called *peripheral chemoreceptors*.
- Chemoreceptors are located on the ventrolateral surface of the medulla oblongata in a region known as the *chemosensitive area*. The neurons in that area respond only to the PCO_2 and pH of the CSF and are often called *central chemoreceptors*.

Chemoreceptors and their effects on cardiovascular function were discussed in Chapters 15 and 21. l**pp. 502, 728–729** Stimulation of these chemoreceptors leads to an increase in the depth and rate of respiration. Under normal conditions, a drop in arterial PO_2 has little effect on the respiratory centers, until the arterial PO_2 drops by about 40 percent, to below 60 mm Hg. If the PO_2 of arterial blood drops to 40 mm Hg (the level in peripheral tissues), the respiratory rate increases by only 50–70 percent. In contrast, a rise of just 10 percent in the arterial PCO_2 causes the respiratory rate to double, even if the PO_2 remains completely normal. Carbon dioxide levels are therefore responsible for regulating respiratory activity under normal conditions.

Although the receptors monitoring CO_2 levels are more sensitive, oxygen and carbon dioxide receptors work together in a crisis. Carbon dioxide is generated during oxygen consumption, so when oxygen concentrations are falling rapidly, CO_2 levels are usually increasing. This cooperation breaks down only under unusual circumstances. For example, you can hold your breath longer than normal by taking deep, full breaths, but the practice is very dangerous. The danger lies in the fact that the increased ability is due not to extra oxygen, but to less carbon dioxide. If the PCO_2 is driven down far enough, your ability to hold your breath can increase to the point at which you become unconscious from oxygen starvation in the brain without ever feeling the urge to breathe. AM: Shallow-Water Blackout

The chemoreceptors are subject to adaptation—a decrease in sensitivity after chronic stimulation—if the PO_2 or PCO_2 remains abnormal for an extended period. This adaptation can complicate the treatment of chronic respiratory disorders. For example, if the PO_2 remains low for an extended period while the PCO_2 remains chronically elevated, the chemoreceptors will reset to those values and will oppose any attempts to return the partial pressures to the proper range. AM: Chemoreceptor Accommodation and Opposition

Because the chemoreceptors monitoring CO_2 levels are also sensitive to pH, any condition altering the pH of blood or CSF will affect respiratory performance. The rise in lactic acid levels after exercise, for example, causes a drop in pH that helps stimulate respiratory activity.

Hypercapnia and Hypocapnia An increase in the PCO_2 of arterial blood constitutes **hypercapnia**. Figure 23–27a• diagrams the central response to hypercapnia, which is triggered by the stimulation of chemoreceptors in the carotid and aortic bodies and is reinforced by the stimulation of CNS chemoreceptors. Carbon dioxide crosses the blood–brain barrier quite rapidly, so a rise in arterial PCO_2 almost immediately elevates CO_2 levels in the CSF, lowering the pH of the CSF and stimulating the chemoreceptive neurons of the medulla oblongata.

These receptors stimulate the respiratory centers to increase the rate and depth of respiration. Your breathing becomes more rapid, and more air moves into and out of your lungs with each breath. Because more air moves into and out of the alveoli each minute, alveolar concentrations of carbon dioxide decline, accelerating the diffusion of carbon dioxide out of alveolar capillaries. Thus, homeostasis is restored.

The most common cause of hypercapnia is hypoventilation. In **hypoventilation**, the respiratory rate remains abnormally low and is insufficient to meet the demands for normal oxygen delivery and carbon dioxide removal. Carbon dioxide then accumulates in the blood.

If the rate and depth of respiration exceed the demands for oxygen delivery and carbon dioxide removal, the condition called **hyperventilation** exists. Hyperventilation gradually leads to **hypocapnia**, an abnormally low PCO_2. If the arterial PCO_2 drops below normal levels, chemoreceptor activity decreases and the respiratory rate falls (Figure 23–27b•). This situation continues until the PCO_2 returns to normal and homeostasis is restored.

The Baroreceptor Reflexes

The effects of carotid and aortic baroreceptor stimulation on systemic blood pressure were described in Chapter 21. l**p. 728** The output from these baroreceptors also affects the respiratory centers. When blood pressure falls, the respiratory rate increases; when blood pressure rises, the respiratory rate declines. This adjustment results from the stimulation or inhibition of the respiratory centers by sensory fibers in the glossopharyngeal (IX) and vagus (X) nerves.

The Hering–Breuer Reflexes

The **Hering–Breuer reflexes** are named after the physiologists who described them in 1865. The sensory information from these reflexes is distributed to the apneustic centers and the ventral respiratory group. The Hering–Breuer reflexes are not involved in normal quiet breathing (eupnea) or in tidal volumes under 1000 ml. There are two such reflexes:

1. The **inflation reflex** prevents overexpansion of the lungs during forced breathing. Stretch receptors located in the smooth muscle tissue around bronchioles are stimulated by lung expansion. Sensory fibers leaving the stretch receptors of each lung reach the respiratory rhythmicity center on the same side via the vagus nerve. As lung volume increases, the dorsal respiratory group is gradually inhibited, and the expiratory center of the VRG is stimulated. Inhalation stops as the lungs near maximum volume, and active exhalation then begins.

2. The **deflation reflex** inhibits the expiratory centers and stimulates the inspiratory centers when the lungs are deflating. These receptors, which are distinct from those of the inflation reflex, are located in the alveolar wall near the alveolar capillary network. The smaller the volume of the lungs, the greater the degree of inhibition, until exhalation stops and inhalation begins. This reflex normally functions only during forced exhalation, when both the inspiratory and expiratory centers are active.

Protective Reflexes

Protective reflexes operate when you are exposed to toxic vapors, chemical irritants, or mechanical stimulation of the respiratory tract. The receptors involved are located in the epithelium of the respiratory tract. Examples of protective reflexes include sneezing, coughing, and laryngeal spasms.

Sneezing is triggered by an irritation of the nasal cavity wall. Coughing is triggered by an irritation of the larynx, trachea, or bronchi. Both reflexes involve **apnea** (AP-n -uh), a period in which respiration is suspended. They are usually followed by a force-
e¯ful expulsion of air to remove the offending stimulus. The glottis is forcibly closed while the lungs are still relatively full. The abdominal and internal intercostal muscles then contract suddenly, creating pressures that blast air out of the respiratory passageways when the glottis reopens. Air leaving the larynx can travel at 160 kph (99 mph), carrying mucus, foreign particles, and irritating gases out of the respiratory tract via the nose or mouth.

Laryngeal spasms result from the entry of chemical irritants, foreign objects, or fluids into the area around the glottis. This reflex generally closes the airway temporarily. A very strong stimulus, such as a toxic gas, could close the glottis so powerfully that you could lose consciousness and die without taking another breath. Fine chicken bones or fish bones that pierce the laryngeal walls can also stimulate laryngeal spasms, swelling, or both, restricting the airway.

Voluntary Control of Respiration

Activity of the cerebral cortex has an indirect effect on the respiratory centers, as the following examples show:

- Conscious thought processes tied to strong emotions, such as rage or fear, affect the respiratory rate by stimulating centers in the hypothalamus.
- Emotional states can affect respiration through the activation of the sympathetic or parasympathetic division of the autonomic nervous system. Sympathetic activation causes bronchodilation and increases the respiratory rate; parasympathetic stimulation has the opposite effect.
- An anticipation of strenuous exercise can trigger an automatic increase in the respiratory rate, along with increased cardiac output, by sympathetic stimulation.

Conscious control over respiratory activities may bypass the respiratory centers completely, using pyramidal fibers that innervate the same lower motor neurons that are controlled by the DRG and VRG. This control mechanism is an essential part of speaking, singing, and swimming, when respiratory activities must be precisely timed. Higher centers can also have an inhibitory effect on the apneustic centers and on the DRG and VRG; this effect is important when you hold your breath.

Your abilities to override the respiratory centers have limits, however. The chemoreceptor reflexes are extremely powerful respiratory stimulators, and they cannot be consciously suppressed. For example, you cannot kill yourself by holding your breath “till you turn blue.” Once the PCO_2 rises to critical levels, you will be forced to take a breath.

100 Keys | A basic pace of respiration is established by the interplay between respiratory centers in the pons and medulla oblongata. That pace is modified in response to input from chemoreceptors, baroreceptors, and stretch receptors. In general, carbon dioxide levels, rather than oxygen levels, are the primary drivers of respiratory activity. Respiratory activity can also be interrupted by protective reflexes and adjusted by the conscious control of respiratory muscles.

Changes in the Respiratory System at Birth

The respiratory systems of fetuses and newborns differ in several important ways. Before delivery, pulmonary arterial resistance is high, because the pulmonary vessels are collapsed. The rib cage is compressed, and the lungs and conducting passageways contain only small amounts of fluid and no air. During delivery, the lungs are compressed further, and as the placental connection is lost, blood oxygen levels fall and carbon dioxide levels climb rapidly. At birth, the newborn infant takes a truly heroic first breath through powerful contractions of the diaphragmatic and external intercostal muscles. The inhaled air must enter the respiratory passageways with enough force to overcome surface tension and inflate the bronchial tree and most of the alveoli. The same drop in pressure that pulls air into the lungs pulls blood into the pulmonary circulation. The changes in blood flow that occur lead to the closure of the *foramen ovale*, an interatrial connection, and the *ductus arteriosus*, the fetal connection between the pulmonary trunk and the aorta. l**p. 754** ATLAS: Embryology Summary 18: The Development of the Respiratory System

The exhalation that follows fails to empty the lungs completely, because the rib cage does not return to its former, fully compressed state. Cartilages and connective tissues keep the conducting passageways open, and surfactant covering the alveolar surfaces prevents their collapse. Subsequent breaths complete the inflation of the alveoli. Pathologists sometimes use these physical changes to determine whether a newborn infant died before delivery or shortly thereafter. Before the first breath, the lungs are completely filled with amniotic fluid, and extracted lungs will sink if placed in water. After the infant's first breath, even the collapsed lungs contain enough air to keep them afloat.

Aging and the Respiratory System

Many factors interact to reduce the efficiency of the respiratory system in elderly individuals. Three examples are particularly noteworthy:

1. As one's age increases, elastic tissue deteriorates throughout the body, reducing the compliance of the lungs and lowering their vital capacity.

2. Chest movements are restricted by arthritic changes in the rib articulations and by decreased flexibility at the costal cartilages. Along with the changes in item 1, the stiffening and reduction in chest movement effectively limit the respiratory minute volume. This restriction contributes to the reduction in exercise performance and capabilities with increasing age.

3. Some degree of emphysema is normal in individuals over age 50. However, the extent varies widely with the lifetime exposure to cigarette smoke and other respiratory irritants. Figure 23–28• compares the respiratory performance of individuals who have never smoked with individuals who have smoked for various periods of time. The message is quite clear: Although some decrease in respiratory performance is inevitable, you can prevent serious respiratory deterioration by stopping smoking or never starting.

Concept Check

☐ What effect does exciting the pneumotaxic centers have on respiration?

☐ Are peripheral chemoreceptors as sensitive to levels of carbon dioxide as they are to levels of oxygen?

☐ Little Johnny is angry with his mother, so he tells her that he will hold his breath until he turns blue and dies. Should Johnny's mother worry?

Answers begin on p. A–1

Review respiratory controls on the **IP CD-ROM: Respiratory System/Control of Respiration.**

Integration with Other Systems

The goal of respiratory activity is to maintain homeostatic oxygen and carbon dioxide levels in peripheral tissues. Changes in respiratory activity alone are seldom sufficient to accomplish this; coordinated changes in cardiovascular activity must also occur.

Consider these examples of the integration between the respiratory and cardiovascular systems:

- At the local level, changes in lung perfusion in response to changes in alveolar PO_2 improve the efficiency of gas exchange within or among lobules.
- Chemoreceptor stimulation not only increases the respiratory drive; it also causes an elevation in blood pressure and increased cardiac output.
- The stimulation of baroreceptors in the lungs has secondary effects on cardiovascular function. For example, the stimulation of airway stretch receptors not only triggers the inflation reflex, but also increases heart rate. Thus, as the lungs fill, cardiac output rises and more blood flows through the alveolar capillaries.

The adaptations that occur at high altitudes provide an excellent example of the functional interplay between the respiratory and cardiovascular systems. Atmospheric pressure decreases with increasing altitude, and so do the partial pressures of the component gases, including oxygen. People living in Denver or Mexico City function normally with alveolar oxygen pressures in the 80–90 mm Hg range. At higher elevations, alveolar PO_2 is even lower. At 3300 meters (10,826 ft), an altitude many hikers and skiers have experienced, alveolar PO_2 is about 60 mm Hg.

Despite the low alveolar PO_2, millions of people live and work at altitudes this high or higher. Important physiological adjustments include increased respiratory rate, increased heart rate, and elevated hematocrit. Thus, even though the hemoglobin is not fully saturated, the bloodstream holds more of it, and the round trip between the lungs and the peripheral tissues takes less time. However, most such adaptations take days to weeks to develop. As a result, athletes planning to compete in events held at high altitude must begin training under such conditions well in advance. AM: Mountain Sickness

The respiratory system is functionally linked to all other systems as well. Figure 23–29• illustrates these interrelationships.

Clinical Patterns

Disorders affecting the respiratory system may (1) interfere with the movement of air along the respiratory passageways, (2) impede the diffusion of gases at the respiratory membrane, or (3) reduce the normal circulation of blood through the alveolar capillaries.

These problems can result from trauma, congenital or degenerative problems, tumors, inflammation, or infection of the lungs. Illnesses caused by infections of the upper respiratory tract include some of the most common diseases, such as the “common cold” and influenza. Infections of the lower respiratory tract include two of the deadliest diseases in human history: pneumonia and tuberculosis. Respiratory system disorders also occur secondarily, as a consequence of dysfunctions of other body systems. For instance, asthma is the result of a problem with immune function, and pulmonary emboli result from cardiovascular problems affecting lung perfusion. You will find details on specific disorders and their classification in the *Applications Manual*.

Chapter Review

Selected Clinical Terminology

anoxia: A condition of tissue oxygen starvation caused by (1) circulatory blockage, (2) respiratory problems, or (3) cardiovascular problems. (p. 830)

asthma: An acute respiratory disorder characterized by unusually sensitive, irritated conducting airways. (p. 826)

atelectasis: A collapsed lung. (p. 834)

bronchitis: An inflammation of the bronchial lining. (p. 826 and [AM])

bronchodilation: An enlargement of the respiratory passageways. (p. 826)

bronchography: A procedure in which radiopaque materials are introduced into the airways to improve x-ray imaging of the bronchial tree. [AM]

bronchoscope: A fiber-optic bundle small enough to be inserted into the trachea and finer airways; the procedure is called *bronchoscopy*. [AM]

cardiopulmonary resuscitation (CPR): The application of cycles of compression to the rib cage and mouth-to-mouth breathing to maintain cardiovascular and respiratory function. [AM]

cystic fibrosis (CF): A lethal inherited disease caused by an abnormal membrane channel protein; mucous secretions become too thick to be transported easily, leading to respiratory problems. (p. 815 and [AM])

decompression sickness, or *the bends***:** A condition caused by a rapid drop in atmospheric pressure and the resulting formation of nitrogen gas bubbles in body fluids, tissues, and organs. (p. 840 and [AM])

emphysema: A chronic, progressive condition characterized by shortness of breath and an inability to tolerate physical exertion. (p. 853 and [AM])

epistaxis: A nosebleed. (p. 819)

Heimlich maneuver, or *abdominal thrust***:** Compression applied to the abdomen just inferior to the diaphragm, to force air out of the lungs to clear a blocked trachea or larynx. [AM]

hypercapnia: An increase in the PCO_2 of arterial blood. (p. 851)

hypocapnia: An abnormally low arterial PCO_2. (p. 852)

hypoxia: A condition of reduced tissue PO_2. (p. 830)

lung cancer *(pleuropulmonary neoplasm)***:** A class of aggressive malignancies originating in the bronchial passageways or alveoli. (p. 853

and [AM]) **mountain sickness:** An acute disorder resulting from CNS effects due to the low gas partial pressures that occur at high altitudes. [AM] **pleurisy:** An inflammation of the pleurae, accompanied by the secretion of excess amounts of pleural fluid. (p. 829) **pneumonia:** A respiratory disorder characterized by fluid leakage into the alveoli or swelling and constriction of the respiratory bronchioles. (p. 827) **pneumothorax:** The entry of air into the pleural cavity. (p. 834) **pulmonary embolism:** Blockage of a branch of a pulmonary artery, with interruption of blood flow to a group of lobules or alveoli.

(p. 829) **respiratory distress syndrome:** A condition resulting from the production of inadequate surfactant and associated alveolar collapse.

(p. 827 and [AM]) **sudden infant death syndrome (SIDS),** or *crib death***:** The death of an infant due to respiratory arrest; the cause remains unclear.

(p. 849) **tracheostomy:** The insertion of a tube directly into the trachea to bypass a blocked or damaged larynx. [AM] **tuberculosis:** A respiratory disorder caused by infection of the lungs by the bacterium *Mycobacterium tuberculosis*. (p. 815 and [AM])

Study Outline

1. Body cells must obtain oxygen and eliminate carbon dioxide. The respiratory surfaces where gas exchange occurs are inside the lungs.

The Respiratory System: An Introduction p. 814 Functions of the Respiratory System p. 814

1. The functions of the **respiratory system** include (1) providing an area for gas exchange between air and circulating blood; (2) moving air to and from exchange surfaces; (3) protecting respiratory surfaces from environmental variations and defending the respiratory system and other tissues from invasion by pathogens; (4) producing sounds; and (5) facilitating the detection of olfactory stimuli.

Organization of the Respiratory System p. 814

2. The respiratory system includes the **upper respiratory system**, composed of the nose, nasal cavity, paranasal sinuses, and pharynx, and the **lower respiratory system**, which includes the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs. *(Figure 23–1)*

3. The **respiratory tract** consists of the conducting airways that carry air to and from the **alveoli**. The passageways of the upper respiratory system filter and humidify incoming air. The lower respiratory system includes delicate conduction passages and the alveolar exchange surfaces.

4. The **respiratory mucosa** (respiratory epithelium and underlying connective tissue) lines the conducting portion of the respiratory tract.

5. The respiratory epithelium changes in structure along the respiratory tract. It is supported by the **lamina propria**, a layer of areolar tissue. *(Figure 23–2)*

6. Contamination of the respiratory system is prevented by the **respiratory defense system**. *(Figure 23–2)*

The Upper Respiratory System p. 817

1. The components of the upper respiratory system consist of the nose, nasal cavity, paranasal sinuses, and pharynx. *(Figures 23–1, 23–3)*

The Nose and Nasal Cavity p. 817

2. Air normally enters the respiratory system through the **external nares**, which open into the *nasal cavity*. The **nasal vestibule** (entryway) is guarded by hairs that screen out large particles. *(Figure 23–3)*

3. Incoming air flows through the **superior**, **middle**, and **inferior meatuses** (narrow grooves) and bounces off the conchal surfaces.

(Figure 23–3)

4. The **hard palate** separates the oral and nasal cavities. The **soft palate** separates the superior nasopharynx from the rest of the pharynx. The connections between the nasal cavity and nasopharynx are the **internal nares**.

5. The nasal mucosa traps particles, warms and humidifies incoming air, and cools and dehumidifies outgoing air.

The Pharynx p. 819

6. The **pharynx** is a chamber shared by the digestive and respiratory systems. The **nasopharynx** is the superior part of the pharynx. The **oropharynx** is continuous with the oral cavity. The **laryngopharynx** includes the narrow zone between the hyoid bone and the entrance to the esophagus. *(Figure 23–3)*

Anatomy 360 | Respiratory System/Pharynx

The Larynx p. 819

1. Inhaled air passes through the **glottis** en route to the lungs; the **larynx** surrounds and protects the glottis. *(Figure 23–4)*

Cartilages and Ligaments of the Larynx p. 819

2. The cylindrical larynx is composed of three large cartilages (the **thyroid cartilage**, **cricoid cartilage**, and **epiglottis**) and three smaller

pairs of cartilages (the **arytenoid**, **corniculate**, and **cuneiform cartilages**). The epiglottis projects into the pharynx. *(Figures 23–4, 23–5)*

3. Two pairs of folds span the glottis: the inelastic **vestibular folds** and the more delicate **vocal folds**. *(Figure 23–5)*

Sound Production p. 821

4. Air passing through the glottis vibrates the vocal folds, producing sound. The pitch of the sound depends on the diameter, length, and tension of the vocal folds.

The Laryngeal Musculature p. 821

5. The muscles of the neck and pharynx position and stabilize the larynx. The smaller intrinsic muscles regulate tension in the vocal folds or open and close the glottis. During swallowing, both sets of muscles help prevent particles from entering the glottis.

Anatomy 360 | Respiratory System/Larynx

The Trachea and Primary Bronchi p. 821 The Trachea p. 821

1. The **trachea** extends from the sixth cervical vertebra to the fifth thoracic vertebra. The **submucosa** contains C-shaped **tracheal cartilages**, which stiffen the tracheal walls and protect the airway. The posterior tracheal wall can distort to permit large masses of food to pass through the esophagus. *(Figure 23–6)*

Anatomy 360 | Respiratory System/Trachea

The Primary Bronchi p. 822

2. The trachea branches within the mediastinum to form the **right** and **left primary bronchi**. Each bronchus enters a lung at the **hilus** (a groove). The **root** is a connective-tissue mass that includes the bronchus, pulmonary vessels, and nerves. *(Figures 23–6, 23–7)*

The Lungs p. 824 Lobes and Surfaces of the Lungs p. 824

1. The **lobes** of the lungs are separated by fissures. The right lung has three lobes, the left lung two. *(Figure 23–7)*

2. The anterior and lateral surfaces of the lungs follow the inner contours of the rib cage. The concavity of the medial surface of the left lung is the **cardiac notch**, which conforms to the shape of the pericardium. *(Figures 23–7, 23–8)*

The Bronchi p. 824

3. The primary bronchi and their branches form the **bronchial tree**. The **secondary** and **tertiary bronchi** are branches within the lungs. As they branch, the amount of cartilage in their walls decreases and the amount of smooth muscle increases. *(Figure 23–9)*

4. Each tertiary bronchus supplies air to a single **bronchopulmonary segment**. *(Figure 23–9)*

Anatomy 360 | Respiratory System/Bronchial Tree

The Bronchioles p. 826

5. **Bronchioles** within the bronchopulmonary segments ultimately branch into **terminal bronchioles**. Each terminal bronchiole delivers air to a single **pulmonary lobule** in which the terminal bronchiole branches into **respiratory bronchioles**. The connective tissues of the root of the lung extend into the parenchyma of the lung as a series of *trabeculae* (partitions) that branch to form **interlobular septa**, which divide the lung into lobules. *(Figure 23–9)*

Alveolar Ducts and Alveoli p. 826

6. The respiratory bronchioles open into **alveolar ducts**, at each of which many alveoli are interconnected. The respiratory exchange surfaces are extensively connected to the circulatory system via the vessels of the pulmonary circuit. *(Figure 23–10)*

7. The **respiratory membrane** consists of a simple squamous epithelium, the endothelial cell lining an adjacent capillary, and the fused basal laminae; **septal cells**

scattered in the respiratory membrane produce **surfactant** that keeps the alveoli from collapsing. **Alveolar macrophages** patrol the epithelium and engulf foreign particles. *(Figure 23–11)*

The Blood Supply to the Lungs p. 829

8. The conducting portions of the respiratory tract receive blood from the external carotid arteries, the thyrocervical trunks, and the bronchial arteries. Venous blood flows into the pulmonary veins, bypassing the rest of the systemic circuit and diluting the oxygenated blood leaving the alveoli.

The Pleural Cavities and Pleural Membranes p. 829

9. Each lung occupies a single **pleural cavity** lined by a **pleura** (serous membrane). The two types of pleurae are the **parietal pleura**, covering the inner surface of the thoracic wall, and the **visceral pleura**, covering the lungs.

Anatomy 360 | Respiratory System/Lungs and Pleurae

An Overview of Respiratory Physiology p. 830

1. Respiratory physiology focuses on a series of integrated processes. **External respiration** (the exchange of oxygen and carbon dioxide between interstitial fluid and the external environment) includes **pulmonary ventilation** (breathing). **Internal respiration** is the exchange of oxygen and carbon dioxide between interstitial fluid and cells. If the oxygen content declines, the affected tissues will suffer from **hypoxia**; if the oxygen supply is completely shut off, **anoxia** and tissue death result. *(Figure 23–12)*

Pulmonary Ventilation p. 830

1. **Pulmonary ventilation** is the physical movement of air into and out of the respiratory tract.

The Movement of Air p. 831

2. As pressure on a gas decreases, its volume expands; as pressure increases, gas volume contracts. This inverse relationship is **Boyle's law**. *(Figure 23–13; Table 23–1)*

3. Lung volume is directly affected by movement of the diaphragm and ribs.

Pressure Changes during Inhalation and Exhalation p. 833

4. The relationship between **intrapulmonary pressure** (the pressure inside the respiratory tract) and **atmospheric pressure** (**atm**) determines the direction of airflow. **Intrapleural pressure** is the pressure in the space between the parietal and visceral pleurae.

(Figures 23–14, 23–15)

5. A **respiratory cycle** is a single cycle of inhalation and exhalation. The amount of air moved in one respiratory cycle is the **tidal volume**. *(Figure 23–15)*

The Mechanics of Breathing p. 835

6. The diaphragm and the external and internal intercostal muscles are involved in normal **quiet breathing**, or **eupnea**. Accessory muscles become active during the active inspiratory and expiratory movements of **forced breathing**, or **hyperpnea**. *(Figure 23–16)*

Respiratory Rates and Volumes p. 837

7. **Alveolar ventilation** is the amount of air reaching the alveoli each minute. The **vital capacity** includes the **tidal volume** plus the **expiratory** and **inspiratory reserve volumes**. The air left in the lungs at the end of maximum exhalation is the **residual volume**.

(Figure 23–17)

Respiratory System/Pulmonary Ventilation

Gas Exchange p. 839 The Gas Laws p. 839

1. In a mixed gas, the individual gases exert a pressure proportional to their abundance in the mixture (**Dalton's law**). The pressure contributed by a single gas is its **partial pressure**. (Table 23–2)

2. The amount of a gas in solution is directly proportional to the partial pressure of that gas (**Henry's law**). *(Figure 23–18)*

Diffusion and Respiratory Function p. 840

3. Alveolar air and atmospheric air differ in composition. Gas exchange across the respiratory membrane is efficient due to differences in partial pressures, the small diffusion distance, lipid-soluble gases, the large surface area of all the alveoli combined, and the coordination of blood flow and airflow. *(Figure 23–19)*

Gas Pickup and Delivery p. 842

1. Blood entering peripheral capillaries delivers oxygen and absorbs carbon dioxide. The transport of oxygen and carbon dioxide in blood involves reactions that are completely reversible.

Oxygen Transport p. 842

2. Oxygen is carried mainly by RBCs, reversibly bound to hemoglobin. At alveolar PO_2, hemoglobin is almost fully saturated; at the PO_2 of peripheral tissues, it retains a substantial oxygen reserve. The effect of pH

on the hemoglobin saturation curve is called the **Bohr effect**. When low plasma PO_2 continues for extended periods, red blood cells generate more **2,3-bisphosphoglycerate (BPG)**, which reduces hemoglobin's affinity for oxygen. *(Figures 23–20, 23–21)*

3. **Fetal hemoglobin** has a stronger affinity for oxygen than does adult hemoglobin, aiding the removal of oxygen from maternal blood.

(Figure 23–22)

100 Keys | p. 845

Carbon Dioxide Transport p. 845

4. Aerobic metabolism in peripheral tissues generates CO2. About 7 percent of the CO_2 transported in blood is dissolved in the plasma,

-

23 percent is bound as **carbaminohemoglobin**, and the rest is converted to carbonic acid, which dissociates into H^+ and HCO3 .

(Figure 23–23)

100 Keys | p. 846

Summary: Gas Transport p. 846

5. Driven by differences in partial pressure, oxygen enters the blood at the lungs and leaves in peripheral tissues; similar forces drive carbon dioxide into the blood at the tissues and into the alveoli at the lungs. (Figure 23–24)

Respiratory System/Gas Transport

Control of Respiration p. 847

1. Normally, the cellular rates of gas absorption and generation are matched by the capillary rates of delivery and removal and are identical to the rates of oxygen absorption and carbon dioxide removal at the lungs. When these rates are unbalanced, homeostatic mechanisms restore equilibrium.

Local Regulation of Gas Transport and Alveolar Function p. 848

2. Local factors regulate alveolar blood flow (*lung perfusion*) and airflow (*alveolar ventilation*). Alveolar capillaries constrict under conditions of low oxygen, and bronchioles dilate under conditions of high carbon dioxide.

Respiratory System/Gas Exchange

The Respiratory Centers of the Brain p. 848

3. The **respiratory centers** include three pairs of nuclei in the reticular formation of the pons and medulla oblongata. The *respiratory rhythmicity centers* set the pace for respiration; the **apneustic centers** cause strong, sustained inspiratory movements; and the **pneumotaxic centers** inhibit the apneustic centers and promote exhalation. *(Figures 23–25, 23–26)*

Respiratory Reflexes p. 850

4. Stimulation of the chemoreceptor reflexes is based on the level of carbon dioxide in the blood and CSF. The **inflation reflex** prevents overexpansion of the lungs during forced breathing. The **deflation reflex** stimulates inhalation when the lungs are collapsing.

(Figures 23–26, 23–27)

Voluntary Control of Respiration p. 852

5. Conscious and unconscious thought processes can affect respiration by affecting the respiratory centers.

100 Keys | p. 853

Changes in the Respiratory System at Birth p. 853

1. Before delivery, the fetal lungs are filled with body fluids and collapsed. At the first breath, the lungs inflate and do not collapse completely thereafter.

Aging and the Respiratory System p. 853

1. The respiratory system is generally less efficient in the elderly because (1) elastic tissue deteriorates, lowering the vital capacity of the lungs, (2) movements of the chest are restricted by arthritic changes and decreased flexibility of costal cartilages, and (3) some degree of emphysema is generally present. *(Figure 23–28)*

Respiratory System/Control of Respiration

Integration with Other Systems p. 854

1. The respiratory system has extensive anatomical and physiological connections to the cardiovascular system. *(Figure 23–29)*

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. Surfactant

(a) protects the surface of the lungs
(b) phagocytizes small particulates
(c) replaces mucus in the alveoli
(d) helps prevent the alveoli from collapsing
(e) is not found in healthy lung tissue

2. The hard palate separates the

(a) nasal cavity from the larynx
(b) left and right sides of the nasal cavity
(c) nasal cavity and the oral cavity

(d) external nares from the internal nares

(e) soft palate from the nasal cavity

3. Air moves into the lungs because

(a) the gas pressure in the lungs is less than atmospheric pressure

(b) the volume of the lungs decreases with inspiration

(c) the thorax is muscular

(d) contraction of the diaphragm decreases the volume of the pleural cavity

(e) the respiratory control center initiates active expansion of the thorax

4. The glottis is closed while the lungs are still full of air. Suddenly the abdominal and internal intercostal muscles contract creating a pressure that blasts the air out of the respiratory passages. This describes a

(a) sneeze **(b)** hiccough

(c) cough **(d)** laryngeal spasm

(e) gag

5. When the diaphragm and external intercostal muscles contract

(a) expiration occurs

(b) intrapulmonary pressure increases

(c) intrapleural pressure decreases

(d) the volume of the lungs decreases

(e) the size of the pleural cavity increases

6. During the winter, Brad sleeps in a dorm room that lacks any humidifier for the heated air. In the mornings he notices that his nose is "stuffy" similar to when he has a cold, but after showering and drinking some water, the stuffiness disappears until the next morning. What might be the cause of Brad's nasal condition?

7. Distinguish between the structures of the upper respiratory system and those of the lower respiratory system.

8. Name the three regions of the pharynx. Where is each region located?

9. List the cartilages of the larynx. What are the functions of each?

10. What four integrated steps are involved in external respiration?

11. What important physiological differences exist between fetal hemoglobin and maternal hemoglobin?

12. By what three mechanisms is carbon dioxide transported in the bloodstream?

LEVEL 2 Reviewing Concepts

13. The process of internal respiration involves each of the following *except* that

(a) oxygen diffuses from the blood to the interstitial spaces

(b) carbon dioxide diffuses from the interstitial spaces to the blood

(c) hemoglobin binds more oxygen

(d) bicarbonate ions are formed in the red blood cells

(e) chloride ions diffuse into red blood cells as bicarbonate ions diffuse out

14. Gas exchange at the respiratory membrane is efficient because

(a) the differences in partial pressure are substantial

(b) the gases are lipid soluble

(c) the total surface area is large

(d) a, b, and c are correct

15. For any partial pressure of oxygen, if the concentration of 2,3-bisphosphoglycerate (BPG) increases,

(a) the amount of oxygen released by hemoglobin will decrease

(b) the oxygen levels in hemoglobin will be unaffected

(c) the amount of oxygen released by hemoglobin will increase

(d) the amount of carbon dioxide carried by hemoglobin will increase

16. An increase in the partial pressure of carbon dioxide in arterial blood causes chemoreceptors to stimulate the respiratory centers, resulting in

(a) a decreased respiratory rate

(b) an increased respiratory rate

(c) hypocapnia

(d) hypercapnia

17. Why is breathing through the nasal cavity more desirable than breathing through the mouth?

18. How would you justify the statement “The bronchioles are to the respiratory system what the arterioles are to the cardiovascular system”?

19. How are septal cells involved with keeping the alveoli from collapsing?

20. How does pulmonary ventilation differ from alveolar ventilation, and what is the function of each type of ventilation?

21. What is the significance of **(a)** Boyle’s law, **(b)** Dalton’s law, and **(c)** Henry’s law to the process of respiration?

22. What happens to the process of respiration when a person is sneezing or coughing?

23. What are the differences between pulmonary volumes and respiratory capacities? How are pulmonary volumes and respiratory capacities determined?

24. What is the functional difference between the dorsal respiratory group (DRG) and the ventral respiratory group (VRG) of the medulla oblongata?

LEVEL 3 Critical Thinking and Clinical Applications

25. Billy’s normal alveolar ventilation rate (AVR) during mild exercise is 6.0 L> min. While at the beach on a warm summer day, he goes
snorkeling. The snorkel has a volume of 50 ml. Assuming that the water is not too cold and that snorkeling for Billy is mild exercise, what would his respiratory rate have to be for him to maintain an AVR of 6.0 L> min while snorkeling? (Assume a constant tidal volume of 500 ml and an anatomic dead space of 150 ml.)

26. Mr. B. has had chronic advanced emphysema for 15 years. While hospitalized with a respiratory infection, he goes into respiratory distress. Without thinking, his nurse immediately administers pure oxygen, which causes Mr. B. to stop breathing. Why?

27. Cary hyperventilates for several minutes before diving into a swimming pool. Shortly after he enters the water and begins swimming, he blacks out and almost drowns. What caused this to happen?

28. Why do individuals who are anemic generally not exhibit an increase in respiratory rate or tidal volume, even though their blood is not carrying enough oxygen?

29. Doris has an obstruction of her right primary bronchus. As a result, how would you expect the oxygen–hemoglobin saturation curve for her right lung to compare with that for her left?

Respiratory System

Can you explain the structure of the alveolus? Stop here to use your **InterActive Physiology CD-ROM** to review the anatomy of the respiratory system. Click on the *Respiratory System* module for interactive exercises, quizzes, and study outlines that explain the respiratory system using animation. The following topics are covered in this module:

- Anatomy Review: Respiratory Structures
- Pulmonary Ventilation
- Gas Exchange
- Gas Transport
- Control of Respiration

At this point in the chapter, click on *Anatomy Review: Respiratory Structures*. Use **IP** to review the structures of the respiratory system and quiz yourself before you read about respiratory physiology. Print out the **IP** Study Outline consisting of notes, diagrams, and study questions. To help ensure your success in anatomy and physiology, review the remaining respiratory system topics as they appear in your text and each time you see the CD icon.

IP

TABLE 23–1 The Four Most Common Methods of Reporting
Gas Pressures

millimeters of mercury (mm Hg): This is the most common method of reporting blood pressure and gas pressures. Normal atmospheric pressure is approximately 760 mm Hg.

torr: This unit of measurement is preferred by many respiratory therapists; it is also commonly used in Europe and in some technical journals. One torr is equivalent to 1 mm Hg; in other words, normal atmospheric pressure is equal to 760 torr.

centimeters of water (cm H2O): In a hospital setting, anesthetic gas pressures and oxygen pressures are commonly measured in centimeters of water. One cm H2O is equivalent to 0.735 mm Hg; normal atmospheric pressure is 1033.6 cm H2O.

pounds per square inch (psi): Pressures in compressed gas cylinders and other industrial applications are generally reported in psi. Normal atmospheric pressure at sea level is approximately 15 psi.

TABLE 23–2 Partial Pressures (mm Hg) and Normal Gas Concentrations (%) in Air

SOURCE OF SAMPLE	**Nitrogen (N_2)**	**Oxygen (O_2)**	**Carbon Dioxide (CO_2)**	**Water Vapor (H_2O)**
Inhaled air (dry)	597 (78.6%)	159 (20.9%)	0.3 (0.04%)	3.7 (0.5%)
Alveolar air (saturated)	573 (75.4%)	100 (13.2%)	40 (5.2%)	47 (6.2%)
Exhaled air (saturated)	569 (74.8%)	116 (15.3%)	28 (3.7%)	47 (6.2%)

- **FIGURE 23–1** The Components of the Respiratory System. Only the conducting portion of the respiratory system is shown; the smaller bronchioles and alveoli have been omitted. ATLAS: Plates 47a,b
- **FIGURE 23–2** The Respiratory Epithelium of the Nasal Cavity and Conducting System. **(a)** A surface view of the epithelium. The cilia of the epithelial cells form a dense layer that resembles a shag carpet. The movement of these cilia propels mucus across the epithelial surface. **(b)** A diagrammatic view of the respiratory epithelium of the trachea, indicating

the mechanism of mucus transport. **(c)** The sectional appearance of the respiratory epithelium, a pseudostratified ciliated columnar epithelium.

- **FIGURE 23–3** Structures of the Upper Respiratory System. **(a)** The nasal cartilages and external landmarks on the nose. **(b)** A frontal section through the head, showing the meatuses and the maxillary sinuses and air cells of the ethmoidal labyrinth. **(c)** The nasal cavity and pharynx, as seen in sagittal section with the nasal septum removed. ATLAS: Plate 19
- **FIGURE 23–4** The Anatomy of the Larynx. **(a)** An anterior view. **(b)** A posterior view. **(c)** A sagittal section through the larynx.
- **FIGURE 23–5** The Glottis and Surrounding Structures. **(a)** A diagrammatic superior view of the entrance to the larynx, with the glottis open (left) and closed (right). **(b)** A fiber-optic view of the entrance to the larynx, corresponding to the right-hand image in part (a). Note that the glottis is almost completely closed by the vocal folds.
- **FIGURE 23–6** The Anatomy of the Trachea. **(a)** A diagrammatic anterior view. **(b)** A cross-sectional view. ATLAS: Plates 42b,c

- **FIGURE 23–13** Gas Pressure and Volume Relationships. Gas molecules in a sealed container bounce off the walls and off one another, traveling the distance indicated in a given period of time. **(a)** If the volume decreases, each molecule travels the same distance in that same period, but strikes the walls more frequently. The pressure exerted by the gas thus increases. **(b)** If the volume of the container increases, each molecule strikes the walls less often, lowering the pressure in the container.
- **FIGURE 23–14** Mechanisms of Pulmonary Ventilation. The Navigator icon in the shadow box highlights the topic of the current figure. **(a)** As the rib cage is elevated or the diaphragm is depressed, the volume of the thoracic cavity increases. **(b)** An anterior view with the diaphragm at rest; no air movement occurs. **(c)** *Inhalation*: Elevation of the rib cage and contraction of the diaphragm increase the size of the thoracic cavity. Pressure within the thoracic cavity decreases, and air flows into the lungs. **(d)** *Exhalation*: When the rib cage returns to its original position, the volume of the thoracic cavity decreases. Pressure rises, and air moves out of the lungs.
- **FIGURE 23–15** Pressure and Volume Changes during Inhalation and Exhalation. One sequence of inhalation and exhalation constitutes a respiratory cycle. **(a, b)** Changes in intrapulmonary and intrapleural pressures during a single respiratory cycle. **(c)** A plot of tidal volume, the amount of air moving into and out of the lungs during a single respiratory cycle.
- **FIGURE 23–16** The Respiratory Muscles. **(a)** Movements of the ribs and diaphragm that increase the volume of the thoracic cavity. Diaphragmatic movements were also illustrated

in *Figure 23–14*. **(b)** An anterior view at rest (with no air movement), showing the primary and accessory respiratory muscles. **(c)** A lateral view during inhalation, showing the muscles that elevate the ribs. **(d)** A lateral view during exhalation, showing the muscles that depress the ribs. The abdominal muscles that assist in exhalation are represented by a single muscle (the rectus abdominis).

• **FIGURE 23–17** Respiratory Volumes and Capacities. The red line indicates the volume of air within the lung as respiratory movements are performed.

• **FIGURE 23–18** Henry's Law and the Relationship between Solubility and Pressure. **(a)** Increasing the pressure drives gas molecules into solution until an equilibrium is established. A sealed can of carbonated soda is under higher-than-atmospheric pressure. **(b)** When the gas pressure decreases, dissolved gas molecules leave the solution until a new equilibrium is reached. Opening the soda can relieves the pressure, and bubbles form as dissolved gases leave the solution.

• **FIGURE 23–19** An Overview of Respiratory Processes and Partial Pressures in Respiration. **(a)** Partial pressures and diffusion at the respiratory membrane. **(b)** Partial pressures and diffusion in other tissues.

The Digestive System: An Overview

Objectives

- Identify the organs of the digestive system and list their major functions.
- Describe the functional histology of the digestive tract.
- Explain the processes by which materials move through the digestive tract.
- Outline the mechanisms that regulate digestion.

The digestive system may not have the visibility of the integumentary system or the glamour of the reproductive system, but it is certainly just as important. All living organisms must obtain nutrients from their environment to sustain life. These substances are used as raw materials for synthesizing essential compounds (anabolism) or are decomposed to provide the energy that cells need to continue functioning (catabolism). l**pp. 35–36, 309–310** The catabolic reactions require two essential ingredients: (1) oxygen and (2) organic molecules (such as carbohydrates, fats, or proteins) that can be broken down by intracellular enzymes. Obtaining oxygen and organic molecules can be relatively straightforward for a single-celled organism like an amoeba, but the situation is much more complicated for animals as large and complex as humans. Along with increasing size and complexity comes a division of labor and the need for the coordination of organ system activities.

In our bodies, the respiratory system works in concert with the cardiovascular system to supply the necessary oxygen. The **digestive system**, working with the cardiovascular and lymphatic systems, provides the organic molecules. In effect, the digestive system provides both the fuel that keeps all the body’s cells running and the building blocks needed for cell growth and repair.

The digestive system consists of a muscular tube, the **digestive tract**, also called the *gastrointestinal (GI) tract* or *alimentary canal*, and various **accessory organs**. The *oral cavity* (mouth), *pharynx*, *esophagus*, *stomach*, *small intestine*, and *large intestine* make up the digestive tract. Accessory digestive organs include the teeth, tongue, and various *glandular organs*, such as the salivary glands, liver, and pancreas, which secrete their products into ducts emptying into the digestive tract. Food enters the digestive tract and passes along its length. On the way, the secretions of the glandular organs, which contain water, enzymes, buffers, and other components, assist in preparing organic and inorganic nutrients for absorption across the epithelium of the digestive tract.

Figure 24–1• shows the major components of the digestive system. The digestive tract begins at the oral cavity and continues through the pharynx, esophagus, stomach, small intestine, and large intestine, which opens to the exterior at the anus. These structures have overlapping functions, but each has certain areas of specialization and shows distinctive histological characteristics.

Functions of the Digestive System

We can regard digestive functions as a series of integrated steps:

1. **1. Ingestion** occurs when materials enter the digestive tract via the mouth. Ingestion is an active process involving conscious choice and decision making.

2. **2. Mechanical processing** is crushing and shearing that makes materials easier to propel along the digestive tract. It also increases their surface area, making them more susceptible to enzymatic attack. Mechanical processing may or may not be required before ingestion; you can swallow liquids immediately, but must process most solids first. Tearing and mashing with the teeth, followed by squashing and compaction by the tongue, are examples of preliminary mechanical processing. Swirling, mixing, and churning motions of the stomach and intestines provide mechanical processing after ingestion.

3. **3. Digestion** refers to the chemical breakdown of food into small organic fragments suitable for absorption by the digestive epithelium. Simple molecules in food, such as glucose, can be absorbed intact, but epithelial cells have no way to absorb molecules the size and complexity of proteins, polysaccharides, or triglycerides. These molecules must be disassembled by digestive enzymes prior to absorption. For example, the starches in a potato are of no nutritional value until enzymes have broken them down to simple sugars that the digestive epithelium can absorb for distribution to body cells.

4. **4. Secretion** is the release of water, acids, enzymes, buffers, and salts by the epithelium of the digestive tract and by glandular organs.

5. **5. Absorption** is the movement of organic substrates, electrolytes (inorganic ions), vitamins, and water across the digestive epithelium and into the interstitial fluid of the digestive tract.

6. **6. Excretion** is the removal of waste products from body fluids. The digestive tract and glandular organs discharge waste products in secretions that enter the lumen of the tract. Most of these waste products, after mixing with the indigestible residue of the

digestive process, will leave the body. The ejection of materials from the digestive tract, a process called **defecation** (def-e-K -shun), or *egestion*, eliminates materials as **feces**.

¯A

The lining of the digestive tract also plays a protective role by safeguarding surrounding tissues against (1) the corrosive effects of digestive acids and enzymes; (2) mechanical stresses, such as abrasion; and (3) bacteria that either are swallowed with food or reside in the digestive tract. The digestive epithelium and its secretions provide a nonspecific defense against these bacteria. When bacteria reach the underlying layer of areolar tissue, the *lamina propria*, they are attacked by macrophages and other cells of the immune system.

We will explore specific functions in more detail as we proceed through the individual regions and components of the system. First, however, we consider several structural and functional characteristics of the system as a whole.

The Digestive Organs and the Peritoneum

The abdominopelvic cavity contains the *peritoneal cavity*, which is lined by a serous membrane consisting of a superficial mesothelium covering a layer of areolar tissue. l**pp. 22–23, 129** We can divide the serous membrane into the serosa, or *visceral peritoneum*, which covers organs within the peritoneal cavity, and the *parietal peritoneum*, which lines the inner surfaces of the body wall.

The serous membrane lining the peritoneal cavity continuously produces peritoneal fluid, which provides essential lubrication. Because a thin layer of peritoneal fluid separates the parietal and visceral surfaces, sliding movement can occur without friction and resulting irritation. About 7 liters of fluid are secreted and reabsorbed each day, although the volume within the peritoneal cavity at any one time is very small. Liver disease, kidney disease, and heart failure can cause an increase in the rate at which fluids move into the peritoneal cavity. The accumulation of fluid creates a characteristic abdominal swelling called **ascites** (a-S
¯I

-t
¯e
z). The distortion of internal organs by this fluid can result in symptoms such as heartburn, indigestion, and lower back pain.

Mesenteries

Portions of the digestive tract are suspended within the peritoneal cavity by sheets of serous membrane that connect the parietal peritoneum with the visceral peritoneum. These **mesenteries** (MEZ-en-ter-z) are double sheets of peritoneal membrane. The areolar tissue between the mesothelial surfaces provides an access route for the passage of blood vessels, nerves, and lymphatic vessels to and from the digestive tract. Mesenteries also stabilize the positions of the attached organs and prevent the intestines from becoming entangled during digestive movements or sudden changes in body position.

During embryonic development, the digestive tract and accessory organs are suspended within the peritoneal cavity by *dorsal* and *ventral mesenteries* (Figure 24–2a•). The ventral mesentery later disappears along most of the digestive tract, persisting in adults in only two places: on the ventral surface of the stomach, between the stomach and the liver (the *lesser omentum*; Figure 24–2b,d•); and between the liver and the anterior abdominal wall (the *falciform ligament*; Figure 24–2c,d•). The **lesser omentum**

¯e

(

¯o

-MEN-tum; *omentum*, fat skin) stabilizes the position of the stomach and provides an access route for blood vessels and other

structures entering or leaving the liver. The **falciform** (FAL-si-form; *falx***,** sickle + *forma*, form) **ligament** helps stabilize the position of the liver relative to the diaphragm and abdominal wall. ATLAS: Embryology Summary 19: The Development of the Digestive System

As the digestive tract elongates, it twists and turns within the crowded peritoneal cavity. The dorsal mesentery of the stomach becomes greatly enlarged and forms an enormous pouch that extends inferiorly between the body wall and the anterior surface of the small intestine. This pouch, the **greater omentum** (see Figure 24–2b,d•), hangs like an apron from the lateral and inferior borders of the stomach. Adipose tissue in the greater omentum conforms to the shapes of the surrounding organs, providing padding and protection across the anterior and lateral surfaces of the abdomen. The lipids in the adipose tissue are an important energy reserve. The greater omentum also provides insulation that reduces heat loss across the anterior abdominal wall.

All but the first 25 cm (10 in.) of the small intestine is suspended by the **mesentery proper**, a thick mesenterial sheet that provides stability, but permits some independent movement. The mesentery associated with the initial portion of the small intestine (the *duodenum*) and the pancreas fuses with the posterior abdominal wall, locking those structures in position. After this fusion is completed, only their anterior surfaces remain covered by peritoneum. Because their mass lies posterior to, rather than within, the peritoneal cavity, these organs are **retroperitoneal** (*retro*, behind).

A **mesocolon** is a mesentery associated with a portion of the large intestine. During normal development, the mesocolon of the *ascending colon*, the *descending colon*, and the *rectum* of the large intestine fuse to the dorsal body wall. These regions become locked in place. Thereafter, these organs are retroperitoneal, with the visceral peritoneum covering only their anterior surfaces and portions of their lateral surfaces (see Figure 24–2b,c,d•). The **transverse mesocolon**, which supports the transverse colon, and the **sigmoid mesocolon**, which supports the sigmoid colon, are all that remains of the original embryonic mesocolon.

Clinical Note

An inflammation of the peritoneal membrane is called peritonitis (per-i-t ¯o -N -tis), a painful condition that interferes with the normal

¯I functioning of the affected organs. Physical damage, chemical irritation, and bacterial invasion of the peritoneum can lead to severe and even fatal cases of peritonitis. In untreated appendicitis, peritonitis may be caused by the rupturing of the appendix and the subsequent release of bacteria into the peritoneal cavity. Peritonitis is a potential complication of any surgery in which the peritoneal cavity is opened, or of any disease or injury that perforates the walls of the stomach or intestines.

Histological Organization of the Digestive Tract

The major layers of the digestive tract include (1) the *mucosa*, (2) the *submucosa*, (3) the *muscularis externa*, and (4) the *serosa*. The structure of these layers varies by region; Figure 24–3• is a composite view that most closely resembles the appearance of the small intestine, the longest segment of the digestive tract.

The Mucosa

The inner lining, or **mucosa**, of the digestive tract is a *mucous membrane* consisting of an epithelium, moistened by glandular secretions, and a *lamina propria* of areolar tissue.

The Digestive Epithelium The mucosal epithelium is either simple or stratified, depending on its location and the stresses to which it is most often subjected. The oral cavity, pharynx, and esophagus (where mechanical stresses are most severe) are lined by a stratified squamous epithelium, whereas the stomach, the small intestine, and almost the entire length of the large intestine (where absorption occurs) have a simple columnar epithelium that contains goblet cells. Scattered among the columnar cells are **enteroendocrine cells**, which secrete hormones that coordinate the activities of the digestive tract and the accessory glands.

The lining of the digestive tract is often thrown into longitudinal folds, which disappear as the tract fills, and permanent transverse folds, or *plicae* (PL

I¯

-s

¯e

; singular, *plica* [PL -ka]) (see Figure 24–3•). The folding dramatically increases the surface area

I¯

available for absorption. The secretions of gland cells located in the mucosa and submucosa—or in accessory glandular organs— are carried to the epithelial surfaces by ducts.

Clinical Note

The life span of a typical epithelial cell varies from two to three days in the esophagus to up to six days in the large intestine. The lining of the entire digestive tract is continuously renewed through the divisions of epithelial stem cells, keeping pace with the rates of cell destruction and loss at epithelial surfaces. This high rate of cell division explains why radiation and anticancer drugs that inhibit mitosis have drastic effects on the digestive tract. Lost epithelial cells are no longer replaced, and the cumulative damage to the epithelial lining quickly leads to problems in absorbing nutrients. In addition, the exposure of

the lamina propria to digestive enzymes
can cause internal bleeding and other serious problems.

The Lamina Propria The lamina propria consists of a layer of areolar tissue that also contains blood vessels, sensory nerve endings, lymphatic vessels, smooth muscle cells, and scattered areas of lymphoid tissue. In the oral cavity, pharynx, esophagus, stomach, and *duodenum* (the proximal portion of the small intestine), the lamina propria also contains the secretory cells of mucous glands.

In most areas of the digestive tract, the lamina propria contains a narrow band of smooth muscle and elastic fibers. This band
is called the **muscularis** (mus-k
¯u
-LA-ris) **mucosae** (m
¯u
-K

O

-s
¯e
) (see Figure 24–3•). The smooth muscle cells in the muscularis
mucosae are arranged in two concentric layers. The inner layer encircles the lumen (the *circular muscle*), and the outer layer contains muscle cells oriented parallel to the long axis of the tract (the *longitudinal layer*). Contractions in these layers alter the shape of the lumen and move the epithelial pleats and folds.

The Submucosa

The **submucosa** is a layer of dense irregular connective tissue that surrounds the muscularis mucosae (see Figure 24–3•). The submucosa has large blood vessels and lymphatic vessels, and in some regions it also contains exocrine glands that secrete buffers and enzymes into the lumen of the digestive tract. Along its outer margin, the submucosa contains a network of intrinisic nerve fibers and scattered neurons. This **submucosal plexus**, or *plexus of Meissner*, contains sensory neurons, parasympathetic ganglionic neurons, and sympathetic postganglionic fibers that innervate the mucosa and submucosa.

The Muscularis Externa

The submucosal plexus lies along the inner border of the **muscularis externa**, a region dominated by smooth muscle cells. Like the smooth muscle cells in the muscularis mucosae, those in the muscularis externa are arranged in an inner circular layer and an outer longitudinal layer. These layers play an essential role in mechanical processing and in the movement of materials along the digestive tract. The movements are coordinated primarily by the sensory neurons, interneurons, and motor neurons of the enteric nervous system (ENS). The ENS is innervated primarily by the parasympathetic division of the ANS. Sympathetic postganglionic

–

fibers also synapse here, although many continue onward to innervate the mucosa and the **myenteric** (m -en-TER-ik) **plexus**

ı (*mys*, muscle + *enteron*, intestine), or *plexus of Auerbach*. This network of parasympathetic ganglia, sensory neurons, interneurons, and sympathetic postganglionic fibers lies sandwiched between the circular and longitudinal muscle layers. In general, parasympathetic stimulation increases muscle tone and activity; sympathetic stimulation promotes muscular inhibition and relaxation.

The Serosa

Along most portions of the digestive tract inside the peritoneal cavity, the muscularis externa is covered by a serous membrane known as the **serosa** (see Figure 24–3•). There is no serosa covering the muscularis externa of the oral cavity, pharynx, esophagus, and rectum, where a dense network of collagen fibers firmly attaches the digestive tract to adjacent structures. This fibrous sheath is called an *adventitia* (ad-ven-TISH-e-uh).

The Movement of Digestive Materials

The muscular layers of the digestive tract consist of *visceral smooth muscle tissue*, a type of smooth muscle introduced in Chapter 10. l**p. 320** The smooth muscle along the digestive tract has rhythmic cycles of activity due to the presence of *pacesetter cells*. These smooth muscle cells undergo spontaneous depolarization, triggering a wave of contraction that spreads throughout the entire muscular sheet. Pacesetter cells are located in the muscularis mucosae and muscularis externa, the layers of which surround the lumen of the digestive tract. The coordinated contractions of the muscularis externa play a vital role in the movement of materials along the tract, through *peristalsis*, and in mechanical processing, through *segmentation*.

Peristalsis

The muscularis externa propels materials from one portion of the digestive tract to another by contractions known as **peristalsis** (per-i-STAL-sis). Peristalsis consists of waves of muscular contractions that move a **bolus** (BO-lus), or small oval mass of digestive contents, along the length of the digestive tract (Figure 24–4•). During a peristaltic movement, the circular muscles contract behind the bolus while circular muscles ahead of the bolus relax. Longitudinal muscles ahead of the bolus then contract, shortening adjacent segments. A wave of contraction in the circular muscles then forces the bolus forward.

Segmentation

Most areas of the small intestine and some portions of the large intestine undergo cycles of contraction that churn and fragment the bolus, mixing the contents with intestinal secretions. This activity, called **segmentation**, does not follow a set pattern, and thus does not push materials along the tract in any one direction.

Control of Digestive Function

The activities of the digestive system are regulated by neural, hormonal, and local mechanisms (Figure 24–5•).

Neural Mechanisms

The movement of materials along your digestive tract, as well as many secretory functions, is controlled primarily by neural mechanisms. For example, peristaltic movements limited to a few centimeters of the digestive tract are triggered by sensory receptors in the walls of the digestive tract. The motor neurons that control smooth muscle contraction and glandular secretion are located in the myenteric plexus. These neurons are usually considered parasympathetic, because some of them are innervated by parasympathetic preganglionic fibers. However, the plexus also contains sensory neurons, motor neurons, and interneurons responsible for local reflexes that operate entirely outside the control of the central nervous system. As noted in Chapter 16, the reflexes controlled by these neurons are called *short reflexes*. l**p. 535** These reflexes are also called *myenteric reflexes*, and the term *enteric nervous system* is often used to refer to the neural network that coordinates the myenteric reflexes along the digestive tract.

In general, short reflexes control relatively localized activities that involve small segments of the digestive tract. For example, they may coordinate local peristalsis and trigger the secretion of digestive glands in response to the arrival of a bolus. Many neurons are involved: The enteric nervous system has roughly as many neurons as the spinal cord, and as many neurotransmitters as the brain. The specific functions and interactions of these neurotransmitters in the enteric nervous system remain largely unknown.

Sensory information from receptors in the digestive tract is also distributed to the CNS, where it can trigger *long reflexes* l**p. 535**, which involve interneurons and motor neurons in the CNS. Long reflexes provide a higher level of control over digestive and glandular activities, generally controlling large-scale peristaltic waves that move materials from one region of the digestive tract to another. Long reflexes may involve parasympathetic motor fibers in the glossopharyngeal, vagus, or pelvic nerves that synapse in the myenteric plexus.

Hormonal Mechanisms

The sensitivity of the smooth muscle cells to neural commands can be enhanced or inhibited by digestive hormones. The digestive tract produces at least 18 hormones that affect almost every aspect of digestive function, and some of them also affect the activities of other systems. The hormones (*gastrin*, *secretin*, and others), which are peptides produced by enteroendocrine cells in the digestive tract, reach their target organs after their distribution in the bloodstream. We will consider each of these hormones further as we proceed down the length of the digestive tract.

Local Mechanisms

Prostaglandins, histamine, and other chemicals released into interstitial fluid may affect adjacent cells within a small segment of the digestive tract. These local messengers are important in coordinating a response to changing conditions (such as variations in the local pH or certain chemical or physical stimuli) that affect only a portion of the tract. For example, the release of histamine in the lamina propria of the stomach stimulates the secretion of acid by cells in the adjacent epithelium.

Concept Check

What is the importance of the mesenteries?

Which is more efficient in propelling intestinal contents from one place to another—peristalsis or segmentation?

What effect would a drug that blocks the parasympathetic stimulation of the digestive tract have on peristalsis?

Answers begin on p. A–1

Our exploration of the digestive tract continues by following the path of ingested materials, beginning at the mouth and continuing to the anus.

The Oral Cavity

Objectives

. • Describe the anatomy of the oral cavity.

. • Discuss the functions of the major structures and regions of the oral cavity.

The mouth opens into the **oral cavity**, or **buccal** (BUK-al) **cavity** (Figure 24–6•). The functions of the oral cavity include

(1) *sensory analysis* of material before swallowing; (2) *mechanical processing* through the actions of the teeth, tongue, and palatal surfaces; (3) *lubrication* by mixing with mucus and salivary gland secretions; and (4) limited *digestion* of carbohydrates and lipids.

The oral cavity is lined by the **oral mucosa**, which has a stratified squamous epithelium. Only the regions exposed to severe abrasion—such as the superior surface of the tongue and the opposing surface of the hard palate (part of the roof of the mouth)— are covered by a layer of keratinized cells. The epithelial lining of the cheeks, lips, and inferior surface of

the tongue is relatively thin, nonkeratinized, and delicate. Although nutrients are not absorbed in the oral cavity, the mucosa inferior to the tongue is thin
enough and vascular enough to permit the rapid absorption of lipid-soluble drugs. *Nitroglycerin* may be administered via this route to treat acute angina attacks. l**p. 683**
The mucosae of the **cheeks**, or lateral walls of the oral cavity, are supported by pads of fat and the buccinator muscles. Ante
riorly, the mucosa of each cheek is continuous with that of the lips, or **labia** (L
¯A

-b
¯e
-uh; singular, *labium*). The **vestibule** is the
space between the cheeks (or lips) and the teeth. The **gingivae** (JIN-ji-v), or *gums*, are ridges of oral mucosa that surround the base of each tooth on the alveolar processes of the maxillary bones and mandible. In most regions, the gingivae are firmly bound to the periostea of the underlying bones.

The roof of the oral cavity is formed by the hard and soft palates; the tongue dominates its floor (Figure 24–6b•). The floor of the mouth inferior to the tongue receives extra support from the geniohyoid and mylohyoid muscles. l**p. 343** The *hard palate* is formed by the palatine processes of the maxillary bones and the horizontal plates of the palatine bones. A prominent central ridge, or *raphe*, extends along the midline of the hard palate. The mucosa lateral and anterior to the raphe is thick, with complex ridges. When your tongue compresses food against the hard palate, these ridges provide traction. The *soft palate* lies posterior to the hard palate. A thinner and more delicate mucosa covers the posterior margin of the hard palate and extends onto the soft palate.
¯e
The posterior margin of the soft palate supports the **uvula** (
¯U

-v

¯u

-luh), a dangling process that helps prevent food from en

tering the pharynx prematurely (Figure 24–6a•). On either side of the uvula are two pairs of muscular *pharyngeal arches* (see Figure

24–6b•). The more anterior **palatoglossal** (pal-a-t

¯o

-GLOS-al) **arch** extends between the soft palate and the base of the tongue.

¯e

¯e

A curving line that connects the palatoglossal arches and uvula forms the boundaries of the **fauces** (FAW-s z), the passageway between the oral cavity and the oropharynx. The more posterior **palatopharyngeal** (pal-a-t -fa-RIN-j -al) **arch** extends from the

¯o

soft palate to the pharyngeal wall. A palatine tonsil lies between the palatoglossal and palatopharyngeal arches on either side.

The Tongue

The **tongue** (see Figure 24–6•) manipulates materials inside the mouth and is occasionally used to bring foods (such as ice cream) into the oral cavity. The primary functions of the tongue are (1) mechanical processing by compression, abrasion, and distortion;

(2) manipulation to assist in chewing and to prepare material for swallowing; (3) sensory analysis by touch, temperature, and taste receptors, and (4) secretion of mucins and the enzyme *lingual lipase*.

We can divide the tongue into an anterior **body**, or *oral portion*, and a posterior **root**, or *pharyngeal portion*. The superior surface, or *dorsum*, of the body contains a forest of fine projections, the *lingual papillae*. l**p. 552** The thickened epithelium covering each papilla assists the tongue in moving materials. A V-shaped line of circumvallate papillae roughly demarcates the boundary between the body and the root of the tongue, which is situated in the oropharynx (see Figure 24–6b•).

The epithelium covering the inferior surface of the tongue is thinner and more delicate than that of the dorsum. Along the inferior midline is the **lingual frenulum** (FREN-ū-lum; *frenulum*, a small bridle), a thin fold of mucous membrane that connects the body of the tongue to the mucosa covering the floor of the oral cavity (see Figure 24–6a•). Ducts from two pairs of salivary glands open on either side of the lingual frenulum, which serves to prevent extreme movements of the tongue. However, an overly restrictive lingual frenulum prevents normal eating or speech. Properly diagnosed, this condition, called *ankyloglossia* (ang-ki-lō-GLOS-ē-uh), can be corrected surgically.

The tongue's epithelium is flushed by the secretions of small glands that extend into the underlying lamina propria. These secretions contain water, mucins, and the enzyme **lingual lipase**, which works over a broad pH range (3.0–6.0), enabling it to start lipid digestion immediately. Because lingual lipase tolerates an acid environment, it can continue to break down lipids—specifically, triglycerides—for a considerable time after the food reaches the stomach.

The tongue contains two groups of skeletal muscles. All gross movements of the tongue are performed by the relatively large **extrinsic tongue muscles**. l**p. 340** The smaller **intrinsic tongue muscles** change the shape of the tongue and assist the extrinsic muscles during precise movements, as in speech. Both intrinsic and extrinsic tongue muscles are under the control of the hypoglossal nerve (XII).

Salivary Glands

Three pairs of salivary glands secrete into the oral cavity (Figure 24–7a•). Each pair has a distinctive cellular organization and produces *saliva*, a mixture of glandular secretions, with slightly different properties:

1. **1.** The large **parotid** (pa-ROT-id) **salivary glands** lie inferior to the zygomatic arch deep to the skin covering the lateral and posterior surface of the mandible. Each gland has an irregular shape, extending from the mastoid process of the temporal bone across the outer surface of the masseter muscle. The parotid salivary glands produce a serous secretion containing large amounts of *salivary amylase*, an enzyme that breaks down starches (complex carbohydrates). The secretions of each parotid gland are drained by a **parotid duct** (*Stensen's duct*), which empties into the vestibule at the level of the second upper molar.

2. **2.** The **sublingual** (sub-LING-gwal) **salivary glands** are covered by the mucous membrane of the floor of the mouth. These glands produce a mucous secretion that acts as a buffer and lubricant. Numerous **sublingual ducts** (*Rivinus' ducts*) open along either side of the lingual frenulum.

3. **3.** The **submandibular salivary glands** are in the floor of the mouth along the inner surfaces of the mandible within a depression called the *mandibular groove*. Cells of the submandibular glands (Figure 24–7b•) secrete a mixture of buffers, glycoproteins called *mucins*, and salivary amylase. The **submandibular ducts** (*Wharton's ducts*) open into the mouth on either side of the lingual frenulum immediately posterior to the teeth (see Figure 24–6a•).

Saliva

The salivary glands produce 1.0–1.5 liters of saliva each day. Saliva is 99.4 percent water; the remaining 0.6 percent includes an assortment of electrolytes (principally Na^+, Cland HCO3), buffers, glycoproteins, antibodies, enzymes, and waste products. The glycoproteins, called **mucins**, are primarily responsible for the lubricating action of saliva. About 70 percent of saliva originates in the submandibular salivary glands, 25 percent in the parotids, and the remaining 5 percent in the sublingual salivary glands.

A continuous background level of saliva secretion flushes the oral surfaces, helping keep them clean. Buffers in the saliva keep the pH of your mouth near 7.0 and prevent the buildup of acids produced by bacterial action. In addition, saliva contains antibodies (IgA) and lysozymes that help control populations of oral bacteria. A reduction in or elimination of salivary secretions— caused by radiation exposure, emotional distress, or other factors— triggers a bacterial population explosion in the oral cavity. This proliferation rapidly leads to recurring infections and progressive erosion of the teeth and gums.

The saliva produced when you eat has a variety of functions, including the following:

- Lubricating the mouth.
- Moistening and lubricating materials in the mouth.
- Dissolving chemicals that can stimulate the taste buds and provide sensory information about the material.
- Initiating the digestion of complex carbohydrates before the material is swallowed. The enzyme involved is **salivary amylase**, also known as *ptyalin* or *alpha-amylase*. Although the digestive process begins in the oral cavity, it is not completed there, and no absorption of nutrients occurs across the lining of the cavity. Saliva also contains a small amount of lingual lipase that is secreted by the glands of the tongue.

Clinical Note

The *mumps virus* most often targets the salivary glands, especially the parotid salivary glands, although other organs can also become infected. Infection typically occurs at 5–9 years of age. The first exposure stimulates the production of antibodies and, in most cases, confers permanent immunity. In post-adolescent males, the mumps virus can also infect the testes and cause sterility. Infection of the pancreas by the mumps virus can produce temporary or permanent diabetes; other organ systems, including the central nervous system, are affected in severe cases. A mumps vaccine effectively confers active immunity. Widespread distribution of that vaccine has almost eliminated the incidence of the disease in the United States.

Control of Salivary Secretions

Salivary secretions are normally controlled by the autonomic nervous system. Each salivary gland receives parasympathetic and

sympathetic innervation. The parasympathetic outflow originates in the **salivatory nuclei** of the medulla oblongata and synapses in the submandibular and otic ganglia. l**pp. 484, 486** Any object in your mouth can trigger a salivary reflex by stimulating receptors monitored by the trigeminal nerve (V) or taste buds innervated by cranial nerves VII, IX, or X. Parasympathetic stimulation accelerates secretion by all the salivary glands, resulting in the production of large amounts of saliva. The role of sympathetic innervation remains unclear; evidence suggests that it provokes the secretion of small amounts of very thick saliva.

The salivatory nuclei are also influenced by other brain stem nuclei, as well as by the activities of higher centers. For example, chewing with an empty mouth, smelling food, or even thinking about food initiates an increase in salivary secretion rates; that is why chewing gum is so effective at keeping your mouth moist. The presence of irritating stimuli in the esophagus, stomach, or intestines also accelerates the production of saliva, as does nausea. Increased saliva production in response to unpleasant stimuli helps reduce the magnitude of the stimulus by dilution, by a rinsing action, or by buffering strong acids or bases.

The Teeth

Movements of the tongue are important in passing food across the opposing surfaces, or occlusal surfaces, of the **teeth**. These surfaces perform chewing, or **mastication** (mas-ti-KA¯-shun), of food. Mastication breaks down tough connective tissues in meat and the plant fibers in vegetable matter, and it helps saturate the materials with salivary secretions and enzymes.

Figure 24–8a• is a sectional view through an adult tooth. The bulk of each tooth consists of a mineralized matrix similar to that of bone. This material, called **dentin**, differs from bone in that it does not contain cells. Instead, cytoplasmic processes extend into the dentin from cells in the central **pulp cavity**, an interior chamber. The pulp cavity receives blood vessels and nerves through the **root canal**, a narrow tunnel located at the **root**, or base, of the tooth. Blood vessels and nerves enter the root canal through an opening called the **apical**

foramen to supply the pulp cavity.

The root of each tooth sits in a bony socket called an *alveolus*. Collagen fibers of the **periodontal ligament** extend from the dentin of the root to the bone of the alveolus, creating a strong articulation known as a gomphosis. l**p. 260** A layer of **cementum** (se-MEN-tum) covers the dentin of the root, providing protection and firmly anchoring the periodontal ligament. Cementum is very similar in histological structure to bone and is less resistant to erosion than is dentin.

The **neck** of the tooth marks the boundary between the root and the **crown**, the exposed portion of the tooth that projects beyond the soft tissue of the gingiva. A shallow groove called the **gingival sulcus** surrounds the neck of each tooth. The mucosa of the gingival sulcus is very thin and is not tightly bound to the periosteum. The epithelium is bound to the tooth over an extensive area. This epithelial attachment prevents bacterial access to the lamina propria of the gingiva and the relatively soft cementum of the root. When you brush and massage your gums, you stimulate the epithelial cells and strengthen the attachment. A condition called *gingivitis*, a bacterial infection of the gingivae, can occur if the attachment breaks down.

The dentin of the crown is covered by a layer of **enamel**. Enamel, which contains calcium phosphate in a crystalline form, is the hardest biologically manufactured substance. Adequate amounts of calcium, phosphates, and vitamin D during childhood are essential if the enamel coating is to be complete and resistant to decay.

Tooth decay generally results from the action of bacteria that inhabit your mouth. Bacteria adhering to the surfaces of the teeth produce a sticky matrix that traps food particles and creates deposits known as *dental plaque*. Over time, this organic material can become calcified, forming a hard layer of *tartar*, or *dental calculus*, which can be difficult to remove. Tartar deposits most commonly develop at or near the gingival sulcus, where brushing cannot remove the relatively soft plaque deposits.

Types of Teeth

The alveolar processes of the maxillary bones and the mandible form the *upper* and *lower dental arches*, respectively. These arches contain four types of teeth, each with specific functions (Figure 24–8b•):

1. **1. Incisors** (in-S -zerz) are blade-shaped teeth located at the front of the mouth. Incisors are useful for clipping or cutting, as when you nip off the tip of a carrot stick. These teeth have a single root.

2. **2.** The **cuspids** (KUS-pidz), or *canines*, are conical, with a sharp ridgeline and a pointed tip. They are used for tearing or slashing. You might weaken a tough piece of celery using the clipping action of the incisors and then take advantage of the shearing action provided by the cuspids. Cuspids have a single root.

¯I

3. Bicuspids (b -KUS-pidz), or *premolars*, have flattened crowns with prominent ridges. They crush, mash, and grind. Bicuspids ı have one or two roots.

4. Molars have very large, flattened crowns with prominent ridges adapted for crushing and grinding. You can usually shift a tough nut to your bicuspids and molars for successful crunching. Molars typically have three or more roots.

Dental Succession

–

During embryonic development, two sets of teeth begin to form. The first to appear are the **deciduous teeth** (de-SID-

¯u

-us;

deciduus, falling off), the temporary teeth of the **primary dentition**. Deciduous teeth are also called *primary teeth*, *milk teeth*, or *baby teeth*. Most children have 20 deciduous teeth—5 on each side of the upper and lower jaws (Figure 24–9a•). On each side of the upper or lower jaw, the primary dentition consists of two incisors, one cuspid, and a pair of deciduous molars. These teeth will later be replaced by the **secondary dentition**, or *permanent dentition* (Figure 24–9b•). Adult jaws are larger and can accommodate more than 20 permanent teeth. Three additional molars appear on each side of the upper and lower jaws as the individual ages, extending the length of the tooth rows posteriorly and bringing the permanent tooth count to 32.

As replacement proceeds, the periodontal ligaments and roots of the primary teeth erode until the deciduous teeth either fall out or are pushed aside by the **eruption**, or emergence, of the secondary teeth. The adult premolars take the place of the deciduous molars, and the adult molars extend the tooth row as the jaw enlarges. The third molars, or *wisdom teeth*, may not erupt before age 21. Wisdom teeth may fail to erupt because they develop in inappropriate positions or because space on the dental arch is inadequate. Any teeth that develop in locations that do not permit their eruption are called *impacted teeth*. Impacted wisdom teeth can be surgically removed to prevent the formation of abscesses. AM: Dental Problems and Solutions

Mastication

The *muscles of mastication* close your jaws and slide or rock your lower jaw from side to side. l**p. 340** Chewing is not a simple process; it can involve any combination of mandibular elevation/depression, protraction/retraction, and medial/lateral movement. (Try classifying the movements involved the next time you eat.)

During mastication, you force food from the oral cavity to the vestibule and back, crossing and recrossing the **occlusal surfaces**. This movement results in part from the action of the muscles of mastication, but control would be impossible without the aid of the muscles of the cheeks, lips, and tongue. Once you have shredded or torn the material to a satisfactory consistency and have moistened it with salivary secretions, your tongue begins compacting the debris into a moist, cohesive bolus that can be swallowed relatively easily.

Concept Check

Which type of epithelium lines the oral cavity?

The digestion of which nutrient would be affected by damage to the parotid salivary glands?

Which type of tooth is most useful for chopping off bits of relatively rigid foods?

Answers begin on p. A–1

The Pharynx

Objective

• Describe the anatomy and functions of the pharynx.

The **pharynx** serves as a common passageway for solid food, liquids, and air. The epithelial lining and regions of the pharynx— the nasopharynx, the oropharynx, and the laryngopharynx—were described in Chapter 23. l**p. 819** Food normally passes through the oropharynx and laryngopharynx on its way to the esophagus. Both of these regions have a stratified squamous epithelium similar to that of the oral cavity. The lamina propria contains scattered mucous glands and the lymphoid tissue of the pharyngeal, palatal, and lingual tonsils. Deep to the lamina propria lies a dense layer of elastic fibers, bound to the underlying skeletal muscles.

The specific pharyngeal muscles involved in swallowing were described in Chapter 11. l**p. 341**

. • The *pharyngeal constrictor muscles* push the bolus toward the esophagus.

. • The *palatopharyngeus* and *stylopharyngeus muscles* elevate the larynx.

. • The *palatal muscles* elevate the soft palate and adjacent portions of the pharyngeal wall.

These muscles cooperate with muscles of the oral cavity and esophagus to initiate swallowing, which pushes the bolus along the esophagus and into the stomach.

The Esophagus

Objective

• Describe the anatomy and functions of the esophagus.

The **esophagus** (Figure 24–10•) is a hollow muscular tube with a length of approximately 25 cm (10 in.) and a diameter of about 2 cm (0.80 in.) at its widest point. The primary function of the esophagus is to convey solid food and liquids to the stomach.

The esophagus begins posterior to the cricoid cartilage, at the level of vertebra C6. From this point, where it is at its narrowest, the esophagus descends toward the thoracic cavity posterior to the trachea. It passes inferiorly along the dorsal wall of the mediastinum and enters the abdominopelvic cavity through the **esophageal hiatus** (h ¯ı-A¯-tus), an opening in the diaphragm. The esophagus then empties into the stomach anterior to vertebra T7.

The esophagus is innervated by parasympathetic and sympathetic fibers from the esophageal plexus. l**p. 533** Resting muscle tone in the circular muscle layer in the superior 3 cm (1.2 in.) of the esophagus normally prevents air from entering the esophagus. A comparable zone at the inferior end of the esophagus normally remains in a state of active contraction. This condition prevents the backflow of materials from the stomach into the esophagus. Neither region has a well-defined sphincter muscle comparable to those located elsewhere along the digestive tract. Nevertheless, the terms *upper esophageal sphincter* and *lower esophageal sphincter (cardiac sphincter)* are often used to describe these regions at either end of the esophagus, because they are similar in function to other sphincters. AM: Esophageal Varices

Histology of the Esophagus

The wall of the esophagus contains mucosal, submucosal, and muscularis layers comparable to those depicted in Figure 24–3•. Distinctive features of the esophageal wall (see Figure 24–10•) include the following:

. • The mucosa of the esophagus contains a nonkeratinized, stratified squamous epithelium similar to that of the pharynx and oral cavity.

. • The mucosa and submucosa are thrown into large folds that extend the length of the esophagus. These folds allow for expansion during the passage of a large bolus; muscle tone in the walls keeps the lumen closed, except when you swallow.

. • The muscularis mucosae consists of an irregular layer of smooth muscle.

. • The submucosa contains scattered *esophageal glands*, which produce a mucous secretion that reduces friction between the bolus and the esophageal lining.

. • The muscularis externa has the usual inner circular and outer longitudinal layers. However, in the superior third of the esophagus, these layers contain skeletal muscle fibers; the middle third contains a mixture of skeletal and smooth muscle tissue; along the inferior third, only smooth muscle occurs.

. • There is no serosa, but an adventitia of connective tissue outside the muscularis externa anchors the esophagus to the dorsal body wall. Over the 1–2 cm (0.4–0.8 in.) between the diaphragm and stomach, the esophagus is retroperitoneal, with peritoneum covering the anterior and left lateral surfaces.

Swallowing

Swallowing, or **deglutition** (de-gloo-TISH-un), is a complex process that can be initiated voluntarily but proceeds automatically once it begins. Although you take conscious control over swallowing when you eat or drink, swallowing is also controlled at the subconscious level. For example, swallowing occurs at regular intervals as saliva collects at the back of the mouth. Each day you swallow approximately 2400 times.

We can divide swallowing into buccal, pharyngeal, and esophageal phases:

1. **1.** The **buccal phase** begins with the compression of the bolus against the hard palate. Subsequent retraction of the tongue then forces the bolus into the oropharynx and assists in the elevation of the soft palate, thereby sealing off the nasopharynx (Figure 24–11, STEP 1•). The buccal phase is strictly voluntary. Once the bolus enters the oropharynx, reflex responses are initiated and the bolus is moved toward the stomach.

2. **2.** The **pharyngeal phase** begins as the bolus comes into contact with the palatoglossal and palatopharyngeal arches and the posterior pharyngeal wall (Figure 24–11, STEP 2•). The **swallowing reflex** begins when tactile receptors on the palatal arches and uvula are stimulated by the passage of the bolus. The information is relayed to the **swallowing center** of the medulla oblongata over the trigeminal and glossopharyngeal nerves. Motor commands originating at this center then signal the pharyngeal musculature, producing a coordinated and stereotyped pattern of muscle contraction. Elevation of the larynx and folding of the epiglottis direct the bolus past the closed glottis while the uvula and soft palate block passage back to the nasopharynx. It takes less than a second for the pharyngeal muscles to propel the bolus into the esophagus. During this period, the respiratory centers are inhibited and breathing stops.

3. **3.** The **esophageal phase** of swallowing begins as the contraction of pharyngeal muscles forces the bolus through the entrance to the esophagus (Figure 24–11, STEP 3•).

Once in the esophagus, the bolus is pushed toward the stomach by a peristaltic wave. The approach of the bolus triggers the opening of the lower esophageal sphincter, and the bolus then continues into the stomach (Figure 24–11, STEP 4•).

Primary peristaltic waves are peristaltic movements coordinated by afferent and efferent fibers in the glossopharyngeal and vagus nerves. For a typical bolus, the entire trip takes about 9 seconds. Liquids may make the journey in a few seconds, flowing ahead of the peristaltic contractions with the assistance of gravity. A dry or poorly lubricated bolus travels much more slowly, and a series of *secondary peristaltic waves* may be required to push it all the way to the stomach. Secondary peristaltic waves are local reflexes triggered by the stimulation of sensory receptors in the esophageal walls. AM: Achalasia and Esophagitis

The Stomach

Objective

- Describe the anatomy of the stomach, its histological features, and its roles in digestion and absorption.

The **stomach** performs four major functions: (1) storage of ingested food, (2) mechanical breakdown of ingested food, (3) disruption of chemical bonds in food material through the action of acids and enzymes, and (4) production of *intrinsic factor*, a glycoprotein whose presence in the digestive tract is required for the absorption of vitamin B12 in the small intestine. Ingested substances combine with the secretions of the glands of the stomach, producing a viscous, highly acidic, soupy mixture of partially digested food called **chyme** (k m).

–

ı

Anatomy of the Stomach

The stomach has the shape of an expanded J (Figure 24–12•). A short **lesser curvature** forms the medial surface of the organ, and a long **greater curvature** forms the lateral surface. The anterior and posterior surfaces are smoothly rounded. The shape and size of the stomach are extremely variable from individual to individual and even from one meal to the next. In an “average” stomach, the lesser curvature has a length of approximately 10 cm (4 in.), and the greater curvature measures about 40 cm (16 in.). The stomach typically extends between the levels of vertebrae T7 and L3.

We can divide the stomach into four regions (see Figure 24–12•):

. **1.** *The Cardia.* The **cardia** (KAR-d -uh) is the smallest part of the stomach. It consists of the superior, medial portion of the stom

. e¯ach within 3 cm (1.2 in.) of the junction between the stomach and the esophagus. The cardia contains abundant mucous glands whose secretions coat the connection with the esophagus and help protect that tube from the acids and enzymes of the stomach.

2. **2.** *The Fundus.* The **fundus** (FUN-dus) is the portion of the stomach that is superior to the junction between the stomach and the esophagus. The fundus contacts the inferior, posterior surface of the diaphragm (Figure 24–12a•).

. **3.** *The Body.* The area of the stomach between the fundus and the curve of the J is the **body**, the largest region of the stomach. The body functions as a mixing tank for ingested food and secretions produced in the stomach. *Gastric glands* (*gaster*, stomach) in

. the fundus and body secrete most of the acids and enzymes involved in gastric digestion.

3. **4.** *The Pylorus.* The **pylorus** (p -LOR-us) forms the sharp curve of the J. The pylorus is divided into a **pyloric antrum** (*antron*,

ı cavity), which is connected to the body, and a **pyloric canal**, which empties into the *duodenum*, the proximal segment of the small intestine. As mixing movements occur during digestion, the pylorus frequently changes shape. A muscular **pyloric sphincter** regulates the release of chyme into the duodenum. Glands in the pylorus secrete mucus and important digestive hormones, including *gastrin*, a hormone that stimulates the activity of gastric glands.

The stomach’s volume increases while you eat and then decreases as chyme enters the small intestine. When the stomach is

–

relaxed (empty), the mucosa is thrown into prominent folds called **rugae** (ROO-g ; wrinkles) (Figure 24–12b•)—temporary features that let the gastric lumen expand. As the stomach fills, the rugae gradually flatten out until, at maximum distension, they almost disappear. When empty, the stomach resembles a muscular tube with a narrow, constricted lumen. When full, it can contain 1–1.5 liters of material.

The muscularis mucosae and muscularis externa of the stomach contain extra layers of smooth muscle cells in addition to the usual circular and longitudinal layers. The muscularis mucosae generally contains an outer, circular layer of muscle cells. The muscularis externa has an inner, **oblique layer** of smooth muscle (see Figure 24–12b•). The extra layers of smooth muscle strengthen the stomach wall and assist in the mixing and churning activities essential to the formation of chyme.

¯e

Histology of the Stomach

A simple columnar epithelium lines all portions of the stomach (Figure 24–13a•). The epithelium is a *secretory sheet*, which produces a carpet of mucus that covers the interior surfaces of the stomach. The alkaline mucous layer protects epithelial cells against the acids and enzymes in the gastric lumen.

Shallow depressions called **gastric pits** open onto the gastric surface (Figure 24–13b•). The mucous cells at the base, or *neck*, of each gastric pit actively divide, replacing superficial cells that are shed into the chyme. A typical gastric epithelial cell has a life span of three to seven days, but exposure to alcohol or other chemicals that damage or kill epithelial cells increases the rate of cell turnover.

Gastric Glands

In the fundus and body of the stomach, each gastric pit communicates with several **gastric glands**, which extend deep into the underlying lamina propria (see Figure 24–13b•). Gastric glands are dominated by two types of secretory cells: *parietal cells* and *chief cells*. Together, they secrete about 1500 ml of **gastric juice** each day.

Parietal cells are especially common along the proximal portions of each gastric gland (see Figure 24–13b•). These cells secrete **intrinsic factor**, a glycoprotein that facilitates the absorption of **vitamin B_{12}** across the intestinal lining. (Recall from

Chapter 19 that this vitamin is essential for normal erythropoiesis.) l**p. 649** Parietal cells also secrete *hydrochloric acid* (HCl). They do not produce HCl in the cytoplasm, however, because it is such a

-

strong acid that it would erode a secretory vesicle and destroy the cell. Instead, H^+ and Cl, the two ions that form HCl, are trans

ported independently by different mechanisms (Figure 24–14•). Hydrogen ions are generated inside a parietal cell as the enzyme carbonic anhydrase converts carbon dioxide and water to carbonic acid (H2CO3). The carbonic acid promptly dissociates into hydrogen ions and bicarbonate ions ($HCO3^-$). The hydrogen ions are actively transported into the lumen of the gastric gland. The bicarbonate ions are ejected into the interstitial fluid by a countertransport mechanism that exchanges intracellular bicarbonate ions for extracellular chloride ions. The chloride ions then diffuse across the cell and through open chloride channels in the cell membrane into the lumen of the gastric gland.

The bicarbonate ions released by parietal cells diffuse through the interstitial fluid into the bloodstream. When gastric glands are actively secreting, enough bicarbonate ions enter the bloodstream to increase the pH of the blood significantly. This sudden influx of bicarbonate ions has been called the *alkaline tide*.

The secretory activities of the parietal cells can keep the stomach contents at pH 1.5–2.0. Although this highly acidic environment does not by itself digest chyme, it has four important functions:

1. **1.** The acidity of gastric juice kills most of the microorganisms ingested with food.
2. **2.** The acidity denatures proteins and inactivates most of the enzymes in food.
3. **3.** The acidity helps break down plant cell walls and the connective tissues in meat.
4. **4.** An acidic environment is essential for the activation and function of *pepsin*, a protein-digesting enzyme secreted by chief cells. **Chief cells** are most abundant near the base of a gastric gland (see Figure 24–13b•). These cells secrete **pepsinogen** (pep-SIN-

¯o

-jen), an inactive proenzyme. Pepsinogen is converted by the acid in the gastric lumen to **pepsin**, an active *proteolytic* (protein digesting) enzyme. Pepsin functions most effectively at a strongly acidic pH of 1.5–2.0. In addition, the stomachs of newborn infants (but not of adults) produce **rennin** (also known as *chymosin*) and **gastric lipase**, enzymes important for the digestion of milk. Rennin coagulates milk proteins; gastric lipase initiates the digestion of milk fats.

Pyloric Glands

Glands in the pylorus produce primarily a mucous secretion, rather than enzymes or acid. In addition, several types of enteroendocrine cells are scattered among the mucus-secreting cells. These enteroendocrine cells produce at least seven hormones, most notably **gastrin** (GAS-trin). Gastrin is produced by *G cells*, which are most abundant in the gastric pits of the pyloric antrum. Gastrin stimulates secretion by both parietal and chief cells, as well as contractions of the gastric wall that mix and stir the gastric contents. The pyloric glands also contain *D cells*, which release **somatostatin**, a hormone that inhibits the release of gastrin. D cells continuously release their secretions into the interstitial fluid adjacent to the G cells. This inhibition of gastrin production can be overridden by neural and hormonal stimuli when the stomach is preparing for digestion or is already engaged in digestion.

Clinical Note

¯lowed drugs, including alcohol and aspirin. Gastritis can also appear after severe emotional or physical stress, bacterial infection of the gastric wall, or ingestion of strongly acidic or alkaline chemicals. Over time, gastritis can lead to the erosion of the gastric lining and the development of *peptic ulcers*. AM: Peptic Ulcers A superficial inflammation of the gastric mucosa is called *gastritis* (gas-TR I -tis). The condition can develop after a person has swal-

Regulation of Gastric Activity

The production of acid and enzymes by the gastric mucosa can be (1) controlled by the CNS, (2) regulated by short reflexes of the enteric nervous system, coordinated in the wall of the stomach, and (3) regulated by hormones of the digestive tract. Gastric control proceeds in three overlapping phases, named according to the location of the control center: the *cephalic phase*, the *gastric phase*, and the *intestinal phase* (Figure 24–15• and Table 24–1).

The Cephalic Phase

The **cephalic phase** of gastric secretion begins when you see, smell, taste, or think of food (Figure 24–15, STEP 1•). This stage, which is directed by the CNS, prepares the stomach to receive food. The neural output proceeds by way of the parasympathetic division of the autonomic nervous system, and the vagus nerves innervate the submucosal plexus of the stomach. Next, postganglionic parasympathetic fibers innervate mucous cells, chief cells, parietal cells, and G cells of the stomach. In response to stimulation, the production of gastric juice accelerates, reaching rates of about 500 ml> h. This phase generally lasts only minutes. Emotional states can exaggerate or inhibit the cephalic phase. For example, anger or hostility leads to excessive gastric secretion, whereas anxiety, stress, or fear decreases gastric secretion and gastric contractions, or *motility*.

The Gastric Phase

The **gastric phase** begins with the arrival of food in the stomach and builds on the stimulation provided during the cephalic phase (Figure 24–15, STEP 2•). The stimuli that initiate the gastric phase are (1) distension of the stomach, (2) an increase in the pH of the gastric contents, and (3) the presence of undigested materials in the stomach, especially proteins and peptides. The gastric phase consists of the following mechanisms:

1. **1.** *A Neural Response.* The stimulation of stretch receptors in the stomach wall and chemoreceptors in the mucosa triggers short reflexes coordinated in the submucosal and myenteric plexuses. The postganglionic fibers leaving the submucosal plexus innervate parietal cells and chief cells, and the release of ACh stimulates their secretion. Proteins, alcohol in small doses, and caffeine enhance gastric secretion markedly by stimulating chemoreceptors in the gastric lining. The stimulation of the myenteric plexus produces mixing waves in the muscularis externa.

2. **2.** *A Hormonal Response.* Neural stimulation and the presence of peptides and amino acids in chyme stimulate the secretion of gastrin, primarily by G cells of the pyloric antrum. Gastrin entering the interstitial fluid of the stomach must penetrate capillaries and complete a round trip of the bloodstream before the hormone stimulates parietal and chief cells of the fundus and body. Both parietal and chief cells respond to the presence of gastrin by accelerating their rates of secretion. The effect on the parietal cells is the most pronounced, and the pH of the gastric juice declines as a result. In addition, gastrin stimulates gastric motility.

3. **3.** *A Local Response.* Distention of the gastric wall also stimulates the release of histamine in the lamina propria. The source of the histamine is thought to be mast cells in the connective tissue of that layer. Histamine binds to receptors on the parietal cells and stimulates acid secretion.

The gastric phase may continue for three to four hours while the ingested materials are processed by the acids and enzymes. During this period, gastrin stimulates contractions in the muscularis externa of the stomach and intestinal tract. The effects are strongest in the stomach, where stretch receptors are stimulated as well. The initial contractions are weak pulsations in the gastric walls. These *mixing waves* occur several times per minute and gradually increase in intensity. After an hour, the material in the stomach is churning like clothing in a washing machine.

When the contractions begin, the pH of the gastric contents is high; only the material in contact with the gastric epithelium is exposed to undiluted digestive acids and enzymes. As mixing occurs, the acid is diluted, and the pH remains elevated until a large volume of gastric juice has been secreted and the contents are thoroughly mixed. This process generally takes several hours. As the pH throughout the chyme reaches 1.5–2.0 and the amount of undigested protein decreases, gastrin production declines, as do the rates of acid and enzyme secretion by parietal and chief cells.

The Intestinal Phase

The **intestinal phase** of gastric secretion begins when chyme first enters the small intestine (Figure 24–15, STEP 3•). The intestinal phase generally starts after several hours of mixing contractions, when waves of contraction begin sweeping down the length of the stomach. Each time the pylorus contracts, a small quantity of chyme squirts through the pyloric sphincter. The function of the intestinal phase is controlling the rate of gastric emptying to ensure that the secretory, digestive, and absorptive functions of the small intestine can proceed with reasonable efficiency. Although here we consider the intestinal phase as it affects stomach activity, the arrival of chyme in the small intestine also triggers other neural and hormonal events that coordinate the activities of the intestinal tract and the pancreas, liver, and gallbladder.

The intestinal phase involves a combination of neural and hormonal responses:

1. **1.** *Neural Responses.* Chyme leaving the stomach relieves some of the distension in the stomach wall, thereby reducing the stimulation of stretch receptors. At the same time, the distension of the duodenum by chyme stimulates stretch receptors and chemoreceptors that trigger the **enterogastric reflex**. This reflex temporarily inhibits both central and local stimulation of gastrin production and gastric contractions, as well as stimulating the contraction of the pyloric sphincter. The net result is that immediately after chyme enters the small intestine, gastric contractions decrease in strength and frequency, and further discharge of chyme is prevented, giving the duodenum time to deal with the arriving acids before the next wave of gastric contraction. At the same time, local reflexes at the duodenum stimulate mucus production, which helps protect the intestinal lining from the arriving acids and enzymes.

2. **2.** *Hormonal Responses.* Several hormonal responses are triggered by the arrival of chyme in the duodenum:

- The arrival of lipids (especially triglycerides and fatty acids) and carbohydrates in the duodenum stimulates the secretion of

the hormones *cholecystokinin* (k

-K -nin), or CCK, and *gastric inhibitory peptide* (GIP). CCK inhibits gastric secretion of acids and enzymes; GIP, which also targets the pancreas, inhibits gastric secretion and reduces the rate and force of gastric contractions. As a result, a meal high in fats stays in the stomach longer, and enters the duodenum at a more leisurely pace, than does a low-fat meal. This delay allows more time for lipids to be digested and absorbed in the small intestine.

•

num. Secretin inhibits parietal cell and chief cell activity in the stomach. It also targets two accessory organs: the pancreas,

where it stimulates the production of buffers that will protect the duodenum by neutralizing the acid in chyme, and the liver,

where it stimulates the secretion of bile.

- The arrival of partially digested proteins in the duodenum stimulates G cells in the duodenal wall. These cells secrete gastrin, which circulates to the stomach and accelerates acid and enzyme production. In effect, this is a feedback mechanism that regulates the amount of gastric processing to meet the requirements of a specific meal.

In general, the rate of movement of chyme into the small intestine is highest when the stomach is greatly distended and the meal contains relatively little protein. A large meal containing small amounts of protein, large amounts of carbohydrates (such as rice or pasta), wine (alcohol), and after-dinner coffee (caffeine) will leave your stomach extremely quickly because both alcohol and caffeine stimulate gastric secretion and motility.

Digestion and Absorption in the Stomach

The stomach performs preliminary digestion of proteins by pepsin and, for a variable period, permits the digestion of carbohydrates and lipids by salivary amylase and lingual lipase. Until the pH throughout the contents of the stomach falls below 4.5, salivary amylase and lingual lipase continue to digest carbohydrates and lipids in the meal. These enzymes generally remain active one to two hours after a meal.

As the stomach contents become more fluid and the pH approaches 2.0, pepsin activity increases and protein disassembly begins. Protein digestion is not completed in the stomach, because time is limited and pepsin attacks only specific types of peptide bonds, not all of them. However, pepsin generally has enough time to break down complex proteins into smaller peptide and polypeptide chains before the chyme enters the duodenum.

Although digestion occurs in the stomach, nutrients are not absorbed there, for several reasons: (1) The epithelial cells are covered by a blanket of alkaline mucus and are not directly exposed to chyme, (2) the epithelial cells lack the specialized transport mechanisms of cells that line the small intestine, (3) the gastric lining is relatively impermeable to water, and (4) digestion has not been completed by the time chyme leaves the stomach. At this stage, most carbohydrates, lipids, and proteins are only partially broken down.

Some drugs can be absorbed in the stomach. For example, ethyl alcohol can diffuse through the mucous barrier and penetrate the lipid membranes of the epithelial cells. As a result, alcohol is absorbed in your stomach before any nutrients in a meal reach the bloodstream. Meals containing large amounts of fat slow the rate of alcohol absorption, because alcohol is lipid soluble, and some of it will be dissolved in fat droplets in the chyme. Aspirin is another lipid-soluble drug that can enter the bloodstream across the gastric mucosa. Such drugs alter the properties of the mucous layer and can promote epithelial damage by stomach acids and enzymes. Prolonged use of aspirin can cause gastric bleeding, so individuals with stomach ulcers usually avoid aspirin. AM: Stomach Cancer

100 Keys | The stomach is a storage site that provides time for the physical breakdown of food that must precede chemical digestion. Protein digestion begins in the acid environment of the stomach through the action of pepsin. Carbohydrate digestion, which began with the release of salivary amylase by the salivary glands before swallowing, continues for a variable period after food arrives in the stomach.

Concept Check

How does a large meal affect the pH of blood leaving the stomach? When a person suffers from chronic gastric ulcers, the branches of the vagus nerve that serve the stomach are sometimes cut in an attempt to provide relief. Why might this be an effective treatment?

Answers begin on p. A–1

The Small Intestine and Associated Glandular Organs

Objectives

. • Describe the anatomical and histological characteristics of the small intestine.

. • Explain the functions of the intestinal secretions and discuss the regulation of secretory activities.

. • Describe the structure, functions, and regulation of the accessory digestive organs.

The stomach is a holding tank in which food is saturated with gastric juices and exposed to stomach acids and the digestive effects of pepsin. These are preliminary steps; most of the important digestive and absorptive functions occur in the small intestine, where chemical digestion is completed and the products of digestion are absorbed. The mucosa of the small intestine produces only a few of the enzymes involved. The pancreas provides digestive enzymes, as well as buffers that help neutralize chyme. The liver secretes *bile*, a solution stored in the gallbladder for subsequent discharge into the small intestine. Bile contains buffers and *bile salts*, compounds that facilitate the digestion and absorption of lipids.

The Small Intestine

The **small intestine** plays the key role in the digestion and absorption of nutrients. Ninety percent of nutrient absorption occurs in the small intestine; most of the rest occurs in the large intestine. The small intestine averages 6 m (19.7 ft) in length (range: 4.5–7.5 m; 14.8–24.6 ft) and has a diameter ranging from 4 cm (1.6 in.) at the stomach to about 2.5 cm (1 in.) at the junction with the large intestine. It occupies all abdominal regions except the right and left hypochondriac and epigastric regions (see Figure 1–7b•, p. 17). The small intestine has three segments: the duodenum, the jejunum, and the ileum (Figure 24–16a•).

The **duodenum** (doo-AH-de-num), 25 cm (10 in.) in length, is the segment closest to the stomach. This portion of the small intestine is a “mixing bowl” that receives chyme from the stomach and digestive secretions from the pancreas and liver. From its connection with the stomach, the duodenum curves in a C that encloses the pancreas. Except for the proximal 2.5 cm (1 in.), the duodenum is in a retroperitoneal position between vertebrae L1 and L4 (see Figure 24–2d•).

A rather abrupt bend marks the boundary between the duodenum and the **jejunum** (je-JOO-num). At this junction, the small intestine reenters the peritoneal cavity, supported by a sheet of mesentery. The jejunum is about 2.5 meters (8.2 ft) long. The bulk of chemical digestion and nutrient absorption occurs in the jejunum.

¯o

The **ileum** (IL--um), the final segment of the small intestine, is also the longest, averaging 3.5 meters (11.48 ft) in length.

¯e

The ileum ends at the **ileocecal** (il---S

¯e

¯E

-kal) **valve**, a sphincter that controls the flow of material from the ileum into the *cecum* of the large intestine.

The small intestine fills much of the peritoneal cavity, and its position is stabilized by the mesentery proper, a broad mesentery attached to the dorsal body wall (see Figure 24–2c,d•). Movement of the small intestine during digestion is restricted by the stomach, the large intestine, the abdominal wall, and the pelvic girdle. Blood vessels, lymphatic vessels, and nerves reach the segments of the small intestine within the connective tissue of the mesentery. The primary blood vessels involved are branches of the superior mesenteric artery and the superior mesenteric vein. l**pp. 744, 752**

The segments of the small intestine—the duodenum, jejunum, and ileum—are distinguished by both histological specialization and primary function.

Anatomy 360 | Review the anatomy of the small intestine on the **Anatomy 360 CD-ROM: Digestive System/ Small Intestine.**

Histology of the Small Intestine

The intestinal lining bears a series of transverse folds called **plicae**, or *plicae circulares* (Figures 24–16b•). Unlike the rugae in the stomach, the plicae are permanent features that do not disappear when the small intestine fills. The small intestine contains roughly 800 plicae—roughly 2 per cm. Their presence greatly increases the surface area available for absorption.

Intestinal Villi The mucosa of the small intestine is thrown into a series of fingerlike projections, the **intestinal villi** (Figure 24–17a,b•). These structures are covered by a simple columnar epithelium that is carpeted with microvilli. Because the microvilli project from the epithelium like the bristles on a brush, these cells are said to have a *brush border* (Figure 24–17d•).

If the small intestine were a simple tube with smooth walls, it would have a total absorptive area of roughly 3300 cm^2 (3.6 ft^2). Instead, the mucosa contains plicae, each plica supports a forest of villi, and each villus is covered by epithelial cells whose exposed surfaces contain microvilli. This arrangement increases the total area for absorption by a factor of more than 600, to approximately 2 million cm^2 (more than 2200 ft^2, roughly the floor space of a spacious four-bedroom home).

The lamina propria of each villus contains an extensive network of capillaries that originate in a vascular network within the submucosa (Figure 24–17c•). These capillaries carry absorbed nutrients to the hepatic portal circulation for delivery to the liver, which adjusts the nutrient concentrations of blood before the blood reaches the general systemic circulation.

In addition to capillaries and nerve endings, each villus contains a lymphatic capillary called a **lacteal** (LAK-te¯-ul; *lacteus*, milky) (see Figure 24–17b,c•). Lacteals transport materials that cannot enter blood capillaries. For example, absorbed fatty acids are assembled into protein–lipid packages that are too large to diffuse into the bloodstream. These packets, called *chylomicrons*, reach the venous circulation via the thoracic duct, which delivers lymph into the left subclavian vein. The name *lacteal* refers to the pale, milky appearance of lymph that contains large quantities of lipids.

Contractions of the muscularis mucosae and smooth muscle cells within the intestinal villi move the villi back and forth, exposing the epithelial surfaces to the liquefied intestinal contents. This movement improves the efficiency of absorption by quickly eliminating local differences in nutrient concentration. Movements of the villi also squeeze the lacteals, thereby assisting in the movement of lymph out of the villi.

Intestinal Glands Goblet cells between the columnar epithelial cells eject mucins onto the intestinal surfaces (see Figure 24–17c,d•). At the bases of the villi are the entrances to the **intestinal glands**, or *crypts of Lieberkühn*. These glandular pockets extend deep into the underlying lamina propria. Near the base of each intestinal gland, stem cell divisions produce new generations of epithelial cells, which are continuously displaced toward the intestinal surface. In a few days the new cells will have reached the tip of a villus, where they are shed into the intestinal lumen. This ongoing process renews the epithelial surface, and the subsequent disintegration of the shed cells adds enzymes to the lumen.

Several important brush border enzymes enter the intestinal lumen in this way. *Brush border enzymes* are integral membrane proteins located on the surfaces of intestinal microvilli. These enzymes perform the important digestive function of breaking down materials that come in contact with the brush border. The breakdown products are then absorbed by the epithelial cells. Once the epithelial cells are shed, they disintegrate within the lumen, releasing intracellular and brush border enzymes. *Enterokinase*, one brush border enzyme that enters the lumen in this way, does not directly participate in digestion, but it activates a key pancreatic proenzyme, trypsinogen. (We will consider the functions of enterokinase and other brush border enzymes in a later section.) Intestinal glands also contain enteroendocrine cells responsible for the production of several intestinal hormones, including gastrin, cholecystokinin, and secretin.

The duodenum has numerous mucous glands, both in the epithelium and deep to it. In addition to intestinal glands, its submucosa contains **duodenal glands**, also called *submucosal glands* or *Brunner's glands*, which produce copious quantities of mucus when chyme arrives from the stomach. The mucus protects the epithelium from the acidity of chyme and also contains buffers that help elevate the pH of the chyme. Along the length of the duodenum, the pH of chyme goes from 1–2 to 7–8. The duodenal glands also secrete the hormone *urogastrone*, which inhibits gastric acid production and stimulates the division of epithelial stem cells along the digestive tract.

Regional Specializations The duodenum has few plicae, and their villi are small. The primary function of the duodenum is to receive chyme from the stomach and neutralize its acids before they can damage the absorptive surfaces of the small intestine. Over the proximal half of the jejunum, however, plicae and villi are very prominent. Thereafter, the plicae and villi gradually decrease in size. This reduction parallels a reduction in absorptive activity: Most nutrient absorption has occurred before ingested materials reach the ileum. One rather drastic surgical method of promoting weight loss is the removal of a significant portion of the jejunum. The resulting reduction in absorptive area causes a marked weight loss and may not interfere with adequate nutrition, but the side effects can be very serious.

AM: Drastic Weight-Loss Techniques

The distal portions of the ileum lack plicae, and the lamina propria there contains 20–30 masses of lymphoid tissue called aggregated lymphoid nodules (*Peyer's patches*). These lymphoid tissues are most abundant in the terminal portion of the ileum, near the entrance to the large intestine. The lymphocytes in the aggregated lymphoid nodules protect the small intestine from bacteria that are normal inhabitants of the large intestine.

Intestinal Secretions

Roughly 1.8 liters of watery **intestinal juice** enters the intestinal lumen each day. Intestinal juice moistens chyme, assists in buffering acids, and keeps both the digestive enzymes and the products of digestion in solution. Much of this fluid volume arrives by osmosis, as water flows out of the mucosa and into the relatively concentrated chyme. The rest is secreted by intestinal glands, stimulated by the activation of touch receptors and stretch receptors in the intestinal walls.

The duodenal glands help protect the duodenal epithelium from gastric acids and enzymes. These glands increase their secretory activities in response to (1) local reflexes, (2) the release of the hormone *enterocrinin* by enteroendocrine cells of the duodenum, and (3) parasympathetic stimulation via the vagus nerves. The first two mechanisms operate only after chyme arrives in the duodenum. However, because vagus nerve activity triggers their secretion, the duodenal glands begin secreting during the cephalic phase of gastric secretion, long before chyme reaches the pyloric sphincter. Thus, the duodenal lining has protection in advance.

Sympathetic stimulation inhibits the activation of the duodenal glands, leaving the duodenal lining relatively unprepared for the arrival of chyme. This fact probably accounts for the common observation that duodenal ulcers can be caused by chronic stress or other factors that promote sympathetic activation.

Intestinal Movements

After chyme has arrived in the duodenum, weak peristaltic contractions move it slowly toward the jejunum. The contractions are myenteric reflexes that are not under CNS control. Their effects are limited to within a few centimeters of the site of the original stimulus. These short reflexes are controlled by motor neurons in the submucosal and myenteric plexuses. In addition, some of the smooth muscle cells contract periodically, even without stimulation, establishing a basic contractile rhythm that then spreads from cell to cell.

The stimulation of the parasympathetic system increases the sensitivity of the weak myenteric reflexes and accelerates both local peristalsis and segmentation. More elaborate reflexes coordinate activities along the entire length of the small intestine. Two reflexes are triggered by the stimulation of stretch receptors in the stomach as it fills. The **gastroenteric reflex** stimulates motility and secretion along the entire small intestine; the **gastroileal** (gas-tr-IL--al) **reflex** triggers the relaxation of the ileocecal valve. The net result is that materials pass from the small intestine into the large intestine. Thus, the gastroenteric and gastroileal reflexes accelerate movement along the small intestine—the opposite effect of the enterogastric reflex.

Hormones released by the digestive tract can enhance or suppress reflexes. For example, the gastroileal reflex is triggered by stretch receptor stimulation, but the degree of ileocecal valve relaxation is enhanced by gastrin, which is secreted in large quantities when food enters the stomach. AM: Vomiting

tamins, and the chemical products released by the action of digestive enzymes produced by intestinal glands and the exocrine glands of the pancreas.

The Pancreas

The **pancreas** lies posterior to the stomach, extending laterally from the duodenum toward the spleen. The pancreas is an elongate, pinkish-gray organ about 15 cm (6 in.) long (Figure 24–18a•) and weighing about 80 g (3 oz). The broad **head** of the pancreas lies within the loop formed by the duodenum as it leaves the pylorus. The slender **body** of the pancreas extends toward the e

The small intestine receives and raises the pH of materials from the stomach. It then absorbs water, ions, vi-

|

100 Keys

spleen, and the **tail** is short and bluntly rounded. The pancreas is retroperitoneal and is firmly bound to the posterior wall of the abdominal cavity. The surface of the pancreas has a lumpy, lobular texture. A thin, transparent capsule of connective tissue wraps the entire organ. The pancreatic lobules, associated blood vessels, and excretory ducts are visible through the anterior capsule and the overlying layer of peritoneum. Arterial blood reaches the pancreas by way of branches of the splenic, superior mesenteric, and common hepatic arteries. The pancreatic arteries and pancreaticoduodenal arteries are the major branches from these vessels. The splenic vein and its branches drain the pancreas.

The pancreas is primarily an exocrine organ, producing digestive enzymes and buffers. The large **pancreatic duct** *(duct of Wirsung)* delivers these secretions to the duodenum. (In 3–10 percent of the population, a small **accessory pancreatic duct** *(duct of Santorini)* branches from the pancreatic duct.) The pancreatic duct extends within the attached mesentery to reach the duodenum, where it meets the *common bile duct* from the liver and gallbladder (see Figure 24–21b•, p. 892). The two ducts then empty into the *duodenal ampulla*, a chamber located roughly halfway along the length of the duodenum. When present, the accessory pancreatic duct generally empties into the duodenum independently, outside the duodenal ampulla.

Histological Organization

Partitions of connective tissue divide the interior of the pancreas into distinct lobules. The blood vessels and tributaries of the pancreatic ducts are situated within these connective-tissue septa (Figure 24–18b•). The pancreas is an example of a *compound tubuloalveolar gland*, a structure described in Chapter 4. l**p. 117** In each lobule, the ducts branch repeatedly before ending in blind

–
o
–

pockets called **pancreatic acini** (AS-i-n). Each pancreatic acinus is lined with a simple cuboidal epithelium. *Pancreatic islets*, the

ı endocrine tissues of the pancreas, are scattered among the acini (Figure 24–18b,c•). The islets account for only about 1 percent of the cell population of the pancreas.

The pancreas has two distinct functions, one endocrine and the other exocrine. The endocrine cells of the pancreatic islets secrete insulin and glucagon into the bloodstream. The exocrine cells include the acinar cells and the epithelial cells that line the duct system. Together, the acinar cells and the epithelial cells secrete **pancreatic juice**—an alkaline mixture of digestive enzymes, water, and ions—into the small intestine. Pancreatic enzymes are secreted by the acinar cells. These enzymes do most of the digestive work in the small intestine, breaking down ingested materials into small molecules suitable for absorption. The water and ions, secreted primarily by the cells lining the pancreatic ducts, assist in diluting and buffering the acids in the chyme.

Physiology of the Pancreas

Each day, the pancreas secretes about 1000 ml (1 qt) of pancreatic juice. The secretory activities are controlled primarily by hormones from the duodenum. When chyme arrives in the duodenum, secretin is released. This hormone triggers the pancreatic secretion of a watery buffer solution with a pH of 7.5–8.8. Among its other components, the secretion contains bicarbonate and phosphate buffers that help elevate the pH of the chyme. A different duodenal hormone, cholecystokinin, stimulates the production and secretion of pancreatic enzymes. Pancreatic enzyme secretion also increases under stimulation by the vagus nerves. As noted earlier, this stimulation occurs during the cephalic phase of gastric regulation, so the pancreas starts to synthesize enzymes before food even reaches the stomach. Such a head start is important, because enzyme synthesis takes much longer than the production of buffers. By starting early, the pancreatic cells are ready to meet the demand when chyme arrives in the duodenum.

The specific pancreatic enzymes involved include the following:

•

Pancreatic alpha-amylase, a **carbohydrase** (kar-b
¯o
-H

¯I

-dr
¯a
s)—an enzyme that breaks down certain starches. Pancreatic
alpha-amylase is almost identical to salivary amylase.

. • Pancreatic lipase, which breaks down certain complex lipids, releasing products (such as fatty acids) that can be easily absorbed.

. • Nucleases, which break down nucleic acids.

. • Proteolytic enzymes, which break certain proteins apart. The proteolytic enzymes of the pancreas include **proteases**, which break apart large protein complexes, and **peptidases**, which break small peptide chains into individual amino acids.

Proteolytic enzymes account for about 70 percent of total pancreatic enzyme production. The enzymes are secreted as inactive proenzymes and are activated only after they reach the small intestine. Proenzymes discussed earlier in the text include pepsinogen, angiotensinogen, plasminogen, fibrinogen, and many of the clotting factors and enzymes of the complement system.

l**pp. 621, 642, 664, 779** As in the stomach, the release of a proenzyme rather than an active enzyme protects the secretory cells in the pancreas from the destructive effects of their own products. Among the proenzymes secreted by the pancreas are **trypsinogen** (trip-SIN-ō-jen), **chymotrypsinogen** (kī-mō-trip-SIN-ō-jen), **procarboxypeptidase** (prō-kar-bok-sē-PEP-ti-dās), and **proelastase** (pro-ē-LAS-tās).

Once inside the duodenum, enterokinase located in the brush border and in the lumen triggers the conversion of trypsinogen to **trypsin**, an active protease. Trypsin then activates the other proenzymes, producing **chymotrypsin**, **carboxypeptidase**, and **elastase**. Each enzyme attacks peptide bonds linking specific amino acids and ignores others. Together, they break down proteins into a mixture of dipeptides, tripeptides, and amino acids.

Clinical Note

Pancreatitis (pan-kr ¯e -a-T I -tis) is an inflammation of the pancreas. A blockage of the excretory ducts, bacterial or viral infections, ischemia, and drug reactions, especially those involving alcohol, are among the factors that may produce this extremely painful condition. These stimuli provoke a crisis by injuring exocrine cells in at least a portion of the organ. Lysosomes in the damaged cells then activate the proenzymes, and autolysis begins. The proteolytic enzymes digest the surrounding, undamaged cells, activating their enzymes and starting a chain reaction. In most cases, only a portion of the pancreas is affected, and the condition subsides in a few days. In 10–15 percent of pancreatitis cases, the process does not subside; the enzymes can then ultimately destroy the pancreas.

If the islet cells are damaged, diabetes mellitus may result. l**p. 619**

100 Keys | The exocrine pancreas produces a mixture of buffers and enzymes essential for normal digestion. Pancreatic secretion occurs in response to the release of regulatory hormones (CCK and secretin) by the duodenum.

The Liver

The **liver**, the largest visceral organ, is one of the most versatile organs in the body. Most of its mass lies in the right hypochondriac and epigastric regions, but it may extend into the left hypochondriac and umbilical regions as well. The liver weighs about 1.5 kg (3.3 lb). This large, firm, reddish-brown organ performs essential metabolic and synthetic functions.

Anatomy of the Liver

The liver is wrapped in a tough fibrous capsule and is covered by a layer of visceral peritoneum. On the anterior surface, the **falciform ligament** marks the division between the organ’s left lobe and the right lobe (Figure 24–19a,b•). A thickening in the posterior margin of the falciform ligament is the **round ligament**, or *ligamentum teres,* a fibrous band that marks the path of the fetal umbilical vein.

On the posterior surface of the liver, the impression left by the inferior vena cava marks the division between the right lobe

¯a

and the small **caudate** (KAW-d t) **lobe** (Figure 24–19a,c•). Inferior to the caudate lobe lies the **quadrate lobe**, sandwiched between the left lobe and the gallbladder. Afferent blood vessels and other structures reach the liver by traveling within the connective tissue of the lesser omentum. They converge at a region called the **porta hepatis** (“doorway to the liver”).

The circulation to the liver was discussed in Chapter 21 and summarized in Figures 21–25 and 21–32•, pp. 744, 753. Roughly one-third of the blood supply to the liver is arterial blood from the hepatic artery proper. The rest is venous blood from the hepatic portal vein, which begins in the capillaries of the esophagus, stomach, small intestine, and most of the large intestine. Liver cells, called **hepatocytes** (hep-a-to-sit), adjust circulating levels of nutrients through selective absorption and secretion. Blood leaving the liver returns to the systemic circuit via the hepatic veins, which open into the inferior vena cava.

Histological Organization of the Liver

Each lobe of the liver is divided by connective tissue into approximately 100,000 **liver lobules**, the basic functional units of the liver. The histological organization and structure of a typical liver lobule are shown in Figure 24–20•.

Each lobule is roughly 1 mm in diameter. Adjacent lobules are separated from each other by an *interlobular septum*. The hepatocytes in a liver lobule form a series of irregular plates arranged like the spokes of a wheel (Figure 24–20a,b•). The plates are only one cell thick, and exposed hepatocyte surfaces are covered with short microvilli. Within a lobule, sinusoids between adjacent plates empty into the **central vein**. (Sinusoids were introduced in Chapter 21. l**p. 715**) The liver sinusoids lack a basal lamina, so large openings between the endothelial cells allow solutes—even those as large as plasma proteins—to pass out of the bloodstream and into the spaces surrounding the hepatocytes.

In addition to containing typical endothelial cells, the sinusoidal lining includes a large number of **Kupffer** (KOOP-fer) **cells**, also known as *stellate reticuloendothelial cells*. l**p. 777** These phagocytic cells, part of the monocyte–macrophage system, engulf pathogens, cell debris, and damaged blood cells. Kupffer cells are also responsible for storing iron, some lipids, and heavy metals (such as tin or mercury) that are absorbed by the digestive tract.

Blood enters the liver sinusoids from small branches of the hepatic portal vein and hepatic artery proper. A typical liver lobule has a hexagonal shape in cross section (see Figure 24–20a•). There are six **portal areas**, or *hepatic triads*, one at each corner of the lobule. A portal area contains three structures: (1) a branch of the hepatic portal vein, (2) a branch of the hepatic artery proper, and (3) a small branch of the bile duct (see Figure 24–20a–c•).

Branches from the arteries and veins deliver blood to the sinusoids of adjacent liver lobules (see Figure 24–20a,b•). As blood flows through the sinusoids, hepatocytes absorb solutes from the plasma and secrete materials such as plasma proteins. Blood then leaves the sinusoids and enters the central vein of the lobule. The central veins ultimately merge to form the hepatic veins, which then empty into the inferior vena cava. Liver diseases, such as the various forms of *hepatitis*, and conditions such as alcoholism can lead to degenerative changes in the liver tissue and constriction of the circulatory supply. AM: Liver Disease

Pressures in the hepatic portal system are usually low, averaging 10 mm Hg or less. This pressure can increase markedly, however, if blood flow through the liver becomes restricted as a result of a blood clot or damage to the organ. Such a rise in portal pressure is called *portal hypertension*. As pressures rise, small peripheral veins and capillaries in the portal system become distended; if they rupture, extensive bleeding can occur. Portal hypertension can also force fluid into the peritoneal cavity across the serosal surfaces of the liver and viscera, producing ascites (p. 864).

The Bile Duct System

The liver secretes a fluid called **bile** into a network of narrow channels between the opposing membranes of adjacent liver cells. These passageways, called **bile canaliculi**, extend outward, away from the central vein (see Figure 24–20b•). Eventually, they connect with fine **bile ductules** (DUK-tu¯lz), which carry bile to bile ducts in the nearest portal area (see Figure 24–20a•). The **right** and **left hepatic ducts** (Figure 24–21a•) collect bile from all the bile ducts of the liver lobes. These ducts unite to form the **common hepatic duct**, which leaves the liver. The bile in the common hepatic duct either flows into the *common bile duct*, which empties into the duodenal ampulla, or enters the *cystic duct*, which leads to the gallbladder.

The **common bile duct** is formed by the union of the **cystic duct** and the common hepatic duct. The common bile duct passes within the lesser omentum toward the stomach, turns, and penetrates the wall of the duodenum to meet the pancreatic duct at the duodenal ampulla (Figure 24–21b•).

The Physiology of the Liver

The liver is responsible for three general categories of functions: (1) *metabolic regulation*, (2) *hematological regulation*, and (3) *bile production*. The liver has more than 200 functions; this discussion will provide only a general overview.

Metabolic Regulation The liver is the primary organ involved in regulating the composition of circulating blood. All blood leaving the absorptive surfaces of the digestive tract enters the hepatic portal system and flows into the liver. Liver cells extract nutrients or toxins from the blood before it reaches the systemic circulation through the hepatic veins. The liver removes and stores excess nutrients, and it corrects nutrient deficiencies by mobilizing stored reserves or performing synthetic activities. The liver’s regulatory activities affect the following:

. • **Carbohydrate Metabolism.** The liver stabilizes blood glucose levels at about 90 mg > dl. If blood glucose levels drop, hepatocytes break down glycogen reserves and release glucose into the bloodstream. They also synthesize glucose from other carbohydrates or from available amino acids. The synthesis of glucose from other compounds is a process called *gluconeogenesis*. If blood glucose levels climb, hepatocytes remove glucose from the bloodstream and either store it as glycogen or use it to synthesize lipids that can be stored in the liver or other tissues. These metabolic activities are regulated by circulating hormones,

. such as insulin and glucagon. l**pp. 617–619**

. • **Lipid Metabolism.** The liver regulates circulating levels of triglycerides, fatty acids, and cholesterol. When those levels decline, the liver breaks down its lipid reserves and releases the breakdown products into the bloodstream. When the levels are high, the lipids are removed for storage. However, because most lipids absorbed by the digestive tract bypass the hepatic portal circulation, this regulation occurs only after lipid levels have risen within the general circulation.

. • **Amino Acid Metabolism.** The liver removes excess amino acids from the bloodstream. These amino acids can be used to synthesize proteins or can be converted to lipids or glucose for storage.

. • **Waste Product Removal.** When converting amino acids to lipids or carbohydrates, or when breaking down amino acids to get energy, the liver strips off the amino groups, a process called *deamination*. Ammonia, a toxic waste product, is formed. The liver neutralizes ammonia by converting it to *urea*, a fairly harmless compound excreted by the kidneys. Other waste products, circulating toxins, and drugs are also removed from the blood for inactivation, storage, or excretion.

. • **Vitamin Storage.** Fat-soluble vitamins (A, D, E, and K) and vitamin B12 are absorbed from the blood and stored in the liver.

. These reserves are called on when your diet contains inadequate amounts of those vitamins.

. • **Mineral Storage.** The liver converts iron reserves to ferritin and stores this protein–iron complex. l**p. 648**

. • **Drug Inactivation.** The liver removes and breaks down circulating drugs, thereby limiting the duration of their effects. When physicians prescribe a particular drug, they must take into account the rate at which the liver removes that drug from the bloodstream. For example, a drug that is absorbed relatively quickly must be administered every few hours to keep plasma concentrations at therapeutic levels.

Clinical Note

Any condition that severely damages the liver represents a serious threat to life. The liver has a limited ability to regenerate itself after injury, but liver function will not fully recover unless the normal vascular pattern is restored. Examples of important types of liver disease include cirrhosis, which is characterized by the replacement of lobules by fibrous tissue, and various forms of *hepatitis* caused by viral infections. In some cases, liver transplants are used to treat liver failure, but the supply of suitable donor tissue is limited, and the success rate is highest in young, otherwise healthy individuals. Clinical trials are now under way to test an artificial liver known as *ELAD* (*e*xtracorporeal *l*iver *a*ssist *d*evice) that may prove suitable for the long-term support of persons with chronic liver disease. AM: Liver Disease

Hematological Regulation The liver, the largest blood reservoir in your body, receives about 25 percent of cardiac output. As blood passes through it, the liver performs the following functions:

- **Phagocytosis and Antigen Presentation.** Kupffer cells in the liver sinusoids engulf old or damaged red blood cells, cellular debris, and pathogens, removing them from the bloodstream. Kupffer cells are antigen-presenting cells that can stimulate an immune response. l**p. 785**
- **Synthesis of Plasma Proteins.** Hepatocytes synthesize and release most of the plasma proteins, including the albumins (which contribute to the osmotic concentration of the blood), the various types of transport proteins, clotting proteins, and complement proteins.
- **Removal of Circulating Hormones.** The liver is the primary site for the

absorption and recycling of epinephrine, norepinephrine, insulin, thyroid hormones, and steroid hormones, such as the sex hormones (estrogens and androgens) and corticosteroids. The liver also absorbs cholecalciferol (vitamin D3) from the blood. Liver cells then convert the cholecalciferol, which may be synthesized in the skin or absorbed in the diet, into an intermediary product, 25-hydroxy-D3, that is released back into

. the bloodstream. This intermediary is absorbed by the kidneys and used to generate calcitriol, a hormone important to Ca^{2+} metabolism. l**p. 621**

. • **Removal of Antibodies.** The liver absorbs and breaks down antibodies, releasing amino acids for recycling.

. • **Removal or Storage of Toxins.** Lipid-soluble toxins in the diet, such as the insecticide DDT, are absorbed by the liver and stored in lipid deposits, where they do not disrupt cellular functions. Other toxins are removed from the bloodstream and are either broken down or excreted in the bile.

. • **The Synthesis and Secretion of Bile.** Bile is synthesized in the liver and excreted into the lumen of the duodenum. Bile consists mostly of water, with minor amounts of ions, *bilirubin* (a pigment derived from hemoglobin), cholesterol, and an assortment of lipids collectively known as the **bile salts**. (Bile salts play a role in the digestion of lipids, as discussed in the next section.) The water and ions assist in the dilution and buffering of acids in chyme as it enters the small intestine.

Bile salts are synthesized from cholesterol in the liver. Several related compounds are involved; the most abundant are derivatives of the steroids *cholate* and *chenodeoxycholate*. The Functions of Bile Most dietary lipids are not water soluble. Mechanical processing in the stomach creates large drops containing a variety of lipids. Pancreatic lipase is not lipid soluble, so the enzymes can interact with lipids only at the surface of a lipid droplet. The larger the droplet, the more lipids are inside, isolated and protected from these enzymes. Bile salts break the droplets

apart in a process called **emulsification** (

¯e

-mul-si-fi-K
¯A

-shun), which dramatically increases the surface area accessible to enzymatic attack.

Emulsification creates tiny *emulsion droplets* with a superficial coating of bile salts. The formation of tiny droplets increases the surface area available for enzymatic attack. In addition, the layer of bile salts facilitates interaction between the lipids and lipid-digesting enzymes supplied by the pancreas. After lipid digestion has been completed, bile salts promote the absorption of lipids by the intestinal epithelium. More than 90 percent of the bile salts are themselves reabsorbed, primarily in the ileum, as lipid digestion is completed. The reabsorbed bile salts enter the hepatic portal circulation and are collected and recycled by the liver. The cycling of bile salts from the liver to the small intestine and back is called the **enterohepatic circulation of bile**.

Anatomy 360 | Review the anatomy of the accessory digestive organs on the **Anatomy 360 CD-ROM: Digestive System/Liver.**

The Gallbladder

The **gallbladder** is a hollow, pear-shaped organ that stores and concentrates bile prior to its excretion into the small intestine. This muscular sac is located in a fossa, or recess, in the posterior surface of the liver's right lobe (see Figure 24–21a•). The gallbladder is divided into three regions: (1) the **fundus**, (2) the **body**, and (3) the **neck**. The cystic duct extends from the gallbladder to the point where its union with the common hepatic duct forms the common bile duct. At the duodenum, the common bile duct meets the pancreatic duct before emptying into a chamber called the **duodenal ampulla** (am-P
¯U

L-a) (see Figure 24–21b•), which receives buffers and enzymes from the pancreas and bile from the liver and gallbladder. The duodenal ampulla opens into the duodenum at the **duodenal papilla**, a small mound.

The muscular **hepatopancreatic sphincter** (*sphincter of Oddi*) encircles the lumen of the common bile duct and, generally, the pancreatic duct and duodenal ampulla as well.

Physiology of the Gallbladder

A major function of the gallbladder is *bile storage*. Bile is secreted continuously—roughly 1 liter is produced each day—but it is released into the duodenum only under the stimulation of the intestinal hormone CCK. In the absence of CCK, the hepatopancreatic sphincter remains closed, so bile exiting the liver in the common hepatic duct cannot flow through the common bile duct and into the duodenum. Instead, it enters the cystic duct and is stored within the expandable gallbladder. Whenever chyme enters the duodenum, CCK is released, relaxing the hepatopancreatic sphincter and stimulating contractions in the walls of the gallbladder that push bile into the small intestine. The amount of CCK secreted increases markedly when the chyme contains large amounts of lipids.

The gallbladder also functions in *bile modification*. When full, the gallbladder contains 40–70 ml of bile. The composition of bile gradually changes as it remains in the gallbladder: Much of the water is absorbed, and the bile salts and other components of bile become increasingly concentrated.

If bile becomes too concentrated, crystals of insoluble minerals and salts begin to form. These deposits are called *gallstones*.

Small gallstones are not a problem so long as they can be flushed down the bile duct and excreted. In *cholecystitis* (k
¯o
-l
¯e
-sis-T
¯I

-tis; *chole*, bile + *kystis*, bladder + *itis*, inflammation), the gallstones are so large that they can damage the wall of the gallbladder or block the cystic or common bile duct. In that case, the gallbladder may need to be surgically removed. This does not seriously impair digestion, because bile production continues at normal levels. However, the bile is more dilute, and its entry into the small intestine is not as closely tied to the arrival of food in the duodenum. AM: Cholecystitis

100 Keys | The liver is the center for metabolic regulation in the body. It also produces bile that is stored in the gallblad

der and ejected into the duodenum under the stimulation of CCK. Bile is essential for the efficient digestion of lipids; it

breaks down large lipid droplets so that individual lipid molecules can be attacked by digestive enzymes.

The Coordination of Secretion and Absorption

A combination of neural and hormonal mechanisms coordinates the activities of the digestive glands. These regulatory mechanisms are centered around the duodenum, where acids must be neutralized and the appropriate enzymes added.

Neural mechanisms involving the CNS (1) prepare the digestive tract for activity (parasympathetic innervation) or inhibit gastrointestinal activity (sympathetic innervation) and (2) coordinate the movement of materials along the length of the digestive tract (the enterogastric, gastroenteric, and gastroileal reflexes).

In addition, motor neurons synapsing in the digestive tract release a variety of neurotransmitters. Many of these chemicals are also released in the CNS, but in general, their functions are poorly understood. Examples of potentially important neurotransmitters include substance P, enkephalins, and endorphins.

We will now summarize the information presented thus far on the regulation of intestinal and glandular function and consider some additional details about the regulatory mechanisms involved.

Intestinal Hormones

The intestinal tract secretes a variety of peptide hormones with similar chemical structures. Many of these hormones have multiple effects in several regions of the digestive tract, and in the accessory glandular organs as well.

Duodenal enteroendocrine cells produce the following hormones known to coordinate digestive functions:

. • **Secretin** is released when chyme arrives in the duodenum. Secretin’s primary effect is an increase in the secretion of bile and buffers by the liver and pancreas. Among its secondary effects, secretin reduces gastric motility and secretory rates.

. • **Cholecystokinin (CCK)** is secreted when chyme arrives in the duodenum, especially when the chyme contains lipids and partially digested proteins. In the pancreas, CCK accelerates the production and secretion of all types of digestive enzymes. It also causes a relaxation of the hepatopancreatic sphincter and contraction of the gallbladder, resulting in the ejection of bile and pancreatic juice into the duodenum. Thus, the net effects of CCK are to increase the secretion of pancreatic enzymes and to push pancreatic secretions and bile into the duodenum. The presence of CCK in high concentrations has two additional effects: It inhibits gastric activity, and it appears to have CNS effects that reduce the sensation of hunger.

. • **Gastric inhibitory peptide (GIP)** is secreted when fats and carbohydrates—especially glucose—enter the small intestine. The inhibition of gastric activity is accompanied by the stimulation of insulin release at the pancreatic islets, so GIP is also known as *glucose-dependent insulinotropic peptide*. This hormone has several secondary effects; for instance, it stimulates the activity of the duodenal glands, stimulates lipid synthesis in adipose tissue, and increases glucose use by skeletal muscles.

. • **Vasoactive intestinal peptide (VIP)** stimulates the secretion of intestinal glands, dilates regional capillaries, and inhibits acid production in the stomach. By dilating capillaries in active areas of the intestinal tract, VIP provides an efficient mechanism for removing absorbed nutrients.

. • **Gastrin** is secreted by G cells in the duodenum when they are exposed to large quantities of incompletely digested proteins. The functions of gastrin include promoting increased stomach motility and stimulating the production of acids and enzymes. (Gastrin is also secreted by the stomach, as detailed on p. 880.)

. • **Enterocrinin**, a hormone released when chyme enters the small intestine, stimulates mucin production by the submucosal glands of the duodenum.

. • **Other intestinal hormones** are produced in relatively small quantities. Examples include *motilin*, which stimulates intestinal contractions; *villikinin*, which promotes the movement of villi and the associated lymph flow; and *somatostatin*, which inhibits gastric secretion.

Table 24–2 summarizes the origins and primary effects of these important digestive hormones. Functional interactions among gastrin, secretin, CCK, GIP, and VIP are diagrammed in Figure 24–22•.

Intestinal Absorption

On average, it takes about five hours for materials to pass from the duodenum to the end of the ileum, so the first of the materials to enter the duodenum after you eat breakfast may leave the small intestine at lunchtime. Along the way, the organ's absorptive effectiveness is enhanced by the fact that so much of the mucosa is movable. The microvilli can be moved by their supporting microfilaments, the individual villi by smooth muscle cells, groups of villi by the muscularis mucosae, and the plicae by the muscularis mucosae and the muscularis externa. These movements stir and mix the intestinal contents, changing the environment around each epithelial cell from moment to moment.

Concept Check

How is the small intestine adapted for the absorption of nutrients?

How does a meal that is high in fat affect the level of cholecystokinin in the blood?

How would the pH of the intestinal contents be affected if the small intestine did not produce secretin?

The digestion of which nutrient would be most impaired by damage to the exocrine pancreas?

Answers begin on p. A–1

The Large Intestine

Objectives

. • Describe the gross and histological structure of the large intestine.

. • List the regional specializations of the large intestine.

. • Explain the significance of the large intestine in the absorption of nutrients.

The horseshoe-shaped **large intestine** begins at the end of the ileum and ends at the anus. The large intestine lies inferior to the stomach and liver and almost completely frames the small intestine (see Figure 24–1•). The major functions of the large intestine include (1) the reabsorption of water and the compaction of the intestinal contents into feces, (2) the absorption of important vitamins liberated by bacterial action, and (3) the storage of fecal material prior to defecation.

The large intestine, also known as the *large bowel*, has an average length of about 1.5 meters (4.9 ft) and a width of 7.5 cm (3 in.). We can divide it into three parts: (1) the pouchlike *cecum*, the first portion of the large intestine; (2) the *colon*, the largest portion; and (3) the *rectum*, the last 15 cm (6 in.) of the large intestine and the end of the digestive tract (Figure 24–23a•).

The Cecum

Material arriving from the ileum first enters an expanded pouch called the **cecum** (SE¯-kum). The ileum attaches to the medial surface of the cecum and opens into the cecum at the *ileocecal valve* (Figure 24–23a,b•). The cecum collects and stores materials from the ileum and begins the process of compaction.

The slender, hollow **appendix**, or *vermiform appendix* (*vermis*, worm), is attached to the posteromedial surface of the cecum (see Figure 24–23a,b•). The appendix is generally about 9 cm (3.6 in.) long, but its size and shape are quite variable. A small mesentery called the **mesoappendix** connects the appendix to the ileum and cecum. The mucosa and submucosa of the appendix are dominated by lymphoid nodules, and the primary function of the appendix is as an organ of the lymphatic system. Inflammation of the appendix is known as *appendicitis*.

The Colon

The **colon** has a larger diameter and a thinner wall than the small intestine. Distinctive features of the colon include the following (see Figure 24–23a•):

- The wall of the colon forms a series of pouches, or **haustra** (HAWS-truh; singular, *haustrum*). Cutting into the intestinal lumen reveals that the creases between the haustra affect the mucosal lining as well, producing a series of internal folds. Haustra permit the expansion and elongation of the colon, rather like the bellows that allow an accordion to lengthen.
- Three separate longitudinal bands of smooth muscle—called the **taeniae coli** (TĒ-nē-ē KŌ-lē; singular, *taenia*)—run along the outer surfaces of the colon just deep to the serosa. These bands correspond to the outer layer of the muscularis externa in other portions of the digestive tract. Muscle tone within the taeniae coli is what creates the haustra.
- The serosa of the colon contains numerous teardrop-shaped sacs of fat called **fatty appendices**, or *epiploic* (ep-i-PLŌ

-ik; *epi*

ploon, omentum) *appendages*.

We can subdivide the colon into four regions: the ascending colon, transverse colon, descending colon, and sigmoid colon (see Figure 24–23a•).

1. **1.** The **ascending colon** begins at the superior border of the cecum and ascends along the right lateral and posterior wall of the peritoneal cavity to the inferior surface of the liver. There, the colon bends sharply to the left at the **right colic flexure**, or *hepatic flexure*, which marks the end of the ascending colon and the beginning of the transverse colon.

2. **2.** The **transverse colon** curves anteriorly from the right colic flexure and crosses the abdomen from right to left. The transverse colon is supported by the transverse mesocolon and is separated from the anterior abdominal wall by the layers of the greater omentum. As the transverse colon reaches the left side of the body, it passes inferior to the greater curvature of the stomach. Near the spleen, the colon makes a 90° turn at the **left colic flexure**, or *splenic flexure*, and becomes the descending colon.

3. **3.** The **descending colon** proceeds inferiorly along the person's left side until reaching the iliac fossa formed by the inner surface of the left ilium. The descending colon is retroperitoneal and firmly attached to the abdominal wall. At the iliac fossa, the descending colon curves at the **sigmoid flexure** and becomes the sigmoid colon.

4. **4.** The sigmoid flexure is the start of the **sigmoid** (SIG-moyd) **colon** (*sigmeidos*, the Greek letter *S*), an S-shaped segment that is only about 15 cm (6 in.) long. The sigmoid colon lies posterior to the urinary bladder, suspended from the sigmoid mesocolon. The sigmoid colon empties into the *rectum*.

The large intestine receives blood from tributaries of the superior mesenteric and inferior mesenteric arteries. Venous blood is collected from the large intestine by the superior mesenteric and inferior mesenteric veins. l**pp. 744, 752**

The Rectum

The **rectum** (REK-tum), which forms the last 15 cm (6 in.) of the digestive tract (Figure

24–23a,c•), is an expandable organ for the temporary storage of feces. The movement of fecal material into the rectum triggers the urge to defecate.

The last portion of the rectum, the **anal canal**, contains small longitudinal folds called **anal columns**. The distal margins of these columns are joined by transverse folds that mark the boundary between the columnar epithelium of the proximal rectum and a stratified squamous epithelium like that in the oral cavity. The **anus**, or *anal orifice*, is the exit of the anal canal. There, the epidermis becomes keratinized and identical to the surface of the skin. The circular muscle layer of the muscularis externa in this region forms the **internal anal sphincter** (see Figure 24–23c•), the smooth muscle cells of which are not under voluntary control. The **external anal sphincter**, which guards the anus, consists of a ring of skeletal muscle fibers that encircles the distal portion of the anal canal. This sphincter consists of skeletal muscle and is under voluntary control.

The lamina propria and submucosa of the anal canal bear a network of veins. If venous pressures there rise too high due to straining during defecation, the veins can become distended, producing *hemorrhoids*. AM: Colon Cancers

Histology of the Large Intestine

Although the diameter of the colon is roughly three times that of the small intestine, its wall is much thinner. The major characteristics of the colon are the lack of villi, the abundance of goblet cells, and the presence of distinctive intestinal glands (Figure 24–24•). The glands in the large intestine are deeper than those of the small intestine and are dominated by goblet cells. The mucosa of the large intestine does not produce enzymes; any digestion that occurs results from enzymes introduced in the small intestine or from bacterial action. The mucus provides lubrication as the fecal material becomes drier and more compact. Mucus is secreted as local stimuli, such as friction or exposure to harsh chemicals, trigger short reflexes involving local nerve plexuses. Large lymphoid nodules are scattered throughout the lamina propria and submucosa.

The muscularis externa of the large intestine is unusual, because the longitudinal layer has been reduced to the muscular bands of the taeniae coli. However, the mixing and propulsive contractions of the colon resemble those of the small intestine. AM:

Diverticulosis and Irritable Bowel Syndrome

Physiology of the Large Intestine

Less than 10 percent of the nutrient absorption under way in the digestive tract occurs in the large intestine. Nevertheless, the absorptive operations in this segment of the digestive tract are important. The large intestine also prepares fecal material for ejection from the body.

Absorption in the Large Intestine

The reabsorption of water is an important function of the large intestine. Although roughly 1500 ml of material enters the colon each day, only about 200 ml of feces is ejected. The remarkable efficiency of digestion can best be appreciated by considering the average composition of feces: 75 percent water, 5 percent bacteria, and the rest a mixture of indigestible materials, small quantities of inorganic matter, and the remains of epithelial cells.

In addition to reabsorbing water, the large intestine absorbs a number of other substances that remain in the feces or were secreted into the digestive tract along its length. Examples include useful compounds such as bile salts and vitamins, organic waste products such as urobilinogen, and various toxins generated by bacterial action. Most of the bile salts entering the large intestine are promptly reabsorbed in the cecum and transported in blood to the liver for secretion into bile.

Vitamins Vitamins are organic molecules that are important as cofactors or coenzymes in many metabolic pathways. The normal bacterial residents of the colon generate three vitamins that supplement our dietary supply:

1. **1.** *Vitamin K*, a fat-soluble vitamin the liver requires for synthesizing four clotting factors, including prothrombin. Intestinal bacteria produce roughly half of your daily vitamin K requirements.

2. **2.** *Biotin*, a water-soluble vitamin important in various reactions, notably those of glucose metabolism.

3. **3.** *Vitamin B*5 (pantothenic acid), a water-soluble vitamin required in the manufacture of steroid hormones and some neurotransmitters.

Vitamin K deficiencies, which lead to impaired blood clotting, result from either (1) a deficiency of lipids in the diet, which impairs the absorption of all fat-soluble vitamins, or (2) problems affecting lipid processing and absorption, such as inadequate bile production or chronic diarrhea. Disorders resulting from deficiencies of biotin or vitamin B5 are extremely rare after infancy, because the intestinal bacteria produce sufficient amounts to supplement any dietary shortage.

Organic Wastes The fate of bilirubin, a breakdown product of heme, was discussed in Chapter 19. l**p. 647** In the large intestine, bacteria convert bilirubin to *urobilinogens* and *stercobilinogens*. Some urobilinogens are absorbed into the bloodstream and then excreted in urine. The urobilinogens and stercobilinogens remaining within the colon are converted to **urobilins** and **stercobilins** by exposure to oxygen. These pigments in various proportions give feces a yellow-brown or brown coloration. Bacterial

action breaks down peptides that remain in the feces and generates (1) ammonia, in the form of soluble *ammonium ions* (NH_4^+);

(2) *indole* and *skatole*, two nitrogen-containing compounds that are primarily responsible for the odor of feces; and (3) hydrogen sulfide (H2S), a gas that produces a “rotten egg” odor. Significant amounts of ammonia and smaller amounts of other toxins cross the colonic epithelium and enter the hepatic portal circulation. These toxins are removed by the liver and converted to relatively nontoxic compounds that can be released into the blood and excreted at the kidneys.

Indigestible carbohydrates are not altered by intestinal enzymes, so they arrive in the colon virtually intact. These complex polysaccharides provide a reliable nutrient source for colonic bacteria, whose metabolic activities are responsible for the small quantities of **flatus**, or intestinal gas, in the large intestine. Meals containing large amounts of indigestible carbohydrates (such as frankfurters and beans) stimulate bacterial gas production, leading to distension of the colon, cramps, and the frequent discharge of intestinal gases.

Movements of the Large Intestine

The gastroileal and gastroenteric reflexes move materials into the cecum while you eat. Movement from the cecum to the transverse colon is very slow, allowing hours for water absorption to convert the already thick material into a sludgy paste. Peristaltic waves move material along the length of the colon, and segmentation movements, called *haustral churning*, mix the contents of adjacent haustra. Movement from the transverse colon through the rest of the large intestine results from powerful peristaltic contractions called **mass movements**, which occur a few times each day. The stimulus is distension of the stomach and duodenum; the commands are relayed over the intestinal nerve plexuses. The contractions force feces into the rectum and produce the conscious urge to defecate.

The rectal chamber is usually empty, except when a powerful peristaltic contraction forces feces out of the sigmoid colon. Distension of the rectal wall then triggers the **defecation reflex**, which involves two positive feedback loops (Figure 24–25•). Both loops are triggered by the stimulation of stretch receptors in the walls of the rectum. The first loop is a short reflex that triggers a series of peristaltic contractions in the rectum that move feces toward the anus (STEPS 1, 2, and 3). The second loop is a long reflex coordinated by the sacral parasympathetic system. This reflex stimulates mass movements that push feces toward the rectum from the descending colon and sigmoid colon (STEPS 1, 2a, and 3).

Rectal stretch receptors also trigger two reflexes important to the *voluntary* control of defecation. One is a long reflex mediated by parasympathetic innervation within the pelvic nerves. This reflex causes the relaxation of the internal anal sphincter, the smooth muscle sphincter that controls the movement of feces into the anal canal. The second (involving STEP 2b in Figure 24–25•)

is a somatic reflex that stimulates the immediate contraction of the external anal sphincter, a skeletal muscle. l**pp. 348–349** The motor commands are carried by the pudendal nerves.

The elimination of feces requires that both the internal and external anal sphincters be relaxed, but the two reflexes just mentioned open the internal sphincter and close the external sphincter. The actual release of feces requires a conscious effort to open the external sphincter. In addition to opening the external sphincter, consciously directed activities such as tensing the abdominal muscles or making expiratory movements while closing the glottis elevate intra-abdominal pressures and help force fecal material out of the rectum.

If the external anal sphincter remains constricted, the peristaltic contractions cease until additional rectal expansion triggers the defecation reflex a second time. The urge to defecate usually develops when rectal pressure reaches about 15 mm Hg. If pressure inside the rectum exceeds 55 mm Hg, the external anal sphincter will involuntarily relax and defecation will occur. This mechanism regulates defecation in infants and in adults with severe spinal cord injuries. AM: Diarrhea, Constipation

100 Keys | The large intestine stores digestive wastes and reabsorbs water. Bacterial residents of the large intestine are an

important source of vitamins, especially vitamin K, biotin, and vitamin B5.

Anatomy 360 | Review the anatomy of the large intestine on the **Anatomy 360 CD-ROM: Digestive System/ Large Intestine.**

Digestion and Absorption

Objectives

. • Specify the nutrients required by the body.

. • Describe the chemical events responsible for the digestion of organic nutrients.

. • Describe the mechanisms involved in the absorption of organic and inorganic nutrients.

A typical meal contains carbohydrates, proteins, lipids, water, electrolytes, and vitamins. The digestive system handles each component differently. Large organic molecules must be broken down by digestion before absorption can occur. Water, electrolytes, and vitamins can be absorbed without preliminary processing, but special transport mechanisms may be involved.

The Processing and Absorption of Nutrients

Food contains large organic molecules, many of them insoluble. The digestive system first breaks down the physical structure of the ingested material and then proceeds to disassemble the component molecules into smaller fragments. This disassembly eliminates any antigenic properties, so that the fragments do not trigger an immune response after absorption. The molecules released into the bloodstream are absorbed by cells and either (1) broken down to provide energy for the synthesis of ATP or (2) used to synthesize carbohydrates, proteins, and lipids. This section focuses on the mechanics of digestion and absorption; the fates of the compounds inside cells are the focus in Chapter 25.

Most ingested organic materials are complex chains of simpler molecules. In a typical dietary carbohydrate, the basic molecules are simple sugars; in a protein, the building blocks are amino acids; in lipids, they are generally fatty acids; and in nucleic acids, they are nucleotides. Digestive enzymes break the bonds between the component molecules of carbohydrates, proteins,

lipids, and nucleic acids in a process called *hydrolysis*. l**p. 35**

The classes of digestive enzymes differ with respect to their targets. *Carbohydrases* break the bonds between simple sugars, *proteases* split the linkages between amino acids, and *lipases* separate fatty acids from glycerides. Some enzymes in each class are even more selective, breaking bonds between specific molecules. For example, a particular carbohydrase might break the bond between two glucose molecules, but not those between glucose and another simple sugar.

Digestive enzymes secreted by the salivary glands, tongue, stomach, and pancreas are mixed into the ingested material as it passes along the digestive tract. These enzymes break down large carbohydrates, proteins, lipids, and nucleic acids into smaller fragments, which in turn must typically be broken down further before absorption can occur. The final enzymatic steps involve brush border enzymes, which are attached to the exposed surfaces of microvilli.

Nucleic acids are broken down into their component nucleotides. Brush border enzymes digest these nucleotides into sugars, phosphates, and nitrogenous bases that are absorbed by active transport. However, nucleic acids represent only a small fraction of all the nutrients absorbed each day. The digestive fates of carbohydrates, lipids, and proteins, the major dietary components, are depicted in Figure 24–26•. Table 24–3 summarizes the major digestive enzymes and their functions. Next we take a closer look at the digestion and absorption of carbohydrates, lipids, and proteins.

Carbohydrate Digestion and Absorption

The digestion of complex carbohydrates (simple polysaccharides and starches) proceeds in two steps. One step involves carbohydrases produced by the salivary glands and pancreas; the other, brush border enzymes.

The Actions of Salivary and Pancreatic Enzymes

The digestion of complex carbohydrates involves two enzymes—salivary amylase and pancreatic alpha-amylase (Figure 24–26a•)— that function effectively at a pH of 6.7–7.5. Carbohydrate digestion begins in the mouth during mastication, through the action of salivary amylase from the parotid and submandibular salivary glands. Salivary amylase breaks down starches (complex carbohydrates), producing a mixture composed primarily of *disaccharides* (two simple sugars) and *trisaccharides* (three simple sugars). Salivary amylase continues to digest the starches and glycogen in the food for 1–2 hours before stomach acids render the enzyme inactive. Because the enzymatic content of saliva is not high, only a small amount of digestion occurs over this period.

In the duodenum, the remaining complex carbohydrates are broken down by the action of pancreatic alpha-amylase. Any disaccharides or trisaccharides produced, and any present in the food, are not broken down further by salivary and pancreatic amylases. Additional hydrolysis does not occur until these molecules contact the intestinal mucosa.

Actions of Brush Border Enzymes

Prior to absorption, disaccharides and trisaccharides are fragmented into *monosaccharides* (simple sugars) by brush border enzymes of the intestinal microvilli. The enzyme **maltase** splits bonds between the two glucose molecules of the disaccharide **maltose**. **Sucrase** breaks the disaccharide **sucrose** into glucose and *fructose*, another six-carbon sugar. **Lactase** hydrolyzes the disaccharide **lactose** into a molecule of glucose and one of *galactose*. Lactose is the primary carbohydrate in milk, so by breaking down lactose, lactase provides an essential function throughout infancy and early childhood. If the intestinal mucosa stops producing lactase by the time of adolescence, the individual becomes **lactose intolerant**. After ingesting milk and other dairy products, lactose-intolerant individuals can experience a variety of unpleasant digestive problems. AM: Diarrhea

Absorption of Monosaccharides

The intestinal epithelium then absorbs the monosaccharides by facilitated diffusion and cotransport mechanisms (see Figure 3–18•,

p. 90). Both methods involve a carrier protein. Facilitated diffusion and cotransport differ in three major ways:

1. *Facilitated Diffusion Moves Only One Molecule or Ion through the Cell Membrane, Whereas Cotransport Moves More Than One Molecule or Ion through the Membrane at the Same Time.* In cotransport, the transported materials move in the same direction: down the concentration gradient for at least one of the transported substances.

1. **2.** *Facilitated Diffusion Does Not Require ATP.* Although cotransport by itself does not consume ATP, the cell must often expend ATP to preserve homeostasis. For example, the process may introduce sodium ions that must later be pumped out of the cell.

2. **3.** *Facilitated Diffusion Will Not Occur if There Is an Opposing Concentration Gradient for the Particular Molecule or Ion.* By contrast, cotransport can occur despite an opposing concentration gradient for one of the transported substances. For example, cells lining the small intestine will continue to absorb glucose when glucose concentrations inside the cells are much higher than they are in the intestinal contents.

The cotransport system responsible for the uptake of glucose also brings sodium ions into the cell. This passive process resembles facilitated diffusion, except that both a sodium ion and a glucose molecule must bind to the carrier protein before they can move into the cell. Glucose cotransport is an example of sodium-linked cotransport. Comparable cotransport mechanisms exist for other simple sugars and for some amino acids. Although these mechanisms deliver valuable nutrients to the cytoplasm, they also bring in sodium ions that must be ejected by the sodium–potassium exchange pump.

The simple sugars that are transported into the cell at its apical surface diffuse through the cytoplasm and reach the interstitial fluid by facilitated diffusion across the basolateral surfaces. These monosaccharides then diffuse into the capillaries of the villus for eventual transport to the liver in the hepatic portal vein.

Lipid Digestion and Absorption

Lipid digestion involves lingual lipase from glands of the tongue, and pancreatic lipase from the pancreas (Figure 24–26b•). The most important and abundant dietary lipids are triglycerides, which consist of three fatty acids attached to a single molecule of glycerol (see Figure 2–15•, p. 46). The lingual and pancreatic lipases break off two of the fatty acids, leaving monoglycerides.

Lipases are water-soluble enzymes, and lipids tend to form large drops that exclude water molecules. As a result, lipases can attack only the exposed surfaces of the lipid drops. Lingual lipase begins breaking down triglycerides in the mouth and continues for a variable time within the stomach, but the lipid drops are so large, and the available time so short, that only about 20 percent of the lipids have been digested by the time the chyme enters the duodenum.

Bile salts improve chemical digestion by emulsifying the lipid drops into tiny emulsion droplets, thereby providing better access for pancreatic lipase. The emulsification occurs only after the chyme has been mixed with bile in the duodenum. Pancreatic lipase then breaks apart the triglycerides to form a mixture of fatty acids and monoglycerides. As these molecules are released, they interact with bile salts in the surrounding chyme to form small lipid–bile salt complexes called **micelles** (m -SELZ). A micelle is

–

ı only about 2.5 nm (0.0025 mm) in diameter.

When a micelle contacts the intestinal epithelium, the lipids diffuse across the cell membrane and enter the cytoplasm. The intestinal cells synthesize new triglycerides from the monoglycerides and fatty acids. These triglycerides, in company with absorbed steroids, phospholipids, and fat-soluble vitamins, are then coated with proteins, creating complexes known as **chylomi**

crons (kı-l -M -kronz; *chylos*, milky lymph

¯I

¯o

–

+

mikros, small).

The intestinal cells then secrete the chylomicrons into interstitial fluid by exocytosis. The superficial protein coating of the chylomicrons keeps them suspended in the interstitial fluid, but their size generally prevents them from diffusing into capillaries. Most of the chylomicrons released diffuse into the intestinal lacteals, which lack basal laminae and have large gaps between adjacent endothelial cells. From the lacteals, the chylomicrons proceed along the lymphatic vessels and through the thoracic duct, finally entering the bloodstream at the left subclavian vein.

Most of the bile salts within micelles are reabsorbed by sodium-linked cotransport. Only about 5 percent of the bile salts secreted by the liver enters the colon, and only about 1 percent is lost in feces.

Protein Digestion and Absorption

Proteins have very complex structures, so protein digestion is both complex and time-consuming. The first task is to disrupt the three-dimensional organization of the food so that proteolytic enzymes can attack individual proteins. This step involves mechanical processing in the oral cavity, through mastication, and chemical processing in the stomach, through the action of hydrochloric acid. Exposure of the bolus to a strongly acidic environment kills pathogens and breaks down plant cell walls and the connective tissues in animal products.

The acidic contents of the stomach also provide the proper environment for the activity of pepsin, the proteolytic enzyme secreted by chief cells of the stomach (Figure 24–26c•). Pepsin, which works effectively at a pH of 1.5–2.0, breaks the peptide bonds within a polypeptide chain. When chyme enters the duodenum, enterokinase produced in the small intestine triggers the conversion of trypsinogen to trypsin, and the pH is adjusted to 7–8. Pancreatic proteases can now begin working. Trypsin, chymotrypsin, and elastase are like pepsin in that they break specific peptide bonds within a polypeptide. For example, trypsin breaks peptide bonds involving the amino acids *arginine* or *lysine*, whereas chymotrypsin targets peptide bonds involving *tyrosine* or *phenylalanine*.

Carboxypeptidase also acts in the small intestine. This enzyme chops off the last amino acid of a polypeptide chain, ignoring the identities of the amino acids involved. Thus, while the other peptidases generate a variety of short peptides, carboxypeptidase produces free amino acids.

Absorption of Amino Acids

The epithelial surfaces of the small intestine contain several peptidases, notably **dipeptidases—**enzymes that break short peptide chains into individual amino acids. (Dipeptidases break apart *dipeptides*.) These amino acids, as well as those produced by the pancreatic enzymes, are absorbed through both facilitated diffusion and cotransport mechanisms.

After diffusing to the basal surface of the cell, the amino acids are released into interstitial fluid by facilitated diffusion and co-transport. Once in the interstitial fluid, the amino acids diffuse into intestinal capillaries for transport to the liver by means of the hepatic portal vein.

Water Absorption

Cells cannot actively absorb or secrete water. All movement of water across the lining of the digestive tract, as well as the production of glandular secretions, involves passive water flow down osmotic gradients. When two fluids are separated by a selectively permeable membrane, water tends to flow into the solution that has the higher concentration of solutes. l**p. 87** Osmotic movements are rapid, so interstitial fluid and the fluids in the intestinal lumen always have the same osmolarity (osmotic concentration of solutes).

Intestinal epithelial cells continuously absorb nutrients and ions, and these activities gradually lower the solute concentration in the lumen. As the solute concentration drops, water moves into the surrounding tissues, maintaining osmotic equilibrium.

Each day, roughly 2000 ml of water enters the digestive tract in the form of food or drink.

The salivary, gastric, intestinal, pancreatic, and bile secretions provide an additional 7000 ml. Of that total, only about 150 ml is lost in feces. The sites of secretion and absorption of water are indicated in Figure 24–27•.

Ion Absorption

Osmosis does not distinguish among solutes; all that matters is the total concentration of solutes. To maintain homeostasis, however, the concentrations of specific ions must be closely regulated. Thus, each ion must be handled individually, and the rate of intestinal absorption of each must be tightly controlled (Table 24–4). Many of the regulatory mechanisms controlling the rates of absorption are poorly understood.

Sodium ions (Na^+), usually the most abundant cations in food, may enter intestinal cells by diffusion, by cotransport with another nutrient, or by active transport. These ions are then pumped into interstitial fluid across the base of the cell. The rate of Na^+ uptake from the lumen is generally proportional to the concentration of Na^+ in the intestinal contents. As a result, eating heavily salted foods leads to increased sodium ion absorption and an associated gain of water through osmosis. The rate of sodium ion absorption by the digestive tract is increased by aldosterone, a steroid hormone from the adrenal cortex. l**p. 613** Calcium ion (Ca^+) absorption involves active transport at the epithelial surface. The rate of transport is accelerated by parathyroid hormone (PTH) and calcitriol. l**p. 612** As other solutes move out of the lumen, the concentration of potassium ions (K^+) increases. These ions can diffuse into the epithelial cells along the concentration gradient. The absorption of magnesium (Mg^{2+}), iron (Fe^{2+}), and other cations involves specific carrier proteins; the cell must use ATP to obtain and transport these ions to interstitial fluid. Regulatory factors controlling their absorption are poorly understood. The anions chloride (Cl^-), iodide (I^-), bicarbonate ($HCO3^-$), and nitrate ($NO3^-$) are absorbed by diffusion or carrier2 mediated transport. Phosphate ($PO4^{3-}$) and sulfate (SO4) ions enter epithelial cells only by active transport.

Vitamin Absorption

Vitamins are organic compounds required in very small quantities. There are two major groups of vitamins: fat-soluble vitamins and water-soluble vitamins. Vitamins A, D, E, and K are **fat-soluble vitamins**; their structure allows them to dissolve in lipids. The nine **water-soluble vitamins** include the B vitamins, common in milk and meats, and vitamin C, found in citrus fruits. We will consider the functions of vitamins and associated nutritional problems in Chapter 25.

All but one of the water-soluble vitamins are easily absorbed by diffusion across the digestive epithelium. Vitamin B12 cannot be absorbed by the intestinal mucosa in normal amounts, unless this vitamin has been bound to *intrinsic factor*, a glycoprotein secreted by the parietal cells of the stomach (p. 879). The combination is then absorbed through active transport.

Fat-soluble vitamins in the diet enter the duodenum in fat droplets, mixed with triglycerides. The vitamins remain in association with these lipids as they form emulsion droplets and, after further digestion, micelles. The fat-soluble vitamins are then absorbed from the micelles along with the fatty acids and monoglycerides. Vitamin K produced in the colon is absorbed with other lipids released through bacterial action. Taking supplements of fat-soluble vitamins while you have an empty stomach, are fasting, or are on a low-fat diet is relatively ineffective, because proper absorption of these vitamins requires the presence of other lipids. AM: Malabsorption

Aging and the Digestive System

Objective

- Summarize the effects of the aging process on the digestive system.

Essentially normal digestion and absorption occur in elderly individuals. However, many changes in the digestive system parallel age-related changes we have already discussed in connection with other systems:

. • **The Division Rate of Epithelial Stem Cells Declines.** The digestive epithelium becomes more susceptible to damage by abrasion, acids, or enzymes. Peptic ulcers therefore become more likely. Stem cells in the epithelium divide less frequently with age, so tissue repair is less efficient. In the mouth, esophagus, and anus, the stratified epithelium becomes thinner and more fragile.

. • **Smooth Muscle Tone Decreases.** General motility decreases, and peristaltic contractions are weaker as a result of a decrease in smooth muscle tone. These changes slow the rate of fecal movement and promote constipation. Sagging and inflammation of the haustra in the colon can occur. Straining to eliminate compacted feces can stress the less resilient walls of blood vessels, producing hemorrhoids. Problems are not restricted to the lower digestive tract; for example, weakening of muscular sphincters can lead to esophageal reflux and frequent bouts of “heartburn.”

. • **The Effects of Cumulative Damage Become Apparent.** A familiar example is the gradual loss of teeth due to *dental caries* (cavities) or gingivitis. Cumulative damage can involve internal organs as well. Toxins such as alcohol and other injurious chemicals that are absorbed by the digestive tract are transported to the liver for processing. The cells of the liver are not immune to these toxic compounds, and chronic exposure can lead to cirrhosis or other types of liver disease.

. • **Cancer Rates Increase.** Cancers are most common in organs in which stem cells divide to maintain epithelial cell populations. Rates of colon cancer and stomach cancer rise with age; oral and pharyngeal cancers are particularly common among elderly smokers.

. • **Changes in Other Systems Have Direct or Indirect Effects on the Digestive System.** For example, reduction in bone mass and calcium content in the skeleton is associated with erosion of the tooth sockets and eventual tooth loss. The decline in olfactory and gustatory sensitivities with age can lead to dietary changes that affect the entire body.

Concept Check

What component of food would increase the number of chylomicrons in the lacteals?

The absorption of which vitamin would be impaired by the removal of the stomach?

Why is it that diarrhea is potentially life-threatening, but constipation is not?

Answers begin on p. A–1

Integration with Other Systems

Figure 24–28• summarizes the physiological relationships between the digestive system and other organ systems. The digestive system has particularly extensive anatomical and physiological connections to the nervous, cardiovascular, endocrine, and lymphatic systems. For example, the enteric nervous system contains as many neurons as the spinal cord and as many neurotransmitters as the brain. As we have seen, the digestive tract is also an endocrine organ that produces a variety of hormones. Many of these hormones, and some of the neurotransmitters produced by the digestive system, can enter the circulation, cross the blood–brain barrier, and alter CNS activity. Thus, a continual exchange of chemical information occurs among these systems.

Clinical Patterns

Because the digestive system has so many components, and those components have so many functions, digestive system disorders are both very diverse and relatively common.

The largest category of digestive disorders includes those resulting from inflammation or infection of the digestive tract. This is so in part because the epithelium lining most of the digestive tract must have two properties that are difficult to reconcile: (1) It must be thin and delicate enough to permit the rapid and efficient absorption of nutrients, and (2) it must resist damage by the ingested materials and the enzymes secreted to promote digestion.

The relative delicacy of the epithelium makes it susceptible to damage from chemical attack or abrasion. For example, *peptic ulcers* develop if acids and enzymes contact and erode the gastric lining. Pathogens in food, including bacteria, viruses, and multicellular parasites, may also penetrate the epithelial barriers and cause infections. Small battles are continually being fought; the fact that 80 percent of the body’s plasma cells are normally located within the lamina propria of the digestive tract indicates how often antigens of one kind or another somehow cross the epithelial barriers.

High rates of cell division and exposure to strong chemical agents are both correlated with an increased risk of cancer. As a result, cancers of the digestive tract are relatively common. Predictably, most of these are epithelial cancers that develop in the stem cell populations responsible for epithelial cell renewal.

Other classes of digestive system disorders are discussed in the *Applications Manual*.

Chapter Review

Selected Clinical Terminology

ascites: Fluid leakage into the peritoneal cavity across the serous membranes of the liver and viscera. (p. 864)

cathartics: Drugs that promote defecation. [AM]

cholecystitis: An inflammation of the gallbladder due to a blockage of the cystic duct or common bile duct by gallstones. (p. 895 and

[AM]) **cholelithiasis:** The presence of gallstones in the gallbladder. [AM] **cholera:** A bacterial infection of the digestive tract that causes massive fluid losses through diarrhea. [AM] **cirrhosis:** A disease characterized by the widespread destruction of hepatocytes due to exposure to drugs (especially alcohol), viral infection, ischemia, or blockage of the hepatic ducts. (p. 893 and [AM]) **colitis:** A general term for a condition characterized by inflammation of the colon. [AM] **constipation:** Infrequent defecation, generally involving dry, hard feces. [AM] **diarrhea:** Frequent, watery bowel movements. [AM] **diverticulitis:** An infection and inflammation of mucosal pockets of the large intestine (diverticula). [AM] **diverticulosis:** The formation of diverticula, generally along the sigmoid colon. [AM] **esophageal varices:** Swollen and fragile esophageal veins that result from portal hypertension. [AM] **gallstones:** Deposits of minerals, bile salts, and cholesterol that form if bile becomes too concentrated. (p. 895 and [AM]) **gastrectomy:** The surgical removal of the stomach, generally to treat advanced stomach cancer. [AM] **gastritis:** An inflammation of the gastric mucosa. (p. 881) **gastroscope:** A fiber-optic instrument inserted into the mouth and directed along the esophagus and into the stomach; used to examine the interior of the stomach and to perform minor surgical procedures. [AM] **hepatitis:**

A virus-induced disease of the liver; forms include *hepatitis A, B,* and *C*. (p. 893 and [AM])

lactose intolerance: A malabsorption syndrome that results from the lack of the enzyme *lactase* at the brush border of the intestinal epithelium. (p. 903 and [AM])

mumps: A viral infection that typically targets the salivary glands (primarily the parotids), usually in children. (p. 872)

pancreatitis: An inflammation of the pancreas. (p. 889)

peptic ulcer: Erosion of the gastric or duodenal lining by stomach acids and enzymes. (p. 881 and [AM])

periodontal disease: A loosening of the teeth within the alveolar sockets caused by erosion of the periodontal ligaments by acids produced through bacterial action. [AM]

peritonitis: An inflammation of the peritoneal membrane. (p. 866)

portal hypertension: High venous pressures in the hepatic portal system. (p. 892)

pulpitis: An infection of the pulp of a tooth; treatment may involve a *root canal* procedure. [AM]

Study Outline

The Digestive System: An Overview p. 863

1. The **digestive system** consists of the muscular **digestive tract** and various **accessory organs**. *(Figure 24–1)*

Functions of the Digestive System p. 863

2. Digestive functions are **ingestion**, **mechanical processing**, **digestion**, **secretion**, **absorption**, and **excretion**.

The Digestive Organs and the Peritoneum p. 864

1. Double sheets of peritoneal membrane called **mesenteries** suspend the digestive tract. The **greater omentum** lies anterior to the abdominal viscera. Its adipose tissue provides padding, protection, insulation, and an energy reserve. *(Figure 24–2)*

Histological Organization of the Digestive Tract p. 866

1. **2.** The digestive tract is lined by a mucous epithelium moistened by glandular secretions of the epithelial and accessory organs.

2. **3.** The *lamina propria* and epithelium form the **mucosa** (mucous membrane) of the digestive tract. Proceeding outward, we encounter the **submucosa**, the **muscularis externa**, and a layer of areolar tissue called the *adventitia*. Within the peritoneal cavity, the muscularis externa is covered by a serous membrane called the **serosa**. *(Figure 24–3)*

The Movement of Digestive Materials p. 868

1. **4.** The *visceral smooth muscle tissue* of the digestive tract undergoes rhythmic cycles of activity due to *pacesetter cells*.

2. **5.** The muscularis externa propels materials through the digestive tract by the contractions of **peristalsis**. **Segmentation** movements in the small intestine churn digestive materials. *(Figure 24–4)*

Control of Digestive Function p. 868

6. Digestive tract activities are controlled by neural, hormonal, and local mechanisms. *(Figure 24–5)*

The Oral Cavity p. 870

1. **1.** The functions of the **oral cavity**, or **buccal cavity**, are (1) *sensory analysis* of foods; (2) *mechanical processing* by the teeth, tongue, and palatal surfaces; (3) *lubrication*, by mixing with mucus and salivary gland secretions; and (4) limited *digestion* of carbohydrates and lipids.

2. **2.** The oral cavity is lined by the **oral mucosa**. The *hard* and *soft palates* form the roof of the oral cavity, and the *tongue* forms its floor. *(Figure 24–6)*

The Tongue p. 871

3. **Intrinsic** and **extrinsic tongue muscles** are controlled by the hypoglossal nerve. *(Figure 24–6)*

Salivary Glands p. 871

4. The **parotid**, **sublingual**, and **submandibular salivary glands** discharge their secretions into the oral cavity. *(Figure 24–7)*

The Teeth p. 873

1. 5. **Mastication** (chewing) of the **bolus** occurs through the contact of the **occlusal** (opposing) **surfaces** of the **teeth**. The **periodontal ligament** anchors each tooth in an *alveolus*, or bony socket. **Dentin** forms the basic structure of a tooth. The **crown** is coated with **enamel**, the **root** with **cementum**. *(Figure 24–8)*

2. 6. The 20 primary teeth, or **deciduous teeth**, are replaced by the 32 teeth of the **secondary dentition** during childhood and early adulthood. *(Figure 24–9)*

The Pharynx p. 875

1. Propulsion of the bolus through the **pharynx** results from contractions of the *pharyngeal constrictor muscles* and the *palatal muscles*, and from elevation of the larynx.

The Esophagus p. 875

1. The **esophagus** carries solids and liquids from the pharynx to the stomach through the **esophageal hiatus**, an opening in the diaphragm. *(Figure 24–10)*

Histology of the Esophagus p. 876

2. The esophageal mucosa consists of a stratified epithelium. Mucous secretion by esophageal glands of the submucosa reduces friction during the passage of foods. The proportions of skeletal and smooth muscle of the muscularis externa change from the pharynx to the stomach. *(Figure 24–10)*

Swallowing p. 876

3. Swallowing (**deglutition**) can be divided into **buccal**, **pharyngeal**, and **esophageal phases**. Swallowing begins with the compaction of a bolus and its movement into the pharynx, followed by the elevation of the larynx, reflection of the *epiglottis*, and closure of the *glottis*. After the *upper esophageal sphincter* is opened, peristalsis moves the bolus down the esophagus to the *lower esophageal sphincter*. *(Figure 24–11)*

The Stomach p. 877

1. The **stomach** has four major functions: (1) storage of ingested food, (2) mechanical breakdown of food, (3) disruption of chemical bonds by acids and enzymes, and (4) production of *intrinsic factor*.

Anatomy of the Stomach p. 877

1. **2.** The four regions of the stomach are the **cardia**, **fundus**, **body**, and **pylorus**. The **pyloric sphincter** guards the exit out of the stomach. In a relaxed state, the stomach lining contains numerous **rugae** (ridges and folds). *(Figure 24–12)*

2. **3.** Within the **gastric glands**, *parietal cells* secrete *intrinsic factor* and *hydrochloric acid*. **Chief cells** secrete **pepsinogen**, which is converted by acids in the gastric lumen to the enzyme **pepsin**. **Enteroendocrine** cells of the stomach secrete several compounds, notably the hormone **gastrin**. *(Figures 24–13, 24–14)*

Regulation of Gastric Activity p. 881

4. Gastric secretion involves (1) the **cephalic phase**, which prepares the stomach to receive ingested materials, (2) the **gastric phase**, which begins with the arrival of food in the stomach, and (3) the **intestinal phase**, which controls the rate of gastric emptying. *(Figure 24–15; Table 24–1)*

Digestion and Absorption in the Stomach p. 883

5. The preliminary digestion of proteins by pepsin begins in the stomach. Very little absorption of nutrients occurs in the stomach.

100 Keys | p. 884

The Small Intestine and Associated Glandular Organs p. 884

1. Most of the important digestive and absorptive functions occur in the **small intestine**. Digestive secretions and buffers are provided by the pancreas, liver, and gallbladder.

The Small Intestine p. 864

2. The small intestine consists of the **duodenum**, the **jejunum**, and the **ileum**. A sphincter, the **ileocecal valve**, marks the transition between the small and large intestines. *(Figure 24–16)*

Anatomy 360 | Digestive System/Small Intestine

Histology of the Small Intestine p. 885

1. **3.** The intestinal mucosa bears transverse folds called **plicae** and small projections called **intestinal villi**. These folds and projections increase the surface area for absorption. Each villus contains a terminal lymphatic called a **lacteal**. Pockets called **intestinal glands** are lined by enteroendocrine, goblet, and stem cells. *(Figures 24–16, 24–17)*

2. **4.** **Intestinal juice** moistens chyme, helps buffer acids, and holds digestive enzymes and digestive products in solution.

3. **5.** The **duodenal** (*submucosal* or *Brunner's*) **glands** of the duodenum produce mucus, buffers, and the hormone **urogastrone**. The ileum contains masses of lymphoid tissue called *aggregated lymphoid nodules*, or *Peyer's patches*, near the entrance to the large intestine.

Intestinal Movements p. 887

6. The **gastroenteric reflex**, initiated by stretch receptors in the stomach, stimulates motility and secretion along the entire small intestine. The **gastroileal reflex** triggers the relaxation of the ileocecal valve.

100 Keys | p. 888

The Pancreas p. 888

1. **7.** The **pancreatic duct** penetrates the wall of the duodenum. Within each lobule of the **pancreas**, ducts branch repeatedly before ending in the **pancreatic acini** (blind pockets). *(Figure 24–18)*

2. **8.** The pancreas has two functions: endocrine (secreting insulin and glucagon into the blood) and exocrine (secreting **pancreatic juice** into the small intestine). Pancreatic enzymes include **carbohydrases**, **lipases**, **nucleases**, and **proteolytic enzymes**.

100 Keys | p. 889

The Liver p. 890

9. The **liver** performs metabolic and hematological regulation and produces **bile**. The bile ducts from all the **liver lobules** unite to form the **common hepatic duct**. That duct meets the **cystic duct** to form the **common bile duct**, which empties into the duodenum.

(Figures 24–19 to 24–21)

1. **10.** The liver lobule is the organ's basic functional unit. **Hepatocytes** form irregular plates arranged in the form of spokes of a wheel. **Bile canaliculi** carry bile to the **bile ductules**, which lead to **portal areas**. *(Figure 24–20)*

2. **11.** In **emulsification**, **bile salts** break apart large drops of lipids, making the lipids accessible to lipases secreted by the pancreas.

Anatomy 360 **|** Digestive System/Liver

The Gallbladder p. 894

12. The **gallbladder** stores, modifies, and concentrates bile. *(Figure 24–21)*

100 Keys | p. 895

The Coordination of Secretion and Absorption p. 895

1. **13.** Neural and hormonal mechanisms coordinate the activities of the digestive glands. Gastrointestinal activity is stimulated by parasympathetic innervation and inhibited by sympathetic innervation. The **enterogastric**, **gastroenteric**, and **gastroileal reflexes** coordinate movement from the stomach to the large intestine.

2. **14.** Intestinal hormones include **secretin**, **cholecystokinin (CCK)**, **gastric inhibitory peptide (GIP)**, **vasoactive intestinal peptide (VIP)**, **gastrin**, and **enterocrinin**. *(Figure 24–22; Table 24–2)*

The Large Intestine p. 896

1. The main functions of the **large intestine** are to (1) reabsorb water and compact materials into feces, (2) absorb vitamins produced by bacteria, and (3) store fecal material prior to defecation. The large intestine consists of the *cecum*, *colon*, and *rectum*. *(Figure 24–23)*

The Cecum p. 897

2. The **cecum** collects and stores material from the ileum and begins the process of compaction. The **appendix** is attached to the cecum.

(Figure 24–23)

The Colon p. 897

1. **3.** The **colon** has a larger diameter and a thinner wall than the small intestine. The colon bears **haustra** (pouches), **taeniae coli** (longitudinal bands of muscle), and sacs of fat (**fatty appendices**). *(Figure 24–23)*

2. **4.** The four regions of the colon are the **ascending colon**, **transverse colon**, **descending colon**, and **sigmoid colon**. *(Figure 24–23)*

3. **5.** The **rectum** terminates in the **anal canal**, leading to the **anus**. *(Figure 24–23)*

The Rectum p. 899

Histology of the Large Intestine p. 899

6. Histological characteristics of the colon include the absence of villi and the presence of goblet cells and deep intestinal glands. *(Figure 24–24)*

Physiology of the Large Intestine p. 899

1. **7.** The large intestine reabsorbs water and other substances such as vitamins, urobilinogen, bile salts, and toxins. Bacteria are responsible for intestinal gas, or **flatus**.

2. **8.** The gastroileal reflex moves materials from the ileum into the cecum while you eat. Distension of the stomach and duodenum stimulates **mass movements** of materials from the transverse colon through the rest of the large intestine and into the rectum. Muscular sphincters control the passage of fecal material to the anus. Distension of the rectal wall triggers the **defecation reflex**. *(Figure 24–25)*

100 Keys | p. 901

Anatomy 360 **|** Digestive System/Large Intestine

Digestion and Absorption p. 902 The Processing and Absorption of Nutrients p. 902

1. The digestive system first breaks down the physical structure of the ingested material and then disassembles the component molecules into smaller fragments by *hydrolysis*. *(Figure 24–26; Summary Table 24–3)*

Carbohydrate Digestion and Absorption p. 902

2. Salivary and pancreatic amylases break down complex carbohydrates into *disaccharides* and *trisaccharides*. These in turn are broken down into *monosaccharides* by enzymes at the epithelial surface. The monosaccharides are then absorbed by the intestinal epithelium by facilitated diffusion or cotransport. *(Figure 24–26)*

Lipid Digestion and Absorption p. 905

3. *Triglycerides* are emulsified into lipid droplets. The resulting fatty acids and *monoglycerides* interact with bile salts to form **micelles**. The lipids diffuse from the micelles across the intestinal epithelium. Triglycerides are then synthesized and released into the interstitial fluid, for transport to the general circulation by way of the lymphatic system. *(Figure 24–26)*

Protein Digestion and Absorption p. 905

4. Protein digestion involves a low pH (which destroys tertiary and quaternary structure), the gastric enzyme pepsin, and various pancreatic proteases. Peptidases liberate amino acids that are absorbed and exported to interstitial fluid. *(Figure 24–26)*

Water Absorption p. 906

5. About 2000 ml of water is ingested each day, and digestive secretions provide another 7000 ml. Nearly all is reabsorbed by osmosis.

(Figure 24–27)

Ion Absorption p. 906

6. Various processes, including diffusion, cotransport, and carrier-mediated and active transport, are responsible for the movements of cations (sodium, calcium, potassium, and so on) and anions (chloride, iodide, bicarbonate, and so on) into epithelial cells. *(Table 24–4)*

Vitamin Absorption p. 907

7. The **water-soluble vitamins** (except B12) diffuse easily across the digestive epithelium. **Fat-soluble vitamins** are enclosed within fat droplets and absorbed with the products of lipid digestion. *(Table 24–4)*

Aging and the Digestive System p. 907

1. Age-related changes include a thinner and more fragile epithelium due to a reduction in epithelial stem cell divisions, weaker peristaltic contractions as smooth muscle tone decreases, the effects of cumulative damage, increased cancer rates, and related changes in other systems.

Integration with Other Systems p. 908

1. The digestive system has extensive anatomical and physiological connections to the nervous, endocrine, cardiovascular, and lymphatic systems. *(Figure 24–28)*

. **(a)** vitamins A, D, and E
. **(b)** B complex vitamins and vitamin C
. **(c)** vitamin K, biotin, and pantothenic acid
. **(d)** niacin, thiamine, and riboflavin
. **10.** The final enzymatic steps in the digestive process are accomplished by
. **(a)** brush border enzymes of the microvilli
. **(b)** enzymes secreted by the stomach
. **(c)** enzymes secreted by the pancreas
. **(d)** the action of bile from the gallbladder
2. **11.** What are the six steps involved in digestion?
3. **12.** Name and describe the layers of the digestive tract, proceeding from the

innermost to the outermost layer.

4. **13.** What three basic mechanisms regulate the activities of the digestive tract?

5. **14.** What are the three phases of swallowing, and how are they controlled?

6. **15.** What are the primary functions of the pancreas, liver, and gallbladder in digestion?

7. **16.** Which hormones produced by duodenal enteroendocrine cells effectively coordinate digestive functions?

8. **17.** What are the three primary functions of the large intestine?

9. **18.** What two positive feedback loops are involved in the defecation reflex?

LEVEL 2 Reviewing Concepts

. **19.** During defecation

. **(a)** stretch receptors in the rectal wall initiate a series of peristaltic contractions in the colon and rectum

. **(b)** stretch receptors in the rectal wall activate parasympathetic centers in the sacral region of the spinal cord

. **(c)** the internal anal sphincter relaxes while the external anal sphincter contracts

. **(d)** all of the above

. **(e)** a and b only

. **20.** *Increased* parasympathetic stimulation of the intestine would result in

. **(a)** decreased motility

. **(b)** decreased secretion

. **(c)** decreased sensitivity of local reflexes

. **(d)** decreased segmentation

. **(e)** none of the above

. **21.** A drop in pH below 4.5 in the duodenum stimulates the secretion of

. **(a)** secretin

. **(b)** cholecystokinin

. **(c)** gastrin

. **(d)** a, b, and c are correct

2. **22.** Through which layers of a molar would an orthodontic surgeon drill to perform a root canal (removal of the alveolar nerve in a severely damaged tooth)?

3. **23.** How is the epithelium of the stomach protected from digestion?

4. **24.** How do the three phases of gastric secretion promote and facilitate gastric control?

5. **25.** Nutritionists have found that after a heavy meal, the pH of blood increases slightly, especially in the veins that carry blood away from the stomach. What causes this “postenteric alkaline tide”?

LEVEL 3 Critical Thinking and Clinical Applications

1. **26.** Some people with gallstones develop pancreatitis. How could this occur?

2. **27.** Harry is suffering from an obstruction in his colon. He notices that when he urinates, the color of his urine is much darker than normal, and he wonders if there is any relationship between the color of his urine and his intestinal obstruction. What would you tell him?

3. **28.** A condition known as lactose intolerance is characterized by painful abdominal cramping, gas, and diarrhea. The cause of the problem is an inability to digest the milk sugar, lactose. How would this cause the observed symptoms?

4. **29.** Recently, more people have turned to surgery to help them lose weight. One of the more radical weight control surgeries involves stapling a portion of the stomach shut, creating a smaller volume. What effects might this procedure have on the physiology of the entire digestive system?

TABLE 24–1 The Phases of Gastric Secretion

Phase	**Functions**	**Duration**	**Mechanism**	**Actions**

An Overview of Metabolism

Objectives

- Define *metabolism* and explain why cells need to synthesize new organic components.

Cells are chemical factories that break down organic molecules to obtain energy, which can then be used to generate ATP. Reactions within mitochondria provide most of the energy needed by a typical cell. l**p. 76** To carry out these metabolic reactions, cells must have a reliable supply of oxygen and nutrients, including water, vitamins, mineral ions, and organic substrates (the reactants in enzymatic reactions). Oxygen is absorbed at the lungs; the other substances are obtained through absorption at the digestive tract. The cardiovascular system then carries these substances throughout the body. They diffuse from the bloodstream into the tissues, where they can be absorbed and used by our cells.

Mitochondria break down the organic nutrients to provide energy for cell growth, cell division, contraction, secretion, and other functions. Each tissue contains a unique mixture of various kinds of cells. As a result, the energy and nutrient requirements of any two tissues—loose connective tissue and cardiac muscle, for instance—can be quite different. Moreover, activity levels can change rapidly within a tissue, and such changes affect the metabolic requirements of the body. For example, when skeletal muscles start contracting, the tissue demand for oxygen skyrockets. Thus, the energy and nutrient requirements of the body vary from moment to moment (resting versus exercising), hour to hour (asleep versus awake), and year to year (growing child versus adult).

The term **metabolism** (me-TAB-o¯-lizm) refers to all the chemical reactions that occur in an organism. Chemical reactions within cells, collectively known as *cellular metabolism*, provide the energy needed to maintain homeostasis and to perform essential functions. Such functions include (1) *metabolic turnover*, the periodic breakdown and replacement of the organic components of a cell; (2) growth and cell division; and (3) special processes, such as secretion, contraction, and the propagation of action potentials.

Figure 25–1• provides a broad overview of the processes involved in cellular metabolism. The cell absorbs organic molecules from the surrounding interstitial fluids. Amino acids, lipids, and simple sugars cross the cell membrane and join nutrients already in the cytoplasm. All the cell’s organic building blocks collectively form a *nutrient pool* that the cell relies on to provide energy and to create new intracellular components.

The breakdown of organic substrates is called **catabolism**. This process releases energy that can be used to synthesize ATP or other high-energy compounds. Catabolism proceeds in a series of steps. In general, the initial steps occur in the cytosol, where enzymes break down large organic molecules previously assembled by the cell (such as glycogen, triglycerides, or proteins) into smaller fragments that join the nutrient pool. For example, carbohydrates are broken down into simple sugars, triglycerides are split into fatty acids and glycerol, and proteins are broken down to individual amino acids.

Relatively little ATP is produced during these preparatory steps. However, further catabolic activity produces smaller organic molecules that can be absorbed and processed by mitochondria. It is that mitochondrial activity that releases significant amounts of energy. As mitochondrial enzymes break the covalent bonds that hold these molecules together, they capture roughly 40 percent of the energy released and use it to convert ADP to ATP. The other 60 percent escapes as heat that warms the interior of the cell and the surrounding tissues.

The ATP produced by mitochondria provides energy to support both **anabolism**—the synthesis of new organic molecules— and other cell functions. Those additional functions, such as ciliary or cell movement, contraction, active transport, and cell division, vary among cell types. For example, muscle fibers need ATP to provide energy for contraction, whereas gland cells need ATP to synthesize and transport their secretions. We have considered such specialized functions in other chapters, so here we will restrict our focus to anabolic processes.

In terms of energy, anabolism is an “uphill” process that involves the formation of new chemical bonds. Cells synthesize new organic components for four basic reasons:

1. *To Perform Structural Maintenance or Repairs.* All cells must expend energy to perform ongoing maintenance and repairs, because most structures in the cell are temporary rather than permanent. Their removal and replacement are part of the process of *metabolic turnover*. l**p. 57**

2. *To Support Growth.* Cells preparing to divide increase in size and synthesize extra proteins and organelles.

3. *To Produce Secretions.* Secretory cells must synthesize their products and deliver them to the interstitial fluid.

4. *To Store Nutrient Reserves.* Most cells “prepare for a rainy day”—a period of emergency, an interval of extreme activity, or a time when the supply of nutrients in the bloodstream is inadequate. Cells prepare for such times by building up reserves—nutrients stored in a form that can be mobilized as needed. The most abundant storage form of carbohydrate is glycogen, a branched chain of glucose molecules; the most abundant storage lipids are triglycerides, consisting primarily of fatty acids. Thus, muscle cells and liver cells, for example, store glucose in the form of glycogen, whereas adipocytes and liver cells store triglycerides. Proteins, the most abundant organic components in the body, perform a variety of vital functions for the cell, and when energy is available, cells synthesize additional proteins. However, when glucose or fatty acids are unavailable, proteins can be broken down into their component amino acids, and the amino acids catabolized as an energy source. So, although their primary function is not to serve as an energy source, proteins are so abundant and accessible that they represent an important “last-ditch” nutrient reserve.

The nutrient pool is the source of the substrates for both catabolism and anabolism. As you might expect, cells tend to conserve the materials needed to build new compounds and break down the rest. Cells continuously replace membranes, organelles, enzymes, and structural proteins. These anabolic activities require more amino acids than lipids, and few carbohydrates. In general, when a cell with excess carbohydrates, lipids, and amino acids needs energy, it will break down carbohydrates first. Lipids are the second choice, and amino acids are seldom broken down if other energy sources are available.

Mitochondria provide the energy that supports cellular operations. The cell feeds its mitochondria from its nutrient pool, and in return, the cell gets the ATP it needs. However, mitochondria are picky eaters: They will accept only specific organic molecules for processing and energy production. Thus, chemical reactions in the cytoplasm take whichever organic nutrients are available and break them down into smaller fragments that the mitochondria can process. The mitochondria then break the fragments down further, generating carbon dioxide, water, and ATP (Figure 25–2•). This mitochondrial activity involves two pathways: the *TCA cycle* and the *electron transport system*. We will describe these important catabolic and anabolic cellular reactions in the next section.

100 Keys | There is an energy cost to staying alive, even at rest. All cells must expend ATP to perform routine maintenance, removing and replacing intracellular and extracellular structures and components. In addition, cells must spend additional energy performing other vital functions, such as growth, secretion, and contraction.

Carbohydrate Metabolism

Objectives

- Describe the basic steps in glycolysis, the TCA cycle, and the electron transport system.
- Summarize the energy yield of glycolysis and cellular respiration.

Most cells generate ATP and other high-energy compounds by breaking down carbohydrates—especially glucose. The complete reaction sequence can be summarized as follows:

$C_6H_{12}O_6$ + 6 O_2 ¡ 6 CO_2 + 6 H_2O

glucose oxygen carbon dioxide water

The breakdown occurs in a series of small steps, several of which release sufficient energy to support the conversion of ADP to ATP. The complete catabolism of one molecule of glucose provides a typical body cell a net gain of 36 molecules of ATP.

Although most ATP production occurs inside mitochondria, the first steps take place in the cytosol. The process of *glycolysis*, which breaks down glucose in the cytosol and generates smaller molecules that can be absorbed and utilized by mitochondria, was introduced in Chapter 10. l**p. 309** Because glycolysis does not require oxygen, the reactions are said to be *anaerobic*. The subsequent reactions, which occur in mitochondria, consume oxygen and are considered *aerobic*. The mitochondrial activity responsible for ATP production is called **aerobic metabolism**, or *cellular respiration.*

Glycolysis

Glycolysis (gl -KOL-i-sis; *glykus*, sweet + *lysis*, dissolution) is the breakdown of glucose to **pyruvic acid**. In this process, a se

–

ı ries of enzymatic steps breaks the six-carbon glucose molecule (C6H12O6) into two three-carbon molecules of pyruvic acid (CH3 ¬ CO ¬ COOH). At the normal pH inside cells, each pyruvic acid molecule loses a hydrogen ion and exists as the nega

-

tively charged ion CH_3 – CO ¬ COO. This ionized form is usually called *pyruvate*, rather than pyruvic acid.

Glycolysis requires (1) glucose molecules, (2) appropriate cytoplasmic enzymes, (3) ATP and ADP, (4) inorganic phosphates, and (5) **NAD** (***n****icotinamide* ***a****denine* ***d****inucleotide*), a coenzyme that removes hydrogen atoms during one of the enzymatic reactions. (Recall from Chapter 2 that coenzymes are organic molecules that are essential to enzyme function. l**p. 53**) If any of these participants is missing, glycolysis cannot occur.

Figure 25–3• provides an overview of the steps in glycolysis. Glycolysis begins when an enzyme *phosphorylates*—that is, attaches a phosphate group—to the last (sixth) carbon atom of a glucose molecule, creating **glucose-6-phosphate**. This step, which “costs” the cell one ATP molecule, has two important results: (1) It traps the glucose molecule within the cell, because phosphorylated glucose cannot cross the cell membrane; and (2) it prepares the glucose molecule for further biochemical reactions.

A second phosphorylation occurs in the cytosol before the six-carbon chain is broken into two three-carbon fragments. Energy benefits begin to appear as these fragments are converted to pyruvic acid. Two of the steps release enough energy to generate ATP from ADP and inorganic phosphate (PO_4^{3-} or P_i). In addition, two molecules of NAD are converted to NADH. The net reaction looks like this:

Glucose + 2 NAD + 2 ADP + 2 Pi ¡

2 Pyruvic acid + 2 NADH + 2 ATP

This anaerobic reaction sequence provides the cell a net gain of two molecules of ATP for each glucose molecule converted to two pyruvic acid molecules. A few highly specialized cells, such as red blood cells, lack mitochondria and derive all their ATP through glycolysis. Skeletal muscle fibers rely on glycolysis for ATP production during periods of active contraction; using the ATP provided by glycolysis alone, most cells can survive for brief periods. However, when oxygen is readily available, mitochondrial activity provides most of the ATP required by cells.

Mitochondrial ATP Production

For the cell, glycolysis yields an immediate net gain of two ATP molecules for each glucose molecule it breaks down. However, a great deal of additional energy is still stored in the chemical bonds of pyruvic acid. The ability to capture that energy depends on the availability of oxygen. If oxygen supplies are adequate, mitochondria absorb the pyruvic acid molecules and break them down.

The hydrogen atoms of each pyruvic acid molecule (CH3

–

CO ¬ COOH)

are removed by coenzymes and are ultimately the source

of most of the cell’s energy gain. The carbon and oxygen atoms are removed and released as carbon dioxide in a process called **dec**

arboxylation (d

¯e

-kar-boks-i-L

¯A

-shun).

Two membranes surround each mitochondrion. The *outer membrane* contains large-diameter pores that are permeable to ions and small organic molecules such as pyruvic acid. Ions and molecules thus easily enter the *intermembrane space* separating the outer membrane from the *inner membrane*. The inner membrane contains a carrier protein that moves pyruvic acid into the mitochondrial matrix.

The TCA Cycle

In the mitochondrion, a pyruvic acid molecule participates in a complex reaction involving NAD and another coenzyme, **coenzyme**

A, or **CoA.** This reaction yields one molecule of carbon dioxide, one of NADH, and one of

acetyl-CoA (as-

¯E

-til-K

¯O

-

¯a

)—a two-

carbon **acetyl group** (CH3CO) bound to coenzyme A. This sets the stage for a sequence of enzymatic reactions called the **tricarb**

oxylic (tr -kar-bok-SIL-ik) **acid (TCA) cycle**, or **citric acid cycle**. In the first step of that cycle, the acetyl group is transferred ı

.

citric acid

, producing

oxaloacetic acid

–

from acetyl-CoA to a four-carbon molecule of

The function of the citric acid cycle is to remove hydrogen atoms from organic molecules and transfer them to coenzymes. The overall pattern of the TCA cycle is shown in Figure 25–4•. For the biochemical details of glycolysis and the TCA cycle, consult the *Applications Manual*. AM: Aerobic Metabolism: A Closer Look

At the start of the TCA cycle, the two-carbon acetyl group carried by CoA is attached to the four-carbon oxaloacetic acid molecule to make the six-carbon compound citric acid. Coenzyme A is released intact and can thus bind another acetyl group. A complete revolution of the TCA cycle removes two carbon atoms, regenerating the four-carbon chain. (This is why the reaction sequence is called a *cycle*.) We can summarize the fate of the atoms in the acetyl group as follows:

- The two carbon atoms are removed in enzymatic reactions that incorporate four oxygen atoms and form two molecules of carbon dioxide, a waste product.
- The hydrogen atoms are removed by the coenzyme NAD or a related coenzyme called **FAD** (***f****lavin* ***a****denine* ***d****inucleotide*) (Figure 25–4b•).

Several of the steps involved in a revolution of the TCA cycle involve more than one reaction and require more than one enzyme. Water molecules are tied up in two of those steps. The entire sequence can be summarized as follows:

CH_3CO -CoA + 3 NAD + FAD + GDP + P_i + 2 H_2O ¡

CoA + 2 CO_2 + 3 NADH + $FADH_2$ + 2 H^+ + GTP

The only immediate energy benefit of one revolution of the TCA cycle is the formation of a single molecule of GTP (*guanosine triphosphate*) from GDP (*guanosine diphosphate*) and Pi. In practical terms, GTP is the equivalent of ATP, because GTP readily transfers a phosphate group to ADP, producing ATP:

GTP + ADP ¡ GDP + ATP

The formation of GTP from GDP in the TCA cycle is an example of **substrate-level phosphorylation**. In this process, an enzyme uses the energy released by a chemical reaction to transfer a phosphate group to a suitable acceptor molecule. Although GTP is formed in the TCA cycle, many reaction pathways in the cytosol phosphorylate ADP and form ATP directly. For example, the ATP produced during glycolysis is generated through substrate-level phosphorylation. Normally, however, substrate-level phosphorylation provides a relatively small amount of energy compared with *oxidative phosphorylation*.

Oxidative Phosphorylation and the ETS

Oxidative phosphorylation is the generation of ATP within mitochondria in a reaction sequence that requires coenzymes and consumes oxygen. The process produces more than 90 percent of the ATP used by body cells. The key reactions take place in the *electron transport system (ETS)*, a series of integral and peripheral proteins in the inner mitochondrial membrane. The basis of oxidative phosphorylation is a very simple reaction:

$2\ H_2 + O_2$ ¡ $2\ H_2O$ Cells can easily obtain the ingredients for this reaction: Hydrogen is a component of all organic molecules, and oxygen is an atmospheric gas. The only problem is that the reaction releases a tremendous amount of energy all at once. In fact, this reaction releases so much energy that it is used to launch space shuttles into orbit. Cells cannot handle energy explosions; energy release must be gradual, as it is in oxidative phosphorylation. This powerful reaction proceeds in a series of small, enzymatically controlled steps. Under these conditions, energy can be captured safely, and ATP generated.

Oxidation, Reduction, and Energy Transfer The enzymatic steps of oxidative phosphorylation involve oxidation and reduction. (There are different types of oxidation and reduction reactions, but for our purposes the most important are those involving the transfer of electrons.) The loss of electrons is a form of **oxidation**; the acceptance of electrons is a form of **reduction**. The two reactions are always paired. When electrons pass from one molecule to another, the electron donor is oxidized and the electron recipient reduced. Oxidation and reduction are important because electrons carry chemical energy. In a typical oxidation–reduction reaction, *the reduced molecule gains energy at the expense of the oxidized molecule*.

In such an exchange, the reduced molecule does not acquire all the energy released by the oxidized molecule. Some energy is always released as heat, but the remaining energy may be used to perform physical or chemical work, such as the formation of ATP. By sending the electrons through a series of oxidation–reduction reactions before they ultimately combine with oxygen atoms, cells can capture and use much of the energy released as water is formed.

Coenzymes play a key role in this process. A coenzyme acts as an intermediary that accepts electrons from one molecule and

transfers them to another molecule. In the TCA cycle, NAD and FAD remove hydrogen atoms from organic substrates. Each hydrogen atom consists of an electron (e^-) and a proton (a hydrogen ion, H^+). Thus, when a coenzyme accepts hydrogen atoms, the coenzyme is reduced and gains energy. The donor molecule loses electrons and energy as it gives up its hydrogen atoms.

As indicated in Figure 25–4a•, NADH and FADH2, the reduced forms of NAD and FAD, then transfer their hydrogen atoms to other coenzymes. The protons are subsequently released, and the electrons, which carry the chemical energy, enter a sequence of oxidation–reduction reactions known as the *electron transport system*. This sequence ends with the electrons' transfer to oxygen and the formation of a water molecule. At several steps along the oxidation–reduction sequence, enough energy is released to support the synthesis of ATP from ADP. We will now consider that reaction sequence in greater detail.

The coenzyme FAD accepts two hydrogen atoms from the TCA cycle and in doing so gains two electrons, forming $FADH_2$. The oxidized form of the coenzyme NAD has a positive charge (NAD^+). This coenzyme also gains two electrons as two hydrogen atoms are removed from the donor molecule, resulting in the formation of NADH and the release of a proton (H^+). For this reason, the reduced form of NAD is often described as "NADH + H^+."

The Electron Transport System The **electron transport system (ETS)**, or *respiratory chain*, is a sequence of proteins called **cyt**

ochromes (SI¯

-t

‾o

-kr

‾o

mz; *cyto*-, cell + *chroma*, color). Each cytochrome has two components: a protein and a pigment. The protein, embedded in the inner membrane of a mitochondrion, surrounds the pigment complex, which contains a metal ion—either iron (Fe^{3+}) or copper (Cu^{2+}). We will consider four cytochromes: ***b***, ***c***, ***a***, and $\boldsymbol{a_3}$**.**

Figure 25–5• summarizes the basic steps in oxidative phosphorylation. We will first consider the general path taken by the electrons that are captured and delivered by coenzymes (Figure 25–5a•):

Step 1 A Coenzyme Strips a Pair of Hydrogen Atoms from a Substrate Molecule. As we have seen, different coenzymes are used for different substrate molecules. During glycolysis, which occurs in the cytoplasm, NAD is reduced to NADH. Within mitochondria, both NAD and FAD are reduced through reactions of the TCA cycle, producing NADH and $FADH_2$, respectively.

Step 2 NADH and $FADH_2$ Deliver Hydrogen Atoms to Coenzymes Embedded in the Inner Mitochondrial Membrane. The electrons carry the energy, and the protons that accompany them are released before the electrons are transferred to the ETS. As indicated in Figure 25–5a•, one of two paths is taken to the ETS; which one depends on whether the donor is NADH or $FADH_2$. The path from NADH involves the coenzyme **FMN** (***f****lavin* ***m****ono****n****ucleotide*), whereas the path from $FADH_2$ proceeds directly to **coenzyme Q** (*ubiquinone*). Both FMN and coenzyme Q are bound to the inner mitochondrial membrane.

Step 3 Coenzyme Q Releases Hydrogen Ions and Passes Electrons to Cytochrome ***b*.**

Step 4 Electrons Are Passed along the Electron Transport System, Losing Energy in a Series of Small Steps. The sequence is

cytochrome *b* to *c* to *a* to *a*3.

Step 5 At the End of the ETS, an Oxygen Atom Accepts the Electrons and Combines with Hydrogen Ions to Form Water.

Notice that this reaction sequence started with the removal of two hydrogen atoms from a substrate molecule and ended with the formation of water from two hydrogen ions and one oxygen ion. This is the reaction previously described as releasing too much energy if performed in a single step. However, because the reaction has occurred in a series of small steps, the combining of hydrogen and oxygen can take place safely rather than explosively.

ATP Generation and the ETS As noted in Chapter 3, concentration gradients across membranes represent a form of potential energy that can be harnessed by the cell. The electron transport system does not produce ATP directly. Instead, it creates the conditions necessary for ATP production by creating a steep concentration gradient across the inner mitochondrial membrane. The electrons that travel along the ETS release energy as they pass from coenzyme to cytochrome and from cytochrome to cytochrome. The energy released at each of several steps drives hydrogen ion pumps that move hydrogen ions from the mitochondrial matrix into the intermembrane space between the inner and outer mitochondrial membranes. These pumps create a large concentration gradient for hydrogen ions across the inner membrane. It is this concentration gradient that provides the energy to convert ADP to ATP.

Despite the concentration gradient, hydrogen ions cannot diffuse into the matrix because they are not lipid soluble. However,

hydrogen ion channels in the inner membrane permit the diffusion of H^+ into the matrix. These ion channels and their attached *coupling factors* use the kinetic energy of passing hydrogen ions to generate ATP in a process known as *chemiosmosis* (kem-e¯-oz-MO-sis), or *chemiosmotic phosphorylation*.

–

Figure 25–5b• diagrams the mechanism of ATP generation. Hydrogen ions are pumped as (1) FMN reduces coenzyme Q,

(2) cytochrome *b* reduces cytochrome *c*, and (3) electrons are passed from cytochrome *a* to cytochrome *a*3.

For each pair of electrons removed from a substrate in the TCA cycle by NAD, six hydrogen ions are pumped across the inner membrane of the mitochondrion and into the intermembrane space (see Figure 25–5b•). Their reentry into the matrix provides the energy to generate three molecules of ATP. Alternatively, for each pair of electrons removed from a substrate in the TCA cycle by FAD, four hydrogen ions are pumped across the inner membrane and into the intermembrane space. Their reentry into the matrix provides the energy to generate two molecules of ATP.

The Importance of Oxidative Phosphorylation Oxidative phosphorylation is the most important mechanism for the generation of ATP. In most cases, if oxidative phosphorylation slows or stops, the cell dies. If many cells are affected, the individual may die. Oxidative phosphorylation requires both oxygen and electrons; the rate of ATP generation is thus limited by the availability of either oxygen or electrons.

Cells obtain oxygen by diffusion from the extracellular fluid. If the supply of oxygen is cut off, mitochondrial ATP production ceases, because reduced cytochrome *a*3 will have no acceptor for its electrons. With the last reaction stopped, the entire ETS comes to a halt, like cars at a washed-out bridge. Oxidative phosphorylation can no longer take place, and cells quickly succumb to energy starvation. Because neurons have a high demand for energy, the brain is one of the first organs to be affected.

Hydrogen cyanide gas is sometimes used as a pesticide to kill rats or mice; in some states where capital punishment is legal, it is used to execute criminals. The cyanide ion (CN^-) binds to cytochrome ***a*3** and prevents the transfer of electrons to oxygen. As a result, cells die from energy starvation.

Energy Yield of Glycolysis and Cellular Respiration

For most cells, the complete reaction pathway that begins with glucose and ends with carbon dioxide and water is the main method of generating ATP. Figure 25–6• summarizes the process in terms of energy production:

- **Glycolysis.** During glycolysis, the cell gains a net two molecules of ATP for each glucose molecule broken down anaerobically to pyruvic acid. Two molecules of NADH are also produced. In most cells, electrons are passed from NADH to FAD via an intermediate in the intermembrane space, and then to CoQ and the electron transport system. This sequence of events ultimately provides an additional four ATP molecules.
- **The Electron Transport System.** The TCA cycle breaks down the 2 pyruvic acid molecules, transferring hydrogen atoms to NADH and FADH2. These coenzymes provide electrons to the ETS; each of the 8 molecules of NADH yields 3 molecules of ATP and 1 water molecule; each of the 2 $FADH_2$ molecules yields 2 ATP molecules and 1 water molecule. Thus, the shuffling from the TCA cycle to the ETS yields 28 molecules of ATP.
- **The TCA Cycle.** Each of the two revolutions of the TCA cycle required to break down both pyruvic acid molecules completely yields one molecule of ATP by way of GTP. This cycling provides an additional gain of two molecules of ATP.

Summing up, for each glucose molecule processed, the cell gains 36 molecules of ATP: 2 from glycolysis, 4 from the NADH generated in glycolysis, 2 from the TCA cycle (by means of GTP), and 28 from the ETS. Cardiac muscle cells and liver cells are able to gain an additional two ATP molecules for each glucose molecule broken down. This gain is accomplished by increasing the energy yield from the NADH generated during glycolysis from four to six ATP molecules. In these cells, each NADH molecule passes electrons to an intermediate that generates NADH, not $FADH_2$, in the mitochondrial matrix. The subsequent transfer of electrons to FMN, CoQ, and the ETS results in the production of six ATP molecules, just as if the two NADH molecules had been generated in the TCA cycle.

Clinical Note

Eating carbohydrates just before exercise does not improve your performance and can decrease your endurance by slowing the mo bilization of existing energy reserves. Runners or swimmers preparing for lengthy endurance events, such as a marathon or 5-km swim, do not eat immediately before participating, and for two hours before the event they limit their intake to drinking water. However, these athletes often eat carbohydrate-rich meals for three days before the event. This *carbohydrate loading* increases the carbohydrate reserves of muscle tissue that will be called on while exercising.

You can obtain maximum effects of carbohydrate loading by exercising to exhaustion for three days before starting a high-carbohydrate diet. This practice, called *carbohydrate depletion/loading*, has a number of potentially harmful side effects, including muscle and kidney damage. Sports physiologists recommend that athletes engage in carbohydrate depletion/loading no more than twice a year. Many clinical practitioners advise against the practice altogether, believing that the potential side effects are too severe to risk for the sake of gains in performance.

Concept Check

What is the primary role of the TCA cycle in the production of ATP?

NADH produced by glycolysis in skeletal muscle fibers leads to the production of two ATP molecules in the mitochondria, but NADH produced by glycolysis in cardiac muscle cells leads to the production of three ATP molecules. Why? How would a decrease in the level of cytoplasmic NAD affect ATP production in mitochondria?

Answers begin on p. A–1

Gluconeogenesis

Because some of the steps in glycolysis—the breakdown of glucose—are essentially irreversible, cells cannot generate glucose by performing glycolysis in reverse, using the same enzymes (Figure 25–7•). Therefore, glycolysis and the production of glucose involve a different set of regulatory enzymes, and the two processes are independently regulated.

Because some three-carbon molecules other than pyruvic acid can be used to synthesize glucose, a cell can create glucose molecules from other carbohydrates, lactic acid, glycerol, or some amino acids. However, cells cannot use acetyl-CoA to make glucose, because the decarboxylation step between pyruvic acid and acetyl-CoA cannot be reversed. **Gluconeogenesis** (gloo-kō-nē-ō-JEN-e-sis) is the synthesis of glucose from noncarbohydrate precursors, such as lactic acid, glycerol, or amino acids. Fatty acids and many amino acids cannot be used for gluconeogenesis, because their catabolic pathways produce acetyl-CoA.

Glucose molecules created by gluconeogenesis can be used to manufacture other simple sugars, complex carbohydrates, proteoglycans, or nucleic acids. In the liver and in skeletal muscle, glucose molecules are stored as glycogen. The formation of glycogen from glucose, known as **glycogenesis**, is a complex process that involves several steps and requires the high-energy compound *uridine triphosphate (UTP)*. Glycogen is an important energy reserve that can be broken down when the cell cannot obtain enough glucose from interstitial fluid. The breakdown of glycogen, called **glycogenolysis**, occurs quickly and involves a single enzymatic step. Although glycogen molecules are large, glycogen reserves take up very little space because they form compact, insoluble granules.

Lipid Metabolism

Objectives

- Describe the pathways involved in lipid metabolism.

- Summarize the mechanisms of lipid transport and distribution.

Like carbohydrates, lipid molecules contain carbon, hydrogen, and oxygen, but the atoms are present in different proportions. Triglycerides are the most abundant lipid in the body, so our discussion will focus on pathways for triglyceride breakdown and synthesis.

Lipid Catabolism

During lipid catabolism, or **lipolysis**, lipids are broken down into pieces that can be either converted to pyruvic acid or channeled directly into the TCA cycle. A triglyceride is first split into its component parts by hydrolysis, yielding one molecule of glycerol and three fatty acid molecules. Glycerol enters the TCA cycle after enzymes in the cytosol convert it to pyruvic acid. The catabolism of fatty acids involves a completely different set of enzymes that generate acetyl-CoA directly.

Beta-Oxidation

Fatty acid molecules are broken down into two-carbon fragments in a sequence of reactions known as **beta-oxidation**. This process occurs inside mitochondria, so the carbon chains can enter the TCA cycle immediately as acetyl-CoA. Figure 25–8• diagrams one step in the process of beta-oxidation. Each step generates molecules of acetyl-CoA, NADH, and $FADH_2$, leaving a shorter carbon chain bound to coenzyme A.

Beta-oxidation provides substantial energy benefits. For each two-carbon fragment removed from the fatty acid, the cell gains 12 ATP molecules from the processing of acetyl-CoA in the TCA cycle, plus 5 ATP molecules from the NADH and FADH2. The cell can therefore gain 144 ATP molecules from the breakdown of one 18-carbon fatty acid molecule. This number of ATP molecules yields almost 1.5 times the energy obtained by the complete breakdown of three 6-carbon glucose molecules. The catabolism of other lipids follows similar patterns, generally ending with the formation of acetyl-CoA.

Lipids and Energy Production

Lipids are important energy reserves because they can provide large amounts of ATP. Because they are insoluble in water, lipids can be stored in compact droplets in the cytosol. This storage method saves space, but when the lipid droplets are large, it is difficult for water-soluble enzymes to get at them. Lipid reserves are therefore more difficult to access than carbohydrate reserves. Also, most lipids are processed inside mitochondria, and mitochondrial activity is limited by the availability of oxygen.

The net result is that lipids cannot provide large amounts of ATP quickly. However, cells with modest energy demands can shift to lipid-based energy production when glucose supplies are limited. Skeletal muscle fibers normally cycle between lipid metabolism and carbohydrate metabolism. At rest (when energy demands are low), these cells break down fatty acids. During activity (when energy demands are large and immediate), skeletal muscle fibers shift to glucose metabolism.

Lipid Synthesis

The synthesis of lipids is known as **lipogenesis** (lip-o¯-JEN-e-sis). Glycerol is synthesized from *dihydroxyacetone phosphate*, one of the intermediate products of glycolysis. The synthesis of most other types of lipids, including nonessential fatty acids and steroids, begins with acetyl-CoA. Lipogenesis can use almost any organic substrate, because lipids, amino acids, and carbohydrates can be converted to acetyl-CoA.

Fatty acid synthesis involves a reaction sequence quite distinct from that of beta-oxidation. Body cells cannot *build* every fatty acid they can break down. For example, **linoleic acid** and **linolenic acid**, both 18-carbon unsaturated fatty acids synthesized by plants, cannot be synthesized in the body. They are thus considered **essential fatty acids**, because they must be included in your diet. These fatty acids are also needed to synthesize prostaglandins and some of the phospholipids incorporated into cell membranes throughout the body.

Lipid Transport and Distribution

Like glucose, lipids are needed throughout the body. All cells require lipids to maintain their cell membranes, and important steroid hormones must reach target cells in many different tissues. Free fatty acids constitute a relatively small percentage of the total circulating lipids. Because most lipids are not soluble in water, special transport mechanisms carry them from one region of the body to another. Most lipids circulate through the bloodstream as lipoproteins.

Free Fatty Acids

Free fatty acids (FFAs) are lipids that can diffuse easily across cell membranes. In the blood, free fatty acids are generally bound to albumin, the most abundant plasma protein. Sources of free fatty acids in the blood include the following:

- Fatty acids that are not used in the synthesis of triglycerides, but diffuse out of the intestinal epithelium and into the blood.
- Fatty acids that diffuse out of lipid stores (such as those in the liver and adipose tissue) when triglycerides are broken down.

Liver cells, cardiac muscle cells, skeletal muscle fibers, and many other body cells can metabolize free fatty acids, which are an important energy source during periods of starvation, when glucose supplies are limited.

Lipoproteins

Lipoproteins are lipid–protein complexes that contain large insoluble glycerides and cholesterol. A superficial coating of phospholipids and proteins makes the entire complex soluble. Exposed proteins, which can bind to specific membrane receptors, determine which cells absorb the associated lipids.

Lipoproteins are usually classified into five major groups according to size and the relative proportions of lipid and protein:

1. *Chylomicrons.* Roughly 95 percent of the weight of a chylomicron consists of triglycerides. The largest lipoproteins, ranging in

diameter from 0.03 to 0.5 mm, chylomicrons are produced by intestinal epithelial cells. l**p. 885** Chylomicrons carry absorbed lipids from the intestinal tract to the bloodstream. The liver is the primary source of all the other groups of lipoproteins,
which shuttle lipids among various tissues.

2. *Very Low-Density Lipoproteins (VLDLs).* Very low-density lipoproteins contain triglycerides manufactured by the liver, plus small amounts of phospholipids and cholesterol. The primary function of VLDLs is to transport these triglycerides to peripheral tissues. The VLDLs range in diameter from 25 to 75 nm (0.025–0.075 mm)

3. *Intermediate-Density Lipoproteins (IDLs).* Intermediate-density lipoproteins are intermediate in size and lipid composition between VLDLs and low-density lipoproteins (LDLs). IDLs contain smaller amounts of triglycerides than do VLDLs, and relatively more phospholipids and cholesterol than do LDLs.

4. *Low-Density Lipoproteins (LDLs).* Low-density lipoproteins contain cholesterol, lesser amounts of phospholipids, and very few triglycerides. These lipoproteins, which are about 25 nm in diameter, deliver cholesterol to peripheral tissues. Because the cholesterol may wind up in arterial plaques, LDL cholesterol is often called “bad cholesterol.”

5. *High-Density Lipoproteins (HDLs).* High-density lipoproteins, about 10 nm in diameter, have roughly equal amounts of lipid and protein. The lipids are largely cholesterol and phospholipids. The primary function of HDLs is to transport excess cholesterol from peripheral tissues back to the liver for storage or excretion in the bile. Because HDL cholesterol is returning from peripheral tissues and does not cause circulatory problems, it is called “good cholesterol.” Actually, applying the terms *good* and *bad* to cholesterol can be misleading, for cholesterol metabolism is complex and variable. (For more details, see the Clinical Note “Dietary Fats and Cholesterol” on p. 929.)

Figure 25–9• depicts the relationships among these lipoproteins. Chylomicrons produced in the intestinal tract enter lymphatic capillaries and travel through the thoracic duct to reach the venous circulation and then the systemic arteries (Figure 25–9a•). Chylomicrons are too large to diffuse across a capillary wall. However, when they contact the endothelial walls of capillaries in skeletal muscle, cardiac muscle, adipose tissue, and the liver, the enzyme **lipoprotein lipase** breaks down the complex lipids in them, releasing fatty acids and monoglycerides that can diffuse across the endothelium and into interstitial fluid.

The liver controls the distribution of other lipoproteins through a series of steps (Figure 25–9b):

Step 1 Liver cells synthesize VLDLs for discharge into the bloodstream.

Step 2 In peripheral capillaries, lipoprotein lipase removes many of the triglycerides from VLDLs, leaving IDLs; the triglycerides are broken down into fatty acids and monoglycerides.

Step 3 When IDLs reach the liver, additional triglycerides are removed, and the protein content of the lipoprotein is altered. This process creates LDLs, which are transported to peripheral tissues to deliver cholesterol.

Step 4 LDLs leave the bloodstream through capillary pores or cross the endothelium by vesicular transport.

Step 5 Once in peripheral tissues, the LDLs are absorbed by means of receptor-mediated endocytosis. l**p. 930** The amino acids and cholesterol then enter the cytoplasm.

Step 6 The cholesterol not used by the cell (in the synthesis of lipid membranes or other products) diffuses out of the cell.

Step 7 The cholesterol then reenters the bloodstream, where it is absorbed by HDLs and returned to the liver.

Step 8 In the liver, the HDLs are absorbed and their cholesterol is extracted. Some of the cholesterol that is recovered is used in

the synthesis of LDLs; the rest is excreted in bile salts.

Step 9 The HDLs stripped of their cholesterol are released into the bloodstream to travel into peripheral tissues and absorb additional cholesterol.

Protein Metabolism

Objectives

- Summarize the main features of protein metabolism and the use of proteins as an energy source.

The body can synthesize 100,000 to 140,000 different proteins with various forms, functions, and structures. Yet, each protein contains some combination of the same 20 amino acids. Under normal conditions, cellular proteins are continuously recycled in the cytosol. Peptide bonds are broken, and the free amino acids are used in new proteins.

If other energy sources are inadequate, mitochondria can generate ATP by breaking down amino acids in the TCA cycle. Not all amino acids enter the cycle at the same point, however, so the ATP benefits vary. Nonetheless, the average ATP yield per gram is comparable to that of carbohydrate catabolism.

Amino Acid Catabolism

The first step in amino acid catabolism is the removal of the amino group (¬ NH2). This process requires a coenzyme derivative

of **vitamin B_6** (*pyridoxine*). The amino group is removed by *transamination* (tranz-am-i-N

A¯

-shun) or *deamination* (d

¯e

-am-i-N A¯

-shun). We will consider other aspects of amino acid catabolism in a later section.

Transamination

Transamination attaches the amino group of an amino acid to a **keto acid** (Figure 25–10a•), which resembles an amino acid except that the second carbon binds an oxygen atom rather than an amino group. Transamination converts the keto acid into an amino acid that can leave the mitochondrion and enter the cytosol, where it can be used for protein synthesis. In the process, the original amino acid becomes a keto acid that can be broken down in the TCA cycle. Cells in many different tissues perform transaminations, enabling cells to synthesize many of the amino acids needed for protein synthesis. Cells of the liver, skeletal muscles, heart, lung, kidney, and brain, which are particularly active in protein synthesis, perform many transaminations.

Deamination

Deamination (Figure 25–10b•) prepares an amino acid for breakdown in the TCA cycle. Deamination is the removal of an amino group and a hydrogen atom in a reaction that generates an ammonium ion (NH4 +). Ammonium ions are highly toxic, even in low concentrations. Liver cells, the primary sites of deamination, have enzymes that use ammonium ions to synthesize **urea**, a relatively harmless water-soluble compound excreted in urine. The **urea cycle** is the reaction sequence responsible for the production of urea (Figure 25–10c•).

When glucose supplies are low and lipid reserves are inadequate, liver cells break down internal proteins and absorb additional amino acids from the blood. The amino acids are deaminated, and the carbon chains are broken down to provide ATP.

Proteins and ATP Production

Three factors make protein catabolism an impractical source of quick energy:

1. Proteins are more difficult to break apart than are complex carbohydrates or lipids.

2. One of the by-products, ammonium ions, is toxic to cells.

3. Proteins form the most important structural and functional components of any cell. Thus extensive protein catabolism threatens homeostasis at the cellular and systems levels.

Several inherited metabolic disorders result from an inability to produce specific enzymes involved in amino acid metabolism.

Individuals with *phenylketonuria* (fen-il-k

¯e

-t

¯o

-NOO-r

¯e

-uh), or PKU, for example, cannot convert phenylalanine to tyrosine, due

to a defect in the enzyme *phenylalanine hydroxylase*. This reaction is an essential step in the synthesis of norepinephrine, epinephrine, dopamine, and melanin. If PKU is not detected in infancy, central nervous system development is inhibited, and severe brain damage results. AM: Phenylketonuria

Protein Synthesis

The basic mechanism for protein synthesis was discussed in Chapter 3 (see Figures 3–12 and 3–13, pp. 81, 82–83). Your body can synthesize roughly half of the various amino acids needed to build proteins. There are 10 **essential amino acids**. Your body cannot synthesize eight of them (*isoleucine*, *leucine*, *lysine*, *threonine*, *tryptophan*, *phenylalanine*, *valine*, and *methionine*); the other two (*arginine* and *histidine*) can be synthesized, but in amounts that are insufficient for growing children. Because the body can make other amino acids on demand, they are called **nonessential amino acids**. Your body cells can readily synthesize the carbon frameworks of the nonessential amino acids, and a nitrogen group can be added by **amination**—the attachment of an amino group (Figure 25–11•)—or by transamination.

Protein deficiency diseases develop when individuals do not consume adequate amounts of all essential amino acids. All amino acids must be available if protein synthesis is to occur. Every transfer RNA molecule must appear at the active ribosome in the proper sequence, bearing its individual amino acid. If that does not happen, the entire process comes to a halt. Regardless of its energy content, if the diet is deficient in essential amino acids, the individual will be malnourished to some degree. Examples of protein deficiency diseases include *marasmus*, *kwashiorkor*, and *pellagra*. More than 100 million children worldwide have symptoms of these disorders, although none of these conditions are common in the United States today. AM: Protein Deficiency Diseases

Figure 25–12• summarizes the metabolic pathways for lipids, carbohydrates, and proteins. Although the diagram presents the reactions in a “typical” cell, no one cell can perform all the anabolic and catabolic operations and interconversions required by the body as a whole. As differentiation proceeds, each type of cell develops its own complement of enzymes that determines the cell’s metabolic capabilities. In the presence of such cellular diversity, homeostasis can be preserved only when the metabolic activities of tissues, organs, and organ systems are coordinated.

Concept Check

How would a diet that is deficient in pyridoxine (vitamin B_6) affect protein metabolism?

Elevated levels of urea in the blood can be an indicator of increased metabolism of which organic compound?

Why are high-density lipoproteins (HDLs) considered beneficial?

Answers begin on p. A–1

Metabolic Interactions

Objectives

- Differentiate between the absorptive and postabsorptive metabolic states and summarize the characteristics of each.

The nutrient requirements of each tissue vary with the types and quantities of enzymes present in the cytoplasm of cells. From a metabolic standpoint, we can consider the body to have five distinctive components: the liver, adipose tissue, skeletal muscle, neural tissue, and other peripheral tissues:

1. *The Liver.* The liver is the focal point of metabolic regulation and control. Liver cells contain a great diversity of enzymes, so they can break down or synthesize most of the carbohydrates, lipids, and amino acids needed by other body cells. Liver cells have an extensive blood supply, so they are in an excellent position to monitor and adjust the nutrient composition of circulating blood. The liver also contains significant energy reserves in the form of glycogen deposits.

2. *Adipose Tissue.* Adipose tissue stores lipids, primarily as triglycerides. Adipocytes are located in many areas: in areolar tissue, in mesenteries, within red and yellow marrows, in the epicardium, and around the eyes and the kidneys.

3. *Skeletal Muscle.* Skeletal muscle accounts for almost half of a healthy individual's body weight, and skeletal muscle fibers maintain substantial glycogen reserves. In addition, if other nutrients are unavailable, their contractile proteins can be broken down and the amino acids used as an energy source.

4. *Neural Tissue.* Neural tissue has a high demand for energy, but the cells do not maintain reserves of carbohydrates, lipids, or proteins. Neurons must be provided with a reliable supply of glucose, because they are generally unable to metabolize other molecules. If blood glucose levels become too low, neural tissue in the central nervous system cannot continue to function, and the individual falls unconscious.

5. *Other Peripheral Tissues.* Other peripheral tissues do not maintain large metabolic reserves, but they are able to metabolize glucose, fatty acids, or other substrates. Their preferred source of energy varies according to instructions from the endocrine system.

The interrelationships among these five components can best be understood by considering events over a typical 24-hour period. During this time, the body experiences two broad patterns of metabolic activity: the *absorptive state* and the *postabsorptive state*.

The **absorptive state** is the period following a meal, when nutrient absorption is under way. After a typical meal, the absorptive state continues for about 4 hours. If you are fortunate enough to eat three meals a day, you spend 12 out of every 24 hours in the absorptive state. Insulin is the primary hormone of the absorptive state, although various other hormones stimulate amino acid uptake (growth hormone, or GH) and protein synthesis (GH, androgens, and estrogens) (Table 25–1).

The **postabsorptive state** is the period when nutrient absorption is not under way and your body must rely on internal energy reserves to continue meeting its energy demands. You spend roughly 12 hours each day in the postabsorptive state, although a person who is skipping meals can extend that time considerably. Metabolic activity in the postabsorptive state is focused on the mobilization of energy reserves and the maintenance of normal blood glucose levels. These activities are coordinated by several hormones, including glucagon, epinephrine, glucocorticoids, and growth hormone (see Table 25–1).

During the postabsorptive state, liver cells conserve glucose and break down lipids and amino acids. Both lipid catabolism and amino acid catabolism generate acetyl-CoA. As the concentration of acetyl-CoA rises, compounds called **ketone bodies** begin to
form. There are three such compounds: (1) **acetoacetate** (as-
¯e
-t
¯o
-AS-e-t
¯a
t), (2) **acetone** (AS-e-t
¯o
n), and (3) **betahydroxybut-**
¯U
¯

-ta-h -droks-
ı the cytoplasm and into the general circulation. Cells in peripheral tissues then absorb the ketone bodies and reconvert them to acetyl-CoA for introduction into the TCA cycle.

The normal concentration of ketone bodies in the blood is about 30 mg > dl, and very few of these compounds appear in urine.

yrate (b
¯a
¯e
-B

¯a

t). Liver cells do not catabolize any of the ketone bodies, and these compounds diffuse through -te-r

During even a brief period of fasting, the increased production of ketone bodies results in *ketosis* (k

¯e

-T

¯

O

-sis), a high concentration of ketone bodies in body fluids. A ketone body is an acid that dissociates in solution, releasing a hydrogen ion. As a result, the appearance of ketone bodies in the bloodstream—*ketonemia*—lowers plasma pH, which must be controlled by buffers. During prolonged starvation, ketone levels continue to rise. Eventually, buffering capacities are exceeded and a dangerous drop in pH

occurs. This acidification of the blood is called *ketoacidosis* (k

¯e

-t

¯o

-as-i-D

¯O

-sis). In severe ketoacidosis, the circulating concentration of ketone bodies can reach 200 mg > dl, and the pH may fall below 7.05. A pH that low can disrupt tissue activities and cause coma, cardiac arrhythmias, and death.

In summary, during the postabsorptive state, the liver acts to stabilize blood glucose concentrations, first through the breakdown of glycogen reserves and later by gluconeogenesis. Over the remainder of the postabsorptive state, the combination of lipid and amino acid catabolism provides the necessary ATP and generates large quantities of ketone bodies that diffuse into the bloodstream.

The changes in activity of the liver, adipose tissue, skeletal muscle, and other peripheral tissues ensure that the supply of glucose to the nervous system continues unaffected, despite daily or even weekly changes in nutrient availability. Only after a prolonged period of starvation will neural tissue begin to metabolize ketone bodies and lactic acid molecules, as well as glucose.

AM: Metabolic Interactions and Adaptations to Starvation

100 Keys | In the absorption state that follows a meal, cells absorb nutrients that are used to support growth and maintenance and stored as energy reserves. Hours later, in the postabsorptive state, blood glucose levels are maintained by gluconeogenesis within the liver, but most cells begin conserving energy and shifting from glucose-based to lipid-based metabolism and, if necessary, ketone bodies become the preferred energy source. This metabolic shift reserves the circulating glucose for use by neurons.

Concept Check

What process in the liver increases after you have eaten a high-carbohydrate meal?

Why does the amount of urea in blood increase during the postabsorptive state?

If a cell accumulates more acetyl-CoA than it can metabolize in the TCA cycle, what products are likely to form?

Answers begin on p. A–1

Diet and Nutrition

Objective

- Explain what constitutes a balanced diet and why such a diet is important.

The postabsorptive state can be maintained for a considerable period, but homeostasis can be maintained indefinitely only if the digestive tract regularly absorbs enough fluids, organic substrates, minerals, and vitamins to keep pace with cellular demands. The absorption of nutrients from food is called **nutrition**.

The body's requirement for each nutrient varies from day to day and from person to person. *Nutritionists* attempt to analyze a diet in terms of its ability to meet the needs of a specific individual. A **balanced diet** contains all the ingredients needed to maintain homeostasis, including adequate substrates for energy generation, essential amino acids and fatty acids, minerals, and vitamins. In addition, the diet must include enough water to replace losses in urine, feces, and evaporation. A balanced diet prevents **malnutrition**, an unhealthy state resulting from inadequate or excessive absorption of one or more nutrients.

Food Groups and the Food Pyramid

One method of avoiding malnutrition is to include members of each of the five **basic food groups** in the diet: (1) the *milk, yogurt, and cheese group*; (2) the *meat, poultry, fish, dry beans, eggs, and nuts group*; (3) the *vegetable group*; (4) the *fruit group*; and (5) the *bread, cereal, rice, and pasta group*. Each group differs in its protein, carbohydrate, and lipid content, as well as in the amount and identity of vitamins and minerals. The components of these groups have been arranged in a *food pyramid*, which is constructed according to number of recommended daily servings (Figure 25–13• and Table 25–2). (The fats, oils, and sweets category that appears at the top of the pyramid includes things like ice cream, butter, and candies, derived from the other groups.) The aim of this display is to emphasize the need to restrict intake of dietary fats, oils, and sugar, and to increase consumption of foods that are rich in complex carbohydrates (polysaccharides such as starch).

These groupings are rather artificial at best, and downright misleading at worst. Many processed foods, for instance, belong in a combination of groups. What is important is that you obtain nutrients in sufficient *quantity* (adequate to meet your energy needs) and *quality* (including essential amino acids, fatty acids, vitamins, and minerals). How these nutrients are packaged is a secondary concern. There is nothing magical about five groups; at various times since 1940, the U.S. government has advocated 11, 7, 4, or 6 food groups. The key is making intelligent choices about what you eat. Poor choices can lead to malnutrition even if all five groups are represented.

For example, consider the essential amino acids. The liver cannot synthesize any of these amino acids, so you must obtain them from your diet. Some members of the meat and dairy groups—specifically, beef, fish, poultry, eggs, and milk—provide all the essential amino acids in sufficient quantities. They are said to contain **complete proteins**. Many plants also supply adequate *amounts* of protein but contain **incomplete proteins**, which are deficient in one or more of the essential amino acids. Vegetarians, who largely restrict themselves to the fruit and vegetable groups (with or without the bread group), must become adept at varying their food choices to include combinations of ingredients that meet all their amino acid requirements. Even with a proper balance of amino acids, vegans, who avoid all animal products, face a significant problem, because vitamin B_{12} is obtained only from animal products or from fortified cereals or tofu. (Although some health-food products, such as *Spirulina*, are marketed as sources of this vitamin, the B_{12} they contain is in a form that humans cannot utilize.)

Nitrogen Balance

A variety of important compounds in the body contain nitrogen atoms. These **N compounds** include:

- Amino acids, which are part of the framework of all proteins and protein derivatives, such as glycoproteins and lipoproteins.
- Purines and pyrimidines, the nitrogenous bases of RNA and DNA.
- *Creatine*, important in energy storage in muscle tissue (as creatine phosphate).
- *Porphyrins*, complex ring-shaped molecules that bind metal ions and are essential to the function of hemoglobin, myoglobin, and the cytochromes.

Despite the importance of nitrogen to these compounds, your body neither stores nitrogen nor maintains reserves of N compounds, as it does carbohydrates (glycogen) and lipids (triglycerides). Your body can synthesize the carbon chains of the N compounds, but you must obtain nitrogen atoms either by recycling N compounds already in the body or by absorbing nitrogen from your diet. You are in **nitrogen balance** when the amount of nitrogen you absorb from the diet balances the amount you lose in urine and feces. This is the normal condition, and it means that the rates of synthesis and breakdown of N compounds are equivalent.

Growing children, athletes, people recovering from an illness or injury, and pregnant or lactating women actively synthesize N compounds, so these individuals must absorb more nitrogen than they excrete. Such individuals are in a state of **positive nitrogen balance**. When excretion exceeds ingestion, a **negative nitrogen balance** exists. This is an extremely unsatisfactory situation: The body contains only about a kilogram of nitrogen tied up in N compounds, and a decrease of one-third can be fatal. Even when energy reserves are mobilized (as during starvation), carbohydrates and lipid reserves are broken down first and N compounds are conserved. AM: RNA Catabolism and Gout

Like N compounds, minerals and vitamins are essential components of the diet. Your body cannot synthesize minerals, and your cells can generate only a small quantity of a very few vitamins. We consider minerals and vitamins next.

100 Keys | A balanced diet contains all the ingredients needed to maintain homeostasis, including adequate substrates

for energy generation, essential amino acids and fatty acids, minerals, vitamins, and water.

Minerals

Minerals are inorganic ions released through the dissociation of electrolytes. Minerals are important for three reasons:

1. *Ions Such as Sodium and Chloride Determine the Osmotic Concentrations of Body Fluids.* Potassium is important in maintaining the osmotic concentration of the cytoplasm inside body cells.

2. *Ions in Various Combinations Play Major Roles in Important Physiological Processes.* As we have seen, these processes include the maintenance of transmembrane potentials, the construction and maintenance of the skeleton, muscle contraction, the generation of action potentials, the release of neurotransmitters, hormone production, blood clotting, the transport of respiratory gases, buffer systems, fluid absorption, and waste removal.

3. *Ions Are Essential Cofactors in a Variety of Enzymatic Reactions.* For example, calcium-dependent ATPase in skeletal muscle also requires the presence of magnesium ions, and another ATPase required for the conversion of glucose to pyruvic acid needs both potassium and magnesium ions. Carbonic anhydrase, important in CO_2 transport, buffering systems, and gastric acid secretion,

requires the presence of zinc ions. Finally, each component of the electron transport system requires an iron atom, and the final cytochrome (*a*3) of the ETS must bind a copper ion as well.

The major minerals and a summary of their functional roles are listed in Table 25–3. Your body contains significant reserves of several important minerals; these reserves help reduce the effects of variations in the dietary supply. However, the reserves are often small, and chronic dietary reductions can lead to a variety of clinical problems. Alternatively, because storage capabilities are limited, a dietary excess of mineral ions can be equally dangerous.

Problems involving iron are particularly common. The body of a healthy man contains about 3.5 g of iron in the ionic form Fe^{2+}. Of that amount, 2.5 g is bound to the hemoglobin of circulating red blood cells, and the rest is stored in the liver and bone marrow. In women, the total body iron content averages 2.4 g, with roughly 1.9 g incorporated into red blood cells. Thus, a woman’s iron reserves consist of only 0.5 g, half that of a typical man. If the diet contains inadequate amounts of iron, premenopausal women are therefore more likely to develop signs of iron deficiency than are men.

Vitamins

Vitamins are assigned to either of two groups based on their chemical structure and characteristics: *fat-soluble vitamins* or *water-soluble vitamins*.

Fat-Soluble Vitamins

Vitamins A, D, E, and K are the **fat-soluble vitamins**. These vitamins are absorbed primarily from the digestive tract along with the lipid contents of micelles. However, when exposed to sunlight, your skin can synthesize small amounts of vitamin D, and intestinal bacteria produce some vitamin K.

The mode of action of these vitamins is unknown. Vitamin A has long been recognized as a structural component of the visual pigment retinal, but its more general metabolic effects are not well understood. Vitamin D is ultimately converted to calcitriol, which binds to cytoplasmic receptors within the intestinal epithelium and promotes an increase in the rate of intestinal calcium and phosphorus absorption. Vitamin E is thought to stabilize intracellular membranes. Vitamin K is a necessary participant in a reaction essential to the synthesis of several proteins, including at least three of the clotting factors. Current information about the fat-soluble vitamins is summarized in Table 25–4.

Because fat-soluble vitamins dissolve in lipids, they normally diffuse into cell membranes and other lipids in the body, including the lipid inclusions in the liver and adipose tissue. Your body therefore contains a significant reserve of these vitamins, and normal metabolic operations can continue for several months after dietary sources have been cut off. For this reason, symptoms of **avitaminosis** (

¯a

-v -ta-min-

¯O

-sis), or **vitamin deficiency disease**, rarely result from a dietary insufficiency of fat-soluble ı vitamins. However, avitaminosis involving either fat-soluble or water-soluble vitamins can be caused by a variety of factors other than dietary deficiencies. An inability to absorb a vitamin from the digestive tract, inadequate storage, or excessive demand may each produce the same result.

–

Too much of a vitamin can also produce harmful effects. **Hypervitaminosis** (h -per-vı-ta-mi-N

ı take exceeds the body’s abilities to store, utilize, or excrete a particular vitamin. This condition most commonly involves one of the fat-soluble vitamins, because the excess is retained and stored in body lipids.

Water-Soluble Vitamins

Most of the **water-soluble vitamins** (Table 25–5) are components of coenzymes. For example, NAD is derived from niacin, FAD from vitamin B_2 (riboflavin), and coenzyme A from vitamin B_5 (pantothenic acid).

–

Water-soluble vitamins are rapidly exchanged between the fluid compartments of the digestive tract and the circulating blood, and excessive amounts are readily excreted in urine. For this reason, hypervitaminosis involving water-soluble vitamins is rela

tively uncommon, except among individuals taking large doses of vitamin supplements. However, only vitamins B_{12} and C are stored in significant quantities, so insufficient intake of other water-soluble vitamins can lead to initial signs and symptoms of vitamin deficiency within a period of days to weeks.

The bacterial inhabitants of the intestines help prevent deficiency diseases by producing small amounts of five of the nine water-soluble vitamins, in addition to fat-soluble vitamin K. The intestinal epithelium can easily absorb all the water-soluble vitamins except B12. The B_{12} molecule is large, and as discussed in Chapter 24, it must be bound to *intrinsic factor* from the gastric

–

mucosa before absorption can occur. l**p. 879**

Clinical Note

“If a little is good, a lot must be better” is a common, but dangerously incorrect, attitude about vitamins. When the dietary supply of fat-sol-uble vitamins is excessive, tissue lipids absorb the additional vitamins. Because these vitamins later diffuse back into the bloodstream, the signs and symptoms of hypervitaminosis, once apparent, are likely to persist. When absorbed in massive amounts (from ten to thousands of times the recommended daily allowance), fat-soluble vitamins can produce acute symptoms of *vitamin toxicity*. Vitamin A toxicity is the most common condition, afflicting some children whose parents are overanxious about proper nutrition and vitamins. A single enormous overdose can produce nausea, vomiting, headache, dizziness, lethargy, and even death. Chronic overdose can lead to hair loss, joint pain, hypertension, weight loss, and liver enlargement.

Diet and Disease

Diet has a profound influence on a person’s general health. We have already considered the effects of too many or too few nutrients, above-normal or below-normal concentrations of minerals, and hypervitaminosis or avitaminosis. More-subtle long-term problems can occur when the diet includes the wrong proportions or combinations of nutrients. The average diet in the United States contains too much sodium, too many calories, and lipids provide too great a proportion of those calories. This diet increases the incidence of obesity, heart disease, atherosclerosis, hypertension, and diabetes in the U.S. population. AM: Eating Disorders

Concept Check

Would an athlete in intensive training try to maintain a positive or a negative nitrogen balance?

How would a decrease in the amount of bile salts in the bile affect the amount of vitamin A in the body?

Answers begin on p. A–1

Energy Gains and Losses

Objectives

- Define *metabolic rate*, and discuss the factors involved in determining an individual’s BMR.
- Discuss the homeostatic mechanisms that maintain a constant body temperature.

When chemical bonds are broken, energy is released. Inside cells, a significant amount of energy may be used to synthesize ATP,

–

O

-sis) occurs when dietary in-

¯e

¯e

but much of it is lost to the environment as heat. The process of *calorimetry* (kal-o-RIM-e-tr) measures the total amount of energy released when the bonds of organic molecules are broken. The unit of measurement is the **calorie** (KAL-o-r), defined as the amount of energy required to raise the temperature of 1 g of water 1 degree centigrade. One gram of water is not a very practical

measure when you are interested in the metabolic operations that keep a 70-kg human alive, so the **kilocalorie** (KIL-

¯o

-kal-o-r

¯e

) (kc), or **Calorie** (with a capital C), also known as “large calorie,” is used instead. One Calorie is the amount of energy needed to raise the temperature of 1 *kilogram* of water 1 degree centigrade. Calorie-counting guides that indicate the caloric value of various foods list Calories, not calories.

The Energy Content of Food

In cells, organic molecules are oxidized to carbon dioxide and water. Oxidation also occurs when something burns, and this process can be experimentally controlled. A known amount of food is placed in a chamber called a **calorimeter** (kal-o-RIM-e-ter), which is filled with oxygen and surrounded by a known volume of water. Once the food is inside, the chamber is sealed and the contents are electrically ignited. When the material has completely oxidized and only ash remains in the chamber, the number of Calories released can be determined by comparing the water temperatures before and after the test.

The energy potential of food is usually expressed in Calories per gram (C g). The catabolism of lipids entails the release of a

> considerable amount of energy, roughly 9.46 C > g. The catabolism of carbohydrates or proteins is not as productive, because many of the carbon and hydrogen atoms are already bound to oxygen. Their average yields are comparable: 4.18 C > g for carbohydrates and

4.32 C > g for proteins. Most foods are mixtures of fats, proteins, and carbohydrates, so the values listed in a “Calorie counter” vary.

Metabolic Rate

Clinicians can examine your metabolic state and determine how many Calories you are utilizing. The result can be expressed as Calories per hour, Calories per day, or Calories per unit of body weight per day. What is actually measured is the sum of all the varied anabolic and catabolic processes occurring in your body—your **metabolic rate** at that time. Metabolic rate changes according to the activity under way; for instance, measurements taken while one is sprinting are quite different from those taken while one is sleeping. In an attempt to reduce the variations, clinicians standardize the testing conditions so as to determine the **basal metabolic rate (BMR)**. Ideally, the BMR is the minimum resting energy expenditure of an awake, alert person.

A direct method of determining the BMR involves monitoring respiratory activity, because in resting individuals energy utilization is proportional to oxygen consumption. If we assume that average amounts of carbohydrates, lipids, and proteins are being catabolized, 4.825 Calories are expended per liter of oxygen consumed.

An average individual has a BMR of 70 C per hour, or about 1680 C per day. Although the test conditions are standardized, many uncontrollable factors, including age, gender, physical condition, body weight, and genetic differences, can influence the BMR.

Because the BMR is technically difficult to measure, and because circulating thyroid hormone levels have a profound effect on the BMR, clinicians usually monitor the concentration of thyroid hormones rather than the actual metabolic rate. The results are then compared with normal values to obtain an index of metabolic activity. One such test, the **T_4 assay**, measures the amount of thyroxine in the blood.

Daily energy expenditures for a given individual vary widely with activity. For example, a person leading a sedentary life may have near-basal energy demands, but a single hour of swimming can increase the daily caloric requirements by 500 C or more. If your daily energy intake exceeds your total energy demands, you will store the excess energy, primarily as triglycerides in adipose tissue. If your daily caloric expenditures exceed your dietary supply, the result is a net reduction in your body's energy reserves and a corresponding loss in weight. This relationship accounts for the significance of both Calorie counting and exercise in a weight-control program.

The control of appetite is poorly understood. Stretch receptors along the digestive tract, especially in the stomach, play a role, but other factors are probably more important. Social factors, psychological pressures, and dietary habits are important. Evidence also indicates that complex hormonal stimuli interact to affect appetite. For example, the hormones *cholecystokinin (CCK)* and *adrenocorticotropic hormone (ACTH)* suppress the appetite. The hormone *leptin*, released by adipose tissues, also plays a role. During the absorptive state, adipose tissues release leptin into the bloodstream as they synthesize triglycerides. When leptin binds to CNS neurons that function in emotion and the control of appetite, the result is a sense of satiation and the suppression of appetite.

Thermoregulation

The BMR estimates the rate of energy use by the body. The energy not captured and harnessed by cells is released as heat and serves an important homeostatic purpose. Humans are subject to vast changes in environmental temperatures, but our complex biochemical systems have a major limitation: Enzymes operate over only a relatively narrow temperature range. Accordingly, our bodies have anatomical and physiological mechanisms that keep body temperatures within acceptable limits, regardless of environmental conditions. This homeostatic process is called **thermoregulation**. Failure to control body temperature can result in a series of physiological changes. For example, a body temperature below 36°C (97°F) or above 40°C (104°F) can cause disorientation, and a temperature above 42°C (108°F) can cause convulsions and permanent cell damage.

We continuously produce heat as a by-product of metabolism. When energy use increases due to physical activity, or when our cells are more active metabolically (as they are during the absorptive state), additional heat is generated. The heat produced by biochemical reactions is retained by water, which accounts for nearly two-thirds of body weight. Water is an excellent conductor of heat, so the heat produced in one region of the body is rapidly distributed by diffusion, as well as through the bloodstream. If body temperature is to remain constant, that heat must be lost to the environment at the same rate it is generated. When environmental conditions rise above or fall below "ideal," the body must control the gains or losses to maintain homeostasis.

Mechanisms of Heat Transfer

Heat exchange with the environment involves four basic processes: (1) *radiation*, (2) *conduction*, (3) *convection*, and (4) *evaporation.*

Warm objects lose heat energy as infrared **radiation**. When you feel the heat from the sun, you are experiencing radiant heat. Your body loses heat the same way, but in proportionately smaller amounts. More than 50 percent of the heat you lose indoors is attributable to radiation; the exact amount varies with both body temperature and skin temperature.

Conduction is the direct transfer of energy through physical contact. When you arrive in an air-conditioned classroom and sit on a cold plastic chair, you are immediately aware of this process. Conduction is generally not an effective mechanism for gaining or losing heat. We cannot estimate the value of its contribution, because it varies with the temperature of the object and with the amount of surface area involved. When you are lying on cool sand in the shade, conductive losses can be considerable; when you are standing, conductive losses are negligible.

Convection is the result of conductive heat loss to the air that overlies the surface of the body. Warm air rises, because it is lighter than cool air. As your body conducts heat to the air next to your skin, that air warms and rises, moving away from the surface of the skin. Cooler air replaces it, and as this air in turn becomes warmed, the pattern repeats. Convection accounts for roughly 15 percent of the body's heat loss indoors but is insignificant as a mechanism of heat gain.

When water evaporates, it changes from a liquid to a vapor. **Evaporation** absorbs energy—roughly 0.58 C per gram of water evaporated—and cools the surface where evaporation occurs. The rate of evaporation occurring at your skin is highly variable. Each hour, 20–25 ml of water crosses epithelia and evaporates from the alveolar surfaces and the surface of the skin. This insensible water loss remains relatively constant; at rest, it accounts for roughly 20 percent of your body's average indoor heat loss. The sweat glands responsible for sensible perspiration have a tremendous scope of activity, ranging from virtual inactivity to secretory rates of 2–4 liters per hour.

The Regulation of Heat Gain and Heat Loss

Heat loss and heat gain involve the activities of many systems. Those activities are coordinated by the **heat-loss center** and **heat-gain center**, respectively, in the preoptic area of the anterior hypothalamus. l**p. 468** These centers modify the activities of other hypothalamic nuclei. The overall effect is to control temperature by influencing two events: the rate of heat production and the rate of heat loss to the environment. These events may be further supported by behavioral modifications.

Mechanisms for Increasing Heat Loss When the temperature at the preoptic nucleus exceeds its set point, the heat-loss center is stimulated, producing three major effects:

1. *The Inhibition of the Vasomotor Center Causes Peripheral Vasodilation, and Warm Blood Flows to the Surface of the Body.* The skin takes on a reddish color, skin temperatures rise, and radiational and convective losses increase.

2. *As Blood Flow to the Skin Increases, Sweat Glands Are Stimulated to Increase their Secretory Output.* The perspiration flows across the body surface, and evaporative heat losses accelerate. Maximal secretion, if completely evaporated, would remove 2320 C per hour.

3. *The Respiratory Centers Are Stimulated, and the Depth of Respiration Increases.* Often, the individual begins respiring through an open mouth rather than through the nasal passageways, increasing evaporative heat losses through the lungs.

Mechanisms for Promoting Heat Gain

–

The function of the heat-gain center of the brain is to prevent **hypothermia** (h -p

ı -uh), or below-normal body temperature. When the temperature at the preoptic nucleus drops below acceptable levels,

¯o

-

THER-m

¯e

the heat-loss center is inhibited and the heat-gain center is activated.

Heat Conservation The sympathetic vasomotor center decreases blood flow to the dermis, thus reducing losses by radiation, convection, and conduction. The skin cools, and with blood flow restricted, it may take on a bluish or pale color. The epithelial cells are not damaged, because they can tolerate extended periods at temperatures as low as 25°C (77°F) or as high as 49°C (120°F).

In addition, blood returning from the limbs is shunted into a network of deep veins. l**p. 746** Under warm conditions, blood flows in a superficial venous network (Figure 25–14a•). In cold conditions, blood is diverted to a network of veins that lie deep to an insulating layer of subcutaneous fat (Figure 25–14b•). This venous network wraps around the deep arteries, and heat is conducted from the warm blood flowing outward to the limbs to the cooler blood returning from the periphery (Figure 25–14c•). This arrangement traps the heat close to the body core and restricts heat loss. Such exchange between fluids that are moving in opposite directions is called *countercurrent exchange*. (We will return to this topic in Chapter 26.)

Heat Generation The mechanisms for generating heat can be divided into two broad categories: shivering thermogenesis and

nonshivering thermogenesis. In **shivering thermogenesis** (ther-m

¯o

-JEN-e-sis), a gradual increase in muscle tone increases the

energy consumption of skeletal muscle tissue throughout your body, and the more energy consumed, the more heat is produced. Both agonists and antagonists are involved, and the degree of stimulation varies with the demand.

If the heat-gain center is extremely active, muscle tone increases to the point at which stretch receptor stimulation will produce brief, oscillatory contractions of antagonistic muscles. In other words, you begin to **shiver**. Shivering increases the workload of the muscles and further elevates oxygen and energy consumption. The heat that is produced warms the deep vessels, to which blood has been shunted by the sympathetic vasomotor center. Shivering can elevate body temperature quite effectively, increasing the rate of heat generation by as much as 400 percent.

Nonshivering thermogenesis involves the release of hormones that increase the metabolic activity of all tissues:

- The heat-gain center stimulates the adrenal medullae via the sympathetic division of the autonomic nervous system, and epinephrine is released. Epinephrine increases the rates of glycogenolysis in liver and skeletal muscle, and the metabolic rate of most tissues. The effects are immediate.
- The preoptic nucleus regulates the production of thyrotropin-releasing hormone (TRH) by the hypothalamus. In children, when body temperatures are below normal, additional TRH is released, stimulating the release of thyroid-stimulating hormone (TSH) by the anterior lobe of the pituitary gland. The thyroid gland responds to this release of TSH by increasing the rate at which thyroxine is released into the blood. Thyroxine increases not only the rate of carbohydrate catabolism, but also the rate of catabolism of all other nutrients. These effects develop gradually, over a period of days to weeks.

Hypothermia may be intentionally produced during surgery to reduce the metabolic rate of a particular organ or of the pa-tient’s entire body. In controlled hypothermia, the individual is first anesthetized to prevent the shivering that would otherwise fight the induction of hypothermia.

During open-heart surgery, the body is typically cooled to 25°–32°C (79°–89°F). This cooling reduces the metabolic demands of the body, which will be receiving blood from an external pump or oxygenator. The heart must be stopped completely during the operation, and it cannot be well supplied with blood over this period. Consequently, the heart is perfused with an *arresting solution* at 0°–4°C (32°–39°F) and maintained at a temperature below 15°C (60°F) for the duration of the operation. At these temperatures, the cardiac muscle can tolerate several hours of ischemia without damage.

Sources of Individual Variation in Thermoregulation

The timing of thermoregulatory responses differs from individual to individual. A person may undergo **acclimatization** (a-kl

–

ı -shun)—a physiological adjustment to a particular environment over time. For example, natives of Tierra del Fuego once

-

ma-ti-Z

¯A

lived naked in the snow, but Hawaii residents often unpack their sweaters when the temperature drops below 22°C (72°F).

Another interesting source of variation is body size. Although heat *production* occurs within the mass of the body, heat *loss* occurs across a body surface. As an object (or person) gets larger, its surface area increases at a much slower rate than does its total volume. This relationship affects thermoregulation, because heat generated by the "volume" (that is, by internal tissues) is lost at the body surface. Hence, small individuals lose heat more readily than do large individuals.

Thermoregulatory Problems of Infants During embryonic development, the maternal surroundings are at normal body temperature. At birth, the infant's temperature-regulating mechanisms are not fully functional; also, infants lose heat quickly as a result of their small size. Consequently, newborns must be dried promptly and kept bundled up; for those born prematurely, a thermally regulated incubator is required. Infants' body temperatures are also less stable than those of adults. Their metabolic rates decline while they sleep and then rise after they awaken.

Infants cannot shiver, but they have a different mechanism for raising body temperature rapidly. In infants, the adipose tissue between the shoulder blades, around the neck, and possibly elsewhere in the upper body is histologically and functionally different from most of the adipose tissue in adults. The tissue is highly vascularized, and individual adipocytes contain numerous mi

tochondria. Together, these characteristics give the tissue a deep, rich color that is responsible for the name **brown fat**. l**p. 122** Individual adipocytes are innervated by sympathetic autonomic fibers. When these nerves are stimulated, lipolysis accelerates in the adipocytes. The cells do not capture the energy released through fatty acid catabolism, and it radiates into the surrounding tissues as heat. This heat quickly warms the blood passing through the surrounding network of vessels, and it is then distributed throughout the body. In this way, an infant can accelerate metabolic heat generation by 100 percent very quickly, whereas non-shivering thermogenesis in an adult raises heat production by only 10–15 percent after a period of weeks.

With increasing age and size, body temperature becomes more stable, so the importance of this thermoregulatory mechanism declines. Adults have little if any brown fat; with increased body size, skeletal muscle mass, and insulation, shivering thermogenesis is significantly more effective in elevating body temperature.

Thermoregulatory Variations among Adults Adults of a given body weight may differ in their thermal responses if their weight is distributed differently. Which tissues account for their weight is also a factor. Adipose tissue is an excellent insulator, conducting heat at only about one-third the rate of other tissues. As a result, individuals with a more substantial layer of subcutaneous fat may not begin to shiver until long after their thinner companions.

Two otherwise similar individuals may also differ in their response to temperature changes because their hypothalamic “thermostats” are at different settings. We experience daily oscillations in body temperature, with temperatures falling 1°–2° (1.8°–3.6°F) at night and peaking during the day or early evening. The ovulatory cycle also causes temperature fluctuations, as you will see in Chapter 28.

Individuals vary in terms of the timing of their maximum temperature setting; some have a series of peaks, with an afternoon low. The origin of these patterns is unclear. It is not the result of daily activity regimens: The temperatures of people who work at night still peak during the same range of times as the rest of the population.

Fevers

–

Any elevated body temperature is called **pyrexia** (p -REK-s

ı maintained at greater than 37.2°C (99°F). We discussed fevers when we examined nonspecific defenses. l**p. 782** Fevers occur for a variety of reasons, not all of them pathological. In young children, transient fevers with no ill effects can result from exercise in warm weather. Similar exercise-related elevations were rarely encountered in adults until running marathons became popular. Temperatures from 39° to 41°C (103° to 109°F) may result. For this reason, competitions are usually held when the air temperature is below 28°C (82°F). Fevers can also result from the following factors:

¯e

-uh). Pyrexia is usually temporary. A **fever** is a body temperature

- Abnormalities affecting the entire thermoregulatory mechanism, such as heat exhaustion or heat stroke.
- Clinical problems that restrict blood flow, such as congestive heart failure.
- Conditions that impair sweat gland activity, such as drug reactions and some skin conditions.
- The resetting of the hypothalamic “thermostat” by circulating *pyrogens*—most notably, interleukin-1.

The classification of fevers as either *chronic* or *acute,* as well as their treatment, is discussed in the *Applications Manual*. AM: Fevers

Chapter Review

Selected Clinical Terminology

avitaminosis: A disease caused by a deficiency in one or more vitamins. (p. 939) **carbohydrate loading:** Eating large quantities of carbohydrates in the days preceding an athletic event in order to increase one’s endurance. (p. 926) **eating disorders:** Psychological problems that result in inadequate or excessive food consumption. Examples include anorexia nervosa

and bulimia. [AM] **heat exhaustion:** A malfunction of thermoregulatory mechanisms, caused by excessive fluid loss in perspiration. (p. 945) **heat stroke:** A condition in which the thermoregulatory center stops functioning and body temperature rises uncontrollably. (p. 945) **hyperuricemia:** A condition in which the plasma uric acid level exceeds 7.4 mg > dl; can result in the condition called *gout*. [AM] **hypervitaminosis:** A disorder caused by the ingestion of excessive quantities of one or more vitamins. (p. 939) **hypothermia:** Below-normal body temperature. (p. 943 and [AM]) **ketoacidosis:** The acidification of blood due to the presence of ketone bodies. (p. 935 and [AM]) **ketonemia:** Elevated levels of ketone bodies in blood. (p. 935) **ketonuria:** The presence of ketone bodies in urine.[AM] **ketosis:** Abnormally high concentration of ketone bodies in body fluids. (p. 935) **obesity:** A body weight more than 20 percent above the ideal weight for a given individual. [AM] **phenylketonuria:** An inherited metabolic disorder resulting from an inability to convert phenylalanine to tyrosine. (p. 932 and [AM]) **protein deficiency diseases:** Nutritional disorders resulting from a lack of one or more essential amino acids. (p. 933 and [AM])

Study Outline

An Overview of Metabolism p. 916

1. In general, during *cellular metabolism*, cells break down excess carbohydrates first and then lipids, while conserving amino acids. Only about 40 percent of the energy released through **catabolism** is captured in ATP; the rest is released as heat. *(Figure 25–1)*

2. Cells synthesize new compounds (**anabolism**) (1) to perform structural maintenance or repairs, (2) to support growth, (3) to produce secretions, and (4) to build and store nutrient reserves.

3. Cells “feed” small organic molecules to their mitochondria; in return, the cells get the ATP they need to perform cellular functions.

(Figure 25–2)

100 Keys | p. 917

Carbohydrate Metabolism p. 918

1. Most cells generate ATP and other high-energy compounds through the breakdown of carbohydrates.

Glycolysis p. 918

2. **Glycolysis** and **aerobic metabolism**, or *cellular respiration*, provide most of the ATP used by typical cells. Glycogen can be broken down to glucose molecules. In glycolysis, each molecule of glucose yields two molecules of **pyruvic acid** (as pyruvate ions), a net two molecules of ATP, and two **NADH** molecules. *(Figure 25–3)*

Mitochondrial ATP Production p. 920

3. In the presence of oxygen, pyruvic acid molecules enter mitochondria, where they are broken down completely in the **tricarboxylic acid (TCA) cycle**. Carbon and oxygen atoms are lost as carbon dioxide (**decarboxylation**); hydrogen atoms are passed to coenzymes, which initiate the oxygen-consuming and ATP-generating reaction **oxidative phosphorylation**. *(Figure 25–4)*

4. **Cytochromes** of the **electron transport system (ETS)** pass electrons to oxygen, resulting in the formation of water. As this transfer occurs, the ETS generates ATP. *(Figure 25–5)*

Energy Yield of Glycolysis and Cellular Respiration p. 924

5. For each glucose molecule processed through glycolysis, the TCA cycle, and the ETS, most cells gain 36 molecules of ATP. *(Figure 25–6)*

6. Cells can break down other nutrients to provide substrates for the TCA cycle if supplies of glucose are limited.

Gluconeogenesis p. 926

7. **Gluconeogenesis**, the synthesis of glucose from noncarbohydrate precursors such as lactic acid, glycerol, or amino acids, enables a liver cell to synthesize glucose molecules when carbohydrate reserves are depleted. **Glycogenesis** is the process of glycogen formation. Glycogen is an important energy reserve when cells cannot obtain enough glucose from interstitial fluid. *(Figure 25–7)*

Lipid Metabolism p. 927 Lipid Catabolism p. 927

1. During **lipolysis** (lipid catabolism), lipids are broken down into pieces that can be converted into pyruvic acid or channeled into the TCA cycle.

2. Triglycerides, the most abundant lipids in the body, are split into glycerol and fatty acids. The glycerol enters the glycolytic pathways, and the fatty acids enter the mitochondria.

3. **Beta-oxidation** is the breakdown of a fatty acid molecule into two-carbon fragments that can be used in the TCA cycle. The steps of beta-oxidation cannot be reversed, and the body cannot manufacture all the fatty acids needed for normal metabolic operations.

(Figure 25–8)

4. Lipids cannot provide large amounts of ATP quickly. However, cells can shift to lipid-based energy production when glucose reserves are limited.

Lipid Synthesis p. 927

5. In **lipogenesis** (the synthesis of lipids), almost any organic substrate can be used to form glycerol. **Essential fatty acids** cannot be synthesized and must be included in the diet.

Lipid Transport and Distribution p. 927

6. Most lipids circulate as **lipoproteins** (lipid–protein complexes that contain large glycerides and cholesterol). The largest lipoproteins, chylomicrons, carry absorbed lipids from the intestinal tract to the bloodstream. All other lipoproteins are derived from the liver and carry lipids to and from various tissues of the body. *(Figure 25–9)*

7. Capillary walls of adipose tissue, skeletal muscle, cardiac muscle, and the liver contain **lipoprotein lipase**, an enzyme that breaks down complex lipids, releasing a mixture of fatty acids and monoglycerides. *(Figure 25–9)*

Protein Metabolism p. 930 Amino Acid Catabolism p. 930

1. If other energy sources are inadequate, mitochondria can break down amino acids in the TCA cycle to generate ATP. In the mitochondria, the amino group can be removed by either **transamination** or **deamination**. *(Figure 25–10)*

2. Protein catabolism is impractical as a source of quick energy.

Protein Synthesis p. 933

3. Roughly half the amino acids needed to build proteins can be synthesized. There are 10 **essential amino acids**, which must be acquired through the diet. **Amination**, the attachment of an amino acid group to a carbon framework, is an important step in the synthesis of **nonessential amino acids**. *(Figures 25–11, 25–12)*

Metabolic Interactions p. 933

1. No one cell of a human can perform all the anabolic and catabolic operations necessary to support life. Homeostasis can be preserved only when metabolic activities of different tissues are coordinated.

2. The body has five metabolic components: the liver, adipose tissue, skeletal muscle, neural tissue, and other peripheral tissues. The liver is the focal point for metabolic regulation and control. Adipose tissue stores lipids, primarily in the form of triglycerides. Skeletal muscle contains substantial glycogen reserves, and the contractile proteins can be mobilized and the amino acids used as an energy source. Neural tissue does not contain energy reserves; glucose must be supplied to it for energy. Other peripheral tissues are able to metabolize glucose, fatty acids, or other substrates under the direction of the endocrine system.

3. For about four hours after a meal, nutrients enter the blood as intestinal absorption proceeds. *(Table 25–1)*

4. The liver closely regulates the glucose content of blood and the circulating levels of amino acids.

5. The **absorptive state** exists when nutrients are being absorbed by the digestive tract. Adipocytes remove fatty acids and glycerol from the bloodstream and synthesize new triglycerides to be stored for later use.

6. During the absorptive state, glucose molecules are catabolized and amino acids are used to build proteins. Skeletal muscles may also catabolize circulating fatty acids, and the energy obtained is used to increase glycogen reserves.

7. The **postabsorptive state** extends from the end of the absorptive state to the next meal.

8. When blood glucose levels fall, the liver begins breaking down glycogen reserves and releasing glucose into the bloodstream. As the time between meals increases, liver cells synthesize glucose molecules from smaller carbon fragments and from glycerol molecules. Fatty acids undergo beta-oxidation; the fragments enter the TCA cycle or combine to form **ketone bodies**. *(Table 25–1)*

9. Some amino acids can be converted to pyruvic acid and used for gluconeogenesis; others, including most of the essential amino acids, are converted to acetyl-CoA and are either catabolized or converted to ketone bodies.

10. Neural tissue continues to be supplied with glucose as an energy source until blood glucose levels become very low.

100 Keys | p. 935

Diet and Nutrition p. 936

1. **Nutrition** is the absorption of nutrients from food. A **balanced diet** contains all the ingredients needed to maintain homeostasis; a balanced diet prevents **malnutrition**.

Food Groups and the Food Pyramid p. 936

2. The five **basic food groups** are milk, yogurt, and cheese; meat, poultry, fish, dry beans, eggs, and nuts; vegetables; fruits; and bread, cereal, rice, and pasta. These are arranged in a *food pyramid* according to the number of daily servings recommended. *(Figure 25–13; Table 25–2)*

Nitrogen Balance p. 937

3. Amino acids, purines, pyrimidines, creatine, and porphyrins are **N compounds**, which contain nitrogen atoms. An adequate dietary supply of nitrogen is essential, because the body does not maintain large nitrogen reserves. **Nitrogen balance** is a state in which the amount of absorbed nitrogen equals that lost in urine and feces.

100 Keys | p. 937

Minerals p. 937

4. **Minerals** act as cofactors in a variety of enzymatic reactions. They also contribute to the osmotic concentration of body fluids and play a role in transmembrane potentials, action potentials, the release of neurotransmitters, muscle contraction, skeletal construction and maintenance, gas transport, buffer systems, fluid absorption, and waste removal. *(Table 25–3)*

Vitamins p. 938

5. Vitamins are needed in very small amounts. Vitamins A, D, E, and K are **fat-soluble vitamins**; taken in excess, they can lead to **hypervitaminosis**. **Water-soluble vitamins** are not stored in the body; a lack of adequate dietary supplies may lead to **vitamin deficiency disease** (**avitaminosis**). *(Table 25–4)*

Diet and Disease p. 940

6. A balanced diet can improve one's general health.

Energy Gains and Losses p. 941

1. The energy content of food is usually expressed in **kilocalories (kc)** or as **Calories** per gram (C g).

>

The Energy Content of Food p. 941

2. The catabolism of lipids releases 9.46 C > g, about twice the amount released by equivalent weights of carbohydrates or proteins.

Metabolic Rate p. 942

3. The sum of all the anabolic and catabolic processes under way is an individual's **metabolic rate**. The **basal metabolic rate (BMR)** is the rate of energy utilization by a person at rest.

Thermoregulation p. 942

4. The homeostatic regulation of body temperature is **thermoregulation**. Heat exchange with the environment involves four processes: **radiation**, **conduction**, **convection**, and **evaporation**.

5. The *preoptic area* of the hypothalamus acts as the body's thermostat, affecting the **heat-loss center** and the **heat-gain center**.

6. Mechanisms for increasing heat loss include both physiological mechanisms (peripheral vasodilation, increased perspiration, and increased respiration) and behavioral modifications.

7. Responses that conserve heat include a decreased blood flow to the dermis and *countercurrent exchange*. *(Figure 25–14)*

8. Heat is generated by **shivering thermogenesis** and **nonshivering thermogenesis**.

9. Thermoregulatory responses differ among individuals. One important source of variation is **acclimatization** (a physiological adjustment to an environment over time).

10. Pyrexia is an elevated body temperature. **Fever**, a body temperature above 37.2°C (99°F), can result from problems with the thermoregulatory mechanism, circulation, or sweat gland activity, or from the resetting of the hypothalamic "thermostat" by circulating pyrogens.

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. Catabolism refers to

(a) the creation of a nutrient pool

(b) the sum total of all chemical reactions in the body

(c) the production of organic compounds

(d) the breakdown of organic substrates

2. The breakdown of glucose to pyruvic acid is an _____ process.

(a) anaerobic **(b)** aerobic

(c) anabolic **(d)** oxidative

3. The process that produces more than 90 percent of the ATP used by our cells is

(a) glycolysis

(b) the TCA cycle

(c) substrate-level phosphorylation

(d) oxidative phosphorylation

4. The sequence of reactions responsible for the breakdown of fatty acid molecules is

(a) beta-oxidation

(b) the TCA cycle

(c) lipogenesis

(d) a, b, and c are correct

5. The TCA cycle must turn _____ times to completely metabolize the pyruvic acid produced from one glucose molecule.

(a) 1 **(b)** 2 **(c)** 3 **(d)** 4 **(e)** 5

6. The process by which ATP is synthesized in the mitochondria is known as

(a) decarboxylation

(b) the TCA cycle

(c) chemiosmosis

(d) substrate phosphorylation

(e) anaerobic respiration

7. The largest metabolic reserves for the average adult are stored as

(a) carbohydrates

(b) proteins

(c) amino acids

(d) triglycerides

(e) fatty acids

8. A complete protein contains

(a) the proper balance of amino acids

(b) all the essential amino acids in sufficient quantities

(c) a combination of nutrients selected from the food pyramid

(d) N compounds produced by the body

9. All minerals and most vitamins

(a) are fat soluble

(b) cannot be stored by the body

(c) cannot be synthesized by the body

(d) must be synthesized by the body because they are not present in adequate amounts in the diet

10. The vitamins generally associated with vitamin toxicity are

(a) fat-soluble vitamins

(b) water-soluble vitamins

(c) the B complex vitamins

(d) vitamins C and B_{12}

11. Define the terms *metabolism, anabolism,* and *catabolism*.

12. Write the complete reaction sequence for carbohydrate metabolism.

13. What is a lipoprotein? What are the major groups of lipoproteins, and how do they differ?

LEVEL 2 Reviewing Concepts

14. During negative nitrogen balance

(a) more nitrogen compounds are ingested than excreted

(b) more nitrogen compounds are excreted than ingested

(c) protein consumption exceeds amino acid catabolism

(d) protein synthesis is accelerated

(e) protein catabolism is inhibited

15. What is oxidative phosphorylation? Explain how the electron transport system is involved in this process.

16. How are lipids catabolized in the body? How is beta-oxidation involved with lipid catabolism?

17. How do the absorptive and postabsorptive states maintain normal blood glucose levels?

18. Why is the liver the focal point for metabolic regulation and control?

19. How can the food pyramid be used as a tool to obtain nutrients in sufficient quantity and quality? Why are the dietary fats, oils, and sugars at the top of the pyramid and bread, cereal, rice, and pasta at the bottom?

20. Why are vitamins and minerals essential components of the diet?

21. Some articles in popular magazines refer to “good cholesterol” and “bad cholesterol.” To which types and functions of cholesterol might these terms refer? Explain your answer.

LEVEL 3 Critical Thinking and Clinical Applications

22. When blood levels of glucose, amino acids, and insulin are high, and glycogenesis is occurring in the liver, the body is in the _____ state.

(a) fasting

(b) postabsorptive

(c) absorptive

(d) stress

(e) bulimic

23. Charlie has a blood test that shows a normal level of LDLs but an elevated level of HDLs in his blood. Since his family has a history of cardiovascular disease, he wonders if he should modify his lifestyle. What would you tell him?

24. Jill suffers from anorexia nervosa. One afternoon she is rushed to the emergency room because of cardiac arrhythmias. Her breath has the smell of an aromatic hydrocarbon, and blood and urine samples contained high levels of ketone bodies. Why do you think she is having the arrhythmias?

TABLE 25–1

Hormone	**Effect on General Peripheral Tissues**	**Selective Effects on Target Tissues**
ABSORPTIVE STATE		
Insulin	Increased glucose uptake and utilization	*Liver*: Glycogenesis *Adipose tissue*: Lipogenesis *Skeletal muscle*: Glycogenesis

Insulin and growth hormone Increased amino acid uptake and protein synthesis *Skeletal muscle*: Fatty acid catabolism

Androgens, estrogens Increased amino acid use in protein synthesis *Skeletal muscle*: Muscle hypertrophy (especially androgens)

POSTABSORPTIVE STATE Glucagon *Liver*: Glycogenolysis

Epinephrine *Liver*: Glycogenolysis *Adipose tissue*: Lipolysis

Glucocorticoids Decreased use of glucose; increased reliance on ketone *Liver*: Glycogenolysis bodies and fatty acids *Adipose tissue*: Lipolysis, gluconeogenesis *Skeletal muscle*: Glycogenolysis, protein breakdown, amino acid release

Growth hormone Complements effects of glucocorticoids Acts with glucocorticoids

TABLE 25–2 Nutrient Groups

Nutrient Group Provides Is Deficient In

Milk, yogurt, cheese Complete proteins; fats; carbohydrates; calcium; potassium; Dietary fiber, vitamins C, A, B12, pantothenic magnesium; sodium; phosphorus; vitamins acid, thiamine, riboflavin

Meat, poultry, fish, dry Complete proteins; fats; potassium; phosphorus; iron; zinc; vitamins E, Carbohydrates, dietary fiber, several **beans, eggs, nuts** B_6 thiamine vitamins

Fruits Carbohydrates; vitamins A, C, E, folacin; dietary fiber; potassium Many are low in fats, calories, and protein

Vegetables Carbohydrates; vitamins A, C, E, folacin; dietary fiber; potassium Many are low in fats, calories, and protein

Bread, cereal, rice, Carbohydrates;
vitamins E, thiamine, niacin, folacin; calcium; Fats
pasta phosphorus; iron; sodium; dietary fiber

TABLE 25–3 Minerals and Mineral Reserves*

Mineral	**Significance**	**Total Body Content**	**Primary Route of Excretion**	**Recommended Daily Intake**
BULK MINERALS				
Sodium	Major cation in body fluids; essential		110 g, primarily	
in	Urine, sweat,	0.5–1.0 g		
	for normal membrane function	body fluids	feces	
Potassium	Major cation in cytoplasm; essential		140 g, primarily	
in	Urine	1.9–5.6 g		
	for normal membrane function	cytoplasm		
Chloride	Major anion in body fluids	89 g, primarily in	Urine, sweat	0.7–1.4 g
body fluids				
Calcium	Essential for normal muscle and neuron		1.36 kg,	
primarily	Urine, feces	0.8–1.2 g		
	function and normal bone structure	in skeleton		
Phosphorus	In high-energy compounds,	744 g, primarily	Urine, feces	0.8–1.2 g
	nucleic acids, and bone matrix (as phosphate)		in skeleton	
Magnesium	Cofactor of enzymes, required for	29 g (skeleton, 17 g;		Urine
	normal membrane functions	cytoplasm and		
body fluids, 12 g)				

TRACE MINERALS

Iron	Component of hemoglobin, myoglobin,		3.9 g (1.6 g	
stored	Urine (traces)	10–18 mg		
	cytochromes	as ferritin or		
hemosiderin)				
Zinc	Cofactor of enzyme systems, notably	2 g	Urine, hair	
(traces)	15 mg			
carbonic anhydrase				
Copper	Required as cofactor for hemoglobin synthesis		127 mg	Urine, feces (trac
Manganese	Cofactor for some enzymes	11 mg	Feces, urine	
(traces)	2.5–5 mg			
Cobalt	Cofactor for transaminations	1.1 g	Feces, urine	0.0001 mg
Selenium	Antioxidant	Variable	Feces, urine	0.05–0.2 mg
Chromium	Cofactor for glucose metabolism	0.0006 mg	Feces, urine	0.005–0.2 mg

* For information on the effects of deficiencies and excesses, see Table 27–2, p. 1006.

TABLE 25–4 The Fat-Soluble Vitamins

Vitamin	**Significance**	**Sources**	**Daily Requirement**	**Effects of Deficiency**	**Effects of Excess**
A	Maintains epithelia;	Leafy green and	1 mg	Retarded growth,	Liver damage, sl
	required for synthesis	yellow vegetables		night blindness,	paling, CNS

Daily

Vitamin Significance Sources Requirement Effects of Deficiency Effects of Exces

B1 (thiamine) Coenzyme in Milk, meat, 1.9 mg
decarboxylations bread cardiovascular problems,

including heart disease;
called *beriberi*

B_2 (riboflavin) Part of FMN and Milk, meat 1.5 mg Epithelial and mucosal Itching, tingling
FAD deterioration

Niacin (nicotinic Part of NAD Meat, bread, 14.6 mg CNS, GI, epithelial, and Itching, burning;
acid) potatoes mucosal deterioration; vasodilation;
called *pellagra* death after large
dose

B_5 (pantothenic Part of acetyl-CoA Milk, meat 4.7 mg Retarded growth, CNS None reported
acid) disturbances

B_6 (pyridoxine) Coenzyme in amino Meat
acid and lipid
metabolisms

1.42 mg Retarded growth, anemia, CNS alterations, convulsions, epithelial perhaps fatal changes
Folacin (folic Coenzyme in amino Vegetables,
acid) acid and nucleic cereal,
acid metabolisms bread

0.1 mg Retarded growth, anemia, Few noted, except gastrointestinal disorders, at massive doses developmental abnormalities
B_{12} (cobalamin) Coenzyme in nucleic Milk, meat 4.5 mg Impaired RBC production, Polycythemia
acid metabolism causing *pernicious anemia*

Biotin Coenzyme in Eggs, meat, 0.1–0.2 mg Fatigue, muscular pain, None reported
decarboxylations vegetables nausea, dermatitis

C (ascorbic acid) Coenzyme; delivers Citrus fruits
hydrogen ions,
antioxidant

60 mg Epithelial and mucosal Kidney stones deterioration; called *scurvy*

- **FIGURE 25–1** An Introduction to Cellular Metabolism. Cells obtain organic molecules from the interstitial fluid and break them down to produce ATP. Only about 40 percent of the energy released by catabolism is captured in the form of ATP; the rest is lost as heat. The ATP generated by catabolism provides energy for all vital cellular activities, including anabolism.
- **FIGURE 25–2** Nutrient Use in Cellular Metabolism. Cells use the contents of the nutrient pool to build up reserves and to synthesize cellular structures. Catabolism within mitochondria provides the ATP needed to sustain cell functions. Mitochondria are "fed" small carbon chains produced by the breakdown of carbohydrates (primarily glucose, stored as glycogen), lipids (especially fatty acids from triglycerides) and proteins (amino acids). The mitochondria absorb these breakdown products for further catabolism by means of the tricarboxylic acid (TCA) cycle and the electron transport system. This figure will be repeated, in reduced and simplified form as Navigator icons, as the text changes topics.
- **FIGURE 25–3** Glycolysis. The Navigator icon in the shadow box highlights the topic under discussion. Glycolysis breaks down a six-carbon glucose molecule into two three-carbon molecules of pyruvic acid through a series of enzymatic steps. This diagram follows the fate of the carbon chain. There is a net gain of two ATP molecules for each glucose molecule converted to two pyruvic acid molecules. In addition, two molecules of the coenzyme NAD are converted to NADH. Once transferred to mitochondria, both pyruvic acid and NADH can still yield a great deal more energy. The further catabolism of pyruvic acid begins with its entry into a mitochondrion. *(See Figure 25–4.)*
- **FIGURE 25–4** The TCA Cycle. **(a)** An overview of the TCA cycle and the distribution of carbon, hydrogen, and oxygen atoms. **(b)** A more detailed view, showing the changes in the carbon chains.
- **FIGURE 25–5** Oxidative Phosphorylation. **(a)** The sequence of oxidation–reduction reactions involved in oxidative phosphorylation. **(b)** The locations of the coenzymes and the electron transport system. Notice the sites where hydrogen ions are pumped into the intermembrane space,

providing the concentration gradient essential to the generation of ATP. The red line indicates the path taken by the electrons.

- **FIGURE 25–6** A Summary of the Energy Yield of Aerobic Metabolism. For each glucose molecule broken down by glycolysis, only two molecules of ATP (net) are produced. However, glycolysis, the formation of acetyl-CoA, and the TCA cycle all yield molecules of reduced coenzymes (NADH or $FADH_2$). Many additional ATP molecules are produced when electrons from these coenzymes pass through the electron transport sys tem. In most cells, each of the two NADH molecules produced in glycolysis provides another two ATP molecules. Each of the eight NADH molecules produced in the mitochondria yields three ATP molecules, for a total of 24. Another two ATP molecules are gained from each of the two $FADH_2$ molecules generated in the mitochondria. The TCA cycle generates an additional two ATP molecules in the form of GTP.
- **FIGURE 25–7** Carbohydrate Breakdown and Synthesis. The pathways for glycolysis and gluconeogenesis. Many of the reactions are freely reversible, but separate regulatory enzymes control the key steps, which are indicated by colored arrows. Some amino acids, carbohydrates (including lactic acid), and glycerol can be converted to glucose. The enzymatic reaction that converts pyruvic acid to acetyl-CoA cannot be reversed.
- **FIGURE 25–8** Beta-Oxidation. During beta-oxidation, the carbon chains of fatty acids are broken down to yield molecules of acetyl-CoA, which can be used in the TCA cycle. The reaction also donates hydrogen atoms to coenzymes, which then deliver them to the electron transport system.
- **FIGURE 25–9** Lipid Transport and Utilization
- **FIGURE 25–10** Amino Acid Catabolism. **(a)** In transamination, an enzyme removes the amino group (¬ NH2) from one molecule and attaches it to a keto acid. **(b)** In deamination, an enzyme strips the amino group and a hydrogen atom from an amino acid and produces a keto acid and an ammonium ion. **(c)** The urea cycle takes two metabolic waste products—ammonium ions and carbon dioxide—and produces urea, a relatively harmless, soluble compound that is excreted in the urine.

• **FIGURE 25–11** Amination. Amination attaches an amino group to a keto acid. This important step in the synthesis of nonessential amino acids attaches an amino group to a keto acid. Amino groups can also be attached through transamination *(see Figure 25–10a)*.

• **FIGURE 25–12** A Summary of the Pathways of Catabolism and Anabolism

• **FIGURE 25–13** The Food Pyramid and Daily Serving Recommendations

• **FIGURE 25–14** Vascular Adaptations for Heat Loss and Conservation. **(a)** Circulation through the blood vessels of the forearm in a warm environment. Blood enters the limb in a deep artery and returns to the trunk in a network of superficial veins that radiate heat into the environment through the overlying skin. **(b)** Circulation through the blood vessels of the forearm in a cold environment. Blood now returns to the trunk via a network of deep veins that flow around the artery. The amount of heat loss is reduced, as indicated in part (c). **(c)** Countercurrent heat exchange occurs as heat radiates from the warm arterial blood into the cooler venous blood flowing in the opposite direction. By the time the arterial blood reaches distal capillaries, where most heat loss to the environment occurs, it is already 13°C cooler than it was when it left the trunk. This mechanism conserves body heat by trapping heat near the trunk and thereby reducing the rate of heat loss.

An Overview of the Urinary System

Objective

- Identify the components of the urinary system and describe the functions it performs.

The **urinary system** (Figure 26–1•) has three major functions: (1) *excretion*, the removal of organic waste products from body fluids, (2) *elimination*, the discharge of these waste products into the environment, and (3) homeostatic regulation of the volume and solute concentration of blood plasma. The excretory functions of the urinary system are performed by the two **kidneys—**organs that produce **urine**, a fluid containing water, ions, and small soluble compounds. Urine leaving the kidneys flows along the **urinary tract**, which consists of paired tubes called **ureters** (

‾u

-R

‾E

-terz), to the **urinary bladder**, a muscular sac for temporary storage of urine.

‾u

‾E

On leaving the urinary bladder, urine passes through the **urethra** (-R -thra), which conducts the urine to the exterior.

The urinary bladder and the urethra are responsible for the elimination of urine, a process called **urination** or **micturition** (mik

t

‾u

-RISH-un). In this process, contraction of the muscular urinary bladder forces urine through the urethra and out of the body.

ATLAS: Embryology Summary 20: The Development of the Urinary System

In addition to removing waste products generated by cells throughout the body, the urinary system has several other essential homeostatic functions that are often overlooked, including the following:

- *Regulating blood volume and blood pressure*, by adjusting the volume of water lost in urine, releasing erythropoietin, and releasing renin.
- *Regulating plasma concentrations of sodium, potassium, chloride, and other ions*, by controlling the quantities lost in urine and controlling calcium ion levels through the synthesis of calcitriol.
- *Helping to stabilize blood pH*, by controlling the loss of hydrogen ions and bicarbonate ions in urine.

- *Conserving valuable nutrients*, by preventing their excretion in urine while excreting organic waste products—especially nitrogenous wastes such as *urea* and *uric acid*.
- *Assisting the liver* in detoxifying poisons and, during starvation, deaminating amino acids so that other tissues can break them down.

These activities are carefully regulated to keep the composition of blood within acceptable limits. A disruption of any one of them has immediate and potentially fatal consequences.

The Kidneys

Objectives

- Describe the location and structural features of the kidneys.
- Identify the major blood vessels associated with each kidney and trace the path of blood flow through a kidney.
- Describe the structure of the nephron and outline the processes involved in the formation of urine.

The kidneys are located on either side of the vertebral column, between vertebrae T_{12} and L_3 (Figure 26–2a•). The left kidney lies slightly superior to the right kidney.

The superior surface of each kidney is capped by an adrenal gland. The kidneys and adrenal glands lie between the muscles of the dorsal body wall and the parietal peritoneum, in a retroperitoneal position (Figure 26–2b•).

The position of the kidneys in the abdominal cavity is maintained by (1) the overlying peritoneum, (2) contact with adjacent visceral organs, and (3) supporting connective tissues. Each kidney is protected and stabilized by three concentric layers of connective tissue (see Figure 26–2b•):

1. The **renal capsule**, a layer of collagen fibers that covers the outer surface of the entire organ.

2. The **adipose capsule**, a thick layer of adipose tissue that surrounds the renal capsule.

3. The **renal fascia**, a dense, fibrous outer layer that anchors the kidney to surrounding structures. Collagen fibers extend outward from the renal capsule through the adipose capsule to this layer. Posteriorly, the renal fascia fuses with the deep fascia surrounding the muscles of the body wall. Anteriorly, the renal fascia forms a thick layer that fuses with the peritoneum.

In effect, each kidney hangs suspended by collagen fibers from the renal fascia and is packed in a soft cushion of adipose tissue. This arrangement prevents the jolts and shocks of day-to-day living from disturbing normal kidney function. If the suspensory fibers break or become detached, a slight bump or jar can displace the kidney and stress the attached vessels and ureter. This condition, called a *floating kidney*, is especially dangerous because the ureters or renal blood vessels can become twisted or kinked during movement.

A typical adult kidney (Figures 26–3 and 26–4•) is reddish-brown and about 10 cm (4 in.) long, 5.5 cm (2.2 in.) wide, and 3 cm (1.2 in.) thick. Each kidney weighs about 150 g (5.25 oz). The **hilum**, a prominent medial indentation, is the point of entry for the *renal artery* and *renal nerves*, and the point of exit for the *renal vein* and the ureter.

Sectional Anatomy of the Kidneys

The fibrous renal capsule covering the outer surface of the kidney also lines the **renal sinus**, an internal cavity within the kidney (Figure 26–4a•). The renal capsule is bound to the outer surfaces of the structures within the renal sinus, stabilizing the positions of the ureter and of the renal blood vessels and nerves.

The kidney itself has an outer cortex and an inner medulla. The **renal cortex** is the superficial portion of the kidney, in contact with the renal capsule. The cortex is reddish brown and granular. The **renal medulla** consists of 6 to 18 distinct conical or triangular structures called **renal pyramids**. The base of each pyramid abuts the cortex, and the tip of each pyramid—a region known as the **renal papilla**—projects into the renal sinus. Each pyramid has a series of fine grooves that converge at the papilla. Adjacent renal pyramids are separated by bands of cortical tissue called **renal columns**, which extend into the medulla. The columns have a distinctly granular texture, similar to that of the cortex. A

renal lobe consists of a renal pyramid, the overlying area of renal cortex, and adjacent tissues of the renal columns.

Urine production occurs in the renal lobes. Ducts within each renal papilla discharge urine into a cup-shaped drain called a

minor calyx (K

¯e

-liks). Four or five minor calyces (KA-li-s z) merge to form a **major calyx**, and two or three major calyces combine to form the **renal pelvis**, a large, funnel-shaped chamber. The renal pelvis, which fills most of the renal sinus, is connected to the ureter, which drains the kidney.

Urine production begins in microscopic, tubular structures called **nephrons** (NEF-ronz) in the cortex of each renal lobe. Each kidney has roughly 1.25 million nephrons, with a combined length of about 145 km (85 miles).

Blood Supply and Innervation of the Kidneys

Your kidneys receive 20–25 percent of your total cardiac output. In normal, healthy individuals, about 1200 ml of blood flows through the kidneys each minute—a phenomenal amount of blood for organs with a combined weight of less than 300 g (10.5 oz)!

Each kidney receives blood through a **renal artery**, which originates along the lateral surface of the abdominal aorta near the level of the superior mesenteric artery (see Figure 21–24a•, p. 742). As it enters the renal sinus, the renal artery provides blood to the **segmental arteries** (Figure 26–5a•). Segmental arteries further divide into a series of **interlobar arteries**, which radiate out-

¯A

ward through the renal columns between the renal pyramids. The interlobar arteries supply blood to the **arcuate** (AR-k

¯u

-

¯a

t) **arteries**, which arch along the boundary between the cortex and medulla of the kidney. Each arcuate artery gives rise to a number of **interlobular arteries**, which supply the cortical portions of the adjacent renal lobes. Branching from each interlobular artery are numerous **afferent arterioles**, which deliver blood to the capillaries supplying individual nephrons (Figure 26–5b,c•).

From the capillaries of the nephrons, blood enters a network of venules and small veins that converge on the **interlobular veins** (see Figure 26–5a,c•). The interlobular veins deliver blood to **arcuate veins**; these in turn empty into **interlobar veins**, which drain directly into the **renal vein**; there are no segmental veins.

The kidneys and ureters are innervated by **renal nerves**. Most of the nerve fibers involved are sympathetic postganglionic fibers from the celiac plexus and the inferior splanchnic nerves. l**pp. 524, 533** A renal nerve enters each kidney at the hilum and follows the tributaries of the renal arteries to reach individual nephrons. The sympathetic innervation (1) adjusts rates of urine formation by changing blood flow and blood pressure at the nephron and (2) stimulates the release of renin, which ultimately restricts losses of water and salt in the urine by stimulating reabsorption at the nephron.

Clinical Note

The rate of blood flow through the kidneys can be estimated by administering the compound *para-aminohippuric acid (PAH),* which is removed at the nephrons and eliminated in urine. Virtually all the PAH contained in the blood that arrives at the kidneys is removed before the blood departs in the renal veins. Renal blood flow can thus be approximated by comparing plasma concentrations of PAH with the amount secreted in urine. In practice, however, it is usually easier to measure the glomerular filtration rate (p. 967). AM: PAH and the Calculation of Renal Blood Flow

Anatomy 360 | Review the anatomy of the kidneys on the **Anatomy 360 CD-ROM: Urinary System/Kidney.**

The Nephron

Each nephron (Figure 26–6•) consists of a renal tubule and a renal corpuscle. The **renal tubule** is a long tubular passageway which may be 50 mm (1.97 in.) in length. It begins at the **renal corpuscle** (KOR-pus-ul), a spherical structure consisting of *Bowman's capsule,* a cup-shaped chamber approximately 200 mm in diameter, and a capillary network known as the *glomerulus*.

Blood arrives at the renal corpuscle by way of an afferent arteriole. This arteriole delivers blood to the **glomerulus** (glo-MER-ū-lus; plural, *glomeruli*), which consists of about 50 intertwining capillaries. The glomerulus projects into Bowman's capsule much as the heart projects into the pericardial cavity. Blood leaves the glomerulus in an **efferent arteriole** and flows into a network of capillaries, the *peritubular capillaries*, that surround the renal tubule. These capillaries in turn drain into small venules that return the blood to the venous system (see Figure 26–5c•).

The renal corpuscle is the site where the process of filtration occurs. In this process, blood pressure forces water and dissolved solutes out of the glomerular capillaries and into a chamber—the *capsular space*—that is continuous with the lumen of the renal tubule (see Figure 26–6•). Filtration produces an essentially protein-free solution, known as a **filtrate**, that is otherwise similar to blood plasma.

From the renal corpuscle, filtrate enters the renal tubule, which is responsible for three crucial functions: (1) reabsorbing all the useful organic nutrients that enter the filtrate, (2) reabsorbing more than 90 percent of the water in the filtrate, and (3) secreting into the tubule any waste products that failed to enter the renal corpuscle through filtration at the glomerulus.

The renal tubule has two convoluted (coiled or twisted) segments—the *proximal convoluted tubule* (PCT) and the *distal con-*

ē

voluted tubule (DCT)—separated by a simple U-shaped tube called the *loop of Henle* (HEN-l). The convoluted segments are in the cortex, and the loop of Henle extends at least partially into the medulla. For clarity, the nephron shown in Figure 26–6• has been shortened and straightened. The regions of the nephron vary by structure and function. As it travels along the tubule, the filtrate, now called **tubular fluid**, gradually changes in composition. The changes that occur and the characteristics of the urine that results vary with the activities under way in each segment of the nephron. Figure 26–6• and Table 26–1 survey the regional specializations.

Each nephron empties into the **collecting system**, a series of tubes that carry tubular fluid away from the nephron. *Collecting ducts* receive this fluid from many nephrons. Each collecting duct begins in the cortex and descends into the medulla, carrying fluid to a *papillary duct* that drains into a minor calyx.

Nephrons from different locations differ slightly in structure. Roughly 85 percent of all nephrons are **cortical nephrons**, located almost entirely within the superficial cortex of the kidney (Figure 26–7a,b•). In a cortical nephron, the loop of Henle is relatively short, and the efferent arteriole delivers blood to a network of **peritubular capillaries**, which surround the entire renal tubule. These capillaries drain into small venules that carry blood to the interlobular veins (see Figure 26–5c•).

The remaining 15 percent of nephrons, termed **juxtamedullary** (juks-ta-MED-

ū

-lar-

ē

) **nephrons** (*juxta*, near), have long

loops of Henle that extend deep into the medulla (see Figure 26–7a,c•). In these nephrons, the peritubular capillaries are connected to the **vasa recta** (*vasa*, vessel + *recta*, straight)—long, straight capillaries that parallel the loop of Henle.

Because they are more numerous than juxtamedullary nephrons, cortical nephrons perform most of the reabsorptive and secretory functions of the kidneys. However, as you will see later in the chapter, it is the juxtamedullary nephrons that enable the kidneys to produce concentrated urine.

Next we examine the structure of each segment of a representative nephron.

100 Keys | The kidneys remove waste products from the blood; they also assist in the regulation of blood volume and

blood pressure, ion levels, and blood pH. Nephrons are the primary functional units of the kidneys.

The Renal Corpuscle

Each renal corpuscle (Figure 26–8•) is 150–250 mm in diameter. It includes both a region known as **Bowman's capsule** and the capillary network of the glomerulus (Figure 26–8a•). Connected to the initial segment of the renal tubule, Bowman's capsule forms the outer wall of the renal corpuscle and encapsulates the glomerular capillaries.

The glomerulus is surrounded by Bowman's capsule, much as the heart is surrounded by the pericardial cavity. The outer wall of the capsule is lined by a simple squamous **parietal epithelium** (see Figure 26–8a•). This layer is continuous with the **visceral epithelium**, which covers the glomerular capillaries. The **capsular space** separates the parietal and visceral epithelia. The two epithelial layers are continuous where the glomerular capillaries are connected to the afferent arteriole and efferent arteriole.

The visceral epithelium consists of large cells with complex processes, or "feet," that wrap around the specialized lamina densa

¯O

of the glomerular capillaries. These unusual cells are called **podocytes** (P

-do-s ts; *podos*, foot

ı known as **pedicels** (Figure 26–8b•). Materials passing out of the blood at the glomerulus must be small enough to pass between the narrow gaps, or **filtration slits**, between adjacent pedicels.

The glomerular capillaries are fenestrated capillaries—that is, their endothelium contains large-diameter pores (see Figure 26–8b•). The lamina densa differs from that found in the basal lamina of other capillary networks in that it may encircle more than one capillary. Special supporting cells that lie between adjacent capillaries play a role in controlling their diameter and thus in the rate of capillary blood flow. Together, the fenestrated endothelium, the lamina densa, and the filtration slits form the *filtration membrane*. During filtration, blood pressure forces water and small solutes across this membrane and into the capsular space. The larger solutes, especially plasma proteins, are excluded. Filtration at the renal corpuscle is both effective and passive, but it has one major limitation: In addition to metabolic wastes and excess ions, compounds such as glucose, free fatty acids, amino

–

acids, vitamins, and other solutes also enter the capsular space. These potentially useful materials are recaptured before filtrate leaves the kidneys; much of the reabsorption occurs in the proximal convoluted tubule.

Clinical Note

Glomerulonephritis (glo-mer-u -l o -nef-R I -tis) is an inflammation of the glomeruli that affects the filtration mechanism of the kid

neys. The condition, which can develop after an infection involving *Streptococcus* bacteria, is an *immune complex disorder*. l

p. 800 The kidneys are not the site of infection, but as the immune system responds, the number of circulating antigen–antibody complexes skyrockets. These complexes are small enough to pass through the lamina densa, but too large to fit between the filtration slits of the filtration membrane. As a result, the complexes clog up the filtration mechanism, and filtrate production drops. Any condition that leads to a massive immune response, including viral infections and autoimmune disorders, can cause glomerulonephritis.

The Proximal Convoluted Tubule

The **proximal convoluted tubule (PCT)** is the first segment of the renal tubule (see Figure 26–6•). The entrance to the PCT lies almost directly opposite the point where the afferent and efferent arterioles connect to the glomerulus. The lining of the PCT is a simple cuboidal epithelium whose apical surfaces bear microvilli (see Table 26–1). The tubular cells absorb organic nutrients, ions, water, and plasma proteins (if present) from the tubular fluid and release them into the **peritubular fluid**, the interstitial fluid surrounding the renal tubule. Reabsorption is the primary function of the PCT, but the epithelial cells can also secrete substances into the lumen.

The Loop of Henle

The PCT makes an acute bend that turns the renal tubule toward the renal medulla. This turn leads to the **loop of Henle**, or *nephron loop* (see Figure 26–7•). The loop of Henle can be divided into a **descending limb** and an **ascending limb**. Fluid in the descending limb flows toward the renal pelvis, and that in the ascending limb flows toward the renal cortex. Each limb contains a **thick segment** and a **thin segment**. The terms *thick* and *thin* refer to the height of the epithelium, not to the diameter of the lumen: Thick segments have a cuboidal epithelium, whereas a squamous epithelium lines the thin segments (see Table 26–1).

The thick descending limb has functions similar to those of the PCT: It pumps sodium and chloride ions out of the tubular fluid. The effect of this pumping is most noticeable in the medulla, where the long ascending limbs of juxtamedullary nephrons create unusually high solute concentrations in peritubular fluid. The thin segments are freely permeable to water, but not to solutes; water movement out of these segments helps concentrate the tubular fluid.

The Distal Convoluted Tubule

The thick ascending limb of the loop of Henle ends where it forms a sharp angle near the renal corpuscle. The **distal convoluted tubule (DCT)**, the third segment of the renal tubule, begins there. The initial portion of the DCT passes between the afferent and efferent arterioles (see Figure 26–8a•).

In sectional view, the DCT differs from the PCT in that the DCT has a smaller diameter and its epithelial cells lack microvilli (see Table 26–1). The DCT is an important site for three vital processes: (1) the active secretion of ions, acids, drugs, and toxins,

(2) the selective reabsorption of sodium ions and calcium ions from tubular fluid, and (3) the selective reabsorption of water, which assists in concentrating the tubular fluid.

The Juxtaglomerular Apparatus The epithelial cells of the DCT near the renal corpuscle are taller than those elsewhere along

+

-*cyte*, cell), and their feet are

the DCT, and their nuclei are clustered together. This region is called the **macula densa** (MAK-

¯u

-la DEN-sa) (see Figure 26–8a•).

The cells of the macula densa are closely associated with unusual smooth muscle fibers in the wall of the afferent arteriole. These fibers are known as **juxtaglomerular cells**. Together, the macula densa and juxtaglomerular cells form the **juxtaglomerular apparatus (JGA)**, an endocrine structure that secretes the hormone *erythropoietin* and the enzyme *renin*. l**p. 621**

The Collecting System

The distal convoluted tubule, the last segment of the nephron, opens into the collecting system (see Figure 26–6•). Individual nephrons drain into a nearby **collecting duct**. Several collecting ducts then converge into a larger **papillary duct**, which in turn empties into a minor calyx. The epithelium lining the collecting system is typically columnar (see Table 26–1).

In addition to transporting tubular fluid from the nephron to the renal pelvis, the collecting system adjusts the fluid’s composition and determines the final osmotic concentration and volume of urine.

Concept Check

Which portions of the nephron are in the renal cortex?

Why don’t plasma proteins pass into the capsular space under normal circumstances?

Damage to which part of the nephron would interfere with the control of blood pressure?

Answers begin on p. A–1

Principles of Renal Physiology

Objectives

- Discuss the major functions of each portion of the nephron and collecting system.
- Identify and describe the major factors responsible for the production of urine.
- Describe the normal characteristics, composition, and solute concentrations of a representative urine sample.

The goal of urine production is to maintain homeostasis by regulating the volume and composition of blood. This process involves the excretion of solutes—specifically, metabolic waste products. Three organic waste products are noteworthy:

1. *Urea.* Urea is the most abundant organic waste. You generate roughly 21 g of urea each day, most of it through the breakdown of amino acids.

2. *Creatinine.* Creatinine is generated in skeletal muscle tissue through the breakdown of *creatine phosphate*, a high-energy com

pound that plays an important role in muscle contraction. l**p. 309** Your body generates roughly 1.8 g of creatinine each day, and virtually all of it is excreted in urine.

3. *Uric Acid.* **Uric acid** is a waste product formed during the recycling of the nitrogenous bases from RNA molecules. You produce approximately 480 mg of uric acid each day.

These waste products are dissolved in the bloodstream and can be eliminated only while dissolved in urine. As a result, their removal is accompanied by an unavoidable water loss. The kidneys are usually capable of producing concentrated urine with an osmotic concentration of 1200–1400 mOsm > L, more than four times that of plasma. (Methods of reporting solute concentrations are discussed in a later section.) If the kidneys were unable to concentrate the filtrate produced by glomerular filtration, fluid losses would lead to fatal dehydration in a matter of hours. The kidneys also ensure that the fluid that *is* lost does not contain potentially useful organic substrates that are present in blood plasma, such as sugars or amino acids. These valuable materials must be reabsorbed and retained for use by other tissues.

Basic Processes of Urine Formation

To perform their functions, the kidneys rely on three distinct processes:

1. *Filtration.* In **filtration**, blood pressure forces water and solutes across the wall of the glomerular capillaries and into the capsular space. Solute molecules small enough to pass through the filtration membrane are carried by the surrounding water molecules.

2. *Reabsorption.* **Reabsorption** is the removal of water and solutes from the filtrate, and their movement across the tubular epithelium and into the peritubular fluid. Reabsorption occurs after filtrate has left the renal corpuscle. Most of the reabsorbed materials are nutrients the body can use. Whereas filtration occurs solely based on size, reabsorption is a selective process involving either simple diffusion or the activity of carrier proteins in the tubular epithelium. The reabsorbed substances in the peritubular fluid eventually reenter the blood. Water reabsorption occurs passively, through osmosis.

3. Secretion. **Secretion** is the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid. Secretion is necessary because filtration does not force all the dissolved materials out of the plasma. Tubular secretion, which provides a backup process for filtration, can further lower the plasma concentration of undesirable materials. Secretion is often the primary method of excretion for some compounds, including many drugs.

Together, these processes produce a fluid that is very different from other body fluids. Table 26–2 indicates the efficiency of the renal system by comparing the concentrations of some substances in urine and plasma. Before considering the functions of the individual portions of the nephron, we will briefly examine each of the three major processes involved in urine formation.

Filtration

In filtration, hydrostatic pressure forces water through membrane pores, and solute molecules small enough to pass through those pores are carried along. Filtration occurs as larger solutes and suspended materials are left behind. We can see filtration in action in a drip coffee machine. Gravity forces hot water through the filter, and the water carries a variety of dissolved compounds into the pot. The large coffee grounds never reach the pot, because they cannot fit through the pores of the filter. In other words, they are “filtered out” of the solution; the coffee we drink is the filtrate.

In the body, the heart pushes blood around the cardiovascular system and generates hydrostatic pressure. Filtration occurs across the walls of capillaries as water and dissolved materials are pushed into the interstitial fluids of the body (see Figure 21–11•, p. 723). In some sites (for example, the liver), the pores are so large that even plasma proteins can enter the interstitial fluids. At the renal corpuscle, however, a specialized filtration membrane restricts the passage of even the smallest circulating proteins.

Reabsorption and Secretion

The processes of reabsorption and secretion at the kidneys involve a combination of diffusion, osmosis, channel-mediated diffusion, and carrier-mediated transport. Diffusion and osmosis were considered in several other chapters, so here we will briefly review carrier-mediated transport mechanisms.

Types of Carrier-Mediated Transport In previous chapters, we considered four major types of *carrier-mediated transport:*

- In *facilitated diffusion*, a carrier protein transports a molecule across the cell membrane without expending energy (see Figure 3–18•, p. 90). Such transport always follows the concentration gradient for the ion or molecule transported.
- *Active transport* is driven by the hydrolysis of ATP to ADP on the inner membrane surface (see Figure 3–19•, p. 91). Exchange pumps and other carrier proteins are active along the kidney tubules. Active transport mechanisms can operate despite an opposing concentration gradient.
- In *cotransport*, carrier protein activity is not directly linked to the hydrolysis of

ATP (see Figure 3–20•, p. 91). Instead, two substrates (ions, molecules, or both) cross the membrane while bound to the carrier protein. The movement of the substrates always follows the concentration gradient of at least one of the transported substances. Cotransport mechanisms are responsible for the reabsorption of organic and inorganic compounds from the tubular fluid.

- *Countertransport* resembles cotransport in all respects, except that the two transported ions move in *opposite* directions (see Figures 23–24, p. 847, and 24–14•, p. 881). Countertransport mechanisms operate in the PCT, DCT, and collecting system.

Characteristics of Carrier-Mediated Transport All carrier-mediated processes share five features that are important for an understanding of kidney function:

A Specific Substrate Binds to a Carrier Protein That Facilitates Movement across the Membrane.

2. *A Given Carrier Protein Typically Works in One Direction Only.* In facilitated diffusion, that direction is determined by the concentration gradient of the substance being transported. In active transport, cotransport, and countertransport, the location and orientation of the carrier proteins determine whether a particular substance is reabsorbed or secreted. The carrier protein that transports amino acids from the tubular fluid to the cytoplasm, for example, will not carry amino acids back into the tubular fluid.

3. *The Distribution of Carrier Proteins Can Vary among Portions of the Cell Surface.* Transport between tubular fluid and interstitial fluid involves two steps—the material must enter the cell at its apical surface and then leave the cell and enter the peritubular fluid at the cell's basolateral surface. Each step involves a different carrier protein. For example, the apical surfaces of cells along the proximal convoluted tubule contain carrier proteins that bring amino acids, glucose, and many other nutrients into these cells by sodium-linked cotransport. In contrast, the basolateral surfaces contain carrier proteins that move those nutrients out of the cell by facilitated diffusion.

4. *The Membrane of a Single Tubular Cell Contains Many Types of Carrier Protein.* Each cell can have multiple functions, and a cell that reabsorbs one compound can secrete another.

5. *Carrier Proteins, Like Enzymes, Can Be Saturated.* When an enzyme is *saturated,* further increases in substrate concentration

have no effect on the rate of reaction. l**p. 52** When a carrier protein is saturated, further increases in substrate concentration have no effect on the rate of transport across the cell membrane. For any substance, the concentration at saturation is called the **transport maximum (*Tm*)** or *tubular maximum*. The saturation of carrier proteins involved in tubular secretion seldom oc

curs in healthy individuals, but carriers involved in tubular reabsorption are often at risk of saturation, especially during the absorptive state following a meal.

T and the Renal Threshold Normally, any plasma proteins and nutrients, such as amino acids and glucose, are removed from

m the tubular fluid by cotransport or facilitated diffusion. If the concentrations of these nutrients rise in the tubular fluid, the rates of reabsorption increase until the carrier proteins are saturated. A concentration higher than the transport maximum will exceed the reabsorptive abilities of the nephron, so some of the material will remain in the tubular fluid and appear in the urine. The transport maximum thus determines the **renal threshold—**the plasma concentration at which a specific compound or ion begins to appear in the urine.

The renal threshold varies with the substance involved. The renal threshold for glucose is approximately 180 mg > dl. When plasma glucose concentrations exceed 180 mg dl, glucose concentrations in tubular fluid exceed the *Tm* of the tubular cells, so

>

glucose appears in urine. The presence of glucose in urine is a condition called *glycosuria*. After you have eaten a meal rich in carbohydrates, your plasma glucose levels may exceed the *Tm* for a brief period. The liver will quickly lower circulating glucose levels, and very little glucose will be lost in your urine. However, chronically elevated plasma and urinary glucose concentrations are highly abnormal. (Glycosuria is one of the key signs of diabetes mellitus. l**p. 621**)

The renal threshold for amino acids is lower than that for glucose; amino acids appear in urine when plasma concentrations exceed 65 mg > dl. Plasma amino acid levels commonly exceed the renal threshold after you have eaten a protein-rich meal, causing some amino acids to appear in your urine. This condition is termed **aminoaciduria** (am-e-no-as-i-DOO-re-uh).

Tm values for water-soluble vitamins are relatively low; as a result, excess quantities of these vitamins are excreted in urine. (This is typically the fate of water-soluble vitamins in daily supplements.) Cells of the renal tubule ignore a number of other compounds in the tubular fluid. As water and other compounds are removed, the concentrations of the ignored materials in the tubular fluid gradually rise. Table 26–3 lists some substances that are actively reabsorbed or secreted by the renal tubules, as well as several that are not transported at all.

An Overview of Renal Function

Figure 26–9• summarizes the general functions of the various segments of the nephron and collecting system in the formation of urine. Most regions perform a combination of reabsorption and secretion, but the balance between the two processes shifts from one region to another:

- Filtration occurs exclusively in the renal corpuscle, across the filtration membrane.
- Water and solute reabsorption occurs primarily along the proximal convoluted tubules, but also elsewhere along the renal tubule and within the collecting system.
- Active secretion occurs primarily at the proximal and distal convoluted tubules.
- The loops of Henle—especially the long loops of the juxtamedullary nephrons—and the collecting system interact to regulate the final volume and solute concentration of the urine.

Normal kidney function can continue only as long as filtration, reabsorption, and secretion function within relatively narrow limits. A disruption in kidney function has immediate effects on the composition of the circulating blood. If both kidneys are affected, death will occur within a few days unless medical assistance is provided.

Next we will proceed along the nephron to consider the formation of filtrate and the changes in the composition and concentration of the filtrate as it passes along the renal tubule. Most of what follows applies equally to cortical and juxtamedullary nephrons. The major differences between the two types of nephron are that the loop of Henle of a cortical nephron is shorter and does not extend as far into the medulla as does the loop of Henle of a juxtamedullary nephron (see Figure 26–7a•, p. 958). The long loop of Henle in a juxtamedullary nephron extends deep into the renal pyramids, where it plays a vital role in water conservation and the formation of concentrated urine. Because this process is so important, affecting the tubular fluid produced by every nephron in the kidney, and because the functions of the renal corpuscle and of the proximal and distal convoluted tubules are the same in all nephrons, we will use a juxtamedullary nephron as our example. Table 26–4 summarizes the functions of the various parts of the nephron.

The osmotic concentration, or *osmolarity*, of a solution is the total number of solute particles in each liter. l**p. 88** Osmolarity is usually expressed in **osmoles** per liter (Osm L) or **milliosmoles** per liter (mOsm L). If each liter of a fluid contains 1 mole of

>> dissolved particles, the solute concentration is 1 Osm > L, or 1000 mOsm > L. Body fluids have an osmotic concentration of about 300 mOsm > L. In comparison, that of seawater is about 1000 mOsm > L, and that of fresh water about 5 mOsm > L. Ion concentrations are often reported in *milliequivalents* per liter (mEq L), whereas the concentrations of large organic molecules are usually

>

reported in grams or milligrams per unit volume of solution (typically, mg or g per dl). AM: Solutions and Concentrations

Renal Physiology:

Filtration at the Glomerulus

Objective

- List and describe the factors that influence filtration pressure and the rate of filtrate formation.

Filtration occurs in the renal corpuscle as fluids move across the wall of the glomerulus and into the capsular space. The process of **glomerular filtration** involves passage across a filtration membrane, which has three components: (1) the capillary endothelium, (2) the lamina densa, and (3) the filtration slits (see Figures 26–8b and 26–10•).

Glomerular capillaries are fenestrated capillaries with pores ranging from 60 to 100 nm (0.06 to 0.1 mm) in diameter. These openings are small enough to prevent the passage of blood cells, but they are too large to restrict the diffusion of solutes, even those the size of plasma proteins. The lamina densa is more selective: Only small plasma proteins, nutrients, and ions can cross it. The filtration slits are the finest filters of all. Their gaps are only 6–9 nm wide, which is small enough to prevent the passage of most small plasma proteins. As a result, under normal circumstances no plasma proteins (except a few albumin molecules, with an average diameter of 7 nm) can cross the filtration membrane and enter the capsular space. However, plasma proteins are all that stay behind, so the filtrate contains dissolved ions and small organic molecules in roughly the same concentrations as in plasma.

Filtration Pressures

The major forces that act across capillary walls were discussed in Chapters 21 and 22. (You may find it helpful to review Figures 21–11 and 21–12•, pp. 723, 724, before you proceed.)

The primary factor involved in glomerular filtration is basically the same as that governing fluid and solute movement across capillaries throughout the body: the balance between hydrostatic pressure (fluid pressure) and colloid osmotic pressure (pressure due to materials in solution) on either side of the capillary walls.

Hydrostatic Pressure

The **glomerular hydrostatic pressure (GHP)** is the blood pressure in the glomerular capillaries. This pressure tends to push water and solute molecules out of the plasma and into the filtrate. The GHP is significantly higher than capillary pressures elsewhere in the systemic circuit, due to the arrangement of vessels at the glomerulus.

Blood pressure is low in typical systemic capillaries because capillary blood flows into the venous system, where resistance is relatively low. However, at the glomerulus, blood leaving the glomerular capillaries flows into an efferent arteriole, whose diameter is *smaller* than that of the afferent arteriole. The efferent arteriole thus offers considerable resistance, so relatively high pressures are needed to force blood into it. As a result, glomerular pressures are similar to those of small arteries, averaging about 50 mm Hg instead of the 35 mm Hg typical of peripheral capillaries.

Glomerular hydrostatic pressure is opposed by the **capsular hydrostatic pressure (CsHP)**, which tends to push water and solutes out of the filtrate and into the plasma. This pressure results from the resistance to flow along the nephron and the conducting system. (Before additional filtrate can enter the capsule, some of the filtrate already present must be forced into the PCT.) The CsHP averages about 15 mm Hg.

The *net hydrostatic pressure (NHP)* is the difference between the glomerular hydrostatic pressure, which tends to push water and solutes out of the bloodstream, and the capsular hydrostatic pressure, which tends to push water and solutes into the bloodstream. Net hydrostatic pressure can be calculated as follows:

NHP = GHP -CsHP = 50 mm Hg -15 mm Hg = 35 mm Hg

Colloid Osmotic Pressure

The colloid osmotic pressure of a solution is the osmotic pressure resulting from the presence of suspended proteins. The **blood colloid osmotic pressure (BCOP)** tends to draw water out of the filtrate and into the plasma; it thus opposes filtration. Over the entire length of the glomerular capillary bed, the BCOP averages about 25 mm Hg. Under normal conditions, very few plasma proteins enter the capsular space, so no opposing colloid osmotic pressure exists within the capsule. However, if the glomeruli are damaged by disease or injury, and plasma proteins begin passing into the capsular space, a *capsular colloid osmotic pressure* is created that promotes filtration and increases fluid losses in urine.

Filtration Pressure

The **filtration pressure (FP)** at the glomerulus is the difference between the hydrostatic pressure and the colloid osmotic pressure acting across the glomerular capillaries. Under normal circumstances, this relationship can be summarized as

FP = NHP -BCOP or

FP = 35 mm Hg -25 mm Hg = 10 mm Hg. This is the average pressure forcing water and dissolved materials out of the glomerular capillaries and into the capsular spaces (Figure 26–10b•). Problems that affect filtration pressure can seriously disrupt kidney function and cause a variety of clinical signs and symptoms. AM: Conditions Affecting Filtration

The Glomerular Filtration Rate

The **glomerular filtration rate (GFR)** is the amount of filtrate the kidneys produce each minute. Each kidney contains about 6 m^2—some 64 square feet—of filtration surface, and the GFR averages an astounding *125 ml per minute*. This means that roughly 10 percent of the fluid delivered to the kidneys by the renal arteries leaves the bloodstream and enters the capsular spaces. A *creatinine clearance test* is often used to estimate the GFR. Creatinine, which results from the breakdown of creatine phosphate in muscle tissue, is normally eliminated in urine. Creatinine enters the filtrate at the glomerulus and is not reabsorbed in significant amounts. By monitoring the creatinine concentrations in blood and the amount excreted in urine in a 24-hour period, a clinician can easily estimate the GFR. Consider, for example, a person who eliminates 84 mg of creatinine each hour and has a plasma creatinine concentration of 1.4 mg > dl. Because the GFR is equal to the amount secreted, divided by the plasma concen

tration, this person's GFR is

84 mg> h

= 60 dl> h = 100 ml> min.

1.4 mg> dl The GFR is usually reported in milliliters per minute. The value 100 ml > min is only an approximation of the GFR, because up to 15 percent of creatinine in the urine enters by means of active tubular secretion. When necessary, a more accurate GFR determination can be performed by using the complex carbohydrate *inulin*, which is not metabolized in the body and is neither reabsorbed nor secreted by the kidney tubules.

In the course of a single day, the glomeruli generate about 180 liters (50 gal) of filtrate, roughly 70 times the total plasma volume. But as filtrate passes through the renal tubules, about 99 percent of it is reabsorbed. You should now appreciate the significance of tubular reabsorption!

The glomerular filtration rate depends on the filtration pressure across glomerular capillaries. Any factor that alters the filtration pressure therefore alters the GFR, thereby affecting kidney function. One of the most significant factors is a drop in renal blood pressure. If blood pressure at the glomeruli drops by 20 percent (from 50 mm Hg to 40 mm Hg), kidney filtration will cease, because the filtration pressure will be 0 mm Hg. The kidneys are therefore sensitive to changes in blood pressure that have little or no effect on other organs. Hemorrhaging, shock, and dehydration are relatively common clinical conditions that can cause a dangerous decline in the GFR and lead to acute renal failure (p. 984).

Control of the GFR

Glomerular filtration is the vital first step essential to all other kidney functions. If filtration does not occur, waste products are not excreted, pH control is jeopardized, and an important mechanism for regulating blood volume is lost. It should be no surprise that a variety of regulatory mechanisms ensure that GFR remains within normal limits.

Filtration depends on adequate blood flow to the glomerulus and on the maintenance of normal filtration pressures. Three interacting levels of control stabilize GFR: (1) *autoregulation*, at the local level, (2) *hormonal regulation*, initiated by the kidneys, and (3) *autonomic regulation*, primarily by the sympathetic division of the autonomic nervous system.

Autoregulation of the GFR

Autoregulation maintains an adequate GFR despite changes in local blood pressure and blood flow. Maintenance of the GFR is accomplished by changing the diameters of afferent arterioles, efferent arterioles, and glomerular capillaries. The most important regulatory mechanisms stabilize the GFR when systemic blood pressure declines. A reduction in blood flow and a decline in glomerular blood pressure trigger (1) dilation of the afferent arteriole, (2) relaxation of supporting cells and dilation of the glomerular capillaries, and (3) constriction of the efferent arteriole. This combination increases blood flow and elevates glomerular blood pressure to normal levels. As a result, filtration rates remain relatively constant. The GFR also remains relatively constant when systemic blood pressure rises. A rise in renal blood pressure stretches the walls of afferent arterioles, and the smooth muscle cells respond by contracting. The reduction in the diameter of afferent arterioles decreases glomerular blood flow and keeps the GFR within normal limits.

Hormonal Regulation of the GFR

The GFR is regulated by the hormones of the renin–

angiotensin system and the natriuretic peptides (ANP and BNP). These hormones and their actions were introduced in Chapters 18 and 21. l**pp. 621–622, 731–732** There are three triggers for the release of renin by the juxtaglomerular apparatus (JGA): (1) a decline in blood pressure at the glomerulus as the result of a decrease in blood volume, a fall in systemic pressures, or a blockage in the renal artery or its tributaries; (2) stimulation of juxtaglomerular cells by sympathetic innervation; or (3) a decline in the osmotic concentration of the tubular fluid at the macula densa. These stimuli are often interrelated. For example, a decline in systemic blood pressure reduces the glomerular filtration rate while baroreceptor reflexes cause sympathetic activation. Meanwhile, a reduction in the GFR slows the movement of tubular fluid along the nephron. Because the tubular fluid is then in the ascending limb of the loop of Henle longer, the concentration of sodium and chloride ions in the tubular fluid reaching the macula densa and DCT becomes abnormally low.

Figure 26–11a• provides a general overview of the response of the renin–angiotensin system to a decline in GFR. A fall in GFR leads to the release of renin, which activates angiotensin. Angiotensin II then elevates the blood volume and blood pressure, increasing the GFR. Figure 26–11b• presents a more detailed view of the mechanisms involved. Once released into the bloodstream by the juxtaglomerular apparatus, renin converts the inactive protein angiotensinogen to angiotensin I. Angiotensin I, which is also inactive, is then converted to angiotensin II by **angiotensin-converting enzyme (ACE)**, primarily in the capillaries of the lungs. Angiotensin II is an active hormone whose primary effects include the following:

- *At the nephron*, angiotensin II causes the constriction of the efferent arteriole, further elevating glomerular pressures and filtration rates. Angiotensin II also directly stimulates the reabsorption of sodium ions and water at the PCT.
- *At the adrenal glands*, angiotensin II stimulates the secretion of aldosterone by the adrenal cortex. The aldosterone then accelerates sodium reabsorption in the DCT and cortical portion of the collecting system.
- *In the CNS*, angiotensin II (1) causes the sensation of thirst; (2) triggers the release of antidiuretic hormone (ADH), stimulating the reabsorption of water in the distal portion of the DCT and the collecting system; and (3) increases sympathetic motor tone, mobilizing the venous reserve, increasing cardiac output, and stimulating peripheral vasoconstriction.
- *In peripheral capillary beds*, angiotensin II causes a brief but powerful vasoconstriction of arterioles and precapillary sphincters, elevating arterial pressures throughout the body.

The combined effect is an increase in systemic blood volume and blood pressure and the restoration of normal GFR.

If blood volume rises, the GFR increases automatically, and this promotes fluid losses that help return blood volume to normal levels. If the elevation in blood volume is severe, hormonal factors further increase the GFR and accelerate fluid losses in the urine. As noted in Chapter 18, the *natriuretic peptides* are released in response to the stretching of the walls of the heart by increased blood volume or blood pressure. These hormones are released by the heart; atrial natriuretic peptide (ANP) is released by the atria, and brain natriuretic peptide (BNP) is released by the ventricles. l**pp. 622, 732** Among their other effects, the natriuretic peptides trigger the dilation of afferent arterioles and constriction of efferent arterioles. This mechanism elevates glomerular pressures and increases the GFR. The natriuretic peptides also increase tubular reabsorption of sodium ions, and the net result is increased urine production and decreased blood volume and pressure.

Autonomic Regulation of the GFR

Most of the autonomic innervation of the kidneys consists of sympathetic postganglionic fibers. (The role of the few parasympathetic fibers in regulating kidney function is not known.) Sympathetic activation has one direct effect on the GFR: It produces a powerful vasoconstriction of afferent arterioles, decreasing the GFR and slowing the production of filtrate. Thus the sympathetic activation triggered by an acute fall in blood pressure or a heart attack overrides the local regulatory mechanisms that act to stabilize the GFR. As the crisis passes and sympathetic tone decreases, the filtration rate gradually returns to normal levels.

When the sympathetic division alters regional patterns of blood circulation, blood flow to the kidneys is often affected. For example, the dilation of superficial vessels in warm weather shunts blood away from the kidneys, so glomerular filtration declines temporarily. The effect becomes especially pronounced during periods of strenuous exercise. As the blood flow to your skin and skeletal muscles increases, kidney perfusion gradually decreases. These changes may be opposed, with variable success, by autoregulation at the local level.

At maximal levels of exertion, renal blood flow may be less than 25 percent of normal resting levels. This reduction can create problems for endurance athletes, because metabolic wastes build up over the course of a long event. *Proteinuria* (protein in the urine) commonly occurs after such events because the glomerular cells have been injured by prolonged hypoxia (low oxygen levels). If the damage is substantial, *hematuria* (blood in the urine) occurs. Hematuria develops in roughly 18 percent of marathon runners. Proteinuria and hematuria generally disappear within 48 hours as the glomerular tissues are repaired. However, a small number of marathon and ultramarathon runners experience *acute renal failure,* with permanent impairment of kidney function.

100 Keys | Roughly 180 L of filtrate is produced at the glomeruli each day, and that represents 70 times the total plasma

volume. Almost all of that fluid volume must be reabsorbed to avoid fatal dehydration.

Review filtrate formation on the **IP CD-ROM: Urinary System/Glomerular Filtration.**

Renal Physiology:
Reabsorption and Secretion

Objectives

- Identify the types of transport mechanisms found along the nephron and discuss the reabsorptive or secretory functions of each segment of the nephron and collecting system.
- Explain the role of countercurrent multiplication in the formation of a concentration gradient in the renal medulla.
- Describe how antidiuretic hormone and aldosterone influence the volume and concentration of urine.

Reabsorption recovers useful materials that have entered the filtrate, and secretion ejects waste products, toxins, or other undesirable solutes that did not leave the bloodstream at the glomerulus. Both processes occur in every segment of the nephron except the renal corpuscle, but their relative importance changes from segment to segment.

Reabsorption and Secretion at the PCT

The cells of the proximal convoluted tubule normally reabsorb 60–70 percent of the volume of the filtrate produced in the renal corpuscle. The reabsorbed materials enter the peritubular fluid and diffuse into peritubular capillaries.

The PCT has five major functions:

1. *Reabsorption of Organic Nutrients.* Under normal circumstances, before the tubular fluid enters the loop of Henle, the PCT reabsorbs more than 99 percent of the glucose, amino acids, and other organic nutrients in the fluid. This reabsorption involves a combination of facilitated transport and cotransport.

2. *Active Reabsorption of Ions.* The PCT actively transports several ions, including sodium, potassium, and bicarbonate ions

(Figure 26–12•), plus magnesium, phosphate, and sulfate ions. The ion pumps involved are individually regulated and may be influenced by circulating ion or hormone levels. For example, angiotensin II stimulates Na^+ reabsorption along the PCT. By absorbing carbon dioxide, the PCT indirectly recaptures roughly 90 percent of the bicarbonate ions from tubular fluid. Bicarbonate is important in stabilizing blood pH, a process we will examine further in Chapter 27.

3. *Reabsorption of Water.* The reabsorptive processes have a direct effect on the solute concentrations inside and outside the tubules. The filtrate entering the PCT has the same osmotic concentration as that of the surrounding peritubular fluid. As transport activities proceed, the solute concentration of tubular fluid decreases, and that of peritubular fluid and adjacent capillaries increases. Osmosis then pulls water out of the tubular fluid and into the peritubular fluid. Along the PCT, this mechanism results

in the reabsorption of roughly 108 liters of water each day.

4. *Passive Reabsorption of Ions.* As active reabsorption of ions occurs and water leaves tubular fluid by osmosis, the concentration of other solutes in tubular fluid increases above that in peritubular fluid. If the tubular cells are permeable to them, those solutes will move across the tubular cells and into the peritubular fluid by passive diffusion. Urea, chloride ions, and lipid-soluble materials may diffuse out of the PCT in this way. Such diffusion further reduces the solute concentration of the tubular fluid and promotes additional water reabsorption by osmosis.

5. *Secretion.* Active secretion also occurs along the PCT. Because the DCT performs comparatively little reabsorption, we will consider secretory mechanisms when we discuss the DCT.

Sodium ion reabsorption plays an important role in all of the foregoing processes. Sodium ions may enter tubular cells by diffusion through Na^+ leak channels; by the sodium-linked cotransport of glucose, amino acids, or other organic solutes; or by countertransport for hydrogen ions (see Figure 26–12•). In tubular cells, sodium ions diffuse toward the basal lamina. The cell membrane in this area contains sodium–potassium exchange pumps that eject sodium ions in exchange for extracellular potassium ions. Reabsorbed sodium ions then diffuse into the adjacent peritubular capillaries.

The reabsorption of ions and compounds along the PCT involves many different carrier proteins. Some people have an inherited inability to manufacture one or more of these carrier proteins and are therefore unable to recover specific solutes from tubular fluid. In *renal glycosuria* (gl -k

ı reabsorb glucose from tubular fluid. AM: Inherited Problems with Tubular Function

Answers begin on p. A–1

The Loop of Henle and Countercurrent Multiplication

Roughly 60–70 percent of the volume of filtrate produced at the glomerulus has been reabsorbed before the tubular fluid reaches the loop of Henle. In the process, useful organic substrates and many mineral ions have been reclaimed. The loop of Henle reab-

–

sorbs roughly half of the water, and two-thirds of the sodium and chloride ions, remaining in the tubular fluid. This

reabsorption

is performed efficiently according to the principle of countercurrent exchange, which was introduced in Chapter 25 in our discussion of heat conservation mechanisms. l**p. 943**

The thin descending limb and the thick ascending limb of the loop of Henle are very close together, separated only by peritubular fluid. The exchange that occurs between these segments is called **countercurrent multiplication**. *Countercurrent* refers to the fact that the exchange occurs between fluids moving in opposite directions: Tubular fluid in the descending limb flows toward the renal pelvis, whereas tubular fluid in the ascending limb flows toward the cortex. *Multiplication* refers to the fact that the effect of the exchange increases as movement of the fluid continues.

The two parallel segments of the loop of Henle have very different permeability characteristics. The thin descending limb is permeable to water but relatively impermeable to solutes. The thick ascending limb, which is relatively impermeable to both water and solutes, contains active transport mechanisms that pump sodium and chloride ions from the tubular fluid into the peritubular fluid of the medulla.

A quick overview of countercurrent multiplication will help you make sense of the details:

- Sodium and chloride are pumped out of the thick ascending limb and into the peritubular fluid.
- This pumping action elevates the osmotic concentration in the peritubular fluid around the thin descending limb.
- The result is an osmotic flow of water out of the thin descending limb and into the peritubular fluid, increasing the solute concentration in the thin descending limb.
- The arrival of the highly concentrated solution in the thick ascending limb accelerates the transport of sodium and chloride ions into the peritubular fluid of the medulla.

Notice that this arrangement is a simple positive feedback loop: Solute pumping at the ascending limb leads to higher solute concentrations in the descending limb, which then result in accelerated solute pumping in the ascending limb.

We can now take a closer look at the mechanics of the process. Figure 26–13a• diagrams ion transport across the epithelium of the thick ascending limb. Active transport at the apical surface moves sodium, potassium, and chloride ions out of the tubular fluid. The carrier is called a **Na – K/2 Cl transporter**, because each cycle of the pump carries a sodium ion, a potassium ion, and two chloride ions into the tubular cell. Potassium and chloride ions are pumped into the peritubular fluid by cotransport carriers. However, potassium ions are removed from the peritubular fluid as the sodium–potassium exchange pump pumps sodium ions out of the tubular cell. The potassium ions then diffuse back into the lumen of the tubule through potassium leak channels.

-

The net result is that Na^+ and Clenter the peritubular fluid of the renal medulla.

¯o

-SOO-r

The removal of sodium and chloride ions from the tubular fluid in the ascending limb elevates the osmotic concentration of the peritubular fluid around the thin descending limb (see Figure 26–13b•). Because the thin descending limb is permeable to water but impermeable to solutes, as tubular fluid travels deeper into the medulla along the thin descending limb, osmosis moves water into the peritubular fluid. Solutes remain behind, so the tubular fluid reaching the turn of the loop of Henle has a higher osmotic concentration than it did at the start.

The pumping mechanism of the thick ascending limb is highly effective: Almost two-thirds of the sodium and chloride ions that enter it are pumped out of the tubular fluid before that fluid reaches the DCT. In other tissues, differences in solute concentration are quickly resolved by osmosis. However, osmosis cannot occur across the wall of the thick ascending limb, because the

-

tubular epithelium there is impermeable to water. Thus, as Na^+ and Clare removed, the solute concentration in the tubular fluid declines. Tubular fluid arrives at the DCT with an osmotic concentration of only about 100 mOsm > L, one-third the concentration of the peritubular fluid of the renal cortex.

The rate of ion transport across the thick ascending limb is proportional to an ion’s concentration in tubular fluid. As a result, more sodium and chloride ions are pumped into the medulla at the start of the thick ascending limb, where NaCl concentrations are highest, than near the cortex. This regional difference in the rate of ion transport is the basis of the concentration gradient within the medulla.

The Concentration Gradient of the Medulla

Normally, the maximum solute concentration of the peritubular fluid near the turn of the loop of Henle is about 1200 mOsm > L (see Figure 26–13b•). Sodium and chloride ions pumped out of the loop’s ascending limb account for roughly two-thirds of that gradient (750 mOsm > L). The rest of the concentration gradient results from the presence of urea. To understand how urea arrived in the medulla, we must look ahead to events in the last segments of the collecting system (Figure 26–13c•). The thick ascending limb of the loop

of Henle, the DCT, and the collecting ducts are impermeable to urea. As water is reabsorbed, the concentration of urea gradually rises. The tubular fluid reaching the papillary duct typically contains urea at a concentration of about 450 mOsm >
L. Because the papillary ducts are permeable to urea, the urea concentration in the deepest parts of the medulla also averages 450 mOsm > L.

Benefits of Countercurrent Multiplication

The countercurrent mechanism performs two functions:

1. It efficiently reabsorbs solutes and water before the tubular fluid reaches the DCT and collecting system.

2. It establishes a concentration gradient that permits the passive reabsorption of water from the tubular fluid in the collecting system. This reabsorption is regulated by circulating levels of antidiuretic hormone (ADH).

The tubular fluid arriving at the descending limb of the loop of Henle has an osmotic concentration of roughly 300 mOsm >

-

L, due primarily to the presence of ions such as Na$^+$ and Cl. The concentration of organic wastes, such as urea, is low. Roughly half of the tubular fluid entering the loop of Henle is reabsorbed along the thin descending limb, and two-thirds of the Na$^+$ and Cl$^-$ is reabsorbed along the thick ascending limb. As a result, the DCT receives a reduced volume of tubular fluid with an osmotic concentration of about 100 mOsm > L. Urea and other organic wastes, which were not pumped out of the thick ascending limb,
now represent a significant proportion of the dissolved solutes.

Review reabsorption and secretion at the PCT and loop of Henle on the **IP CD-ROM: Urinary System/Early Filtrate Processing**.

Reabsorption and Secretion at the DCT

The composition and volume of tubular fluid change dramatically as it flows from the capsular space to the distal convoluted tubule. Only 15–20 percent of the initial filtrate volume reaches the DCT, and the concentrations of electrolytes and organic wastes in the arriving tubular fluid no longer resemble the concentrations in blood plasma. Selective reabsorption or secretion, primarily along the DCT, makes the final adjustments in the solute composition and volume of the tubular fluid.

Reabsorption at the DCT

-

Throughout most of the DCT, the tubular cells actively transport Na^+ and Clout of the tubular fluid (Figure 26–14a•). Tubular cells along the distal portions of the DCT also contain ion pumps that reabsorb tubular Na^+ in exchange for another cation (usually K^+) (Figure 26–14b•). The ion pump and the Na^+ channels involved are controlled by the hormone *aldosterone*, produced by the adrenal cortex. Aldosterone stimulates the synthesis and incorporation of sodium ion pumps and sodium channels in cell membranes along the DCT and collecting duct. The net result is a reduction in the number of sodium ions lost in urine. However, sodium ion conservation is associated with potassium ion loss. Prolonged aldosterone stimulation can therefore produce *hyp*

okalemia, a dangerous reduction in the plasma K^+ concentration. The secretion of aldosterone and its actions on the DCT and collecting system are opposed by the natriuretic peptides (ANP and BNP).

The DCT is also the primary site of Ca^{2+} reabsorption, a process regulated by circulating levels of parathyroid hormone and calcitriol. l**p. 612**

Secretion at the DCT

The blood entering peritubular capillaries still contains a number of potentially undesirable substances that did not cross the filtration membrane at the glomerulus. In most cases, the concentrations of these materials are too low to cause physiological problems. However, any ions or compounds that are present in peritubular capillaries will diffuse into the peritubular fluid. If those concentrations become too high, the tubular cells may absorb these materials from the peritubular fluid and secrete them into the tubular fluid. Table 26–3, p. 963, lists some of the substances secreted into tubular fluid by the distal and proximal convoluted tubules.

The rate of K^+ and H^+ secretion rises or falls in response to changes in their concentrations in peritubular fluid. The higher their concentration in the peritubular fluid, the higher the rate of secretion. Potassium and hydrogen ions merit special attention, because their concentrations in body fluids must be maintained within relatively narrow limits.

Potassium Ion Secretion Figure 26–14a,b• diagrams the mechanism of K^+ secretion. Potassium ions are removed from the peritubular fluid in exchange for sodium ions obtained from the tubular fluid. These potassium ions diffuse into the lumen through potassium channels at the apical surfaces of the tubular cells. In effect, tubular cells trade sodium ions in the tubular fluid for excess potassium ions in body fluids.

Hydrogen Ion Secretion Hydrogen ion secretion is also associated with the reabsorption of sodium. Figure 26–14c• depicts two routes of secretion. Both involve the generation of carbonic acid by the enzyme *carbonic anhydrase*. l**pp. 846, 879** Hydrogen ions generated by the dissociation of the carbonic acid are secreted by sodium-linked countertransport in exchange for Na^+ in the tubular fluid. The bicarbonate ions diffuse into the peritubular fluid and then into the bloodstream, where they help prevent changes in plasma pH.

Hydrogen ion secretion acidifies the tubular fluid while elevating the pH of the blood. Hydrogen ion secretion accelerates when the pH of the blood falls—as in *lactic acidosis*, which can develop after exhaustive muscle activity, or *ketoacidosis*, which can develop in starvation or diabetes mellitus. l**p. 935** The combination of H^+ removal and HCO_3 production at the kidneys plays an important role in the control of blood pH. Because one of the secretory pathways is aldosterone sensitive, aldosterone stimulates H^+ secretion. Prolonged aldosterone stimulation can cause *alkalosis*, or abnormally high blood pH.

In Chapter 25, we noted that the production of lactic acid and ketone bodies during the postabsorptive state can cause acidosis. Under these conditions, the PCT and DCT deaminate amino acids in reactions that strip off the amino groups (-NH2). The

-

reaction sequence ties up H$^+$ and yields both **ammonium ions** (NH4$^+$) and HCO3 . As indicated in Figure 26–14c•, the ammonium ions are then pumped into the tubular fluid by sodium-linked countertransport, and the bicarbonate ions enter the bloodstream by way of the peritubular fluid.

Tubular deamination thus has two major benefits: It provides carbon chains suitable for catabolism, and it generates bicarbonate ions that add to the buffering capabilities of plasma.

Reabsorption and Secretion along the Collecting System

The collecting ducts receive tubular fluid from many nephrons and carry it toward the renal sinus, through the concentration gradient in the medulla. The normal amount of water and solute loss in the collecting system is regulated in two ways:

- By aldosterone, which controls sodium ion pumps along most of the DCT and the proximal portion of the collecting system. As noted above, these actions are opposed by the natriuretic peptides.
- By ADH, which controls the permeability of the DCT and collecting system to water. The secretion of ADH is suppressed by the natriuretic peptides, and this—combined with its effects on aldosterone secretion and action—can dramatically increase urinary water losses.

The collecting system also has other reabsorptive and secretory functions, many of which are important to the control of body fluid pH.

Reabsorption in the Collecting System

Important examples of solute reabsorption in the collecting system include the following:

- **Sodium Ion Reabsorption.** The collecting system contains aldosterone-sensitive ion pumps that exchange Na^+ in tubular fluid for K^+ in peritubular fluid (see Figure 26–14b•).

- **Bicarbonate Reabsorption.** Bicarbonate ions are reabsorbed in exchange for chloride ions in the peritubular fluid (see Figure 26–14c•).
- **Urea Reabsorption.** The concentration of urea in the tubular fluid entering the collecting duct is relatively high. The fluid entering the papillary duct generally has the same osmotic concentration as that of interstitial fluid of the medulla—about 1200 mOsm > L—but contains a much higher concentration of urea. As a result, urea tends to diffuse out of the tubular fluid

and into the peritubular fluid in the deepest portion of the medulla.

Secretion in the Collecting System

The collecting system is an important site for the control of body fluid pH by means of the secretion of hydrogen or bicarbonate ions. If the pH of the peritubular fluid declines, carrier proteins pump hydrogen ions into the tubular fluid and reabsorb bicarbonate ions that help restore normal pH. If the pH of the peritubular fluid rises (a much less common event), the collecting system secretes bicarbonate ions and pumps hydrogen ions into the peritubular fluid. The net result is that the body eliminates a buffer and gains hydrogen ions that lower the pH. We will examine these responses in more detail in Chapter 27, when we consider acid–base balance.

100 Keys | Reabsorption involves a combination of diffusion, osmosis, channel-mediated diffusion, and active transport.

Many of these processes are independently regulated by local or hormonal mechanisms. The primary mechanism governing water reabsorption can be described as "water follows salt." Secretion is a selective, carrier-mediated process.

The Control of Urine Volume and Osmotic Concentration

Urine volume and osmotic concentration are regulated through the control of water reabsorption. Water is reabsorbed by osmosis in the proximal convoluted tubule and the descending limb of the loop of Henle. The water permeabilities of these regions cannot be adjusted, and water reabsorption occurs whenever the osmotic concentration of the peritubular fluid exceeds that of the tubular fluid. The ascending limb of the loop of Henle is impermeable to water, but 1–2 percent of the volume of water in the original filtrate is recovered during sodium ion reabsorption in the distal convoluted tubule and collecting system. Because these water movements cannot be prevented, they represent *obligatory water reabsorption*, which usually recovers 85 percent of the volume of filtrate produced.

The volume of water lost in urine depends on how much of the water in the remaining tubular fluid (15 percent of the filtrate volume, or roughly 27 liters per day) is reabsorbed along the DCT and collecting system. The amount can be precisely controlled by a process called *facultative water reabsorption*. Precise control is possible because these segments are relatively impermeable to water except in the presence of ADH. This hormone causes the appearance of special *water channels* in the apical cell membranes, dramatically enhancing the rate of osmotic water movement. The higher the circulating levels of ADH, the greater the number of water channels, and the greater the water permeability of these segments.

As noted earlier in this chapter, the tubular fluid arriving at the DCT has an osmotic concentration of only about 100 mOsml > L. In the presence of ADH, osmosis occurs, and water moves out of the DCT until the osmotic concentration of the tubular fluid equals that of the surrounding cortex (roughly 300 mOsm > L). The tubular fluid then flows along the collecting duct, which passes through the concentration gradient of the medulla. Additional water is then reabsorbed, and the urine reaching the minor calyx has an osmotic concentration closer to 1200 mOsml > L. Just how closely the osmotic concentration approaches 1200 mOsml > L depends on how much ADH is present.

Figure 26–15• diagrams the effects of ADH on the DCT and collecting system. In the absence of ADH (Figure 26–15a•), water is not reabsorbed in these segments, so all the fluid reaching the DCT is lost in the urine. The individual then produces large amounts of very dilute urine. That is just what happens in cases of *diabetes insipidus* l**p. 605**, in which urinary water losses may reach 24 liters per day and the urine osmotic concentration is 30–400 mOsm > L. As ADH levels rise (Figure 26–15b•), the DCT and collecting system become more permeable to water, the amount of water reabsorbed increases, and the urine osmotic concentration climbs. Under maximum ADH stimulation, the DCT and collecting system become so permeable to water that the osmotic concentration of the urine is equal to that of the deepest portion of the medulla. Note that the concentration of urine can never *exceed* that of the medulla, because the concentrating mechanism relies on osmosis. AM: Diuretics

The hypothalamus continuously secretes ADH at low levels, and the DCT and collecting system always have a significant degree of water permeability. The DCT normally reabsorbs roughly 9 liters of water per day, or about 5 percent of the original volume of filtrate produced by the glomeruli. At normal ADH levels, the collecting system reabsorbs roughly 16.8 liters per day, or about 9.3 percent of the original volume of filtrate. A healthy adult typically produces 1200 ml of urine per day (about 0.6 percent

of the filtrate volume), with an osmotic concentration of 800–1000 mOsm > L. The effects of ADH are opposed by those of the natriuretic peptides ANP and BNP. These hormones stimulate the production of a large volume of relatively dilute urine, soon restoring plasma volume to normal.

ı promote the loss of water in urine. The usual goal in diuretic therapy is a reduction in blood volume, blood pressure, extracellular fluid volume, or all three. The ability to control renal water losses with relatively safe and effective diuretics has saved the lives of many individuals, especially those with high blood pressure or congestive heart failure.

The Function of the Vasa Recta

The solutes and water reabsorbed in the medulla must be returned to the general circulation without disrupting the concentration gradient. This return is the function of the vasa recta. Blood entering the vasa recta has an osmotic concentration of approximately 300 mOsm > L. The blood descending into the medulla gradually increases in osmotic concentration as the solute concentration

-RET-iks) are drugs that

-

in the peritubular fluid rises. This increase in blood osmotic concentration involves both solute absorption and water loss, but solute absorption predominates, because the plasma proteins limit osmotic flow out of the blood. l**p. 723** Blood flowing toward the cortex gradually decreases in osmotic concentration as the solute concentration of the peritubular fluid declines. Again, this decrease involves a combination of solute diffusion and osmosis, but in this case osmosis predominates, because the presence of plasma proteins does not oppose the osmotic flow of water into the blood.

The net results are that (1) some of the solutes absorbed in the descending portion of the vasa recta do not diffuse out in the ascending portion and (2) more water moves into the ascending portion of the vasa recta than is moved out in the descending portion. Thus, the vasa recta carries both water and solutes out of the medulla. Under normal conditions, the removal of solutes and water by the vasa recta precisely balances the rates of solute reabsorption and osmosis in the medulla.

The Composition of Normal Urine

More than 99 percent of the 180 liters of filtrate produced each day by the glomeruli is reabsorbed and never reaches the renal pelvis. General characteristics of the remaining filtrate—normal urine—are listed in Table 26–5. However, the composition of the urine produced each day varies with the metabolic and hormonal events under way.

The composition and concentration of urine are two related but distinct properties. The *composition* of urine reflects the filtration, absorption, and secretion activities of the nephrons. Some compounds (such as urea) are neither actively excreted nor reabsorbed along the nephron. In contrast, organic nutrients are completely reabsorbed, and other compounds, such as creatinine, that are missed by the filtration process are actively secreted into the tubular fluid.

The processes mentioned in the previous paragraph determine the identities and amounts of materials excreted in urine. The *concentration* of these components in a given urine sample depends on the osmotic movement of water across the walls of the tubules and collecting ducts. Because the composition and concentration of urine vary independently, you can produce a small volume of concentrated urine or a large volume of dilute urine and still excrete the same amount of dissolved materials. As a result, physicians who are interested in a detailed assessment of renal function commonly analyze the urine produced over a 24hour period rather than testing a single urine sample.

Normal urine is a clear, sterile solution. Its yellow color results from the presence of the pigment urobilin, generated in the kidneys from the urobilinogens produced by intestinal bacteria and absorbed in the colon (see Figure 19–4•, p. 647). The evaporation of small molecules, such as ammonia, accounts for the characteristic odor of urine. Other substances not normally present, such as acetone or other ketone bodies, can also impart a distinctive smell. **Urinalysis**, the analysis of a urine sample, is a diagnostic tool of considerable importance, even in high-technology medicine. A standard urinalysis includes an assessment of the color and appearance of urine, two characteristics that can be determined without specialized equipment. In the 17th century, physicians classified the taste of the urine as sweet, salty, and so on, but quantitative analytical tests have long since replaced the taste-bud assay. Table 26–6 gives some typical values obtained from urinalysis. AM: Urinalysis

Summary: Renal Function

Table 26–4, p. 965, lists the functions of each segment of the nephron and collecting system. Figure 26–16• provides a functional overview that summarizes the major steps involved in the reabsorption of water and the production of concentrated urine:

Step 1 The filtrate produced at the renal corpuscle has the same osmotic concentration as does plasma—about 300 mOsm > L. It has the composition of blood plasma, minus the plasma proteins.

Step 2 In the PCT, the active removal of ions and organic substrates produces a continuous osmotic flow of water out of the tubular fluid. This process reduces the volume of filtrate but keeps the solutions inside and outside the tubule isotonic. Between 60 and 70 percent of the filtrate volume has been reabsorbed before the tubular fluid reaches the descending limb of the loop of Henle.

Step 3 In the PCT and descending limb of the loop of Henle, water moves into the surrounding peritubular fluids, leaving a small volume (15–20 percent of the original filtrate) of highly concentrated tubular fluid. The reduction in volume has occurred by obligatory water reabsorption.

Step 4 The thick ascending limb is impermeable to water and solutes. The tubular cells actively transport and out of the tubular fluid, thereby lowering the osmotic concentration of tubular fluid without affecting its volume. The tubular fluid reaching the distal convoluted tubule is hypotonic relative to the peritubular fluid, with an osmotic concentration of only about 100 mOsmL. Because only and are removed, urea accounts for a significantly higher proportion of the total osmotic concentration at the end of the loop than it did at the start of it.

Step 5 The final adjustments in the composition of the tubular fluid are made in the DCT and the collecting system. Although the DCT and collecting duct are generally impermeable to solutes, the osmotic concentration of tubular fluid can be adjusted through active transport (reabsorption or secretion). Some of these transport activities are hormonally regulated.

Step 6 The final adjustments in the volume and osmotic concentration of the tubular fluid are made by controlling the water permeabilities of the distal portions of the DCT and the collecting system. These segments are relatively impermeable to water unless exposed to ADH. Under maximum ADH stimulation, urine volume is at a minimum, and urine osmotic concentration is equal to that of the peritubular fluid in the deepest portion of the medulla (roughly 1200 mOsmL).

Step 7 The vasa recta absorbs solutes and water reabsorbed by the loop of Henle and the collecting ducts, thereby maintaining the concentration gradient of the medulla.

Concept Check

What effect would increased amounts of aldosterone have on the concentration in urine?

What effect would a decrease in the concentration of filtrate have on the pH of tubular fluid?

How would the lack of juxtamedullary nephrons affect the volume and osmotic concentration of urine?

Why does a decrease in the amount of in the distal convoluted tubule lead to an increase in blood pressure?

Answers begin on p. A–1

Review reabsorption and secretion at the DCT and collecting duct on the **IP CD-ROM: Urinary System/ Late Filtrate Pro**
cessing.

Urine Transport, Storage, and Elimination

Objectives

- Describe the structures and functions of the ureters, urinary bladder, and urethra.
- Discuss the voluntary and involuntary regulation of urination and describe the micturition reflex.

Filtrate modification and urine production end when the fluid enters the renal pelvis. The urinary tract (the ureters, urinary bladder, and urethra) is responsible for the transport, storage, and elimination of urine. A **pyelogram** (P-el--gram) is an image of the urinary system, obtained by taking an x-ray of the kidneys after a radiopaque compound has been administered. Such an image provides an orientation to the relative sizes and positions of the main structures (Figure 26–17•). The sizes of the minor and major calyces, the renal pelvis, the ureters, the urinary bladder, and the proximal portion of the urethra are somewhat variable, because these regions are lined by a *transitional epithelium* that can tolerate cycles of distension and contraction without damage. l**p. 114**

Clinical Note

Local blockages of the collecting ducts or ureters can result from the formation of *casts*—small blood clots, epithelial cells, lipids, or other materials. Casts are commonly eliminated in urine and are visible in microscopic analyses of urine samples. **Renal calculi** (KAL-k-l), or *kidney stones,* form within the urinary tract from calcium deposits, magnesium salts, or crystals of uric acid. The condition is called *nephrolithiasis* (nef-r-li-TH-a-sis). The blockage of the urinary passage by a stone or by other means (such as external com pression) results in **urinary obstruction**, a serious problem because, in addition to causing pain, it reduces or prevents filtration in the affected kidney by elevating the capsular hydrostatic pressure.

Calculi are generally visible on an x-ray. If peristalsis and fluid pressures are insufficient to dislodge them, they must be either surgically removed or destroyed. One interesting nonsurgical procedure involves disintegrating the stones with a *lithotripter*, a device originally developed from machines used to de-ice airplane wings. Lithotripters focus sound waves on the stones, breaking them into smaller fragments that can be passed in the urine. Another nonsurgical approach is the insertion of a catheter armed with a laser that can shatter calculi with intense light beams.

The Ureters

The ureters are a pair of muscular tubes that extend from the kidneys to the urinary bladder—a distance of about 30 cm (12 in.). Each ureter begins at the funnel-shaped renal pelvis (see Figure 26–4•, p. 954). The ureters extend inferiorly and medially, passing over the anterior surfaces of the *psoas major muscles* (see Figure 26–3•, p. 954). The ureters are retroperitoneal and are firmly attached to the posterior abdominal wall. The paths taken by the ureters in men and women are different, due to variations in the nature, size, and position of the reproductive organs. In males, the base of the urinary bladder lies between the rectum and the pubic symphysis (Figure 26–18a•); in females, the base of the urinary bladder sits inferior to the uterus and anterior to the vagina (Figure 26–18b•).

The ureters penetrate the posterior wall of the urinary bladder without entering the peritoneal cavity. They pass through the bladder wall at an oblique angle, and the **ureteral openings** are slitlike rather than rounded (Figure 26–18c•). This shape helps prevent the backflow of urine toward the ureter and kidneys when the urinary bladder contracts.

Anatomy 360 | Review the anatomy of the ureters on the **Anatomy 360 CD-ROM: Urinary System/Ureters.**

Histology of the Ureters

The wall of each ureter consists of three layers (Figure 26–19a•): (1) an inner mucosa, comprising a transitional epithelium and the surrounding lamina propria; (2) a middle muscular layer made up of longitudinal and circular bands of smooth muscle; and

(3) an outer connective-tissue layer that is continuous with the fibrous renal capsule and peritoneum. About every 30 seconds, a peristaltic contraction begins at the renal pelvis and sweeps along the ureter, forcing urine toward the urinary bladder.

The Urinary Bladder

The urinary bladder is a hollow, muscular organ that functions as a temporary reservoir for the storage of urine (see Figure 26–18c•). The dimensions of the urinary bladder vary with its state of distension, but a full urinary bladder can contain as much as a liter of urine.

The superior surfaces of the urinary bladder are covered by a layer of peritoneum; several peritoneal folds assist in stabilizing its position. The **middle umbilical ligament** extends from the anterior, superior border toward the umbilicus (navel). The **lateral umbilical ligaments** pass along the sides of the bladder to the umbilicus. These fibrous cords are the vestiges of the two *umbilical*

arteries, which supplied blood to the placenta during embryonic and fetal development. l**p. 753** The urinary bladder’s posterior, inferior, and anterior surfaces lie outside the peritoneal cavity. In these areas, tough ligamentous bands anchor the urinary bladder to the pelvic and pubic bones.

In sectional view, the mucosa lining the urinary bladder is usually thrown into folds, or **rugae**, that disappear as the bladder fills. The triangular area bounded by the openings of the ureters and the entrance to the urethra constitutes a region called the **trigone** (TR-gn) of the urinary bladder. There, the mucosa is smooth and very thick. The trigone acts as a funnel that channels urine into the urethra when the urinary bladder contracts.

The urethral entrance lies at the apex of the trigone, at the most inferior point in the urinary bladder. The region surrounding the urethral opening, known as the **neck** of the urinary bladder, contains a muscular **internal urethral sphincter**, or *sphincter vesicae*. The smooth muscle fibers of this sphincter provide involuntary control over the discharge of urine from the bladder. The urinary bladder is innervated by postganglionic fibers from ganglia in the hypogastric plexus and by parasympathetic fibers from intramural ganglia that are controlled by branches of the pelvic nerves.

Anatomy 360 | Review the anatomy of the urinary bladder on the **Anatomy 360 CD-ROM: Urinary System/Urinary Bladder.**

Histology of the Urinary Bladder

The wall of the urinary bladder contains mucosa, submucosa, and muscularis layers (Figure 26–19b•). The muscularis layer consists of inner and outer layers of longitudinal smooth muscle, with a circular layer between the two. Collectively, these layers form the powerful **detrusor** (de-TROO-sor) **muscle** of the urinary bladder. Contraction of this muscle compresses the urinary bladder and expels its contents into the urethra. AM: Bladder Cancer

The Urethra

The urethra extends from the neck of the urinary bladder to the exterior of the body. The urethrae of males and females differ in length and in function. In males, the urethra extends from the neck of the urinary bladder to the tip of the penis (see Figure 26–18a,c•), a distance that may be 18–20 cm (7–8 in.). The male urethra can be subdivided into three portions: the prostatic urethra, the membranous urethra, and the spongy urethra. The **prostatic urethra** passes through the center of the prostate gland. The **membranous urethra** includes the short segment that penetrates the *urogenital diaphragm,* the muscular floor of the pelvic cavity. The **spongy urethra**, or *penile* (P-nl) *urethra*, extends from the distal border of the urogenital diaphragm to the external opening, or **external urethral orifice**, at the tip of the penis. In females, the urethra is very short, extending 3–5 cm (1–2 in.) from the bladder to the vestibule (see Figure 26–18b•). The external urethral orifice is near the anterior wall of the vagina.

In both sexes, where the urethra passes through the urogenital diaphragm, a circular band of skeletal muscle forms the **external urethral sphincter**. This muscular band acts as a valve.

The external urethral sphincter, which is under voluntary control via the perineal branch of the pudendal nerve, has a resting muscle tone and must be voluntarily relaxed to permit micturition.

Anatomy 360 | Review the anatomy of the urethra on the **Anatomy 360 CD-ROM: Urinary System/Urethra.**

Histology of the Urethra

The urethral lining consists of a stratified epithelium that varies from transitional at the neck of the urinary bladder, to stratified columnar at the midpoint, to stratified squamous near the external urethral orifice. The lamina propria is thick and elastic, and the mucous membrane is thrown into longitudinal folds (Figure 26–19c•). Mucin-secreting cells are located in the epithelial pockets. In males, the epithelial mucous glands may form tubules that extend into the lamina propria. Connective tissues of the lamina propria anchor the urethra to surrounding structures. In females, the lamina propria contains an extensive network of veins, and the entire complex is surrounded by concentric layers of smooth muscle. AM: Urinary Tract Infections

The Micturition Reflex and Urination

Urine reaches the urinary bladder by peristaltic contractions of the ureters. The process of urination is coordinated by the **micturition reflex** (Figure 26–20•).

Stretch receptors in the wall of the urinary bladder are stimulated as the bladder fills with urine. Afferent fibers in the pelvic nerves carry the impulses generated to the sacral spinal cord. The increased level of activity in the fibers (1) facilitates parasympathetic motor neurons in the sacral spinal cord and (2) stimulates interneurons that relay sensations to the thalamus and then, through projection fibers, to the cerebral cortex. As a result, you become aware of the fluid pressure in your urinary bladder.

The urge to urinate generally appears when the bladder contains about 200 ml of urine. The micturition reflex begins to function when the stretch receptors have provided adequate stimulation to parasympathetic preganglionic motor neurons (STEP 1). Action potentials carried by efferent fibers within the pelvic nerves then stimulate ganglionic neurons in the wall of the urinary bladder (STEP 2a). These neurons in turn stimulate sustained contraction of the detrusor muscle (STEP 3a).

This contraction elevates fluid pressure in the urinary bladder, but urine ejection does not occur unless both the internal and external urethral sphincters are relaxed. An awareness of the fullness of the urinary bladder depends on interneurons that relay information from stretch receptors to the thalamus (STEP 2b) and from the thalamus to the cerebral cortex (STEP 3b). The relaxation of the external urethral sphincter occurs under voluntary control; when the external urethral sphincter relaxes, so does the internal urethral sphincter, and urination occurs (STEP 4). If the external urethral sphincter does not relax, the internal urethral sphincter remains closed, and the urinary bladder gradually relaxes.

A further increase in bladder volume begins the cycle again, usually within an hour. Each increase in urinary volume leads to an increase in stretch receptor stimulation that makes the sensation more acute. Once the volume exceeds 500 ml, the bladder contractions triggered by the micturition reflex may generate enough pressure to force open the internal urethral sphincter. This opening leads to a reflexive relaxation of the external urethral sphincter, and urination occurs despite voluntary opposition or potential inconvenience. At the end of a typical micturition, less than 10 ml of urine remains in the bladder.

Infants lack voluntary control over urination, because the necessary corticospinal connections have yet to be established. Accordingly, “toilet training” before age 2 often involves training the parent to anticipate the timing of the reflex rather than training the child to exert conscious control.

Incontinence (in-KON-ti-nens) is the inability to control urination voluntarily. Trauma to the internal or external urethral sphincter can contribute to incontinence in otherwise healthy adults. For example, some mothers develop *stress incontinence* if childbirth overstretches and damages the sphincter muscles. In this condition, elevated intra-abdominal pressures—caused, for example, by a cough or sneeze—can overwhelm the sphincter muscles, causing urine to leak out. Incontinence can also develop in older individuals due to a general loss of muscle tone.

Damage to the central nervous system, the spinal cord, or the nerve supply to the urinary bladder or external urethral sphincter can also produce incontinence. For example, incontinence commonly accompanies Alzheimer’s disease or spinal cord damage. In most cases, the affected individual develops an *automatic bladder*. The micturition reflex remains intact, but voluntary control of the external urethral sphincter is lost, so the person cannot prevent the reflexive emptying of the urinary bladder. Damage to the pelvic nerves can abolish the micturition reflex entirely, because those nerves carry both afferent and efferent fibers of this reflex arc. The urinary bladder then becomes greatly distended with urine and remains filled to capacity while the excess urine flows into the urethra in an uncontrolled stream. The insertion of a catheter is often needed to facilitate the discharge of urine.

Aging and the Urinary System

In general, aging is associated with an increased incidence of kidney problems. One example— *nephrolithiasis*, the formation of calculi, or kidney stones—was described earlier in the chapter (page 983). Other age-related changes in the urinary system include the following:

- **A Decline in the Number of Functional Nephrons.** The total number of kidney nephrons drops by 30–40 percent between ages 25 and 85.
- **A Reduction in the GFR.** This reduction results from fewer glomeruli, cumulative damage to the filtration apparatus in the remaining glomeruli, and diminished renal blood flow.
- **A Reduced Sensitivity to ADH.** With age, the distal portions of the nephron and collecting system become less responsive to ADH. Reabsorption of water and sodium ions occurs at a reduced rate, and more sodium ions are lost in urine.
- **Problems with the Micturition Reflex.** Three factors are involved in such problems: (1) The sphincter muscles lose muscle tone and become less effective at voluntarily retaining urine. This leads to incontinence, often involving a slow leakage of

urine.

(2) The ability to control micturition can be lost after a stroke, Alzheimer's disease, or other CNS problems affecting the cerebral cortex or hypothalamus. (3) In males, *urinary retention* may develop if enlargement of the prostate gland compresses the urethra and restricts the flow of urine.

Concept Check

What effect would a high-protein diet have on the composition of urine?

Obstruction of a ureter by a kidney stone would interfere with the flow of urine between which two points?

The ability to control the micturition reflex depends on your ability to control which muscle?

Answers begin on p. A–1

Integration with Other Systems

The urinary system is not the only organ system involved in excretion. Indeed, the urinary, integumentary, respiratory, and digestive systems are together regarded as an anatomically diverse **excretory system** whose components perform all the excretory functions that affect the composition of body fluids:

- **Integumentary System.** Water losses and electrolyte losses in sensible perspiration can affect the volume and composition of the plasma. The effects are most apparent when losses are extreme, such as during peak sweat production. Small amounts of metabolic wastes, including urea, also are eliminated in perspiration.
- **Respiratory System.** The lungs remove the carbon dioxide generated by cells. Small amounts of other compounds, such as acetone and water, evaporate into the alveoli and are eliminated when you exhale.
- **Digestive System.** The liver excretes small amounts of metabolic waste products in bile, and you lose a variable amount of water in feces.

These excretory activities have an impact on the composition of body fluids. The respiratory system, for example, is the primary site of carbon dioxide excretion. Even though these excretory activities have an effect on the composition of body fluids, the excretory functions of these systems are not regulated as closely as are those of the kidneys. Under normal circumstances, the effects of integumentary and digestive excretory activities are minor compared with those of the urinary system.

Figure 26–21• summarizes the functional relationships between the urinary system and other systems. We will explore many of these relationships further in Chapter 27 when we consider major aspects of fluid, pH, and electrolyte balance.

Clinical Patterns

Clinical conditions involving the urinary system can be sorted into the same general categories as disorders affecting other systems: (1) degenerative disorders, such as renal failure (p. 984) from diabetes or hypertension; (2) congenital disorders; (3) inflammatory and infectious disorders, such as urinary tract infections; (4) tumors of the urinary system; and (5) immune disorders, such as glomerulonephritis (p. 960). Several other disorders involve the urinary system but reflect ongoing problems with other systems. Examples include problems with fluid, electrolyte, and acid–base balance that are discussed in Chapter 27. The *Applications Manual* has extended discussions of each of these categories of urinary system disorders. It also discusses common tests of renal function, and gives examples of the calculations involved in estimating renal blood flow, renal clearance, and GFR.

Chapter Review

Selected Clinical Terminology

aminoaciduria: Amino acid loss in urine; the most common form is *cystinuria*. (p. 963 and [AM])

calculi: Insoluble deposits that form within the urinary tract from calcium salts, magnesium salts, or uric acid. (p. 983)

clearance test: A procedure that estimates the GFR by comparing plasma and renal concentrations of a specific solute, such as creatinine. (p. 967 and [AM]) **diuretics:** Drugs that promote fluid loss in urine. (p. 978 and [AM]) **glomerulonephritis:** An inflammation of the renal cortex. (p. 960) **hematuria:** The presence of blood in urine. (p. 969 and [AM]) **hemodialysis:** A technique in which an artificial membrane is used to regulate the composition of blood when kidney function is seriously impacted. [AM] **incontinence:** An inability to control urination voluntarily. (p. 987) **polycystic kidney disease:** An inherited abnormality that affects the development and structure of kidney tubules. [AM] **proteinuria:** The presence of protein in urine. (p. 969 and [AM]) **pyelogram:** An x-ray image of the kidneys after a radiopaque compound has been administered. (p. 982 and [AM]) **renal failure:** An inability of the kidneys to excrete wastes in sufficient quantities to maintain homeostasis. (p. 984) **urinalysis:** A physical and chemical assessment of urine. (p. 978) **urinary obstruction:** A blockage of the urinary tract. (p. 983)

Study Outline

An Overview of the Urinary System p. 952

1. The two major functions of the **urinary system** are *excretion*—the removal of organic waste products from body fluids—and -*elimination*—the discharge of these waste products into the environment. Other functions include regulating blood volume and pressure by adjusting the volume of water lost and releasing hormones; regulating plasma concentrations of ions; helping to stabilize blood pH; conserving nutrients; and assisting the liver in detoxifying poisons and, during starvation, deaminating amino acids so that they can be catabolized by other tissues.

2. The urinary system includes the **kidneys**, the **ureters**, the **urinary bladder**, and the

urethra. The kidneys produce **urine**, a fluid containing water, ions, and soluble compounds. During **urination** (**micturition**), urine is forced out of the body. *(Figure 26–1)*

The Kidneys p. 952

1. The left kidney extends superiorly slightly more than the right kidney. Both kidneys and the adrenal gland that overlies each are retroperitoneal. *(Figures 26–1, 26–2, 26–3)*

2. The **hilum**, a medial indentation, provides entry for the *renal artery* and *renal nerves* and exit for the *renal vein* and the ureter. *(Figures -26–3, 26–4)*

Sectional Anatomy of the Kidneys p. 953

The superficial portion of the kidney, the cortex, surrounds the **medulla**. The ureter communicates with the **renal pelvis**, a chamber that branches into two **major calyces**. Each major calyx is connected to four or five **minor calyces**, which enclose the **renal papillae**.*(Figure 26–4)*

Blood Supply and Innervation of the Kidneys p. 953

4. The blood supply to the kidneys includes the **renal**, **segmental**, **interlobar**, **arcuate**, and **interlobular arteries**. *(Figure 26–5)*

5. The **renal nerves**, which innervate the kidneys and ureters, are dominated by sympathetic postganglionic fibers.

Anatomy 360 | Urinary System/Kidney

The Nephron p. 956

6. The **nephron** (the basic functional unit in the kidney) consists of the **renal corpuscle** and **renal tubule**. The renal tubule is long and narrow and divided into the *proximal convoluted tubule*, the *loop of Henle*, and the *distal convoluted tubule*. **Filtrate** is produced at the renal corpuscle. The nephron empties **tubular fluid** into the **collecting system**, consisting of **collecting ducts** and **papillary ducts**. *(Figures 26–6, 26–7)*

7. Nephrons are responsible for the production of filtrate, the reabsorption of organic nutrients, the reabsorption of water and ions, and the secretion into the tubular fluid of waste products missed by filtration. *(Summary Table 26–1)*

8. Roughly 85 percent of the nephrons are **cortical nephrons**, located in the renal cortex. **Juxtamedullary nephrons** are closer to the renal medulla, with their *loops of Henle* extending deep into the **renal pyramids**. *(Figure 26–7)*

9. Blood travels from the efferent arteriole to the **peritubular capillaries** and the **vasa recta**. *(Figure 26–7)*

100 Keys | p. 959

10. The renal tubule begins at the renal corpuscle and includes a knot of intertwined capillaries called the **glomerulus**, surrounded by **Bowman's capsule**. Blood arrives at the glomerulus via the **afferent arteriole** and departs in the **efferent arteriole**. *(Figure 26–8)*

11. At the glomerulus, **podocytes** cover the **lamina densa** of the capillaries that project into the **capsular space**. The **pedicels** of the podocytes are separated by narrow **filtration slits**. *(Figure 26–8)*

12. The **proximal convoluted tubule (PCT)** actively reabsorbs nutrients, plasma proteins, and ions from filtrate. These substances are released into the **peritubular fluid**, which surrounds the nephron. *(Figure 26–6)*

13. The **loop of Henle** includes a **descending limb** and an **ascending limb**; each limb contains a **thick segment** and a **thin segment**. The ascending limb delivers fluid to the **distal convoluted tubule (DCT)**, which actively secretes ions, toxins, and drugs, and reabsorbs sodium ions from the tubular fluid. *(Figures 26–6, 26–7)*

Principles of Renal Physiology p. 961

Urine production maintains homeostasis by regulating the blood volume and composition. In the process, organic waste products— notably urea, creatinine, and uric acid—are excreted.

Basic Processes of Urine Formation p. 961

2. Urine formation involves **filtration**, **reabsorption**, and **secretion**.

3. Four types of *carrier-mediated transport* (*facilitated diffusion*, *active transport*, *cotransport*, and *countertransport*) are involved in modifying filtrate. The saturation limit of a carrier protein is its **transport maximum**, which determines the **renal threshold—**the plasma concentration at which various compounds will appear in urine. *(Table 26–2)*

4. The transport maximum determines the renal threshold for the reabsorption of substances in tubular fluid. *(Table 26–3)*

An Overview of Renal Function p. 963

Most regions of the nephron perform a combination of reabsorption and secretion. *(Figure 26–9, Summary Table 26–4)*

Renal Physiology: Filtration at the Glomerulus p. 965 Filtration Pressures p. 966

Glomerular filtration occurs as fluids move across the wall of the glomerulus into the capsular space in response to the **glomerular hydrostatic pressure (GHP)—**the hydrostatic (blood) pressure in the glomerular capillaries. This movement is opposed by the **capsular hydrostatic pressure (CsHP)** and by the **blood colloid osmotic pressure (BCOP)**. The **filtration pressure (FP)** at the glomerulus is the difference between the blood pressure and the opposing capsular and osmotic pressures. *(Figure 26–10)*

The Glomerular Filtration Rate p. 967

The **glomerular filtration rate (GFR)** is the amount of filtrate produced in the kidneys each minute. Any factor that alters the filtration pressure acting across the glomerular capillaries will change the GFR and affect kidney function.

Control of the GFR p. 967

A drop in filtration pressures stimulates the **juxtaglomerular apparatus (JGA)** to release renin and erythropoietin.

(Figure 26–11)

Sympathetic activation (1) produces a powerful vasoconstriction of the afferent arterioles, decreasing the GFR and slowing the production of filtrate, (2) alters the GFR by changing the regional pattern of blood circulation, and (3) stimulates the release of renin by the juxtaglomerular apparatus. *(Figure 26–11)*

100 Keys | p. 969

Urinary System/Glomerular Filtration

Renal Physiology: Reabsorption and Secretion p. 969 Reabsorption and Secretion at the PCT p. 970

1. Glomerular filtration produces a filtrate with a composition similar to blood plasma, but with few, if any, plasma proteins.

2. The cells of the PCT normally reabsorb sodium and other ions, water, and almost all the organic nutrients that enter the filtrate. These cells also secrete various substances into the tubular fluid. *(Figure 26–12)*

The Loop of Henle and Countercurrent Multiplication p. 970

Water and ions are reclaimed from tubular fluid by the loop of Henle. A concentration gradient in the renal medulla encourages the osmotic flow of water out of the tubular fluid. The **countercurrent multiplication** between the ascending and descending limbs of the loop of Henle helps create the osmotic gradient in the medulla. As water is lost by osmosis and the volume of tubular fluid decreases, the urea concentration rises. *(Figure 26–13)*

Urinary System/Early Filtrate Processing

Reabsorption and Secretion at the DCT p. 973

The DCT performs final adjustments by actively secreting or absorbing materials. Sodium ions are actively absorbed, in exchange for potassium or hydrogen ions discharged into tubular fluid. Aldosterone secretion increases the rate of sodium reabsorption and potassium loss. *(Figure 26–14)*

Reabsorption and Secretion along the Collecting System p. 975

The amount of water and solutes in the tubular fluid of the collecting ducts is further regulated by aldosterone and ADH secretions.

(Figure 26–14)

100 Keys | p. 976

The Control of Urine Volume and Osmotic Concentration p. 976

Urine volume and osmotic concentration are regulated by controlling water reabsorption. Precise control over this occurs via *facultative water reabsorption. (Figure 26–15)*

The Function of the Vasa Recta p. 978

Normally, the removal of solutes and water by the vasa recta precisely balances the rates of reabsorption and osmosis in the renal medulla.

The Composition of Normal Urine p. 978

8. More than 99 percent of the filtrate produced each day is reabsorbed before reaching the renal pelvis. *(Table 26–5)*

9. *Urinalysis* is the chemical and physical analysis of a urine sample. *(Table 26–6)*

Summary: Renal Function p. 980

10. Each segment of the nephron and collecting system contributes to the production of concentrated urine. *(Figure 26–16, Summary Table 26–4)*

Urinary System/Late Filtrate Processing

Urine Transport, Storage, and Elimination p. 982

Urine production ends when tubular fluid enters the renal pelvis. The rest of the urinary system is responsible for transporting, storing, and eliminating urine. *(Figure 26–17)*

The Ureters p. 983

The ureters extend from the renal pelvis to the urinary bladder. Peristaltic contractions by smooth muscles move the urine along the tract. *(Figures 26–18, 26–19)*

Anatomy 360 | Urinary System/Ureters

The Urinary Bladder p. 984

The urinary bladder is stabilized by the **middle umbilical ligament** and the **lateral umbilical ligaments**. Internal features include the **trigone**, the **neck**, and the **internal urethral sphincter**. The mucosal lining contains prominent **rugae** (folds). Contraction of the **detrusor muscle** compresses the urinary bladder and expels urine into the urethra. *(Figures 26–18, 26–19)*

Anatomy 360 | Urinary System/Urinary Bladder

The Urethra p. 985

In both sexes, where the urethra passes through the *urogenital diaphragm*, a circular band of skeletal muscles forms the **external urethral sphincter**, which is under voluntary control. *(Figure 26–18)*

Anatomy 360 | Urinary System/Urethra

The Micturition Reflex and Urination p. 986

Urination is coordinated by the **micturition reflex**, which is initiated by stretch receptors in the wall of the urinary bladder. Voluntary urination involves coupling this reflex with the voluntary relaxation of the external urethral sphincter, which allows the opening of the **internal urethral sphincter**. *(Figure 26–20)*

Aging and the Urinary System p. 987

Aging is generally associated with increased kidney problems. Age-related changes in the urinary system include (1) declining numbers of functional nephrons, (2) reduced GFR, (3) reduced sensitivity to ADH, and (4) problems with the micturition reflex. (**Urinary retention** may develop in men whose prostate gland is enlarged.)

Integration with Other Systems p. 988

The urinary system is the major component of an *excretory system* that includes the integumentary system, the respiratory system, and the digestive system.

Review Questions

My A&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

The basic functional unit of the kidney is the

(a) nephron **(b)** renal corpuscle

(c) glomerulus **(d)** loop of Henle

(e) filtration unit

The process of urine formation involves all of the following, *except*

(a) filtration of plasma

(b) reabsorption of water

(c) reabsorption of certain solutes

(d) secretion of wastes

(e) secretion of excess lipoprotein and glucose molecules

The glomerular filtration rate is regulated by all of the following, *except*

(a) autoregulation **(b)** sympathetic neural control

(c) cardiac output **(d)** autogensin II

(e) the hormone ADH

The distal convoluted tubule is an important site for

(a) active secretion of ions

(b) active secretion of acids and other materials

(c) selective reabsorption of sodium ions from the tubular fluid

(d) a, b, and c are correct

Changing the diameter of the afferent and efferent arterioles to alter the GFR can be an example of ______________ regulation.

(a) hormonal **(b)** autonomic

(c) autoregulation or local **(d)** a, b, and c are correct

6. What is the primary function of the urinary system?

7. What structures are components of the urinary system?

8. Trace the pathway of the protein-free filtrate from the time it is produced in the renal corpuscle until it drains into the renal pelvis in the form of urine. (Use arrows to indicate the direction of flow.)

9. Name the segments of the nephron distal to the renal corpuscle and state the function(s) of each.

10. What is the function of the juxtaglomerular apparatus?

11. Using arrows, trace a drop of blood from its entry into the renal artery until its exit via a renal vein.

12. Name and define the three distinct processes involved in the production of urine.

13. What are the primary effects of angiotensin II on kidney function and regulation?

14. Which parts of the urinary system are responsible for the transport, storage, and elimination of urine?

LEVEL 2 Reviewing Concepts

15. When the renal threshold for a substance exceeds its tubular maximum

(a) more of the substance will be filtered

(b) more of the substance will be reabsorbed

(c) more of the substance will be secreted

(d) the amount of substance that exceeds the tubular maximum will be found in the urine

(e) both a and d

16. Sympathetic activation of the nerve fibers in the nephron causes

(a) the regulation of glomerular blood flow and pressure

(b) the stimulation of renin release from the juxtaglomerular apparatus

(c) the direct stimulation of water and Na^+ reabsorption

(d) a, b, and c are correct

17. Sodium reabsorption in the DCT and cortical portion of the collecting system is accelerated by the secretion of

(a) ADH

(b) renin

(c) aldosterone

(d) erythropoietin

18. When ADH levels rise,

(a) the amount of water reabsorbed increases

(b) the DCT becomes impermeable to water

(c) the amount of water reabsorbed decreases

(d) sodium ions are exchanged for potassium ions

19. The control of blood pH by the kidneys during acidosis involves

(a) the secretion of hydrogen ions and reabsorption of bicarbonate ions from the tubular fluid

(b) a decrease in the amount of water reabsorbed

(c) hydrogen ion reabsorption and bicarbonate ion loss

(d) potassium ion secretion

20. How are proteins excluded from filtrate? Why?

21. What interacting controls stabilize the glomerular filtration rate (GFR)?

22. What primary changes occur in the composition and concentration of filtrate as a result of activity in the proximal convoluted tubule?

23. What two functions does the countercurrent mechanism perform for the kidney?

24. Describe the micturition reflex.

LEVEL 3 Critical Thinking and Clinical Applications

25. In a normal kidney, which of the following conditions would cause an increase in the glomerular filtration rate (GFR)?

(a) constriction of the afferent arteriole

(b) a decrease in the pressure of the glomerulus

(c) an increase in the capsular hydrostatic pressure

(d) a decrease in the concentration of plasma proteins in the blood

(e) a decrease in the net glomerular filtration process

26. In response to *excess* water in the body,

(a) antidiuretic hormone is secreted by the anterior lobe of the pituitary gland

(b) the active transport mechanisms in the ascending limb of the loop of Henle cease functioning

(c) the permeability of the distal convoluted tubules and collecting ducts to water is decreased

(d) the permeability of the ascending limb of the loop of Henle is increased

(e) the glomerular filtration rate is reduced

27. Sylvia is suffering from severe edema in her arms and legs. Her physician prescribes a diuretic (a substance that will increase the volume of urine produced). Why might this help to alleviate Sylvia’s problem?

28. David’s grandfather suffers from hypertension. His doctor tells him that part of his problem stems from renal arteriosclerosis. Why would this cause hypertension?

29. *Mannitol* is a sugar that is filtered, but not reabsorbed, by the kidneys. What effect would drinking a solution of mannitol have on the volume of urine produced?

30. The drug *Diamox* is sometimes used in the treatment of mountain sickness. Diamox inhibits the action of carbonic anhydrase in the proximal convoluted tubule. Polyuria (the elimination of an unusually large volume of urine) is a side effect associated with the medication. Why does this symptom occur?

| SUMMARY TABLE 26–1 | THE ORGANIZATION OF THE NEPHRON AND COLLECTING SYSTEM

Region Length Diameter Primary Function Histological Characteristics

NEPHRON

Renal corpuscle 150–250 mm 150–250 mm Filtration of plasma Glomerulus (capillary knot),

(spherical) supporting cells, and lamina densa, enclosed by Bowman's capsule; visceral epithelium (podocytes) and parietal epithelium separated by capsular space

Renal tubule

Proximal convoluted 14 mm 60 mm Reabsorption of ions, Cuboidal cells with microvilli
tubule (PCT) organic molecules,
vitamins, water; secretion
of drugs, toxins, acids

Loop of Henle 30 mm Squamous or low cuboidal cells
15 mm Descending limb: reabsorption of water from tubular fluid
30 mm Ascending limb: reabsorption of ions; assists in creation of a concentration gradient in the medulla
Distal convoluted tubule (DCT) 5 mm 30–50 mm Reabsorption of sodium Cuboidal cells with few if any ions and calcium ions; microvilli secretion of acids, ammonia, drugs, toxins

COLLECTING SYSTEM

Collecting duct 15 mm 50–100 mm Reabsorption of water, Cuboidal to columnar cells sodium ions; secretion or reabsorption of bicarbonate ions or hydrogen ions

Papillary duct 5 mm 100–200 mm Conduction of tubular fluid Columnar cells to minor calyx; contributes to concentration gradient of the medulla

| SUMMARY TABLE 26–4 | RENAL STRUCTURES AND THEIR FUNCTIONS

Segment General Functions

Renal corpuscle *Filtration* of plasma; generates approximately 180 L > day of filtrate similar in composition to blood plasma without plasma proteins

Proximal convoluted *Reabsorption* of 60–70% of the **tubule (PCT)** water (108–116 L > day), 99–100% of the organic substrates, and 60–70% of the sodium and chloride ions in the original filtrate

Loop of Henle	*Reabsorption* of 25% of the water (45 L day) and 20–25% of the > sodium and chloride ions present in the original filtrate; creation of the concentration gradient in the medulla
Distal convoluted tubule (DCT)	*Reabsorption* of a variable amount of water (usually 5%, or 9 L day), > under ADH stimulation, and a variable amount of sodium ions, under aldosterone

stimulation

Collecting system *Reabsorption* of a variable amount of water (usually 9.3%, or 16.8 L > day) under ADH stimulation, and a variable amount of sodium ions, under aldosterone stimulation

Peritubular capillaries *Redistribution* of water and solutes reabsorbed in the cortex

Vasa recta *Redistribution* of water and solutes reabsorbed in the medulla and stabilization of the concentration gradient of the medulla

TABLE 26–5 General Characteristics of Normal Urine

Specific Functions

Filtration of water, inorganic and organic solutes from plasma; retention of plasma proteins and blood cells

Reabsorption: Active: glucose, other simple sugars, amino acids, vitamins, ions (including sodium, potassium, calcium, magnesium, phosphate, and bicarbonate) Passive: urea, chloride ions, lipid-soluble materials, water

Secretion: Hydrogen ions, ammonium ions, creatinine, drugs, and toxins (as at DCT)

Reabsorption: Sodium and chloride ions Water

Reabsorption: Sodium and chloride ions Sodium ions (variable)

Calcium ions (variable)

Water (variable) *Secretion*: Hydrogen ions, ammonium ions Creatinine, drugs, toxins

Reabsorption: Sodium ions (variable)

Bicarbonate ions (variable)

Water (variable)

Urea (distal portions only)

Secretion: Potassium and hydrogen ions (variable)

Return of water and solutes to the general circulation

Return of water and solutes to the general circulation

Mechanisms

Glomerular hydrostatic (blood) pressure working across capillary endothelium, lamina densa, and filtration slits

Carrier-mediated transport, including facilitated transport (glucose, amino acids), cotransport (glucose, ions), and countertransport (with secretion of H^+)

Diffusion (solutes) or osmosis (water)

Countertransport with sodium ions

Active transport via Na^+ –K^+ > 2 Cl^- transporter Osmosis

Cotransport

Countertransport with potassium ions; aldosterone-regulated

Carrier-mediated transport stimulated by parathyroid hormone and calcitriol

Osmosis; ADH regulated Countertransport with sodium ions Carrier-mediated transport

Countertransport with potassium or hydrogen ions; aldosterone-regulated

Diffusion, generated within tubular cells Osmosis; ADH-regulated Diffusion Carrier-mediated transport

Osmosis and diffusion

Osmosis and diffusion

Characteristic	**Normal Range**
pH	4.5–8 (average: 6.0)
Specific gravity	1.003–1.030
Osmotic concentration (osmolarity)	855–1335 mOsm L>
Water content	93–97%
Volume	700–2000 ml day >
Color	Clear yellow
Odor	Varies with composition
Bacterial content	None (sterile)

TABLE 26–6 Typical Values Obtained from Standard Urinalysis

Compound	**Primary Source**	**Daily Elimination***	**Concentration**	**Remarks**
NITROGENOUS WASTES				
Urea	Deamination of amino acids by liver and kidneys	21 g	1.8 g dl>	Rises if negative nitrogen balance exists
Creatinine	Breakdown of creatine phosphate in skeletal muscle	1.8 g	150 mg dl>	Proportional to muscle mass; decreases during atrophy or muscle disease
Ammonia	Deamination by liver and kidney, absorption from intestinal tract	0.68 g	60 mg dl>	
Uric acid	Breakdown of purines	0.53 g	40 mg dl>	Increases in gout, liver diseases
Hippuric acid	Breakdown of dietary toxins	4.2 mg	350 mg> dl	
Urobilin	Urobilinogens absorbed at colon	1.5 mg	125 mg> dl	Gives urine its yellow color
Bilirubin	Hemoglobin breakdown product	0.3 mg	20 mg> dl	Increase may indicate problem with liver elimination or

			excess production; causes yellowing of skin and mucous membranes in jaundice
NUTRIENTS AND METABOLITES			
Carbohydrates	0.11 g	9 mg> dl	Primarily glucose; *glycosuria* develops if is exceeded Tm
Ketone bodies	0.21 g	17 mg> dl	Ketonuria may occur during postabsorptive state
Lipids	0.02 g	1.6 mg> dl	May increase in some kidney diseases
Amino acids	2.25 g	287.5 mg> dl	Note relatively high loss compared with other metabolites due to low ; excess (*aminoaciduria*)*Tm* indicates problem Tm

IONS

Sodium 4.0 g 333 mg > dl Varies with diet, urine pH, hormones, etc.

Chloride 6.4 g 533 mg > dl

Potassium 2.0 g 166 mg > dl Varies with diet, urine pH, hormones, etc.

Calcium 0.2 g 17 mg > dl Hormonally regulated (PTH > CT)
Magnesium 0.15 g 13 mg > dl

BLOOD CELLS[†]
RBCs 130,000 > day 100 > ml Excess (*hematuria*) indicates
vascular damage

WBCs 650,000 > day 500 > ml Excess (*pyuria*) indicates renal
infection or inflammation

Representative values for a 70-kg male.

[†] Usually estimated by counting the cells in a sample of sediment after urine centrifugation.

Fluid, Electrolyte, and Acid–Base Balance: An Overview

Objective

- Explain what is meant by the terms *fluid balance*, *electrolyte balance*, and *acid–base balance* and discuss their importance for homeostasis.

The next time you see a small pond, think about the fish it contains. They live out their lives totally dependent on the quality of that isolated environment. Severe water pollution will kill them, but even subtle changes can have equally grave effects. Changes in the volume of the pond, for example, can be quite important. If evaporation removes too much of the water, the fish become overcrowded; oxygen and food supplies run out, and the fish suffocate or starve. The ionic concentration of the water is also crucial. Most of the fish in a freshwater pond will die if the water becomes too salty; those in a saltwater pond will die if their environment becomes too dilute. The pH of the pond water, too, is a vital factor; that is one reason acid rain is such a problem.

Your cells live in a pond whose shores are the exposed surfaces of your skin. Most of your body weight is water. Water accounts for up to 99 percent of the volume of the fluid outside cells, and it is an essential ingredient of cytoplasm. All of a cell’s operations rely on water as a diffusion medium for the distribution of gases, nutrients, and waste products. If the water content of the body changes, cellular activities are jeopardized. For example, when the water content reaches very low levels, proteins denature, enzymes cease functioning, and cells die.

To survive, we must maintain a normal volume and composition of both the **extracellular fluid** or **ECF** (the interstitial fluid, plasma, and other body fluids), and the **intracellular**

fluid or **ICF** (the cytosol). The ionic concentrations and pH (hydrogen ion concentration) of these fluids are as important as their absolute quantities. If concentrations of calcium or potassium ions in the ECF become too high, cardiac arrhythmias develop and death can result. A pH outside the normal range can also lead to a variety of serious problems. Low pH is especially dangerous, because hydrogen ions break chemical bonds, change the shapes of complex molecules, disrupt cell membranes, and impair tissue functions.

In this chapter, we will consider the dynamics of exchange among the various body fluids, and between the body and the external environment. Stabilizing the volumes, solute concentrations, and pH of the ECF and the ICF involves three interrelated processes:

1. *Fluid Balance.* You are in **fluid balance** when the amount of water you gain each day is equal to the amount you lose to the environment. The maintenance of normal fluid balance involves regulating the content and distribution of body water in the ECF and the ICF. The digestive system is the primary source of water gains; a small amount of additional water is generated by metabolic activity. The urinary system is the primary route for water loss under normal conditions, but as we saw in Chapter 25, sweat gland activity can become important when body temperature is elevated. l**p. 943** Although cells and tissues cannot transport water, they can transport ions and create concentration gradients that are then eliminated by osmosis.

2. *Electrolyte Balance.* **Electrolytes** are ions released through the dissociation of inorganic compounds; they are so named because they can conduct an electrical current in a solution. l**p. 39** Each day, your body fluids gain electrolytes from the food and drink you consume, and lose electrolytes in urine, sweat, and feces. For each ion, daily gains must balance daily losses. For example, if you lose 500 mg of Na^+ in urine and insensible perspiration, you need to gain 500 mg of Na^+ from food and drink to remain in sodium balance. If the gains and losses for every electrolyte are in balance, you are said to be in **electrolyte balance**. Electrolyte balance primarily involves balancing the rates of absorption across the digestive tract with rates of loss at the kidneys, although losses at sweat glands and other sites can play a secondary role.

3. *Acid–Base Balance.* You are in **acid–base balance** when the production of hydrogen ions in your body is precisely offset by their loss. When acid–base balance exists, the pH of body fluids remains within normal limits. l**p. 40** Preventing a reduction in pH is the primary problem, because your body generates a variety of acids during normal metabolic operations. The kidneys play a major role by secreting hydrogen ions into the urine and generating buffers that enter the bloodstream. Such secretion occurs primarily in the distal segments of the distal convoluted tubule (DCT) and along the collecting system. l**p. 975**

The lungs also play a key role through the elimination of carbon dioxide.
Much of the material in this chapter was introduced in earlier chapters, in discussions considering aspects of fluid, electrolyte, or acid–base balance that affect specific systems. This chapter provides an overview that integrates those discussions to highlight important functional patterns. Few other chapters have such wide-ranging clinical importance: The treatment of any serious illness affecting the nervous, cardiovascular, respiratory, urinary, or digestive system must include steps to restore normal fluid, electrolyte, and acid–base balances. Because this chapter builds on information presented in earlier chapters, you will encounter many references to relevant discussions and figures that can provide a quick review.

An Introduction to Fluid and Electrolyte Balance

Objectives

- Compare the composition of intracellular and extracellular fluids.
- Explain the basic concepts involved in the regulation of fluids and electrolytes.
- Identify the hormones that play important roles in regulating fluid balance and electrolyte balance and describe their effects.

Figure 27–1a• presents an overview of the body composition of a 70-kg (154-pound) individual with a minimum of body fat. The distribution was obtained by averaging values for males and females ages 18–40 years. Water accounts for roughly 60 percent of the total body weight of an adult male, and 50 percent of that of an adult female (Figure 27–1b•). This difference between the sexes primarily reflects the proportionately larger mass of adipose tissue in adult females, and the greater average muscle mass in adult males. (Adipose tissue is only 10 percent water, whereas skeletal muscle is 75 percent water.) In both sexes, intracellular fluid contains a greater proportion of total body water than does extracellular fluid. Exchange between the ICF and the ECF occurs across cell membranes by osmosis, diffusion, and carrier-mediated transport. (To review the mechanisms involved, see Table 3–3, p. 94.)

The ECF and the ICF

The largest subdivisions of the ECF are the interstitial fluid of peripheral tissues and the plasma of circulating blood (see Figure 27–1a•). Minor components of the ECF include lymph, cerebrospinal fluid (CSF), synovial fluid, serous fluids (pleural, pericardial, and peritoneal fluids), aqueous humor, perilymph, and endolymph. More precise measurements of total body water provide additional information on sex-linked differences in the distribution of body water (see Figure 27–1b•). The greatest variation is in the ICF, as a result of differences in the intracellular water content of fat versus muscle. Less striking differences occur in the ECF values, due to variations in the interstitial fluid volume of various tissues and the larger blood volume in males versus females.

In clinical situations, it is customary to estimate that two-thirds of the total body water is in the ICF and one-third in the ECF. This ratio underestimates the real volume of the ECF, but that underestimation is appropriate because portions of the ECF— including the water in bone, in many dense connective tissues, and in many of the minor ECF components—are relatively isolated. Exchange between these fluid volumes and the rest of the ECF occurs more slowly than does exchange between plasma and other interstitial fluids. As a result, they can be safely ignored in many cases. Clinical attention is usually focused on the rapid fluid and solute movements associated with the administration of blood, plasma, or saline solutions to counteract blood loss or dehydration.

Exchange among the subdivisions of the ECF occurs primarily across the endothelial lining of capillaries. Fluid may also travel from the interstitial spaces to plasma through lymphatic vessels that drain into the venous system. l**p. 767** The identities and quantities of dissolved electrolytes, proteins, nutrients, and waste products in the ECF vary regionally. (For a chemical analysis of the composition of ECF compartments, see Appendix IV.) Still, the variations among the segments of the ECF seem minor compared with the major differences between the ECF and the ICF.

The ECF and ICF are called **fluid compartments**, because they commonly behave as distinct entities. The presence of a cell membrane and active transport at the membrane surface enable cells to maintain internal environments with a composition that differs from their surroundings. The principal ions in the ECF are sodium, chloride, and bicarbonate. The ICF contains an abundance of potassium, magnesium, and phosphate ions, plus large numbers of negatively charged proteins. Figure 27–2• compares the ICF with the two major subdivisions of the ECF.

If the cell membrane were freely permeable, diffusion would continue until these ions were evenly distributed across the membrane. But it does not, because cell membranes are selectively permeable: Ions can enter or leave the cell only via specific membrane channels. In addition, carrier mechanisms move specific ions into or out of the cell.

Despite the differences in the concentration of specific substances, the osmotic concentrations of the ICF and ECF are identical. Osmosis eliminates minor differences in concentration almost at once, because most cell membranes are freely permeable to water. (The only noteworthy exceptions are the apical surfaces of epithelial cells along the ascending limb of the loop of Henle, the distal convoluted tubule, and the collecting system.) Because changes in solute concentrations lead to immediate changes in water distribution, the regulation of fluid balance and that of electrolyte balance are tightly intertwined.

Physiologists and clinicians pay particular attention to ionic distributions across membranes and to the electrolyte composition of body fluids. Appendix IV reports normal values in the units most often used in clinical reports.

Basic Concepts in the Regulation of Fluids and Electrolytes

Before we can proceed to a discussion of fluid balance and electrolyte balance, you must understand four basic principles:

1. *All the Homeostatic Mechanisms That Monitor and Adjust the Composition of Body Fluids Respond to Changes in the ECF, Not in the ICF.* Receptors monitoring the composition of two key components of the ECF—plasma and cerebrospinal fluid—detect significant changes in their composition or volume and trigger appropriate neural and endocrine responses. This arrangement makes functional sense, because a change in one ECF component will spread rapidly throughout the extracellular compartment and affect all the body's cells. In contrast, the ICF is contained within trillions of individual cells that are physically and chemically isolated from one another by their cell membranes. Thus, changes in the ICF in one cell have no direct effect on the composition of the ICF in distant cells and tissues, unless those changes also affect the ECF.

2. *No Receptors Directly Monitor Fluid or Electrolyte Balance.* In other words, receptors cannot detect how many liters of water or grams of sodium, chloride, or potassium the body contains, or count how many liters or grams we gain or lose in the course of a day. But receptors *can* monitor *plasma volume* and *osmotic concentration*. Because fluid continuously circulates between interstitial fluid and plasma, and because exchange occurs between the ECF and the ICF, the plasma volume and osmotic concentration are good indicators of the state of fluid balance and electrolyte balance for the body as a whole.

3. *Cells Cannot Move Water Molecules by Active Transport.* All movement of water across cell membranes and epithelia occurs passively, in response to osmotic gradients established by the active transport of specific ions, such as sodium and chloride. You may find it useful to remember that "*water follows salt*." As we saw in earlier chapters, when sodium and chloride ions (or other solutes) are actively transported across a membrane or epithelium, water follows by osmosis. l**p. 972** This basic principle accounts for water absorption across the digestive epithelium, and for water conservation in the kidneys.

4. *The Body's Content of Water or Electrolytes Will Rise if Dietary Gains Exceed Losses to the Environment, and Will Fall if Losses Exceed Gains.* This basic rule is important when you consider the mechanics of fluid balance and electrolyte balance. Homeostatic adjustments generally affect the balance between urinary excretion and dietary absorption. As we saw in Chapter 26, the physiological adjustments in renal function are regulated primarily by circulating hormones. These hormones can also produce complementary changes in behavior. For example, the combination of angiotensin II and aldosterone can give you a sensation of thirst—which stimulates you to drink fluids—and a taste for heavily salted foods.

An Overview of the Primary Regulatory Hormones

Major physiological adjustments affecting fluid balance and electrolyte balance are mediated by three hormones: (1) *antidiuretic hormone (ADH)*, (2) *aldosterone*, and (3) the *natriuretic peptides (ANP and BNP)*. These hormones were introduced and discussed in earlier chapters; we will summarize their effects next. Those interested in a more detailed review should refer to the appropriate sections of Chapters 18, 21, and 26. The interactions among these hormones were illustrated in Figures 18–17b, 21–16, 21–17,
and 26–11•. l**pp. 623, 731, 734, 968**

Antidiuretic Hormone

The hypothalamus contains special cells known as **osmoreceptors**, which monitor the osmotic concentration of the ECF. These cells are sensitive to subtle changes: A 2 percent change in osmotic concentration (approximately 6 mOsm> L) is sufficient to alter osmoreceptor activity.

The population of osmoreceptors includes neurons that secrete ADH. These neurons are located in the anterior hypothalamus, and their axons release ADH near fenestrated capillaries in the posterior lobe of the pituitary gland. The rate of ADH release varies directly with osmotic concentration: The higher the osmotic concentration, the more ADH is released.

Increased release of ADH has two important effects: (1) It stimulates water conservation at the kidneys, reducing urinary water losses and concentrating the urine; and (2) it stimulates the thirst center, promoting the intake of fluids. As we saw in Chapter21, the combination of decreased water loss and increased water gain gradually restores the normal plasma osmotic concentration.

l**pp. 730–732**

Aldosterone

The secretion of aldosterone by the adrenal cortex plays a major role in determining the rate of Na^+ absorption and K^+ loss along the distal convoluted tubule (DCT) and collecting system of the kidneys. l**p. 974** The higher the plasma concentration of aldosterone, the more efficiently the kidneys conserve Na^+. Because “water follows salt,” the conservation of Na^+ also stimulates water retention: As Na^+ is reabsorbed, Cl^- follows (see Figure 26–14a•, p. 974), and as sodium and chloride ions move out of the tubular fluid, water follows by osmosis. Aldosterone also increases the sensitivity of salt receptors on the tongue. This effect may increase your interest in, and consumption of, salty foods.

Aldosterone is secreted in response to rising K^+ or falling Na^+ levels in the blood reaching the adrenal cortex, or in response to the activation of the renin–angiotensin system. As we saw in earlier chapters, renin release occurs in response to (1) a drop in plasma volume or blood pressure at the juxtaglomerular apparatus of the nephron, (2) a decline in filtrate osmotic concentration at the DCT, or, as we will soon see, (3) falling Na^+ or rising K^+ concentrations in the renal circulation.

Natriuretic Peptides

The natriuretic peptides ANP and BNP are released by cardiac muscle cells in response to abnormal stretching of the heart walls, caused by elevated blood pressure or an increase in blood volume. Among their other effects, they reduce thirst and block the release of ADH and aldosterone that might otherwise lead to the conservation of water and salt. The resulting diuresis (fluid loss at the kidneys) lowers both blood pressure and plasma volume, eliminating the source of the stimulation.

The Interplay between Fluid Balance and Electrolyte Balance

At first glance, it can be very difficult to distinguish between water balance and electrolyte balance. For example, when you lose body water, plasma volume decreases and electrolyte concentrations rise. Conversely, when you gain or lose excess electrolytes, there is an associated water gain or loss due to osmosis. However, because the regulatory mechanisms involved are quite different, it is often useful to consider fluid balance and electrolyte balance as distinct entities. This distinction is absolutely vital in a clinical setting, where problems with fluid balance and electrolyte balance must be identified and corrected promptly.

Fluid Balance

Objective

- Describe the movement of fluid within the ECF, between the ECF and the ICF, and between the ECF and the environment.

Water circulates freely within the ECF compartment. At capillary beds throughout the body, hydrostatic pressure forces water out of plasma and into interstitial spaces. Some of that water is reabsorbed along the distal portion of the capillary bed, and the rest enters lymphatic vessels for transport to the venous circulation. There is also a continuous movement of fluid among the minor components of the ECF:

1. Water moves back and forth across the mesothelial surfaces that line the peritoneal, pleural, and pericardial cavities and through the synovial membranes that line joint capsules. The flow rate is significant; for example, roughly 7 liters of peritoneal fluid is produced and reabsorbed each day. The actual volume present at any time in the peritoneal cavity, however, is very small—less than 35 ml.

2. Water also moves between blood and cerebrospinal fluid (CSF), between the aqueous humor and vitreous humor of the eye, and between the perilymph and endolymph of the inner ear. The volumes involved in these water movements are very small, and the volume and composition of the fluids are closely regulated. For those reasons, we will largely ignore them in the discussion that follows.

Water movement can also occur between the ECF and the ICF, but under normal circumstances the two are in osmotic equilibrium, and no large-scale circulation occurs between the two compartments. (A small amount of water moves from the ICF to the ECF each day, as the result of mitochondrial water generation; this will be considered in a separate section.)

The body's water content cannot easily be determined. However, the concentration of Na^+, the most abundant ion in the ECF, provides useful clues to the state of water balance. When the body's water content rises, the Na^+ concentration of the ECF becomes abnormally low; when the body water content declines, the Na^+ concentration becomes abnormally high.

Fluid Movement within the ECF

In the discussion of capillary dynamics in Chapter 21, we considered the basic principles that determine fluid movement among the divisions of the ECF. l**p. 724** The exchange between plasma and interstitial fluid, by far the largest components of the ECF, is determined by the relationship between the net hydrostatic pressure, which tends to push water out of the plasma and into the interstitial fluid, and the net colloid osmotic pressure, which tends to draw water out of the interstitial fluid and into the plasma. The interaction between these opposing forces, diagrammed in Figure 21–12• (p. 724), results in the continuous filtration of fluid from the capillaries into the interstitial fluid. This volume of fluid is then redistributed: After passing through the channels of the lymphatic system, the fluid returns to the venous system. At any moment, interstitial fluid and minor fluid compartments contain roughly 80 percent of the ECF volume, and plasma contains the other 20 percent.

Any factor that affects the net hydrostatic pressure or the net colloid osmotic pressure will alter the distribution of fluid within the ECF. The movement of abnormal amounts of water from plasma into interstitial fluid is called *edema*. Pulmonary edema, for example, can result from an increase in the blood pressure in pulmonary capillaries, and generalized edema can result from a decrease in blood colloid osmotic pressure (as in advanced starvation, when plasma protein concentrations decline). Localized edema can result from damage to capillary walls (as in bruising), the constriction of regional venous circulation, or a blockage of the lymphatic drainage (as in *lymphedema*, introduced in Chapter 22). l**p. 767**

Fluid Gains and Losses

Figure 27–3• and Table 27–1 indicate the major factors involved in fluid balance and highlight the routes of fluid exchange with the environment:

- **Water Losses.** You lose roughly 2500 ml of water each day through urine, feces, and *insensible perspiration*—the gradual movement of water across the epithelia of the skin and respiratory tract. The losses due to *sensible perspiration*—the secretory activities of the sweat glands—vary with the activities you undertake. Sensible perspiration can cause significant water deficits, with maximum perspiration rates reaching 4 liters per hour. l**p. 943** Fever can also increase water losses. For each degree that body temperature rises above normal, daily insensible water losses increase by 200 ml. The advice "Drink plenty of fluids" for anyone who is sick has a definite physiological basis.
- **Water Gains.** A water gain of roughly 2500 ml day is required to balance your average water losses. This value amounts to

> roughly 40 ml> kg of body weight per day. You obtain water through eating (1000 ml), drinking (1200 ml), and *metabolic generation* (300 ml). **Metabolic generation** of water is the production of water within cells, primarily as a result of oxidative phosphorylation in mitochondria. (The synthesis of water at the end of the electron transport system was described in Chapter 25. l**p. 924**) When a cell breaks down 1 g of lipid, 1.7 ml of water is generated. Breaking down proteins or carbohydrates yields much lower values
(0.41 ml> g and 0.55 ml> g, respectively). A typical diet in the United States contains 46 percent carbohydrates, 40 percent lipids, and 14 percent protein. Such a diet produces roughly 300 ml of water per day, about 12 percent of your average daily requirement.

Fluid Shifts

A rapid water movement between the ECF and the ICF in response to an osmotic gradient is called a **fluid shift**. Fluid shifts occur rapidly in response to changes in the osmotic concentration of the ECF and reach equilibrium within minutes to hours.

- **If the Osmotic Concentration of the ECF Increases, That Fluid Will Become Hypertonic with Respect to the ICF.** Water
will then move from the cells into the ECF until osmotic equilibrium is restored. The osmotic concentration of the ECF will increase if you lose water but retain electrolytes.
- **If the Osmotic Concentration of the ECF Decreases, that Fluid Will Become Hypotonic with Respect to the ICF.** Water will then move from the ECF into the cells, and the ICF volume will increase. The osmotic concentration of the ECF will decrease if you gain water but do not gain electrolytes.

In sum, if the osmotic concentration of the ECF changes, a fluid shift between the ICF and ECF will tend to oppose the change. Because the volume of the ICF is much greater than that of the ECF, the ICF acts as a water reserve. In effect, instead of a large change in the osmotic concentration of the ECF, smaller changes occur in both the ECF and ICF. Two examples will demonstrate the dynamic exchange of water between the ECF and ICF.

Allocation of Water Losses

Dehydration, or *water depletion*, develops when water losses outpace water gains. When you lose water but retain electrolytes, the osmotic concentration of the ECF rises. Osmosis then moves water out of the ICF and into the ECF until the two solutions are again isotonic. At that point, both the ECF and ICF are somewhat more concentrated than normal, and both volumes are lower than they were before the fluid loss. Because the ICF has roughly twice the functional volume of the ECF, the net change in the ECF is relatively small. However, if the fluid imbalance continues unchecked, the loss of body water will produce severe thirst, dryness, and wrinkling of the skin. Eventually a significant fall in plasma volume and blood pressure occurs, and shock may develop. AM: Shock

Conditions that cause severe water losses include excessive perspiration (brought about by exercising in hot weather), inadequate water consumption, repeated vomiting, and diarrhea. These conditions promote water losses far in excess of electrolyte losses, so body fluids become increasingly concentrated, and sodium ion concentrations become abnormally high (a condition called *hypernatremia*). Homeostatic responses include physiologic mechanisms (ADH and renin secretion) and behavioral changes (increasing fluid intake, preferably as soon as possible). Clinical therapies for acute dehydration include administering hypotonic fluids by mouth or intravenous infusion. These procedures rapidly increase ECF volume and promote the shift of water back into the ICF. AM: Water and Weight Loss

Distribution of Water Gains

When you drink a glass of pure water or when you are given hypotonic solutions intravenously, your body’s water content increases without a corresponding increase in the concentration of electrolytes. As a result, the ECF increases in volume but becomes hypotonic with respect to the ICF. A fluid shift then occurs, and the volume of the ICF increases at the expense of the ECF. Once again, the larger volume of the ICF limits the amount of osmotic change. After the fluid shift, the ECF and ICF have slightly larger volumes and slightly lower osmotic concentrations than they did originally.

Normally, this situation will be promptly corrected. The reduced plasma osmotic concentration depresses the secretion of ADH, discouraging fluid intake and increasing water losses in urine. If the situation is *not* corrected, a variety of clinical problems will develop as water shifts into the intracellular fluid, distorting cells, changing the solute concentrations around enzymes, and disrupting normal cell functions. This condition is called **overhydration**, or *water excess*. It can be caused by (1) the ingestion of a large volume of fresh water or the infusion (injection into the bloodstream) of a hypotonic solution; (2) an inability to eliminate excess water in urine, due to chronic renal failure, heart failure, cirrhosis, or some other disorder; and (3) endocrine disorders, such as excessive ADH production.

The most obvious sign of overhydration is abnormally low sodium ion concentrations (*hyponatremia*), and the reduction in Na^+ concentrations in the ECF leads to a fluid shift into the ICF. The first signs are the effects on central nervous system function. The individual initially behaves as if drunk on alcohol. This condition, called *water intoxication*, may sound odd, but is extremely dangerous. Untreated cases can rapidly progress from confusion to hallucinations, convulsions, coma, and then death. Treatment of severe overhydration generally involves administering diuretics and infusing a concentrated salt solution that promotes a fluid shift from the ICF to the ECF and returns Na^+ concentrations to near-normal levels.

Concept Check

- What effect would drinking a pitcher of distilled water have on ADH levels?
- What effect would being in the desert without water for a day have on your plasma osmotic concentration?

Answers begin on p. A–1

Review fluid balance on the **IP CD-ROM: Fluids and Electrolytes/Water Homeostasis**.

Electrolyte Balance

Objective

- Discuss the mechanisms by which sodium, potassium, calcium, and chloride ion concentrations are regulated to maintain electrolyte balance.

You are in electrolyte balance when the rates of gain and loss are equal for each electrolyte in your body. Electrolyte balance is important because:

- *Total electrolyte concentrations directly affect water balance*, as previously described, and
- *The concentrations of individual electrolytes can affect cell functions.* We saw many examples in earlier chapters, including the effect of abnormal Na^+ concentrations on neuron activity and the effects of high or low Ca^{2+} and K^+ concentrations on cardiac muscle tissue.

Two cations, Na^+ and K^+, merit particular attention, because (1) they are major contributors to the osmotic concentrations of the ECF and the ICF, respectively, and (2) they directly affect the normal functioning of all cells. Sodium is the dominant cation in the ECF. More than 90 percent of the osmotic concentration of the ECF results from the presence of sodium salts, mainly sodium chloride (NaCl) and sodium bicarbonate (NaHCO3), so changes in the osmotic concentration of body fluids generally reflect changes in Na^+ concentration. Normal Na^+ concentrations in the ECF average about 140 mEq> L, versus 10 mEq> L or less in the ICF. Potassium is the dominant cation in the ICF, where concentrations reach 160 mEq> L. Extracellular K^+ concentrations are generally very low, from 3.8 to 5.0 mEq> L.

Two general rules concerning sodium balance and potassium balance are worth noting:

1. *The Most Common Problems with Electrolyte Balance Are Caused by an Imbalance between Gains and Losses of Sodium Ions.*

2. *Problems with Potassium Balance Are Less Common, but Significantly More Dangerous than Are Those Related to Sodium Balance.*

Sodium Balance

The total amount of sodium in the ECF represents a balance between two factors:

1. *Sodium Ion Uptake across the Digestive Epithelium.* Sodium ions enter the ECF by crossing the digestive epithelium through diffusion and carrier-mediated transport. The rate of absorption varies directly with the amount of sodium in the diet.

2. *Sodium Ion Excretion at the Kidneys and Other Sites.* Sodium losses occur primarily by excretion in urine and through perspiration. The kidneys are the most important sites of Na^+ regulation. The mechanisms for sodium reabsorption at the kidneys were discussed in Chapter 26. l**pp. 970, 974**

A person in sodium balance typically gains and loses 48–144 mEq (1.1–3.3 g) of Na^+ each day. When sodium gains exceed sodium losses, the total Na^+ content of the ECF goes up; when losses exceed gains, the Na^+ content declines. However, a change in the Na^+ content of the ECF does not produce a change in the Na^+ concentration. When sodium intake or output changes, a corresponding gain or loss of water tends to keep the Na^+ concentration constant. For example, if you eat a very salty meal, the osmotic concentration of the ECF will not increase. When sodium ions are pumped across the digestive epithelium, the solute concentration in that portion of the ECF increases, whereas that of the intestinal contents decreases. Osmosis then occurs. Additional water enters the ECF from the digestive tract, elevating the blood volume and blood pressure. For this reason, people with high blood pressure are advised to restrict the amount of salt in their diets.

Sodium Balance and ECF Volume

The sodium regulatory mechanism, diagrammed in Figure 27–4•, changes the ECF volume but keeps the Na^+ concentration relatively stable. If you consume large amounts of salt *without* adequate fluid, as when you eat salty potato chips without taking a drink, the plasma Na^+ concentration rises temporarily. A change in ECF volume soon follows, however. Fluid will exit the ICF, increasing ECF volume and lowering Na^+ concentrations somewhat. The secretion of ADH restricts water loss and stimulates thirst, promoting additional water consumption. Due to the inhibition of water receptors in the pharynx, ADH secretion begins even before Na^+ absorption occurs; the secretion rate rises further after Na^+ absorption, due to osmoreceptor stimulation.

l**pp. 553, 605**

When sodium losses exceed gains, the volume of the ECF decreases. This reduction occurs without a significant change in the osmotic concentration of the ECF. Thus, if you perspire heavily but consume only pure water, you will lose sodium, and the osmotic concentration of the ECF will drop briefly. However, as soon as the osmotic concentration drops by 2 percent or more, ADH secretion decreases, so water losses at your kidneys increase. As water leaves the ECF, the osmotic concentration returns to normal.

Minor changes in ECF volume do not matter, because they do not cause adverse physiological effects. If, however, regulation of Na^+ concentrations results in a large change in ECF volume, the situation will be corrected by the same homeostatic mechanisms responsible for regulating blood volume and blood pressure. This is the case because when ECF volume changes, so does plasma volume and, in turn, blood volume. If ECF volume rises, blood volume goes up; if ECF volume drops, blood volume goes down. As we saw in Chapter 21, blood volume has a direct effect on blood pressure. A rise in blood volume elevates blood pressure; a drop lowers blood pressure. The net result is that homeostatic mechanisms can monitor ECF volume indirectly by monitoring blood pressure. The receptors involved are baroreceptors at the carotid sinus, the aortic sinus, and the right atrium. The regulatory steps involved are reviewed in Figure 27–5•.

Sustained abnormalities in the Na^+ concentration in the ECF occur only when there are severe problems with fluid balance, such as dehydration or overhydration. When the body's water content rises enough to reduce the Na^+ concentration of the ECF below 130 mEq> L, a state of *hyponatremia* (*natrium*, sodium) exists. When the body water content declines, the Na^+ concentration rises; when that concentration exceeds 150 mEq> L, *hypernatremia* exists.

If the ECF volume is inadequate, both blood volume and blood pressure decline, and the renin–angiotensin system is activated. In response, losses of water and Na^+ are reduced, and gains of water and Na^+ are increased. The net result is that ECF volume increases. Although the total amount of Na^+ in the ECF is increasing (gains exceed losses), the Na^+ concentration in the

ECF remains unchanged, because absorption is accompanied by osmotic water movement.

If the plasma volume becomes abnormally large, venous return increases, stretching the atrial and ventricular walls and stimulating the release of natriuretic peptides (ANP and BNP). This in turn reduces thirst and blocks the secretion of ADH and aldosterone, which together promote water or salt conservation. As a result, salt and water loss at the kidneys increases and the volume of the ECF declines.

Potassium Balance

Roughly 98 percent of the potassium content of the human body is in the ICF. Cells expend energy to recover potassium ions as they diffuse out of the cytoplasm and into the ECF. The K^+ concentration outside the cell is relatively low, and the concentration in the ECF at any moment represents a balance between (1) the rate of gain across the digestive epithelium and (2) the rate of loss

into urine. Potassium loss in urine is regulated by controlling the activities of ion pumps along the distal portions of the nephron and collecting system. Whenever a sodium ion is reabsorbed from the tubular fluid, it generally is exchanged for a cation (typically K^+) in the peritubular fluid.

Urinary K^+ losses are usually limited to the amount gained by absorption across the digestive epithelium, typically 50–150 mEq (1.9–5.8 g) per day. (Potassium losses in feces and perspiration are negligible.) The K^+ concentration in the ECF is controlled by adjustments in the rate of active secretion along the distal convoluted tubule and collecting system of the nephron.

The rate of tubular secretion of K^+ varies in response to three factors:

1. *Changes in the K^+ Concentration of the ECF.* In general, the higher the extracellular concentration of potassium, the higher the rate of secretion.

2. *Changes in pH.* When the pH of the ECF falls, so does the pH of peritubular fluid. The rate of potassium secretion then de

clines, because hydrogen ions, rather than potassium ions, are secreted in exchange for sodium ions in tubular fluid. The mechanisms for H^+ secretion were summarized in Figure 26–14c• (p. 975).

3. *Aldosterone Levels.* The rate at which K^+ is lost in urine is strongly affected by aldosterone, because the ion pumps that are sensitive to this hormone reabsorb Na^+ from filtrate in exchange for K^+ from peritubular fluid. Aldosterone secretion is stimulated by angiotensin II as part of the regulation of blood volume. High plasma K^+ concentrations also stimulate aldosterone secre

tion directly. Either way, under the influence of aldosterone the amount of sodium conserved and the amount of potassium excreted in urine are directly related.

When the plasma concentration of potassium falls below 2 mEq> L, extensive muscular weakness develops, followed by eventual paralysis. This condition, called *hypokalemia* (*hypo*-, below + *kalium*, potassium), has potentially lethal effects on cardiac function. AM: Hypokalemia and Hyperkalemia

Balance of Other Electrolytes

The ECF concentrations of other electrolytes are regulated as well. Here we will consider the most important ions involved. Additional information about sodium, potassium, and these other ions is listed in Table 27–2.

Calcium Balance

Calcium is the most abundant mineral in the body. A typical individual has 1–2 kg (2.2–4.4 lb) of this element, 99 percent of which is deposited in the skeleton. In addition to forming the crystalline component of bone, calcium ions play key roles in the control of muscular and neural activities, in blood clotting, as cofactors for enzymatic reactions, and as second messengers.

As noted in Chapters 6 and 18, calcium homeostasis primarily reflects an interplay between the reserves in bone, the rate of absorption across the digestive tract, and the rate of loss at the kidneys. The hormones parathyroid hormone (PTH), calcitriol, and (to a lesser degree) calcitonin maintain calcium homeostasis in the ECF. Parathyroid hormone and calcitriol raise Ca^{2+} concentrations; their actions are opposed by calcitonin. l**pp. 610–612**

A small amount of Ca^{2+} is lost in the bile, and under normal circumstances very little Ca^{2+} escapes in urine or feces. To keep pace with biliary, urinary, and fecal Ca^{2+} losses, an adult must absorb only 0.8 – 1.2 g> day of Ca^{2+}. That amount represents only about 0.03 percent of the calcium reserve in the skeleton. Calcium absorption at the digestive tract and reabsorption along the distal convoluted tubule are stimulated by PTH from the parathyroid glands and calcitriol from the kidneys.

Hypercalcemia exists when the Ca^{2+} concentration of the ECF exceeds 11 mEq> L. The primary cause of hypercalcemia in adults is *hyperparathyroidism*, a condition resulting from oversecretion of PTH. Less common causes include malignant cancers of the breast, lung, kidney, and bone marrow, and excessive use of calcium or vitamin D supplements. Severe hypercalcemia (12 – 13 mEq> L) causes such signs and symptoms as fatigue, confusion, cardiac arrhythmias, and calcification of the kidneys and soft tissues throughout the body. *Hypocalcemia* (a Ca^{2+} concentration under 4 mEq> L) is much less common than hypercalcemia. *Hypoparathyroidism* (undersecretion of PTH), vitamin D deficiency, or chronic renal failure is typically responsible for hypocalcemia. Signs and symptoms include muscle spasms, sometimes with generalized convulsions, weak heartbeats, cardiac arrhythmias, and osteoporosis.

Magnesium Balance

The adult body contains about 29 g of magnesium; almost 60 percent of it is deposited in the skeleton. The magnesium in body fluids is contained primarily in the ICF, where the concentration of Mg^{2+} averages about 26 mEq> L. Magnesium is required as a cofactor for several important enzymatic reactions, including the phosphorylation of glucose within cells and the use of ATP by contracting muscle fibers. Magnesium is also important as a structural component of bone.

The Mg^{2+} concentration of the ECF averages about 2 mEq> L, considerably lower than levels in the ICF. The proximal convoluted tubule reabsorbs magnesium very effectively. Keeping pace with the daily urinary loss requires a minimum dietary intake of only 24–32 mEq (0.3–0.4 g) per day.

Phosphate Balance

Phosphate ions are required for bone mineralization, and roughly 740 g of PO_4^{3-} is bound up in the mineral salts of the skeleton. In body fluids, the most important functions of $PO4^{3-}$ involve the ICF, where the ions are required for the formation of high-energy compounds, the activation of enzymes, and the synthesis of nucleic acids.

The $PO4^{3-}$ concentration of the plasma is usually 1.8–2.6 mEq L. Phosphate ions are reabsorbed from tubular fluid along the

>

proximal convoluted tubule; urinary and fecal losses of $PO4^{3-}$ amount to 30–45 mEq (0.8–1.2 g) per day. Phosphate ion reabsorption along the PCT is stimulated by calcitriol.

Chloride Balance

Chloride ions are the most abundant anions in the ECF. The plasma concentration ranges from 100 – 108 mEq> L. In the ICF, Cl^- concentrations are usually low (3 mEq> L). Chloride ions are absorbed across the digestive tract together with sodium ions; several

carrier proteins along the renal tubules reabsorb Clwith Na^+ . l**pp. 972, 974** The rate of Clloss is small; a gain of 48–146
mEq (1.7–5.1 g) per day will keep pace with losses in urine and perspiration.

100 Keys | Fluid balance and electrolyte balance are interrelated. Small water gains or losses affect electrolyte concentrations only temporarily. The impacts are reduced by fluid shifts between the ECF and ICF, and by hormonal responses that adjust the rates of water intake and excretion. Similarly, electrolyte gains or losses produce only temporary changes in solute concentration. These changes are opposed by fluid shifts, adjustments in the rates of ion absorption and secretion, and adjustments to the rates of water gain and loss.

Concept Check

☐ Why does prolonged sweating increase plasma sodium ion levels?

☐ Which is more dangerous, disturbances of sodium balance or disturbances of potassium balance?

Answers begin on p. A–1

Review ion balance on the **IP CD-ROM: Fluids and Electrolytes/Electrolyte Homeostasis**.

Acid–Base Balance

Objectives

- Explain the buffering systems that balance the pH of the intracellular and extracellular fluids.
- Describe the compensatory mechanisms involved in the maintenance of acid–base balance.

The topic of pH and the chemical nature of acids, bases, and buffers was introduced in Chapter 2. Table 27–3 reviews key terms important to the discussion that follows. If you need a more detailed review, refer to the appropriate sections of Chapter 2 before you proceed. l**pp. 37–41**

The pH of body fluids can be altered by the introduction of either acids or bases. In general, acids and bases can be categorized as either *strong* or *weak*.

- *Strong acids* and *strong bases* dissociate completely in solution. For example, hydrochloric acid (HCl), a strong acid, dissociates in solution via the reaction

HCl ¡ H^+ + Cl^-.

- When *weak acids* or *weak bases* enter a solution, a significant number of molecules remain intact; dissociation is not complete. Thus, if you place molecules of a weak acid in one solution and the same number of molecules of a strong acid in another solution, the weak acid will liberate fewer hydrogen ions and have less effect on the pH of the solution than will the strong acid. Carbonic acid is a weak acid. At the normal pH of the ECF, an equilibrium state exists, and the reaction can be diagrammed as follows:

H2CO3 Δ H^+ + HCO3 carbonic acid bicarbonate ion

The Importance of pH Control

The pH of body fluids reflects interactions among all the acids, bases, and salts in solution in the body. The pH of the ECF normally remains within relatively narrow limits, usually 7.35–7.45. Any deviation from the normal range is extremely dangerous, because changes in H^+ concentrations disrupt the stability of cell membranes, alter the structure of proteins, and change the activities of important enzymes. You could not survive for long with an ECF pH below 6.8 or above 7.7.

When the pH of plasma falls below 7.35, *acidemia* exists. The physiological state that results is called **acidosis**. When the pH of plasma rises above 7.45, *alkalemia* exists. The physiological state that results is called **alkalosis**. Acidosis and alkalosis affect virtually all body systems, but the nervous and cardiovascular systems are particularly sensitive to pH fluctuations. For example, severe acidosis (pH below 7.0) can be deadly, because (1) central nervous system function deteriorates, and the individual may become comatose; (2) cardiac contractions grow weak and irregular, and signs and symptoms of heart failure may develop; and

(3) peripheral vasodilation produces a dramatic drop in blood pressure, potentially producing circulatory collapse.

The control of pH is therefore a homeostatic process of great physiological and clinical significance. Although both acidosis and alkalosis are dangerous, in practice problems with acidosis are much more common. This is so because several acids, including carbonic acid, are generated by normal cellular activities.

Types of Acids in the Body

The body contains three general categories of acids: (1) *volatile acids*, (2) *fixed acids*, and (3) *organic acids*.

A **volatile acid** is an acid that can leave solution and enter the atmosphere. Carbonic acid (H2CO3) is an important volatile acid in body fluids. At the lungs, carbonic acid breaks down into carbon dioxide and water; the carbon dioxide diffuses into the alveoli. In peripheral tissues, carbon dioxide in solution interacts with water to form carbonic acid, which dissociates to release hydrogen ions and bicarbonate ions. The complete reaction sequence is:

CO2 + H2O Δ H2CO3 Δ H+ + HCO3 -
carbon water carbonic bicarbonate
dioxide acid ion

This reaction occurs spontaneously in body fluids, but it proceeds much more rapidly in the presence of *carbonic anhydrase (CA)*, an enzyme found in the cytoplasm of red blood cells, liver and kidney cells, parietal cells of the stomach, and many other types of cells.

Because most of the carbon dioxide in solution is converted to carbonic acid, and most of the carbonic acid dissociates, the partial pressure of carbon dioxide and the pH are inversely related (Figure 27–6•). When carbon dioxide levels rise, additional hydrogen ions and bicarbonate ions are released, so the pH goes down. (Recall that the pH is a *negative exponent*, so when the concentration of hydrogen ions goes up, the pH goes down.) The PCO_2 is the most important factor affecting the pH in body tissues.

At the alveoli, carbon dioxide diffuses into the atmosphere, the number of hydrogen ions and bicarbonate ions in the alveolar capillaries drops, and blood pH rises. We will consider this process, which effectively removes hydrogen ions from solution, in more detail later in the chapter.

Fixed acids are acids that do not leave solution; once produced, they remain in body fluids until they are eliminated at the kidneys. Sulfuric acid and phosphoric acid are the most important fixed acids in the body. They are generated in small amounts during the catabolism of amino acids and compounds that contain phosphate groups, including phospholipids and nucleic acids.

Organic acids are acid participants in or by-products of aerobic metabolism. Important organic acids include lactic acid, produced by the anaerobic metabolism of pyruvate, and ketone bodies, synthesized from acetyl-CoA. Under normal conditions, most organic acids are metabolized rapidly, so significant accumulations do not occur. But relatively large amounts of organic acids are produced (1) during periods of anaerobic metabolism, because lactic acid builds up rapidly, and (2) during starvation or excessive lipid catabolism, because ketone bodies accumulate.

Mechanisms of pH Control

To maintain acid–base balance over long periods of time, your body must balance gains and losses of hydrogen ions. Hydrogen ions are gained at the digestive tract and through metabolic activities within cells. Your body must eliminate these ions at the kidneys, by secreting H^+ into urine, and at the lungs, by forming water and carbon dioxide from H^+ and $HCO3^-$. The sites of elimination are far removed from the sites of acid production. As the hydrogen ions travel through the body, they must be neutralized to avoid tissue damage.

The acids produced in the course of normal metabolic operations are temporarily neutralized by buffers and buffer systems in

body fluids. *Buffers* are dissolved compounds that stabilize the pH of a solution by providing or removing H^+. Buffers include weak acids that can donate H^+, and weak bases that can absorb H^+.A **buffer system** in body fluids generally consists of a combination of a weak acid and the anion released by its dissociation. The anion functions as a weak base. In solution, molecules of the weak acid exist in equilibrium with its dissociation products. In chemical notation, this relationship is represented as:

$HY \Delta H^+ + Y^-$

Adding H^+ to the solution upsets the equilibrium, and the resulting formation of additional molecules of the weak acid removes H+

some of the from the solution. The body has three major buffer systems, each with slightly different characteristics and distributions (Figure 27–7•):

1. *Protein buffer systems* contribute to the regulation of pH in the ECF and ICF. These buffer systems interact extensively with the other two buffer systems.

2. *The carbonic acid–bicarbonate buffer system* is most important in the ECF.

3. *The phosphate buffer system* has an important role in buffering the pH of the ICF and of urine.

Protein Buffer Systems

Protein buffer systems depend on the ability of amino acids to respond to pH changes by accepting or releasing H^+. The underlying mechanism is shown in Figure 27–8•:

- If pH climbs, the carboxyl group (¬ COOH) of the amino acid can dissociate, acting as a weak acid and releasing a hydrogen ion. The carboxyl group then becomes a carboxylate ion (¬ COO^-). At the normal pH of body fluids (7.35–7.45), the carboxyl groups of most amino acids have already given up their hydrogen ions. (Proteins carry negative charges primarily for that rea son.) However, some amino acids, notably *histidine* and *cysteine*, have R groups (side chains) that will donate hydrogen ions if the pH climbs outside the normal range. Their buffering effects are very important in both the ECF and the ICF.

- If pH drops, the carboxylate ion and the amino group (¬ NH_2) can act as weak bases and accept additional hydrogen ions, forming a carboxyl group (¬ COOH) and an amino ion (¬ NH_3^+), respectively. This effect is limited primarily to free amino

acids and to the last amino acid in a polypeptide chain, because the carboxyl and amino groups in peptide bonds cannot function as buffers.

Plasma proteins contribute to the buffering capabilities of blood. Interstitial fluid contains extracellular protein fibers and dissolved amino acids that also assist in regulating pH. In the ICF of active cells, structural and other proteins provide an extensive buffering capability that prevents destructive changes in pH when organic acids, such as lactic acid or pyruvic acid, are produced by cellular metabolism.

Because exchange occurs between the ECF and the ICF, the protein buffer system can help stabilize the pH of the ECF. For example, when the pH of the ECF decreases, cells pump H^+ out of the ECF and into the ICF, where they can be buffered by intracellular proteins. When the pH of the ECF rises, pumps in cell membranes exchange H^+ in the ICF for K^+ in the ECF.

These mechanisms can assist in buffering the pH of the ECF. The process is slow, however, because hydrogen ions must be individually transported across the cell membrane. As a result, the protein buffer system in most cells cannot make rapid, large-scale adjustments in the pH of the ECF.

The Hemoglobin Buffer System The situation is somewhat different for red blood cells. These cells, which contain roughly 5.5 percent of the ICF, are normally suspended in the plasma. They are densely packed with hemoglobin, and their cytoplasm contains large amounts of carbonic anhydrase. Red blood cells have a significant effect on the pH of the ECF, because they absorb carbon dioxide from the plasma and convert it to carbonic acid. Carbon dioxide can diffuse across the RBC membrane very quickly, so no transport

mechanism is needed. As the carbonic acid dissociates, the bicarbonate ions diffuse into the plasma in exchange
for chloride ions, a swap known as the *chloride shift*. l**p. 846** The hydrogen ions are buffered by hemoglobin molecules. At the lungs, the entire reaction sequence diagrammed in Figure 23–23• (p. 846) proceeds in reverse. This mechanism is known as the **hemoglobin buffer system**.

The hemoglobin buffer system is the only intracellular buffer system that can have an immediate effect on the pH of the ECF. *The hemoglobin buffer system helps prevent drastic changes in pH when the plasma* PCO_2 *is rising or falling*.

The Carbonic Acid–Bicarbonate Buffer System

With the exception of red blood cells, some cancer cells, and tissues temporarily deprived of oxygen, body cells generate carbon dioxide virtually 24 hours a day. As we have seen, most of the carbon dioxide is converted to carbonic acid, which then dissociates into a hydrogen ion and a bicarbonate ion. The carbonic acid and its dissociation products form the **carbonic acid–bicarbonate buffer system**. The primary role of the carbonic acid–bicarbonate buffer system is to prevent changes in pH caused by organic acids and fixed acids in the ECF.

This buffer system consists of the reaction introduced in our discussion of volatile acids (Figure 27–9a•):

$CO_2 + H_2O \Delta H_2CO_3 \Delta H^+ + HCO_3^-$ carbon water carbonic bicarbonate dioxide acid ion

Because the reaction is freely reversible, a change in the concentration of any participant affects the concentrations of all other participants. For example, if hydrogen ions are added, most of them will be removed by interactions with HCO_3^-, forming H_2CO_3 (carbonic acid). In the process, the HCO_3^- acts as a weak base that buffers the excess H^+. The H_2CO_3 formed in this way in turn dissociates into CO_2 and water (Figure 27–9b•).

The extra CO2 can then be excreted at the lungs. In effect, this reaction takes the H^+ released by a strong organic or fixed acid and generates a volatile acid that can easily be eliminated.

The carbonic acid–bicarbonate buffer system can also protect against increases in pH, although such changes are relatively rare. If hydrogen ions are removed from the plasma, the reaction is driven to the right: The PCO_2 declines, and the dissociation of H2CO3 replaces the missing .

H+

The carbonic acid–bicarbonate buffer system has three important limitations:

1. *It Cannot Protect the ECF from Changes in pH that Result from Elevated or Depressed Levels of* ***CO*2.** A buffer system cannot pro

tect against changes in the concentration of its own weak acid. As Figure 27–9a• indicates, an equilibrium exists among the components of this buffer system. Thus, in this system, the addition of excess H^+ from an outside source would drive the reaction to the left. But the addition of excess CO2 would form H2CO3 and drive the reaction to the right. The dissociation of

-

H2CO3 would release H^+ and HCO3 , reducing the pH of the plasma.

2. *It Can Function Only When the Respiratory System and the Respiratory Control Centers Are Working Normally.* Normally, the elevation in PCO_2 that occurs when fixed or organic acids are buffered stimulates an increase in the respiratory rate. This increase accelerates the removal of CO2 at the lungs. If the respiratory passageways are blocked, or blood flow to the lungs

is impaired, or the respiratory centers do not respond normally, the efficiency of the buffer system will be reduced. This buffer system cannot eliminate the H^+ and remove the threat to homeostasis unless the respiratory system is functioning normally.

3. *The Ability to Buffer Acids Is Limited by the Availability of Bicarbonate Ions.* Every time a hydrogen ion is removed from the plasma, a bicarbonate ion goes with it. When all the bicarbonate ions have been tied up, buffering capabilities are lost.

-

Problems due to a lack of bicarbonate ions are rare, for several reasons. First, body fluids contain a large reserve of HCO3 , primarily in the form of dissolved molecules of the weak base *sodium bicarbonate* (NaHCO3). This readily available supply of

-

HCO3 is known as the **bicarbonate reserve**. The reaction involved (see Figure 27–9a•) is

-

Na$^+$ + HCO3 Δ NaHCO3.
bicarbonate sodium
ion bicarbonate

When hydrogen ions enter the ECF, the bicarbonate ions tied up in H2CO3 molecules are replaced by HCO3 $^-$from the bicarbonate reserve (Figure 27–9b•).

-

Second, additional HCO3 can be generated at the kidneys, through mechanisms described in Chapter 26 (see Figure 26–14c•,
p. 975). In the distal convoluted tubule and collecting system, carbonic anhydrase converts CO2 within tubular cells into H2CO3, which then dissociates. The hydrogen ion is pumped into tubular fluid in exchange for a sodium ion, and the bicarbonate ion is transported into peritubular fluid in exchange for a chloride ion. In effect, tubular cells remove HCl from peritubular fluid in exchange for NaHCO3.

The Phosphate Buffer System

-

The **phosphate buffer system** consists of the anion H_2PO_4 , which is a weak acid. The operation of the phosphate buffer system resembles that of the carbonic acid–bicarbonate buffer system. The reversible reaction involved is

-

$H_2PO_4 \, \Delta \, H^+ + HPO_4^{2-}$.
dihydrogen monohydrogen
phosphate phosphate

The weak acid is *dihydrogen phosphate* ($H_2PO_4^-$), and the anion released is *monohydrogen phosphate* (HPO_4^{2-}). In the ECF,
the phosphate buffer system plays only a supporting role in the regulation of pH, primarily because the concentration of HCO_3 far exceeds that of HPO_4^{2-}. However, the phosphate buffer system is quite important in buffering the pH of the ICF. In addition, cells contain a *phosphate reserve* in the form of the weak base *sodium monohydrogen phosphate* (Na_2HPO_4). The phosphate buffer
system is also important in stabilizing the pH of urine. The dissociation of Na_2HPO_4 provides additional HPO_4^{2-} for use by this buffer system:

$2Na^+ + HPO_4^{2-} \, \Delta \, Na_2HPO_4$
monohydrogen sodium
phosphate monohydrogen
phosphate

Maintenance of Acid–Base Balance

Although buffer systems can tie up excess H^+, they provide only a temporary solution to an acid–base imbalance. The hydrogen ions are not eliminated, but merely rendered harmless. For homeostasis to be preserved, the captured H^+ must ultimately be either permanently tied

up in water molecules, through the removal of carbon dioxide at the lungs, or removed from body fluids, through secretion at the kidneys. The underlying problem is that the body's supply of buffer molecules is limited. Suppose that a buffer molecule prevents a change in pH by binding a hydrogen ion that enters the ECF. That buffer molecule is then tied up, reducing the capacity of the ECF to cope with any additional H^+. Eventually, all the buffer molecules are bound to H^+, and further
pH control becomes impossible.

The situation can be resolved only by either removing the H^+ from the ECF (thereby freeing the buffer molecules) or replacing the buffer molecules. Similarly, if a buffer provides a hydrogen ion to maintain normal pH, homeostatic conditions will return only when either another hydrogen ion has been obtained or the buffer has been replaced.

The maintenance of acid–base balance thus includes balancing H^+ gains and losses. This "balancing act" involves coordinating the actions of buffer systems with respiratory mechanisms and renal mechanisms. These mechanisms support the buffer systems by (1) secreting or absorbing H^+, (2) controlling the excretion of acids and bases, and, when necessary, (3) generating additional buffers. It is the *combination* of buffer systems and these respiratory and renal mechanisms that maintains body pH within narrow limits.

Respiratory Compensation

Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Respiratory compensation occurs whenever body pH strays outside normal limits. Such compensation is effective because respiratory activity has a direct effect on the carbonic acid–bicarbonate buffer system. Increasing or decreasing the rate of respiration alters pH by lowering or raising the PCO_2. When the PCO_2 rises, the pH falls, because the addition of CO2 drives the carbonic acid–bicarbonate buffer system
to the right. When the PCO_2 falls, the pH rises because the removal of CO2 drives that buffer system to the left. The mechanisms responsible for the control of respiratory rate were described in Chapter 23; hence, only a brief summary is presented here. (If necessary, review Figures 23–26 and 23–27•.) l**pp. 850, 851** Chemoreceptors of the carotid and aortic

bodies are sensitive to the PCO_2 of circulating blood; other receptors, located on the ventrolateral surfaces of the medulla oblongata, monitor the PCO_2 of the

CSF. A rise in PCO_2 stimulates the chemoreceptors, leading to an increase in the respiratory rate. As the rate of respiration increases, more CO2 is lost at the lungs, so the PCO_2 returns to normal levels. Conversely, when the PCO_2 of the blood or CSF declines, the chemorecep

tors are inhibited. Respiratory activity becomes depressed and the breathing rate decreases, causing an elevation of the PCO_2 in the ECF.

Renal Compensation

-

Renal compensation is a change in the rates of H^+ and HCO3 secretion or reabsorption by the kidneys in response to changes in plasma pH. Under normal conditions, the body generates enough organic and fixed acids to add about 100 mEq of H^+ to the ECF each day. An equivalent number of hydrogen ions must therefore be excreted in urine to maintain acid–base balance. In addition, the kidneys assist the lungs by eliminating any CO2 that either enters the renal tubules during filtration or diffuses into the tubular fluid as it travels toward the renal pelvis.

Hydrogen ions are secreted into the tubular fluid along the proximal convoluted tubule (PCT), the distal convoluted tubule (DCT), and the collecting system. The basic mechanisms involved are depicted in Figures 26–12 and 26–14c• (pp. 971, 975). The ability to eliminate a large number of hydrogen ions in a normal volume of urine depends on the presence of buffers in the urine. The secretion of H^+ can continue only until the pH of the tubular fluid reaches 4.0–4.5. (At that point, the H^+ concentration gradient is so great that hydrogen ions leak out of the tubule as fast as they are pumped in.)

If the tubular fluid lacked buffers, the kidneys could secrete less than 1 percent of the acid produced each day before the pH reached this limit. To maintain acid balance under these conditions, the kidneys would have to produce about 1000 liters of urine each day just to keep pace with the generation of H^+ in the body. Buffers in tubular fluid are therefore extremely important, because they keep the pH high enough for H^+ secretion to continue. Metabolic acids are being generated continuously; without these buffering mechanisms, the kidneys would be unable to maintain homeostasis.

Figure 27–10• diagrams the primary routes of H^+ secretion and the buffering mechanisms that stabilize the pH of tubular fluid. The three major buffers involved are the carbonic acid–bicarbonate buffer system, the phosphate buffer system, and the ammonia buffer system (Figure 27–10a•). Glomerular filtration puts components of the carbonic acid–bicarbonate and phosphate buffer systems into the filtrate. The ammonia is generated by tubule cells (primarily those of the PCT).

Figure 27–10a• shows the secretion of H^+ , which relies on carbonic anhydrase (CA) activity within tubular cells. The hydrogen ions generated may be pumped into the lumen in exchange for sodium ions, individually or together with chloride ions. The net result is the secretion of H^+ , accompanied by the removal of CO2 (from the tubular fluid, the tubule cells, and the ECF), and the release of sodium bicarbonate into the ECF.

Figure 27–10b• shows the generation of ammonia within the tubules. As tubule cells use the enzyme *glutaminase* to break down the amino acid *glutamine*, amino groups are released as either ammonium ions (NH_4^+) or ammonia (NH3). The ammonium ions are transported into the lumen in exchange for Na^+ in the tubular fluid. The NH3, which is highly volatile and also toxic to cells, diffuses rapidly into the tubular fluid. There it reacts with a hydrogen ion, forming $NH4^+$.

This reaction buffers the tubular fluid and removes a potentially dangerous compound from body fluids. The carbon chains of the glutamine molecules are ultimately converted to $HCO3^-$, which is cotransported with Na^+ into the ECF. The generation of ammonia by tubule cells thus ties up H^+ in the tubular fluid and releases sodium bicarbonate into the ECF, where it contributes to the bicarbonate reserve. These mechanisms of H^+ secretion and buffering are always functioning, but their levels of activity vary widely with the pH of the ECF.

The Renal Responses to Acidosis and Alkalosis Acidosis (low body fluid pH) develops when the normal plasma buffer mechanisms are stressed by excessive numbers of hydrogen ions. The kidney tubules do not distinguish among the various acids that may cause acidosis. Whether the fall in pH results from the production of volatile, fixed, or organic acids, the renal contribution remains limited to (1) the secretion of H^+, (2) the activity of buffers in the tubular fluid, (3) the removal of CO_2, and (4) the reabsorption of $NaHCO_3$.

Tubule cells thus bolster the capabilities of the carbonic acid–bicarbonate buffer system. They do so by increasing the concentration of bicarbonate ions in the ECF, replacing those already used to remove hydrogen ions from solution. In a starving individual, tubule cells break down amino acids, yielding ammonium ions that are pumped into the tubular fluid, carbon chains for catabolism, and bicarbonates to help buffer ketone bodies in the blood (see Figure 26–14c•, p. 975).

When alkalosis (high body fluid pH) develops, (1) the rate of H^+ secretion at the kidneys declines, (2) tubule cells do not reclaim the bicarbonates in tubular fluid, and (3) the collecting system transports HCO_3^- into tubular fluid while releasing a strong acid (HCl) into peritubular fluid (Figure 27–10c•). The concentration of HCO_3^- in plasma decreases, promoting the dissociation of H_2CO_3 and the release of hydrogen ions. The additional H^+ generated at the kidneys helps return the pH to normal levels.

Disturbances of Acid–Base Balance

Objectives

- Identify the most frequent threats to acid–base balance.

- Explain how the body responds when the pH of body fluids varies outside normal limits.

Figure 27–11• summarizes the interactions among buffer systems, respiration, and renal function in maintaining normal acid–base balance. In combination, these mechanisms can generally control pH very precisely, so the pH of the ECF seldom varies more than 0.1 pH unit, from 7.35 to 7.45. When buffering mechanisms are severely stressed, however, the pH drifts outside these limits, producing symptoms of alkalosis or acidosis.

If you are considering a career in a health-related field, an understanding of acid–base dynamics will be essential for clinical diagnosis and patient management under a variety of conditions. Temporary shifts in the pH of body fluids occur frequently. Rapid and complete recovery involves a combination of buffer system activity and the respiratory and renal responses. More serious and prolonged disturbances of acid–base balance can result under the following circumstances:

- **Any Disorder Affecting Circulating Buffers, Respiratory Performance, or Renal Function.** Several conditions, including *emphysema* and *renal failure*, are associated with dangerous changes in pH. l**pp. 853, 984**
- **Cardiovascular Conditions.** Conditions such as *heart failure* or *hypotension* can affect the pH of internal fluids by causing fluid shifts and by changing glomerular filtration rates and respiratory efficiency. l**pp. 694, 722**
- **Conditions Affecting the Central Nervous System.** Neural damage or disease that affects the CNS can affect the respiratory and cardiovascular reflexes that are essential to normal pH regulation.

Serious abnormalities in acid–base balance generally have an initial *acute phase*, in which the pH moves rapidly out of the normal range. If the condition persists, physiological adjustments occur; the individual then enters the *compensated phase*. Unless the underlying problem is corrected, compensation cannot be completed, and blood chemistry will remain abnormal. The pH typically remains outside normal limits even after compensation has occurred. Even if the pH is within the normal range, the PCO_2 or $HCO3^-$ concentrations can be abnormal.

The primary source of the problem is usually indicated by the name given to the resulting condition:

- *Respiratory acid–base disorders* result from a mismatch between carbon dioxide generation in peripheral tissues and carbon dioxide excretion at the lungs. When a respiratory acid–base disorder is present, the carbon dioxide level of the ECF is abnormal.
- *Metabolic acid–base disorders* are caused by the generation of organic or fixed acids or by conditions affecting the concentration of $HCO3^-$ in the ECF.

Respiratory compensation alone may restore normal acid–base balance in individuals with respiratory acid–base disorders. In contrast, compensation mechanisms for metabolic acid–base disorders may be able to stabilize pH, but other aspects of acid–base balance (buffer system function, bicarbonate and PCO_2 levels) remain abnormal until the underlying metabolic cause is corrected.

We can subdivide the respiratory and metabolic categories to create four
major classes of acid–base disturbances: (1) *respiratory acidosis*, (2) *respiratory alkalosis*, (3) *metabolic acidosis*, and (4) *metabolic alkalosis*.

Respiratory Acidosis

Respiratory acidosis develops when the respiratory system cannot eliminate all the carbon dioxide generated by peripheral tissues. The primary sign is low plasma pH due to **hypercapnia**, an elevated plasma PCO_2. The usual cause is hypoventilation, an abnormally low respiratory rate. When the PCO_2 in the ECF rises, H^+ and $HCO3^-$ concentrations also begin rising as H2CO3 forms and dissociates. Other buffer systems can tie up some of the H^+, but once the combined buffering capacity has been exceeded, the pH begins to fall rapidly. The effects are diagrammed in Figure 27–12a•.

Respiratory acidosis is the most common challenge to acid–base equilibrium. Body tissues generate carbon dioxide rapidly. Even a few minutes of hypoventilation can cause acidosis, reducing the pH of the ECF to as low as 7.0. Under normal circumstances, the chemoreceptors that monitor the PCO_2 of plasma and of cerebrospinal fluid (CSF) eliminate the problem by calling
for an increase in breathing (pulmonary ventilation) rates.

If the chemoreceptors fail to respond, if the breathing rate cannot be increased, or if the circulatory supply to the lungs is inadequate, pH will continue to decline. If the decline is severe, **acute respiratory acidosis** develops. Acute respiratory acidosis is an immediate, life-threatening condition. It is especially dangerous in people whose tissues are generating large amounts of carbon dioxide, or in individuals who are incapable of normal respiratory activity. For this reason, the reversal of acute respiratory acidosis is probably the major goal in the resuscitation of cardiac arrest or drowning victims. Thus first-aid, CPR, and lifesaving courses always stress the "ABCs" of emergency care: *A*irway, *B*reathing, and *C*irculation.

Chronic respiratory acidosis develops when normal respiratory function has been compromised, but the compensatory mechanisms have not failed completely. For example, normal respiratory compensation may not occur in response to chemoreceptor stimulation in individuals with CNS injuries and those whose respiratory centers have been desensitized by drugs such as alcohol or barbiturates. As a result, these people are prone to developing acidosis due to chronic hypoventilation.

Even when respiratory centers are intact and functional, damage to some respiratory system components can prevent increased pulmonary exchange. Examples of conditions fostering chronic respiratory acidosis include emphysema, congestive heart failure, and pneumonia (in which alveolar damage or blockage typically occurs). Pneumothorax and respiratory muscle paralysis have a similar effect, because they, too, limit the ability to maintain adequate breathing rates.

When a normal pulmonary response does not occur, the kidneys respond by increasing the rate of H^+ secretion into tubular fluid. This response slows the rate of pH change. However, renal mechanisms alone cannot return the pH to normal until the underlying respiratory or circulatory problems are corrected.

The primary problem in respiratory acidosis is that the rate of pulmonary exchange is inadequate to keep the arterial PCO_2 within normal limits. Breathing efficiency can typically be improved temporarily by inducing bronchodilation or by using mechanical aids that provide air under positive pressure. If breathing has ceased, artificial respiration or a mechanical ventilator is required. These measures may restore normal pH if the respiratory acidosis was neither severe nor prolonged. Treatment of acute respiratory acidosis is complicated by the fact that, as we will soon see, it causes a complementary *metabolic acidosis* due to the generation of lactic acid in oxygen-starved tissues.

Respiratory Alkalosis

Problems resulting from **respiratory alkalosis** (Figure 27–12b•) are relatively uncommon. Respiratory alkalosis develops when respiratory activity lowers plasma PCO_2 to below-normal levels, a condition called **hypocapnia**. A temporary hypocapnia can be produced by *hyperventilation* when increased respiratory activity leads to a reduction in the arterial PCO_2. Continued hyperventilation can elevate the pH to levels as high as 8.0. This condition generally corrects itself, because the reduction in PCO_2 halts the stimulation of the chemoreceptors, so the urge to breathe fades until carbon dioxide levels have returned to normal. *Respiratory alkalosis caused by hyperventilation seldom persists long enough to cause a clinical emergency*.

Common causes of hyperventilation include physical stresses such as pain, or psychological stresses such as extreme anxiety. Hyperventilation gradually elevates the pH of the cerebrospinal fluid, and central nervous system function is affected. The initial symptoms involve tingling sensations in the hands, feet, and lips. A light-headed feeling may also be noted. If hyperventilation continues, the individual may lose consciousness. When unconsciousness occurs, any contributing psychological stimuli are removed, and the breathing rate declines. The PCO_2 then rises until pH returns to normal.

A simple treatment for respiratory alkalosis caused by hyperventilation consists of having the individual rebreathe air exhaled into a small paper bag. As the PCO_2 in the bag rises, so do the person's alveolar and arterial CO2 concentrations. This change eliminates the problem and restores the pH to normal levels. Other problems with respiratory alkalosis are rare and involve primarily (1) individuals adapting to high altitudes, where the low PCO_2 promotes hyperventilation, (2) patients on mechanical respirators, or (3) individuals whose brain
stem injuries render them incapable of responding to shifts in plasma CO2 concentrations.

Metabolic Acidosis

Metabolic acidosis is the second most common type of acid–base imbalance. It has three major causes:

1. The most widespread cause of metabolic acidosis is the production of a large number of fixed or organic acids. The hydrogen ions released by these acids overload the carbonic acid–bicarbonate buffer system, so pH begins to decline (Figure 27–13a•). We considered two examples of metabolic acidosis earlier:

- Lactic acidosis can develop after strenuous exercise or prolonged tissue hypoxia (oxygen starvation) as active cells rely on anaerobic respiration (see Figure 10–21c•, p. 314).
- **Ketoacidosis** results from the generation of large quantities of ketone bodies during the postabsorptive state of metabolism. Ketoacidosis is a problem in starvation, and a potentially lethal complication of poorly controlled diabetes mellitus. In either case, peripheral tissues are unable to obtain adequate glucose from the bloodstream and begin metabolizing lipids and ketone bodies.

2. A less common cause of metabolic acidosis is an impaired ability to excrete H^+ at the kidneys (see Figure 27–13a•). For example, conditions marked by severe kidney damage, such as *glomerulonephritis*, typically result in severe metabolic acidosis.

l**p. 960** Metabolic acidosis is also caused by diuretics that "turn off" the sodium–hydrogen transport system in the kidney tubules. The secretion of H^+ is directly or indirectly linked to the reabsorption of Na^+. When Na^+ reabsorption stops, so does H+ secretion.

3. Metabolic acidosis occurs after severe bicarbonate loss (Figure 27–13b•). The carbonic acid–bicarbonate buffer system relies on bicarbonate ions to balance hydrogen ions that threaten pH balance. A drop in the $HCO3^-$ concentration in the ECF thus

-

reduces the effectiveness of this buffer system, and acidosis soon develops. The most common cause of HCO3 depletion is chronic diarrhea. Under normal conditions, most of the bicarbonate ions secreted into the digestive tract in pancreatic, hepatic, and mucous secretions are reabsorbed before the feces are eliminated. In diarrhea, these bicarbonates are lost, and thus the

-

HCO3 concentration of the ECF drops.

The nature of the problem must be understood before treatment can begin. Potential causes are so varied that clinicians must piece together relevant clues to make a diagnosis. In some cases, the diagnosis is straightforward; for example, a patient with metabolic acidosis after a bicycle race probably has lactic acidosis. In other cases, clinicians must be detectives.

Compensation for metabolic acidosis generally involves a combination of respiratory and renal mechanisms. Hydrogen ions interacting with bicarbonate ions form carbon dioxide molecules that are eliminated at the lungs, whereas the kidneys excrete additional hydrogen ions into the urine and generate bicarbonate ions that are released into the ECF.

Combined Respiratory and Metabolic Acidosis

Respiratory acidosis and metabolic acidosis are typically linked, because oxygen-starved tissues generate large quantities of lactic acid, and because sustained hypoventilation leads to decreased arterial PO_2. The problem can be especially serious in cases of near drowning, in which body fluids have high PCO_2, low PO_2, and large amounts of lactic acid generated by the muscles of the struggling person. Prompt emergency treatment is essential. The usual procedure involves some form of artificial or mechanical respiratory assistance, coupled with intravenous infusion of an isotonic solution that contains sodium lactate, sodium gluconate, or sodium bicarbonate.

Metabolic Alkalosis

Metabolic alkalosis occurs when $HCO3^-$ concentrations become elevated (Figure 27–14•). The bicarbonate ions then interact with hydrogen ions in solution, forming H2CO3. The resulting reduction in H^+ concentrations causes symptoms of alkalosis.

Metabolic alkalosis is relatively rare, but we noted one interesting cause in Chapter 24. l**p. 879** The phenomenon known as the *alkaline tide*—produced by the influx into the ECF of large numbers of bicarbonate ions associated with the secretion of hydrochloric acid (HCl) by the gastric mucosa—temporarily elevates the $HCO3^-$ concentration in the ECF during meals. But serious metabolic alkalosis may result from bouts of repeated vomiting, because the stomach continues to generate stomach acids to

-

replace those that are lost. As a result, the HCO3 concentration of the ECF continues to rise.

-

Compensation for metabolic alkalosis involves a reduction in the breathing rate, coupled with an increased loss of HCO3 in urine. Treatment of mild cases typically addresses the primary cause—generally by controlling the vomiting—and may involve the administration of solutions that contain NaCl or KCl.

Treatment of acute cases of metabolic alkalosis may involve the administration of ammonium chloride (NH4Cl). Metabolism of the ammonium ion in the liver liberates a hydrogen ion, so in effect the introduction of NH4Cl leads to the internal generation of HCl, a strong acid. As the HCl diffuses into the bloodstream, pH falls toward normal levels.

The Detection of Acidosis and Alkalosis

Virtually anyone who has a problem that affects the cardiovascular, respiratory, urinary, digestive, or nervous system may develop potentially dangerous acid–base imbalances. For this reason, most diagnostic blood tests include several screens designed to provide information about pH and buffer function. Standard tests monitor blood pH, PCO_2, and $HCO3^{-}$ levels. These measurements make recognition of acidosis or alkalosis, and the classification of a particular condition as respiratory or metabolic, relatively straightforward. Figure 27–15• and Table 27–4 indicate the patterns that characterize the four major categories of acid–base disorders. Additional steps, such as determining the *anion gap*, plotting blood test results on a graph or *nomogram*, or using a diagnostic chart can help in identifying possible causes of the problem and in distinguishing compensated from uncompensated conditions. Details are included in the *Applications Manual*. AM: Diagnostic Classification of Acid–Base Disorders

100 Keys | The most common and acute acid–base disorder is respiratory acidosis, which develops when respiratory activity cannot keep pace with the rate of carbon dioxide generation in peripheral tissues.

Review acid–base balance on the **IP CD-ROM**: **Fluids and Electrolytes/Acid–Base Homeostasis**.

Concept Check

☐ What effect would a decrease in the pH of body fluids have on the respiratory rate?

☐ Why must tubular fluid in nephrons be buffered?

☐ How would a prolonged fast affect the body’s pH?

☐ Why can prolonged vomiting produce metabolic alkalosis?

Answers begin on p. A–1

Aging and Fluid, Electrolyte, and Acid–Base Balance

Objective

- Describe the effects of aging on fluid, electrolyte, and acid–base balance.

Fetuses and infants have very different requirements for the maintenance of fluid, electrolyte, and acid–base balance than do adults.

A fetus obtains the water, organic nutrients, and electrolytes it needs from the maternal bloodstream. Buffers in the fetal bloodstream provide short-term pH control, and the maternal kidneys eliminate the H^+ generated. A newborn's body water content is high: At birth, water accounts for roughly 75 percent of body weight, compared with 50–60 percent in adults. Basic aspects of electrolyte balance are the same in newborns as in adults, but the effects of fluctuations in the diet are much more immediate in newborns because reserves of minerals and energy sources are much smaller. (Readers seeking additional details should refer to the *Applications Manual*.) AM: Fluid, Electrolyte, and Acid–Base Balance in Infants

The descriptions of fluid, electrolyte, and acid–base balance in this chapter were based on the responses of normal, healthy adults under age 40. Aging affects many aspects of fluid, electrolyte, and acid–base balance, including the following:

- Total body water content gradually decreases with age. Between ages 40 and 60, average total body water content declines slightly, to 55 percent for males and 47 percent for females. After age 60, the values decline further, to roughly 50 percent for males and 45 percent for females. Among other effects, each decrease reduces the dilution of waste products, toxins, and any drugs that have been administered.
- A reduction in the glomerular filtration rate and in the number of functional nephrons reduces the body's ability to regulate pH through renal compensation.
- The body's ability to concentrate urine declines, so more water is lost in urine. In addition, the rate of insensible perspiration increases as the skin becomes thinner and more delicate. Maintaining fluid balance therefore requires a higher daily water intake. A reduction in ADH and aldosterone sensitivity makes older people less able than younger people to conserve body water when losses exceed gains.

- Many people over age 60 experience a net loss in body mineral content as muscle mass and skeletal mass decrease. This loss can be prevented, at least in part, by a combination of exercise and an increased dietary mineral supply.
- The reduction in vital capacity that accompanies aging reduces the body's ability to perform respiratory compensation, increasing the risk of respiratory acidosis. This problem can be compounded by arthritis, which can reduce vital capacity by limiting rib movements, and by emphysema, another condition that, to some degree, develops with aging.
- Disorders affecting major systems become more common with increasing age. Most, if not all, of these disorders have some effect on fluid, electrolyte, and/or acid–base balance.

Chapter Review

Selected Clinical Terminology

hyperkalemia: Plasma K^+ levels above 8 mEq> L. (p. 1006 and [AM]) **hypernatremia:** Plasma Na^+ levels above 150 mEq> L. (p. 1003) **hypokalemia:** Plasma K^+ levels below 2 mEq> L. (p. 1005) **hyponatremia:** Plasma Na^+ levels below 130 mEq>L. (p. 1003)

metabolic acidosis: Acidosis caused by the kidneys' inability to excrete hydrogen ions, the production of numerous fixed or organic

acids, or a severe bicarbonate loss. (p. 1017 and [AM]) **metabolic alkalosis:** A rare form of alkalosis resulting from high concentrations of bicarbonate ions in body fluids. (p. 1018 and [AM]) **respiratory acidosis:** Acidosis resulting from inadequate respiratory activity, characterized by elevated levels of carbon dioxide (hypercapnia) in body fluids. (p. 1015 and [AM]) **respiratory alkalosis:** Alkalosis due to excessive respiratory activity, which depresses carbon dioxide levels and elevates the pH of body fluids. (p. 1017 and [AM])

Study Outline

Fluid, Electrolyte, and Acid–Base Balance: An Overview p. 995

1. The maintenance of normal volume and normal composition of extracellular and intracellular fluids is vital to life. Three types of homeostasis are involved: **fluid balance**, **electrolyte balance**, and **acid–base balance**.

An Introduction to Fluid and Electrolyte Balance p. 996 The ECF and the ICF p. 996

1. The **intracellular fluid (ICF)** contains nearly two-thirds of the total body water; the **extracellular fluid (ECF)** contains the rest. Exchange occurs between the ICF and the ECF, but the two **fluid compartments** retain their distinctive characteristics. *(Figures 27–1, 27–2)*

Basic Concepts in the Regulation of Fluids and Electrolytes p. 998

2. Homeostatic mechanisms that monitor and adjust the composition of body fluids respond to changes in the ECF.

3. No receptors directly monitor fluid or electrolyte balance; receptors involved in fluid balance and in electrolyte balance respond to changes in plasma volume and osmotic concentration.

4. Body cells cannot move water molecules by active transport; all movements of water across cell membranes and epithelia occur passively, in response to osmotic gradients.

5. The body’s content of water or electrolytes will rise if intake exceeds outflow and will fall if losses exceed gains.

An Overview of the Primary Regulatory Hormones p. 998

6. ADH encourages water reabsorption at the kidneys and stimulates thirst. Aldosterone increases the rate of sodium reabsorption at the kidneys. Natriuretic peptides (ANP and BNP) oppose those actions and promote fluid and electrolyte losses in urine.

The Interplay between Fluid Balance and Electrolyte Balance p. 999

7. The regulatory mechanisms of fluid balance and electrolyte balance are quite different, and the distinction is clinically important.

Fluid Balance p. 999 Fluid Movement within the ECF p. 1000

1. Water circulates freely within the ECF compartment.

2. Water losses are normally balanced by gains through eating, drinking, and **metabolic generation**. *(Figure 27–3; Table 27–1)*

Fluid Gains and Losses p. 1000 Fluid Shifts p. 1001

3. Water movement between the ECF and ICF is called a **fluid shift**. If the ECF becomes hypertonic relative to the ICF, water will move from the ICF into the ECF until osmotic equilibrium has been restored. If the ECF becomes hypotonic relative to the ICF, water will move from the ECF into the cells, and the volume of the ICF will increase.

Fluids and Electrolytes/Water Homeostasis

Electrolyte Balance p. 1002

1. Problems with electrolyte balance generally result from a mismatch between gains and losses of sodium. Problems with potassium balance are less common, but more dangerous.

Sodium Balance p. 1002

2. The rate of sodium uptake across the digestive epithelium is directly proportional to the amount of sodium in the diet. Sodium losses occur mainly in urine and through perspiration. *(Figure 27–4)*

3. Shifts in sodium balance result in expansion or contraction of the ECF. Large variations in ECF volume are corrected by homeostatic mechanisms triggered by changes in blood volume. If the volume becomes too low, ADH and aldosterone are secreted; if the volume becomes too high, ANP is secreted. *(Figure 27–5)*

Potassium Balance p. 1004

4. Potassium ion concentrations in the ECF are very low and not as closely regulated as are sodium ion concentrations. Potassium excretion increases as ECF concentrations rise, under aldosterone stimulation, and when the pH rises. Potassium retention occurs when the pH falls.

Balance of Other Electrolytes p. 1005

5. ECF concentrations of other electrolytes, such as calcium, magnesium, phosphate, and chloride, are also regulated. *(Table 27–2)*

100 Keys | p. 1007

Fluids and Electrolytes/Electrolyte Homeostasis

Acid–Base Balance p. 1007

1. Acids and bases are either *strong* or *weak*. *(Table 27–3)*

The Importance of pH Control p. 1008

2. The pH of normal body fluids ranges from 7.35 to 7.45; variations outside this relatively narrow range produce symptoms of **acidosis** or **alkalosis**.

Types of Acids in the Body p. 1008

3. **Volatile acids** can leave solution and enter the atmosphere; **fixed acids** remain in body fluids until excreted at the kidneys; **organic acids** are participants in, or by-products of, aerobic metabolism.

4. Carbonic acid is the most important factor affecting the pH of the ECF. In solution, CO2 reacts with water to form carbonic acid. An inverse relationship exists between pH and the concentration of CO2. *(Figure 27–6)*

5. Sulfuric acid and phosphoric acid, the most important fixed acids, are generated during the catabolism of amino acids and compounds containing phosphate groups.

6. Organic acids include metabolic products such as lactic acid and ketone bodies.

Mechanisms of pH Control p. 1009

7. A **buffer system** typically consists of a weak acid and the anion released by its dissociation. The ion functions as a weak base. The three major buffer systems are (1) **protein buffer systems** in the ECF and ICF; (2) the **carbonic acid–bicarbonate buffer system**, most important in the ECF; and (3) the **phosphate buffer system** in the ICF and urine. *(Figure 27–7)*

8. In protein buffer systems, the component amino acids respond to changes in pH by accepting or releasing hydrogen ions. The **hemoglobin buffer system** is a protein buffer system that helps prevent drastic changes in pH when the PCO_2 is rising or falling.

(Figure 27–8)

9. The carbonic acid–bicarbonate buffer system prevents pH changes caused by organic acids and fixed acids in the ECF. The readily available supply of bicarbonate ions is the **bicarbonate reserve**. *(Figure 27–9)*

10. The phosphate buffer system plays a supporting role in regulating the pH of the ECF, but it is important in buffering the pH of the ICF and of urine.

Maintenance of Acid–Base Balance p. 1012

11. The lungs help regulate pH by affecting the carbonic acid–bicarbonate buffer system. A change in respiratory rate can raise or lower the PCO_2 of body fluids, affecting the body's buffering capacity. This process is called **respiratory compensation**.

12. In **renal compensation**, the kidneys vary their rates of hydrogen ion secretion and bicarbonate ion reabsorption, depending on the pH of the ECF. *(Figure 27–10)*

Disturbances of Acid–Base Balance p. 1014

1. Interactions among buffer systems, respiration, and renal function normally maintain tight control of the pH of the ECF, generally within a range of 7.35–7.45. *(Figure 27–11)*

2. *Respiratory acid–base disorders* result when abnormal respiratory function causes an extreme rise or fall in CO2 levels in the ECF. *Metabolic acid–base disorders* are caused by the generation of organic or fixed acids or by conditions affecting the concentration of bicarbonate ions in the ECF.

Respiratory Acidosis p. 1015

3. **Respiratory acidosis** results from excessive levels of CO2 in body fluids. *(Figure 27–12)*

Respiratory Alkalosis p. 1017

4. **Respiratory alkalosis** is a relatively rare condition associated with hyperventilation. *(Figure 27–12)*

Metabolic Acidosis p. 1017

5. **Metabolic acidosis** results from the depletion of the bicarbonate reserve, caused by an inability to excrete hydrogen ions at the kidneys, the production of large numbers of fixed and organic acids, or bicarbonate loss that accompanies chronic diarrhea. *(Figure 27–13)*

Metabolic Alkalosis p. 1018

6. **Metabolic alkalosis** occurs when bicarbonate ion concentrations become elevated, as from extended periods of vomiting.

(Figure 27–14)

The Detection of Acidosis and Alkalosis p. 1019

7. Standard diagnostic blood tests such as blood pH, PCO_2, and bicarbonate levels are used to recognize and classify acidosis and alkalosis conditions as respiratory or metabolic in nature. *(Figure 27–15; Table 27–4)*

100 Keys | p. 1019

Fluids and Electrolytes/Acid–Base Homeostasis

Aging and Fluid, Electrolyte, and Acid–Base Balance p. 1019

1. Changes affecting fluid, electrolyte, and acid–base balance in the elderly include (1) reduced total body water content, (2) impaired ability to perform renal compensation, (3) increased water demands due to reduced ability to concentrate urine and reduced sensitivity to ADH and aldosterone, (4) a net loss of minerals, (5) reductions in respiratory efficiency that affect the ability to perform respiratory compensation, and (6) increased incidence of conditions that secondarily affect fluid, electrolyte, or acid–base balance.

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The primary components of the extracellular fluid are

(a) lymph and cerebrospinal fluid

(b) plasma and serous fluids

(c) interstitial fluid and plasma

(d) a, b, and c are correct

2. The principal anions in the ICF are

(a) phosphate and proteins (Pr^-)

(b) phosphate and bicarbonate

(c) sodium and chloride

(d) sodium and potassium

3. Osmoreceptors in the hypothalamus monitor the osmotic concentration of the ECF and secrete _____ in response to higher osmotic concentrations.

(a) BNP **(b)** ANP

(c) aldosterone **(d)** ADH

4. Calcium homeostasis primarily reflects

(a) a balance between absorption in the gut and excretion by the kidneys

(b) careful regulation of blood calcium levels by the kidneys

(c) an interplay between parathormone and aldosterone

(d) an interplay between reserves in the bone, the rate of absorption, and the rate of excretion

(e) hormonal control of calcium reserves in the bones

5. The *most* important factor affecting the pH of body tissues is the concentration of

(a) lactic acid

(b) ketone bodies

(c) organic acids

(d) carbon dioxide

(e) hydrochloric acid

6. Changes in the pH of body fluids are compensated for by all of the following, *except*

(a) an increase in urine output

(b) the carbonic acid–bicarbonate buffer system

(c) the phosphate buffer system

(d) changes in the rate and depth of breathing

(e) protein buffers

7. Respiratory acidosis develops when the plasma pH is

(a) elevated due to a decreased plasma PCO_2 level

(b) decreased due to an elevated plasma PCO_2 level

(c) elevated due to an elevated plasma PCO_2 level

(d) decreased due to a decreased plasma PCO_2 level

8. Metabolic alkalosis occurs when

(a) bicarbonate ion concentrations become elevated

(b) there is a severe bicarbonate loss

(c) the kidneys fail to excrete hydrogen ions

(d) ketone bodies are generated in abnormally large quantities

9. Identify four hormones that mediate major physiological adjustments that affect fluid and electrolyte balance. What are the primary effects of each hormone?

LEVEL 2 Reviewing Concepts

10. Drinking a hypotonic solution causes the ECF to

(a) increase in volume and become hypertonic with respect to the ICF

(b) decrease in volume and become hypertonic
with respect to the ICF

(c) decrease in volume and become hypotonic
with respect to the ICF

(d) increase in volume and become hypotonic
with respect to the ICF

11. The osmotic concentration of the ECF decreases if the individual gains water without a corresponding

(a) gain of electrolytes

(b) loss of water

(c) fluid shift from the ECF to the ICF

(d) a, b, and c are correct

12. When the pH of body fluids begins to *fall*, proteins will

(a) release a hydrogen from the carboxyl group

(b) release a hydrogen from the amino group

(c) release a hydrogen at the carboxyl group

(d) bind a hydrogen at the amino group

13. In a protein buffer system, if the pH rises,

(a) the protein acquires a hydrogen ion from carbonic acid

(b) hydrogen ions are buffered by hemoglobin molecules

(c) a hydrogen ion is released and a carboxyl ion is formed

(d) a chloride shift occurs

14. Differentiate among fluid balance, electrolyte balance, and acid–base balance and explain why each is important to homeostasis.

15. What are fluid shifts? What is their function and what factors can cause them?

16. Why should a person with a fever drink plenty of fluids?

17. Define and give an example of **(a)** a volatile acid, **(b)** a fixed acid, and **(c)** an organic acid. Which represent(s) the greatest threat to acid–base balance? Why?

18. What are the three major buffer systems in body fluids? How does each system work?

19. How do respiratory and renal mechanisms support the buffer systems?

20. Differentiate between respiratory compensation and renal compensation.

21. Distinguish between respiratory and metabolic disorders that disturb acid–base balance.

22. What is the difference between metabolic acidosis and respiratory acidosis? What can cause these conditions?

23. The most recent advice from medical and nutritional experts is to decrease one's intake of salt so that it does not exceed the amount needed to maintain a constant ECF composition. What effect does excessive salt and water ingestion have on **(a)** urine volume, **(b)**

urine concentration, and **(c)** blood pressure?

24. Exercise physiologists recommend that adequate amounts of fluid be ingested before, during, and after exercise. Why is fluid replacement during extensive sweating important?

LEVEL 3 Critical Thinking and Clinical Applications

25. After falling into an abandoned stone quarry filled with water and nearly drowning, a young boy is rescued. His rescuers assess his condition. They find that his body fluids have high PCO_2 and low PO_2 levels and that large amounts of lactic acid were generated by

the boy's muscles as he struggled in the water. As a clinician, diagnose the boy's condition and recommend the necessary treatment to restore his body to homeostasis.

26. Dan has been lost in the desert for 2 days with very little water. As a result of this exposure you would expect to observe which of the following:

(a) elevated ADH levels

(b) decreased blood osmolarity

(c) normal urine production

(d) increased blood volume

(e) cells enlarged with fluid

27. Mary, a nursing student, has been caring for burn patients. She notices that they consistently show elevated levels of potassium in their urine and wonders why. What would you tell her?

28. While visiting a foreign country, Milly inadvertently drinks some water, even though she had been advised not to. She contracts an intestinal disease that causes severe diarrhea. How would you expect her condition to affect her blood pH, urine pH, and pattern of ventilation?

29. Yuka is dehydrated, so her physician prescribes intravenous fluids. The attending nurse becomes distracted and erroneously gives Yuka a hypertonic glucose solution instead of normal saline. What effect will this mistake have on Yuka's plasma levels of ADH and urine volume?

30. Refer to the diagnostic flowchart in Figure 27–15•. Use information from the blood test results in the accompanying table to categorize the acid–base disorders that affect the patients represented in the table.

Results	**Patient 1**	**Patient 2**		**Patient 3**
pH	7.5	7.2	7.0	7.7
PCO2	32	45	60	50
Na	138	140	140	136
HCO3	22	20	28	34
Cl	106	102	101	91
Anion gap *		10	18	12

* Anion gap = Na^+ concentration – (HCO_3^- concentration + Cl^- concentration).

Fluids and Electrolytes

Can you compare the composition of intracellular and extracellular fluids? Stop here to view the *Fluids and Electrolytes* module of your **InterActive Physiology CD-ROM.** This module contains interactive exercises, quizzes, and study outlines on the following topics:

- Introduction to Body Fluids
- Water Homeostasis
- Electrolyte Homeostasis
- Acid/Base Homeostasis

At this point in the chapter, click on *Introduction to Body Fluids*. Use **IP** to review the composition of fluid compartments. A Study Outline consisting of notes, diagrams, and study questions for each topic can also be printed from **IP**. To help ensure your success in anatomy and physiology, review the remaining topics as they appear in your text and each time you see the CD icon.

TABLE 27–1 Water Balance

(6 1) weakness, cardiomyopathy, malabsorption syndrome; vitamin D and/or
osteoporosis hyperparathyroidism; calcitriol vitamin D deficiency supplementation
Chloride Hyperchloremia Acidosis, hyperkalemia Dietary excess; Infusion of hypotonic (100–108) (7 112) increased chloride solution to lower retention plasma concentration Hypochloremia Alkalosis, anorexia, Vomiting; hypokalemia Diuretic use and infusion (6 95) muscle cramps, apathy of hypertonic salt solution
TABLE 27–3 A Review of Important Terms Relating
to Acid–Base Balance

pH The negative exponent (negative logarithm) of the hydrogen ion concentration $[H^+]$

Neutral A solution with a pH of 7; the solution contains equal numbers of hydrogen ions and hydroxide ions

Acidic A solution with a pH below 7; in this solution, hydrogen ions predominate

Basic, or A solution with a pH above 7; in this solution,

-

alkaline hydroxide ions (OH) predominate

Acid A substance that dissociates to release hydrogen ions, decreasing pH

Base A substance that dissociates to release hydroxide ions or to tie up hydrogen ions, increasing pH

Salt An ionic compound consisting of a cation other than hydrogen and an anion other than a hydroxide ion

Buffer A substance that tends to oppose changes in the pH of a solution by removing or replacing hydrogen ions; in body fluids, buffers maintain blood pH within normal limits (7.35–7.45)

TABLE 27–4 Changes in Blood Chemistry Associated with the Major Classes of Acid–Base Disorders

pH (normal (normal HCO3

Disorder 7.35–7.45)

- **FIGURE 27–5** The Integration of Fluid Volume Regulation and Sodium Ion Concentrations in Body Fluids. NP = Natriuretic peptides
- **FIGURE 27–6** The Basic Relationship between PCO_2 and Plasma pH. The PCO_2 is inversely related to the pH.
- **FIGURE 27–7** Buffer Systems in Body Fluids. Phosphate buffers occur primarily in the ICF, whereas the carbonic acid–bicarbonate buffer system occurs primarily in the ECF. Protein buffer systems are in both the ICF and the ECF. Extensive interactions take place among these systems.
- **FIGURE 27–8** The Role of Amino Acids in Protein Buffer Systems. Depending on the pH of their surroundings, amino acids either donate a hydrogen ion (as at left) or accept a hydrogen ion (as at right).
- **FIGURE 27–9** The Carbonic Acid–Bicarbonate Buffer System. **(a)** Basic components of the carbonic acid–bicarbonate buffer system, and their relationships to carbon dioxide and the bicarbonate reserve. **(b)** The response of the carbonic acid–bicarbonate buffer system to hydrogen ions generated by fixed or organic acids in body fluids.
- **FIGURE 27–10** Kidney Tubules and pH Regulation. **(a)** The three major buffering mechanisms in tubular fluid, which are essential to the secretion of hydrogen ions. **(b)** The production of ammonium ions and ammonia by the breakdown of glutamine. **(c)** The response of the kidney tubules to alkalosis.
- **FIGURE 27–11** Interactions among the Carbonic Acid–Bicarbonate Buffer System and Compensatory Mechanisms in the Regulation of Plasma pH. The central role of the carbonic acid–bicarbonate buffer system is highlighted. **(a)** The response to acidosis caused by the addition of H^+. **(b)** The response to alkalosis caused by the removal of H^+.

- **FIGURE 27–12** Respiratory Acid–Base Regulation. Respiratory acidosis **(a)** and respiratory alkalosis **(b)**, which result from inadequate and excessive breathing, respectively. In healthy individuals, respiratory responses, combined with renal responses, can generally restore normal acid–base balance.
- **FIGURE 27–13** Responses to Metabolic Acidosis. Metabolic acidosis can result from either **(a)** increased acid production or decreased acid secretion, leading to a buildup of H^+ in body fluids, or **(b)** a loss of bicarbonate ions that makes the carbonic acid–bicarbonate buffer system in capable of preventing a fall in pH. Respiratory and renal compensation mechanisms can stabilize pH, but blood chemistry remains abnormal until the levels of acid production, acid secretion, and bicarbonate ions return to normal.
- **FIGURE 27–14** Metabolic Alkalosis. Metabolic alkalosis most commonly results from the loss of acids, especially stomach acid lost through vomiting. As replacement gastric acids are produced, the alkaline tide introduces a great many bicarbonate ions into the bloodstream, so pH increases.
- **FIGURE 27–15** A Diagnostic Chart for Acid–Base Disorders. The anion gap is defined as: Na^+ concentration – (HCO_3 concentration + Clconcentration). For additional discussion of important diagnostic procedures, see the *Applications Manual: Diagnostic Classification of Acid–Base Disorders.*

6

Continuity of Life

Chapter 28, The Reproductive System, discusses how the male and female reproductive organs (gonads) produce and store specialized reproductive cells (gametes) that combine to form new individuals, and how the gonads also secrete hormones that play major roles in the maintenance of normal sexual function.

Chapter 29, Development and Inheritance, describes how genetic programming, environmental factors, and various physiological processes affect the events following the union of male and female gametes, from prenatal development, through childhood and adolescence, and into maturity and senescence (aging).

The End of Chapter questions within this unit include critical thinking questions about both normal and abnormal functions. For comprehensive exercises covering material in the unit as a whole, see the Clinical Problems at the end of the corresponding unit in the *Applications Manual* [AM].

Introduction to the Reproductive System

Objective

• Specify the principal components of the human reproductive system and summarize their functions.

In this chapter we examine the anatomy and physiology of the human **reproductive system**, which is the only system that is not essential to the life of the individual. This system does, however, ensure the continued existence of the human species—by pro-

¯e

ducing, storing, nourishing, and transporting functional male and female reproductive cells, or **gametes** (GAM-ts). The reproductive system includes the following components:

–

. • **Gonads** (GO-nadz), or reproductive organs that produce gametes and hormones.

. • Ducts that receive and transport the gametes.

. • Accessory glands and organs that secrete fluids into the ducts of the reproductive system or into other excretory ducts.

•

Perineal structures that are collectively known as the **external genitalia** (jen-i-TA¯-l

¯e

-uh).

In both males and females, the ducts are connected to chambers and passageways that open to the exterior of the body. The structures involved constitute the *reproductive tract*. The male and female reproductive systems are functionally quite different,

however. In adult males, the **testes** (TES-t z; singular, *testis*), or male gonads, secrete sex hormones called *androgens* (principally *testosterone*, which, together with other sex hormones, was introduced in Chapter 18). l**p. 622** The testes also produce the male

¯e

gametes, called **spermatozoa** (sper-ma-t
¯o
-Z

¯O

-uh; singular, *spermatozoon*), or *sperm*—one-half billion each day. During *emission*, mature spermatozoa travel along a lengthy duct system, where they are mixed with the secretions of accessory glands. The mixture created is known as **semen** (S
¯E

-men). During *ejaculation*, semen is expelled from the body.

In adult females, the **ovaries**, or female gonads, typically release only one immature gamete, an **oocyte**, per month. This immature gamete travels along one of two short *uterine tubes*, which end in the muscular organ called the *uterus* (
¯U

-ter-us). If a sperm reaches the oocyte and initiates the process of fertilization, the oocyte matures into an **ovum** (plural, *ova*). A short passageway, the *vagina* (va-J -nuh), connects the uterus with the exterior. Ejaculation introduces semen into the vagina during *sexual intercourse*,
I¯and the spermatozoa then ascend the female reproductive tract. If fertilization occurs, the uterus will enclose and support a developing *embryo* as it grows into a *fetus* and prepares for birth.

Next we will examine the anatomy of the male and female reproductive systems further, and will consider the physiological and hormonal mechanisms responsible for the regulation of reproductive function. Earlier chapters introduced the anatomical reference points used in the discussions that follow; you may find it helpful to review the figures on the pelvic girdle (Figures 8–7 and 8–8•, pp. 246, 247), perineal musculature (Figure 11–12•, p. 348), pelvic innervation (Figure 13–12•, p. 436), and regional blood supply (Figures 21–25 and 21–29•, pp. 744, 749).

The Reproductive System of the Male

Objectives

. • Describe the components of the male reproductive system.

. • Outline the processes of meiosis and spermatogenesis

in the testes.

. • Explain the roles played by the male reproductive tract and accessory glands in the functional maturation, nourishment, storage, and transport of spermatozoa.

. • Specify the normal composition of semen.

. • Summarize the hormonal mechanisms that regulate male reproductive functions.

The principal structures of the male reproductive system are shown in Figure 28–1•. Proceeding from a testis, the spermatozoa travel within the *epididymis* (ep-i-DID-i-mus); the *ductus deferens* (DUK-tus DEF-e-renz), or *vas deferens*; the *ejaculatory duct*; and

¯a

the *urethra* before leaving the body. Accessory organs—the *seminal* (SEM-i-nal) *vesicles*, the *prostate* (PROS-t t) *gland*, and the E¯

bulbourethral (bul-b

¯o ¯u

-R

-thral) *glands*—secrete various fluids into the ejaculatory ducts and urethra. The external genitalia

-

¯O

-tum), which encloses the testes, and the *penis* (P
¯E

-nis), an erectile organ through which the distal
consist of the *scrotum* (SKR
portion of the urethra passes.

The Testes

Each testis has the shape of a flattened egg that is roughly 5 cm (2 in.) long, 3 cm (1.2 in.) wide, and 2.5 cm (1 in.) thick. Each has a weight of 10–15 g (0.35–0.53 oz). The testes hang within the **scrotum**, a fleshy pouch suspended inferior to the perineum, anterior to the anus and posterior to the base of the penis (see Figure 28–1•). ATLAS: Embryology Summary 21: The Development of the Reproductive System

Descent of the Testes

During development of the fetus, the testes form inside the body cavity adjacent to the kidneys. A bundle of connective-tissue
fibers—called the **gubernaculum testis** (goo-bur-NAK-
¯u
-lum TES-tis)—extends from each testis to the posterior wall of a small
anterior and inferior pocket of the peritoneum (Figure 28–2a•). As the fetus grows, the gubernacula do not get any longer, so they lock the testes in position. As a result, the relative position of each testis changes as the body enlarges: The testis gradually moves inferiorly and anteriorly toward the anterior abdominal wall. During the seventh developmental month, fetal growth continues at a rapid pace, and circulating hormones stimulate a contraction of the gubernaculum testis. Over this period, each testis moves through the abdominal musculature, accompanied by small pockets of the peritoneal cavity. This process is called the **descent of the testes**.

In *cryptorchidism* (krip-TOR-ki-dizm; *crypto*, hidden + *orchis*, testis), one or both of the testes have not descended into the scrotum by the time of birth. Typically, the cryptorchid (abdominal) testes are lodged in the abdominal cavity or within the inguinal canal. Cryptorchidism occurs in about 3 percent of full-term deliveries and in roughly 30 percent of premature births. In most instances, normal descent occurs a few weeks later, but the condition can be surgically corrected if it persists. Corrective measures should be taken before *puberty* (sexual maturation), because a cryptorchid testis will not produce spermatozoa. If both testes are cryptorchid, the individual will be *sterile* (*infertile*) and unable to father children. If the testes cannot be moved into the scrotum, in most cases they will be removed, because about 10 percent of males with uncorrected cryptorchid testes eventually develop testicular cancer. This surgical procedure is called an *orchiectomy* (or-kē-EK-to-mē).

As each testis moves through the body wall, it is accompanied by the ductus deferens and the testicular blood vessels, nerves, and lymphatic vessels. Together, these structures form the body of the spermatic cord, which we will discuss next.

The Spermatic Cords

The **spermatic cords** are paired structures extending between the abdominopelvic cavity and the testes (Figure 28–3•). Each spermatic cord consists of layers of fascia and muscle enclosing the ductus deferens and the blood vessels, nerves, and lymphatic vessels that supply the testes. The blood vessels include the *deferential artery*, a *testicular artery*, and the **pampiniform** (pam-PIN-i-form; *pampinus*, tendril + *forma*, form) **plexus** of a testicular vein. Branches of the *genitofemoral nerve* from the lumbar plexus provide innervation. Each spermatic cord begins at the entrance to the *inguinal canal* (a passageway through the abdominal musculature). After passing through the inguinal canal, the spermatic cord descends into the scrotum.

The inguinal canals form during development as the testes descend into the scrotum; at that time, these canals link the scrotal cavities with the peritoneal cavity. In normal adult males, the inguinal canals are closed, but the presence of the spermatic cords creates weak points in the abdominal wall that remain throughout life. As a result, *inguinal hernias*—protrusions of visceral tissues or organs into the inguinal canal—are relatively common in males. Note that the inguinal canals in females are very small, containing only the *ilioinguinal nerves* and the *round ligaments* of the uterus; the abdominal wall is nearly intact, so inguinal hernias in women are very rare.

The Scrotum and the Position of the Testes

The scrotum is divided internally into two chambers. The partition between the two is marked by a raised thickening in the scrotal surface known as the **raphe** (RĀ-fē) (see Figure 28–3•). Each testis lies in a separate chamber, or **scrotal cavity**. Because the scrotal cavities are separated by a partition, infection or inflammation of one testis does not ordinarily spread to the other. A narrow space separates the inner surface of the scrotum from the outer surface of the testis. The **tunica vaginalis** (TOO-ni-ka vaj-i-NAL-is), a serous membrane, lines the scrotal cavity and reduces friction between the opposing parietal (scrotal) and visceral (testicular) surfaces. The tunica vaginalis is an isolated portion of the peritoneum that lost its connection with the peritoneal cavity after the testes descended, when the inguinal canal closed.

The scrotum consists of a thin layer of skin and the underlying superficial fascia. The dermis contains a layer of smooth muscle, the **dartos** (DAR-tōs) **muscle**. Resting muscle tone in the dartos muscle elevates the testes and causes the characteristic wrinē

kling of the scrotal surface. A layer of skeletal muscle, the **cremaster** (kr -MAS-ter) **muscle**, lies deep to the dermis. Contraction of the cremaster muscle during sexual arousal or in response to decreased testicular temperature tenses the scrotum and pulls the testes closer to the body. Normal development of spermatozoa in the testes requires temperatures about 1.1°C (2°F) lower than those elsewhere in the body. The cremaster and dartos muscles relax or contract to move the testes away from or toward the body as needed to maintain acceptable testicular temperatures. When air or body temperature rises, these muscles relax and the testes move away from the body. Sudden cooling of the scrotum, as occurs during entry into a cold swimming pool, results in contractions that pull the testes closer to the body and keep testicular temperatures from falling.

Structure of the Testes

Deep to the tunica vaginalis covering the testis is the **tunica albuginea** (al-b

ū

-JIN-

ē

-uh), a dense layer of connective tissue rich in collagen fibers (Figure 28–4a•). These fibers are continuous with those surrounding the adjacent epididymis and extend into the substance of the testis. There they form fibrous partitions, or *septa*, that converge toward the region nearest the entrance to the epididymis. The connective tissues in this region support the blood vessels and lymphatic vessels that supply and drain the testis, and the *efferent ductules*, which transport spermatozoa to the epididymis.

Histology of the Testes

The septa subdivide the testis into a series of **lobules** (see Figure 28–4a•). Distributed among the lobules are roughly 800 slender, tightly coiled **seminiferous** (sem-i-NIF-er-us) **tubules** (Figures 28–4 and 28–5•). Each tubule averages about 80 cm (32 in.) in length, and a typical testis contains nearly one-half mile of seminiferous tubules. Sperm production occurs within these tubules.

Each seminiferous tubule forms a loop that is connected to a maze of passageways known as the **rete** (R
¯E

-t
¯e
; *rete*, a net) **testis**
(see Figure 28–4•). Fifteen to 20 large **efferent ductules** connect the rete testis to the epididymis.

Because the seminiferous tubules are tightly coiled, most histological preparations show them in transverse section (Figure 28–5a•). Each tubule is surrounded by a delicate connective tissue capsule (Figure 28–5b•), and areolar tissue fills the spaces between the tubules. Within those spaces are numerous blood vessels and large **interstitial cells** (*cells of Leydig*). Interstitial cells are responsible for the production of *androgens*, the dominant sex hormones in males. *Testosterone* is the most important androgen.

Spermatozoa are produced by the process of **spermatogenesis** (sper-ma-t
¯o
-JEN-e-sis). Spermatogenesis begins at the outer
most layer of cells in the seminiferous tubules and proceeds toward the lumen (Figure 28–5c•). At each step in this process, the
daughter cells move closer to the lumen. First, stem cells called **spermatogonia** (sper-ma-t
¯o
-G

–

O
-n
¯e

-uh) divide by mitosis to

produce two daughter cells, one of which remains at that location as a spermatogonium while the other differentiates into a pri

mary spermatocyte. **Primary spermatocytes** (sper-MA-t

ı involved only in the production of gametes (spermatozoa in males, ova in females). Primary spermatocytes give rise to **secondary spermatocytes** that differentiate into **spermatids** (SPER-ma-tidz)—immature gametes that subsequently differentiate into spermatozoa. The spermatozoa lose contact with the wall of the seminiferous tubule and enter the fluid in the lumen.

Each seminiferous tubule contains spermatogonia, spermatocytes at various stages of meiosis, spermatids, spermatozoa, and

–

–o

ts) are the cells that begin *meiosis*, a specialized form of cell division-s

large **sustentacular** (sus-ten-TAK-

–u

-lar) **cells** (or *Sertoli cells*). Sustentacular cells are attached to the tubular capsule and extend

to the lumen between the other types of cells (see Figure 28–5b,c•).

Spermatogenesis

Spermatogenesis involves three integrated processes:

1. *Mitosis.* Spermatogonia undergo cell divisions throughout adult life. (You can review the description of mitosis and cell division in Chapter 3. l**pp. 97–98**) One daughter cell from each division remains in place while the other is pushed toward the

lumen of the seminiferous tubule. The displaced cells differentiate into primary spermatocytes, which prepare to begin meiosis.

–

O

2. *Meiosis.* Meiosis (m

ı chromosomes, half the normal set. As a result, the fusion of the nuclei of a male gamete and a female gamete produces a cell that has the normal number of chromosomes (46), rather than twice that number. In the seminiferous tubules, meiotic divisions that begin with primary spermatocytes produce spermatids, the undifferentiated male gametes.

2. **3.** *Spermiogenesis*. Spermatids are small, relatively unspecialized cells. In *spermiogenesis*, spermatids differentiate into physically mature spermatozoa, which are among the most highly specialized cells in the body. Spermiogenesis involves major changes in a spermatid’s internal and external structures.

–

Mitosis and Meiosis

In both males and females, mitosis and meiosis differ significantly in terms of the events occurring in the nucleus. As you may recall from Chapter 3, somatic cells contain 23 pairs of chromosomes. Each pair consists of one chromosome provided by the father, and another provided by the mother, at the time of fertilization. Mitosis is part of the process of somatic cell division, producing two daughter cells each containing identical pairs of chromosomes; the pattern is illustrated in Figure 28–6a•. Because daughter cells contain both members of each chromosome pair (for a total of 46 chromosomes), they are called **diploid** (DIP-loyd; *diplo*, double) cells. Meiosis (Figure 28–6b•) involves two cycles of cell division (*meiosis I* and *meiosis II*) and produces four cells, each of which contains 23 *individual* chromosomes. Because these cells contain only one member of each pair of chromosomes, they are called **haploid** (HAP-loyd; *haplo*, single) cells. The events in the nucleus shown in Figure 28–6b• are the same for the formation of spermatozoa or ova.

As a cell prepares to begin meiosis, DNA replication occurs within the nucleus just as it does in a cell preparing to undergo mitosis. This similarity continues as prophase I arrives; the chromosomes condense and become visible with a light microscope. As in mitosis, each chromosome consists of two duplicate *chromatids*.

At this point, the close similarities between meiosis and mitosis end. In meiosis, the corresponding maternal and paternal chromosomes now come together, an event known as

synapsis (si-NAP-sis). Synapsis involves 23 pairs of chromosomes; each member of each pair consists of two chromatids. A matched set of four chromatids is called a **tetrad** (TET-rad; *tetras*, four) (see Figure 28–6b•). Some exchange of genetic material can occur between the chromatids of a chromosome pair at this stage of meiosis. Such an exchange, called *crossing over*, increases genetic variation among offspring; we will discuss it in Chapter 29.

Meiosis includes two division cycles, referred to as **meiosis I** and **meiosis II**. The stages within each phase are identified as prophase I, metaphase II, and so on. The nuclear envelope disappears at the end of prophase I. As metaphase I begins, the tetrads line up along the metaphase plate. As anaphase I begins, the tetrads break up—the maternal and paternal chromosomes separate. This is a major difference between mitosis and meiosis: In mitosis, each daughter cell receives one of the two copies of every chromosome, maternal and paternal; in meiosis I, each daughter cell receives both copies of *either* the maternal chromosome *or* the paternal chromosome from each tetrad. (Compare the two parts of Figure 28–6•.)

As anaphase proceeds, the maternal and paternal components are randomly and independently distributed. That is, as each tetrad splits, one cannot predict which daughter cell will receive copies of the maternal chromosome, and which will receive copies

-sis) is a special form of cell division involved in gamete production. In humans, gametes contain 23

-

of the paternal chromosome. As a result, telophase I ends with the formation of two daughter cells containing unique combinations of maternal and paternal chromosomes. Both cells contain 23 chromosomes. Because the first meiotic division reduces the number of chromosomes from 46 to 23, it is called a **reductional division**. Each of these chromosomes still consists of two duplicate chromatids. The duplicates will separate during meiosis II.

The interphase separating meiosis I and meiosis II is very brief, and no DNA is replicated during that period. Each cell proceeds through prophase II, metaphase II, and anaphase II. During anaphase II, the duplicate chromatids separate. Telophase II thus yields *four cells*, each containing 23 chromosomes. Because the number of chromosomes has not changed, meiosis II is an **equational division**. Although chromosomes are evenly distributed among these four cells, the cytoplasm may not be. In males, meiosis produces four immature gametes that are identical in size; each will develop into a functional sperm. In females, meiosis produces one huge ovum and three tiny, nonfunctional polar bodies. We will examine the details of spermatogenesis here and will consider oogensis in a later section.

In spermatogenesis (Figure 28–7•), the mitotic division of each diploid spermatogonium produces two daughter cells. One is a spermatogonium that remains in contact with the basal lamina, and the other is a primary spermatocyte that is displaced toward the lumen. As meiosis begins, each primary spermatocyte contains 46 individual chromosomes. At the end of meiosis I, the daughter cells are called **secondary spermatocytes**. Every secondary spermatocyte contains 23 chromosomes, each of which consists of a pair of duplicate chromatids. The secondary spermatocytes soon enter prophase II. The completion of metaphase II, anaphase II, and telophase II yields four haploid spermatids, each containing 23 chromosomes.

For each primary spermatocyte that enters meiosis, four spermatids are produced. Because cytokinesis (cytoplasmic division) is not completed in meiosis I or meiosis II, the four spermatids initially remain interconnected by bridges of cytoplasm. These connections assist in the transfer of nutrients and hormones between the cells, helping ensure that the cells develop in synchrony. The bridges are not broken until the last stages of physical maturation.

100 Keys | Meiosis produces gametes that contain half the number of chromosomes found in somatic cells. For each cell

entering meiosis, the testes produce four spermatozoa, whereas the ovaries produce a single ovum.

Spermiogenesis

In **spermiogenesis**, the last step of spermatogenesis, each spermatid matures into a single spermatozoon, or sperm (see Figure 28–7•). Developing spermatocytes undergoing meiosis, and spermatids undergoing spermiogenesis, are not free in the seminiferous tubules. Instead, they are surrounded by the cytoplasm of the sustentacular cells. As spermiogenesis proceeds, the spermatids gradually develop the appearance of mature spermatozoa. At *spermiation*, a spermatozoon loses its attachment to the sustentacular cell and enters the lumen of the seminiferous tubule. The entire process, from spermatogonial division to spermiation, takes approximately nine weeks.

Sustentacular Cells Sustentacular cells, also called *Sertoli cells*, play a key role in spermatogenesis. These cells have six important functions that directly or indirectly affect mitosis, meiosis, and spermiogenesis within the seminiferous tubules:

1. *Maintenance of the Blood–Testis Barrier.* The seminiferous tubules are isolated from the general circulation by a **blood–testis barrier**, comparable in function to the blood–brain barrier. l**p. 458** Sustentacular cells are joined by tight junctions, forming a layer that divides the seminiferous tubule into an outer *basal compartment*, which contains the spermatogonia, and an inner *luminal compartment* (or *adluminal compartment*), where meiosis and spermiogenesis occur (see Figure 28–5c•). Transport across the sustentacular cells is tightly regulated, so conditions in the luminal compartment remain very stable. The fluid in the lumen of a seminiferous tubule is produced by the sustentacular cells, which also regulate the fluid's composition. This fluid is very different from the surrounding interstitial fluid; it is high in androgens, estrogens, potassium, and amino acids. The blood–testis barrier is essential to preserving the differences between the tubular fluid and the interstitial fluid. In addition, this

barrier prevents immune system cells from detecting and attacking the developing spermatozoa, which have in their cell membranes sperm-specific antigens not found in somatic cell membranes and thus might be identified as "foreign."

2. **2.** *Support of Mitosis and Meiosis.* Spermatogenesis depends on the stimulation of sustentacular cells by circulating follicle-stimulating hormone (FSH) and testosterone. Stimulated sustentacular cells then promote the division of spermatogonia and the meiotic divisions of spermatocytes.

3. **3.** *Support of Spermiogenesis.* Spermiogenesis requires the presence of sustentacular cells. These cells surround and enfold the spermatids, providing nutrients and chemical stimuli that promote their development. Sustentacular cells also phagocytize cytoplasm that is shed by spermatids as they develop into spermatozoa.

4. **4.** *Secretion of Inhibin.* Sustentacular cells secrete the peptide hormone *inhibin* (in-HIB-in) in response to factors released by developing spermatozoa. Inhibin depresses the pituitary production of FSH, and perhaps the hypothalamic secretion of gonadotropin-releasing hormone (GnRH). The faster the rate of sperm production, the more inhibin is secreted. By regulating FSH and GnRH secretion, sustentacular cells provide feedback control of spermatogenesis.

5. **5.** *Secretion of Androgen-Binding Protein. Androgen-binding protein (ABP)* binds androgens (primarily testosterone) in the fluid contents of the seminiferous tubules. This protein is thought to be important in both elevating the concentration of androgens within the seminiferous tubules and stimulating spermiogenesis. The production of ABP is stimulated by FSH.

6. **6.** *Secretion of Müllerian-Inhibiting Factor. Müllerian-inhibiting factor (MIF)* is secreted by sustentacular cells in the developing testes. This hormone causes regression of the fetal *Müllerian ducts*, passageways that participate in the formation of the uterine tubes and the uterus in females. In males, inadequate MIF production during fetal development leads to the retention of these ducts and the failure of the testes to descend into the scrotum. AM: Testicular Cancer

The Anatomy of a Spermatozoon

Each spermatozoon has three distinct regions: the head, the middle piece, and the tail (Figure 28–8a•). In humans, the **head** is a flattened ellipse containing a nucleus with densely packed chromosomes. At the tip of the head is the **acrosomal** (ak-rō-SO-mal) **cap**, a membranous compartment containing enzymes essential to fertilization. During spermiogenesis, saccules of the spermatid’s Golgi apparatus fuse and flatten into an *acrosomal vesicle*, which ultimately forms the acrosomal cap of the spermatozoon.

A short **neck** attaches the head to the **middle piece**. The neck contains both centrioles of the original spermatid. The microtubules of the distal centriole are continuous with those of the middle piece and tail. Mitochondria in the middle piece are arranged in a spiral around the microtubules. Mitochondrial activity provides the ATP required to move the tail.

The **tail** is the only flagellum in the human body. A *flagellum*, a whiplike organelle, moves a cell from one place to another. Whereas cilia beat in a predictable, wavelike fashion, the flagellum of a spermatozoon has a complex, corkscrew motion.

Unlike other, less specialized cells, a mature spermatozoon lacks an endoplasmic reticulum, a Golgi apparatus, lysosomes, peroxisomes, inclusions, and many other intracellular structures. The loss of these organelles reduces the cell’s size and mass; it is essentially a mobile carrier for the enclosed chromosomes, and extra weight would slow it down. Because the cell lacks glycogen or other energy reserves, it must absorb nutrients (primarily fructose) from the surrounding fluid.

100 Keys | Spermatogenesis begins at puberty and continues until relatively late in life (past age 70). It is a continuous process, and all stages of meiosis can be observed within the seminiferous tubules.

The Male Reproductive Tract

The testes produce physically mature spermatozoa that are incapable of successfully fertilizing an oocyte. The other portions of the male reproductive system are responsible for the functional maturation, nourishment, storage, and transport of spermatozoa.

The Epididymis

Late in their development, spermatozoa detach from the sustentacular cells and lie within the lumen of the seminiferous tubule. They have most of the physical characteristics of mature spermatozoa, but are functionally immature and incapable of coordinated locomotion or fertilization. Fluid currents, created by cilia lining the efferent ductules, transport the immobile gametes into the epididymis (see Figure 28–4a•). The **epididymis**, the start of the male reproductive tract, is a coiled tube bound to the posterior border of the testis.

The epididymis can be felt through the skin of the scrotum. A tubule almost 7 m (23 ft) long, the epididymis is coiled and twisted so as to take up very little space. It has a head, a body, and a tail (Figure 28–9a•). The superior **head** is the portion of the epididymis proximal to the testis. The head receives spermatozoa from the efferent ductules.

The **body** begins distal to the last efferent ductule and extends inferiorly along the posterior margin of the testis. Near the inferior border of the testis, the number of coils decreases, marking the start of the **tail**. The tail recurves and ascends to its connection with the ductus deferens. Spermatozoa are stored primarily within the tail of the epididymis.

The epididymis has three functions:

1. **1.** *It Monitors and Adjusts the Composition of the Fluid Produced by the Seminiferous Tubules.* The pseudostratified columnar epithelial lining of the epididymis bears distinctive stereocilia (Figure 28–9b•), which increase the surface area available for absorption from, and secretion into, the fluid in the tubule.

2. **2.** *It Acts as a Recycling Center for Damaged Spermatozoa.* Cellular debris and damaged spermatozoa are absorbed in the epididymis, and the products of enzymatic breakdown are released into the surrounding interstitial fluids for pickup by the epididymal blood vessels.

3. **3.** *It Stores and Protects Spermatozoa and Facilitates Their Functional Maturation.* A spermatozoon passes through the epididymis in about two weeks and completes its functional maturation at that time. Over this period, spermatozoa exist in a sheltered environment that is precisely regulated by the surrounding epithelial cells. Although spermatozoa leaving the epididymis are mature, they remain immobile. To become *motile* (actively swimming) and fully functional, spermatozoa must undergo a process called **capacitation**. Capacitation normally occurs in two steps: (1) Spermatozoa become motile when they are mixed with secretions of the seminal vesicles, and (2) they become capable of successful fertilization when exposed to conditions in the female reproductive tract. The epididymis secretes a substance (as yet unidentified) that prevents premature capacitation.

Transport along the epididymis involves a combination of fluid movement and peristaltic contractions of smooth muscle in the walls of the epididymis. After passing along the tail of the epididymis, the spermatozoa enter the ductus deferens.

The Ductus Deferens

Each **ductus deferens**, or *vas deferens*, is 40–45 cm (16–18 in.) long. It begins at the tail of the epididymis (see Figure 28–9a•) and, as part of the spermatic cord, ascends through the inguinal canal (see Figure 28–3•, p. 1033). Inside the abdominal cavity, the ductus deferens passes posteriorly, curving inferiorly along the lateral surface of the urinary bladder toward the superior and posterior margin of the prostate gland (see Figure 28–1•). Just before the ductus deferens reaches the prostate gland and seminal vesicles, its lumen enlarges. This expanded portion is known as the **ampulla** (am-PUL-uh) of the ductus deferens

–

(Figure 28–10a•).

The wall of the ductus deferens contains a thick layer of smooth muscle (Figure 28–10b•). Peristaltic contractions in this layer propel spermatozoa and fluid along the duct, which is lined by a pseudostratified ciliated columnar epithelium. In addition to transporting spermatozoa, the ductus deferens can store spermatozoa for several months. During this time, the spermatozoa remain in a state of suspended animation and have low metabolic rates.

The junction of the ampulla with the duct of the seminal vesicle marks the start of the **ejaculatory duct**. This short passageway (2 cm, or less than 1 in.) penetrates the muscular wall of the prostate gland and empties into the urethra near the opening of the ejaculatory duct from the opposite side (see Figures 28–1 and 28–10a•).

The Urethra

In males, the **urethra** extends 18–20 cm (7–8 in.) from the urinary bladder to the tip of the penis (see Figure 28–1•). It is divided into *prostatic*, *membranous*, and *spongy* regions. The male urethra is a passageway used by both the urinary and reproductive systems.

The Accessory Glands

The fluids contributed by the seminiferous tubules and the epididymis account for only about 5 percent of the volume of semen. The fluid component of semen is a mixture of secretions—each with distinctive biochemical characteristics— from many glands. Important glands include the *seminal vesicles*, the *prostate gland*, and the *bulbourethral glands*, all of which occur only in males. Among the major functions of these glands are (1) activating spermatozoa; (2) providing the nutrients spermatozoa need for motility; (3) propelling spermatozoa and fluids along the reproductive tract, mainly by peristaltic contractions; and (4) producing buffers that counteract the acidity of the urethral and vaginal environments.

The Seminal Vesicles

The ductus deferens on each side ends at the junction between the ampulla and the duct that drains the seminal vesicle (see Figure 28–10a•). The **seminal vesicles** are glands embedded in connective tissue on either side of the midline, sandwiched between the posterior wall of the urinary bladder and the rectum. Each seminal vesicle is a tubular gland with a total length of about 15 cm (6 in.). The body of the gland has many short side branches. The entire assemblage is coiled and folded into a compact, tapered mass roughly 5 cm * 2.5 cm (2 in. * 1 in.).

Seminal vesicles are extremely active secretory glands with an epithelial lining that contains extensive folds (Figure 28–10c•). The seminal vesicles contribute about 60 percent of the volume of semen. Although the vesicular fluid generally has the same osmotic concentration as that of blood plasma, the compositions of the two fluids are quite different. In particular, the secretion of the seminal vesicles contains (1) higher concentrations of fructose, which is easily metabolized by spermatozoa; (2) prostaglandins, which can stimulate smooth muscle contractions along the male and female reproductive tracts; and (3) fibrinogen, which after ejaculation forms a temporary clot within the vagina. The secretions of the seminal vesicles are slightly alkaline, helping to neutralize acids in the secretions of the prostate gland and within the vagina. When mixed with the secretions of the seminal vesicles, previously inactive but functional spermatozoa undergo the first step in capacitation and begin beating their flagella, becoming highly motile.

The secretions of the seminal vesicles are discharged into the ejaculatory duct at *emission*, when peristaltic contractions are under way in the ductus deferens, seminal vesicles, and prostate gland. These contractions are under the control of the sympathetic nervous system.

The Prostate Gland

The **prostate gland** is a small, muscular, rounded organ about 4 cm (1.6 in.) in diameter. The prostate gland encircles the proximal portion of the urethra as it leaves the urinary bladder (see Figure 28–10•). The glandular tissue of the prostate (Figure 28–10d•) consists of a cluster of 30–50 compound tubuloalveolar glands. l**p. 117** These glands are surrounded by and wrapped in a thick blanket of smooth muscle fibers.

The prostate gland produces **prostatic fluid**, a slightly acidic solution that contributes 20–30 percent of the volume of semen. In addition to several other compounds of uncertain significance, prostatic secretions contain **seminalplasmin** (sem-i-nal-PLAZ-min), an antibiotic that may help prevent urinary tract infections in males. These secretions are ejected into the prostatic urethra by peristaltic contractions of the muscular prostate wall.

Prostatic inflammation, or **prostatitis** (pros-ta-T -tis), can occur in males at any age, but it most commonly afflicts older men.

Ï Prostatitis can result from bacterial infections but also occurs in the apparent absence of pathogens. Symptoms can resemble those of prostate cancer. Individuals with prostatitis may complain of pain in the lower back, perineum, or rectum, in some cases accompanied by painful urination and the discharge of mucous secretions from the external urethral orifice. Antibiotic therapy is effective in treating most cases that result from bacterial infection.

The Bulbourethral Glands

The paired **bulbourethral glands**, or *Cowper's glands*, are situated at the base of the penis, covered by the fascia of the urogenital diaphragm (Figure 28–10a and 28–11a•). The bulbourethral glands are round, with diameters approaching 10 mm (less than 0.5 in.). The duct of each gland travels alongside the penile urethra for 3–4 cm (1.2–1.6 in.) before emptying into the urethral lumen. The bulbourethral glands are compound, tubuloalveolar mucous glands (Figure 28–10e•) that secrete a thick, alkaline mucus. The secretion helps neutralize any urinary acids that may remain in the urethra, and it lubricates the *glans*, or tip of the penis.

Semen

A typical ejaculation releases 2–5 ml of semen; an abnormally low volume may indicate problems with the prostate gland or seminal vesicles. When sampled for analysis, semen is collected after a 36-hour period of sexual abstinence. The volume of fluid produced by an ejaculation, called the **ejaculate**, typically contains the following:

- **Spermatozoa.** The normal **sperm count** ranges from 20 million to 100 million spermatozoa per milliliter of semen. Most individuals with lower sperm counts are infertile, because too few spermatozoa survive the ascent of the female reproductive tract to perform fertilization. A low sperm count may reflect inflammation of the epididymis, ductus deferens, or prostate gland. In a fertile male, at least 60 percent of the spermatozoa in the sample are normal in appearance; common abnormalities are malformed heads and "twin" spermatozoa that did not separate at the time of spermiation. The normal sperm will be swimming actively.
- **Seminal Fluid. Seminal fluid**, the fluid component of semen, is a mixture of glandular secretions with a distinct ionic and nutrient composition. A typical sample of seminal fluid contains the combined secretions of the seminal vesicles (60 percent), the prostate gland (30 percent), the sustentacular cells and epididymis (5 percent), and the bulbourethral glands (less than 5 percent).
- **Enzymes.** Several important enzymes are present in seminal fluid, including (1) a protease that may help dissolve mucous secretions in the vagina; (2) seminalplasmin, an antibiotic prostatic enzyme that kills a variety of bacteria, including *Escherichia coli*; (3) a prostatic enzyme that coagulates the semen within a few minutes after ejaculation by converting fibrinogen to fibrin; and (4) *fibrinolysin*, which liquefies the clotted semen after 15–30 minutes.

A complete chemical analysis of semen appears in Appendix IV.

The External Genitalia

The male external genitalia consist of the scrotum and penis. The structure of the scrotum has already been described (p. 1033). The **penis** is a tubular organ through which the distal portion of the urethra passes (see Figure 28–11a•). It conducts urine to the exterior and introduces semen into the female’s vagina during sexual intercourse. The penis is divided into three regions: the root, the body, and the glans (Figure 28–11c•). The **root** of the penis is the fixed portion that attaches the penis to the body wall. This connection occurs within the urogenital triangle immediately inferior to the pubic symphysis. The **body (shaft)** of the penis is the tubular, movable portion of the organ. The **glans** of the penis is the expanded distal end that surrounds the external urethral orifice. The *neck* is the narrow portion of the penis between the shaft and the glans.

The skin overlying the penis resembles that of the scrotum. The dermis contains a layer of smooth muscle that is a continuation of the dartos muscle of the scrotum, and the underlying areolar tissue allows the thin skin to move without distorting underlying structures. The subcutaneous layer also contains superficial arteries, veins, and lymphatic vessels.

A fold of skin called the **prepuce** (PRE¯
-p
¯u
s), or *foreskin*, surrounds the tip of the penis. The prepuce attaches to the relatively
narrow neck of the penis and continues over the glans. **Preputial** (pr
¯e
-P

–

U
-sh
¯e
-al) **glands** in the skin of the neck and the inner

surface of the prepuce secrete a waxy material known as **smegma** (SMEG-ma). Unfortunately, smegma can be an excellent nutrient source for bacteria. Mild inflammation and infections in this locale are common, especially if the area is not washed thoroughly and frequently. One way to avoid trouble is **circumcision** (ser-kum-SIZH-un), the surgical removal of the prepuce. In Western societies (especially the United States), this procedure is generally performed shortly after birth. Although the practice of circumcision remains controversial, strong religious and cultural biases and epidemiological evidence suggest that it will continue.

Deep to the areolar tissue, a dense network of elastic fibers encircles the internal structures of the penis. Most of the body of the penis consists of three cylindrical columns of **erectile tissue** (Figure 28–11b•). Erectile tissue consists of a three-dimensional maze of vascular channels incompletely separated by partitions of elastic connective tissue and smooth muscle fibers. In the resting state, the arterial branches are constricted and the muscular partitions are tense. This combination restricts blood flow into the erectile tissue. The parasympathetic innervation of the penile arteries involves neurons that release nitric oxide (NO) at their synaptic knobs. The smooth muscles in the arterial walls relax when NO is released, at which time the vessels dilate, blood flow increases, the vascular channels become engorged with blood, and **erection** of the penis occurs. The flaccid (nonerect) penis hangs inferior to the pubic symphysis and anterior to the scrotum, but during erection the penis stiffens and assumes a more upright position.

The anterior surface of the flaccid penis covers two cylindrical masses of erectile tissue: the **corpora cavernosa** (KOR-por-a
ka-ver-N
¯O

-suh; singular, *corpus cavernosum*). The two are separated by a thin septum and encircled by a dense collagenous sheath
(see Figure 28–11b•). The corpora cavernosa diverge at their bases, forming the **crura** (*crura*, legs; singular, *crus*) of the penis (see

Figure 28–11a•). Each crus is bound to the ramus of the ischium and pubis by tough connective-tissue ligaments. The corpora cavernosa extend along the length of the penis as far as its neck. The erectile tissue within each corpus cavernosum surrounds a central artery (see Figure 28–11b•).

The relatively slender **corpus spongiosum** (spon-j
¯e
-

¯O

-sum) surrounds the penile urethra (see Figure 28–11a,b•). This erectile body extends from the superficial fascia of the urogenital diaphragm to the tip of the penis, where it expands to form the glans. The sheath surrounding the corpus spongiosum contains more elastic fibers than does that of the corpora cavernosa, and the erectile tissue contains a pair of small arteries.

Anatomy 360 | Review the anatomy of the male reproductive system on the **Anatomy 360 CD-ROM: Reproductive Sys-tem/Male Reproductive System.**

Hormones and Male Reproductive Function

The hormonal interactions that regulate male reproductive function are diagrammed in Figure 28–12•. The major reproductive hormones were introduced in Chapter 18. l**p. 622** The anterior lobe of the pituitary gland releases *follicle-stimulating hormone* **(FSH)** and *luteinizing hormone* **(LH)**. The pituitary release of these hormones occurs in response to *gonadotropin-releasing hormone* **(GnRH)**, a peptide synthesized in the hypothalamus and carried to the anterior lobe by the hypophyseal portal system.

The hormone GnRH is secreted in pulses rather than continuously. In adult males, small pulses occur at 60–90-minute intervals. As levels of GnRH change, so do the rates of secretion of FSH and LH (and testosterone, which is released in response to LH). Unlike the situation in women, which we will consider later in the chapter, the GnRH pulse frequency in adult males remains relatively steady from hour to hour, day to day, and year to year. As a result, plasma levels of FSH, LH, and testosterone remain within a relatively narrow range until relatively late in life (see p. 1067).

FSH and Spermatogenesis

In males, FSH targets primarily the sustentacular cells of the seminiferous tubules. Under FSH stimulation, and in the presence of testosterone from the interstitial cells, sustentacular cells (1) promote spermatogenesis and spermiogenesis and (2) secrete androgen-binding protein (ABP).

The rate of spermatogenesis is regulated by a negative feedback mechanism involving GnRH, FSH, and inhibin. Under GnRH stimulation, FSH promotes spermatogenesis along the seminiferous tubules. As spermatogenesis accelerates, however, so does the rate of inhibin secretion by the sustentacular cells of the testes (see Figure 28–12•). Inhibin inhibits FSH production in the anterior lobe of the pituitary gland and may also suppress the secretion of GnRH at the hypothalamus.

The net effect is that when FSH levels become elevated, inhibin production increases until FSH levels return to normal. If FSH levels decline, inhibin production falls, so the rate of FSH production accelerates.

LH and Androgen Production

In males, LH induces the secretion of testosterone and other androgens by the interstitial cells of the testes. Testosterone, the most important androgen, has numerous functions: (1) stimulating spermatogenesis and promoting the functional maturation of spermatozoa, through its effects on sustentacular cells; (2) affecting central nervous system (CNS) function, including the libido (sexual drive) and related behaviors; (3) stimulating metabolism throughout the body, especially pathways concerned with protein synthesis, blood cell formation, and muscle growth; (4) establishing and maintaining male secondary sex characteristics, such as the distribution of facial hair, increased muscle mass and body size, and the quantity and location of characteristic adipose tissue deposits; and (5) maintaining the accessory glands and organs of the male reproductive tract.

Testosterone functions like other steroid hormones, circulating in the bloodstream while bound to one of two types of transport proteins: (1) *gonadal steroid-binding globulin*

(GBG), which carries roughly two-thirds of the circulating testosterone, and
(2) the albumins, which bind the remaining one-third. Testosterone diffuses across the cell membrane of target cells and binds to an intracellular receptor. The hormone–receptor complex then binds to the DNA in the nucleus. In many target tissues, some of the arriving testosterone is converted to **dihydrotestosterone (DHT)**. A small amount of DHT diffuses back out of the cell and into the bloodstream, and DHT levels are usually about 10 percent of circulating testosterone levels. Dihydrotestosterone can also enter peripheral cells and bind to the same hormone receptors targeted by testosterone. In addition, some tissues (notably those of the external genitalia) respond to DHT rather than to testosterone, and other tissues (including the prostate gland) are more sensitive to DHT than to testosterone.

Testosterone production begins around the seventh week of fetal development and reaches a prenatal peak after roughly six months. Over this period, the secretion of Müllerian-inhibiting factor by developing sustentacular cells leads to the regression of the Müllerian ducts. The early surge in testosterone levels stimulates the differentiation of the male duct system and accessory organs and affects CNS development. The best-known CNS effects occur in the developing hypothalamus. There, testosterone apparently programs the hypothalamic centers that are involved with (1) GnRH production and the regulation of pituitary FSH and LH secretion, (2) sexual behaviors, and (3) sexual drive. As a result of this prenatal exposure to testosterone, the hypothalamic centers will respond appropriately when the individual becomes sexually mature. The factors responsible for regulating the fetal production of testosterone are not known.

Testosterone levels are low at birth. Until puberty, background testosterone levels, although still relatively low, are higher in males than in females. Testosterone secretion accelerates markedly at puberty, initiating sexual maturation and the appearance of secondary sex characteristics. In adult males, negative feedback controls the level of testosterone production. Above-normal testosterone levels inhibit the release of GnRH by the hypothalamus, causing a reduction in LH secretion and lowering testosterone levels (see Figure 28–12•).

The plasma of adult males also contains relatively small amounts of estradiol (2 ng > dl, versus 525 ng > dl of testosterone). Seventy percent of the estradiol is formed from circulating testosterone; the rest is secreted, primarily by the interstitial and sustentacular cells of the testes. The conversion of testosterone to estradiol is performed by an enzyme called *aromatase*. For unknown reasons, estradiol production increases in older men.

Clinical Note

Dehydroepiandrosterone, or **DHEA**, is the primary androgen secreted by the zona reticularis of the adrenal cortex. l**p. 615** As noted in Chapter 18, these androgens, which are secreted in small amounts, are converted to testosterone (or estrogens) by other tissues.

The significance of this small adrenal androgen contribution in both sexes remains unclear, but DHEA is being promoted as a wonder drug for increasing vitality, strength, and muscle mass, and food supplements prepared from wild Mexican yams are now being advertised as containing “DHEA precursors.” These claims are false; the compounds contained in these supplements have no effect on circulating DHEA levels. The current recommendations are that DHEA use be restricted to controlled, supervised clinical trials, and that no one under age 40 use the drug. The effects of long-term high doses of DHEA remain largely unknown; however, recall from Chapter 18 that the long-term effects of androgen abuse can be quite serious. l**p. 629** High levels of DHEA in women have been linked to an increased risk of ovarian cancer as well as to masculinization, due to the conversion of DHEA to testosterone. The IOC (International Olympic Committee), NCAA, and NFL have banned the use of DHEA for muscle enhancement.

Concept Check

On a warm day, would the cremaster muscle be contracted or relaxed? Why?

What will happen if the arteries within the penis dilate?

What effect would low levels of FSH have on sperm production?

Answers begin on p. A–1

The Reproductive System of the Female

Objectives

- Describe the components of the female reproductive system.
- Outline the processes of meiosis and oogenesis in the ovaries.
- Identify the phases and events of the ovarian and uterine cycles.
- Describe the structure, histology, and functions of the vagina.
- Summarize the anatomical, physiological, and hormonal aspects of the female reproductive cycle.

A woman’s reproductive system produces sex hormones and functional gametes, and it must also be able to protect and support a developing embryo and nourish a newborn infant. The principal organs of the female reproductive system are the *ovaries*, the *uterine tubes*, the *uterus*, the *vagina*, and the components of the external genitalia (Figure 28–13•). As in males, a variety of accessory glands release secretions into the female reproductive tract.

The ovaries, uterine tubes, and uterus are enclosed within an extensive mesentery known as the **broad ligament**. The uterine tubes run along the superior border of the broad ligament and open into the pelvic cavity lateral to the ovaries. The **mesovarium** (mes-ō-VA-rē-um), a thickened fold of mesentery, supports and stabilizes the position of each ovary (see Figure 28–14a•).

The broad ligament attaches to the sides and floor of the pelvic cavity, where it becomes continuous with the parietal peritoneum. The broad ligament thus subdivides this part of the peritoneal cavity. The pocket formed between the posterior wall of the uterus and the anterior surface of the colon is the **rectouterine** (rek-t

¯o

-

U¯

-ter-in) **pouch** (see Figure 28–13•); the pocket formed between
the uterus and the posterior wall of the bladder is the **vesicouterine** (ves-i-k

¯o

-

–

U

-ter-in) **pouch**. These subdivisions are most apparent in sagittal section.

Several other ligaments assist the broad ligament in supporting and stabilizing the position of the uterus and associated reproductive organs. These ligaments lie within the mesentery sheet of the broad ligament and are connected to the ovaries or uterus. The broad ligament limits side-to-side movement and rotation, and the other ligaments (described in our discussion of the ovaries and uterus) prevent superior–inferior movement.

The Ovaries

The paired ovaries are small, lumpy, almond-shaped organs near the lateral walls of the pelvic cavity (Figure 28–14•). The ovaries perform three main functions: (1) production of immature female gametes, or oocytes, (2) secretion of female sex hormones, including estrogens and progestins, and (3) secretion of inhibin, involved in the feedback control of pituitary FSH production.

The position of each ovary is stabilized by the mesovarium and by a pair of supporting ligaments: the ovarian ligament and the suspensory ligament (see Figure 28–14a•). The **ovarian ligament** extends from the uterus, near the attachment of the uterine tube, to the medial surface of the ovary. The **suspensory ligament** extends from the lateral surface of the ovary past the open end of the uterine tube to the pelvic wall. The suspensory ligament contains the major blood vessels of the ovary: the **ovarian artery** and **ovarian vein**. These vessels are connected to the ovary at the **ovarian hilum**, where the ovary attaches to the mesovarium (Figure 28–14b•).

A typical ovary is about 5 cm long, 2.5 cm wide, and 8 mm thick (2 in. * 1 in. * 0.33 in.) and weighs 6–8 g (roughly

0.25 oz). An ovary is pink or yellowish and has a nodular consistency. The visceral peritoneum, or *germinal epithelium*, covering the surface of each ovary consists of a layer of columnar epithelial cells that overlies a dense connective-tissue layer called the **tunica albuginea** (see Figure 28–14b•). We can divide the interior tissues, or **stroma**, of the ovary into a superficial *cortex* and a deeper *medulla*. Gametes are produced in the cortex.

Oogenesis

Ovum production, or **oogenesis** (

¯o

-

¯o

-JEN-e-sis), begins before a woman’s birth, accelerates at puberty, and ends at *menopause*. Between puberty and menopause, oogenesis occurs on a monthly basis as part of the *ovarian cycle*.

Oogenesis is summarized in Figure 28–15•. Unlike spermatogonia, the **oogonia** (

¯o

-

¯o

-G

¯

O
-n
‾e
-uh), or stem cells of females,
complete their mitotic divisions before birth. Between the third and seventh months of fetal development, the daughter cells, or
‾

primary oocytes (O
ı comes to a halt. The primary oocytes remain in a state of suspended development until the individual reaches puberty, when rising levels of FSH trigger the start of the ovarian cycle. Each month thereafter, some of the primary oocytes are stimulated to undergo further development. Not all primary oocytes produced during development survive until puberty. The ovaries have roughly 2 million *primordial follicles* at birth, each containing a primary oocyte. By the time of puberty, the number has dropped to about
‾

‾o
ts), prepare to undergo meiosis. They proceed as far as the prophase of meiosis I, but then the process -
-s
400,000. The rest of the primordial follicles degenerate in a process called **atresia** (a-TR
‾E

-z
‾e
-uh).

Although the nuclear events in the ovaries during meiosis are the same as those in the testes, the process differs in two important details:

1. **1.** The cytoplasm of the primary oocyte is unevenly distributed during the two meiotic divisions. Oogenesis produces one functional ovum, which contains most of the original cytoplasm, and two or three **polar bodies**, nonfunctional cells that later disintegrate (see Figure 28–15•).

2. **2.** The ovary releases a **secondary oocyte** rather than a mature ovum. The secondary oocyte is suspended in metaphase of meiosis II; meiosis will not be completed unless and until fertilization occurs.

The Ovarian Cycle

Ovarian follicles are specialized structures in the cortex of the ovaries where both oocyte growth and meiosis I occur. Primary oocytes are located in the outer portion of the ovarian cortex, near the tunica albuginea, in clusters called *egg nests* (Figure 28–16•). Each primary oocyte within an egg nest is surrounded by a single squamous layer of *follicle cells*. The primary oocyte and its follicle cells form a **primordial follicle**. After sexual maturation, a different group of primordial follicles is activated each month. This monthly process is known as the **ovarian cycle**.

The ovarian cycle can be divided into a **follicular phase**, or *preovulatory phase*, and a **luteal phase**, or *postovulatory phase*. Important steps in the ovarian cycle can be summarized as follows (see Figure 28–16•):

Step 1 The Formation of Primary Follicles. The ovarian cycle begins as activated primordial follicles develop into **primary follicles**. In a primary follicle, the follicle cells enlarge and undergo repeated divisions that create several layers of follicle cells around the oocyte. These follicle cells, which become rounded in appearance, are now called **granulosa cells**.

As layers of granulosa cells develop around the primary oocyte, microvilli from the surrounding granulosa cells intermingle with those of the primary oocyte. The microvilli are surrounded by a layer of glycoproteins; the entire region is called the **zona pellucida** (ZO-na pe-LOO-sid-uh). The microvilli increase the surface area available for the transfer of materials from the granu

–

losa cells to the rapidly enlarging primary oocyte.

The conversion from primordial to primary follicles and subsequent follicular development occurs under stimulation of FSH from the anterior lobe of the pituitary gland. As the granulosa cells enlarge and multiply, adjacent cells in the ovarian stroma form a layer of **thecal cells** around the follicle. Thecal cells and granulosa cells work together to produce sex hormones called *estrogens*.

Step 2 The Formation of Secondary Follicles. Although many primordial follicles develop into primary follicles, only a few will proceed to this step. The transformation begins as the wall of the follicle thickens and the granulosa cells begin secreting small amounts of fluid. This **follicular fluid**, or *liquor folliculi*, accumulates in small pockets that gradually expand and separate the inner and outer layers of the follicle. At this stage, the complex is known as a **secondary follicle**. Although the primary oocyte continues to grow at a steady pace, the follicle as a whole now enlarges rapidly because follicular fluid accumulates.

Step 3 The Formation of a Tertiary Follicle. Eight to 10 days after the start of the ovarian cycle, the ovaries generally contain only a single secondary follicle destined for further development. By the 10th to the 14th day of the cycle, that follicle has become a

¯e

tertiary follicle, or *mature Graafian* (GRAF--an) *follicle*, roughly 15 mm in diameter. This complex spans the entire width of the ovarian cortex and distorts the ovarian capsule, creating a prominent bulge in the surface of the ovary. The oocyte projects into the **antrum** (AN-trum), or expanded central chamber of the follicle. The antrum is surrounded by a mass of granulosa cells.

Until this time, the primary oocyte has been suspended in prophase of meiosis I. As the development of the tertiary follicle ends, LH levels begin rising, prompting the primary oocyte to complete meiosis I. Instead of producing two secondary oocytes, the first meiotic division yields a secondary oocyte and a small, nonfunctional polar body. The secondary oocyte then enters meiosis II, but stops once again upon reaching metaphase. Meiosis II will not be completed unless fertilization occurs.

Generally, on day 14 of a 28-day cycle, the secondary oocyte and the attached granulosa cells lose their connections with the follicular wall and drift free within the antrum. The

granulosa cells still associated with the secondary oocyte form a protective
layer known as the **corona radiata** (ko-R
¯O

-nuh r
¯a
-d
¯e
-A-tuh).

Step 4 Ovulation. At **ovulation**, the tertiary follicle releases the secondary oocyte. The distended follicular wall suddenly ruptures, ejecting the follicular contents, including the secondary oocyte and corona radiata, into the pelvic cavity. The sticky follicular fluid keeps the corona radiata attached to the surface of the ovary, where direct contact with projections surrounding the entrance to the uterine tube or with fluid currents established by the ciliated epithelium lining the uterus can transfer the secondary oocyte to the uterine tube. Ovulation marks the end of the follicular phase of the ovarian cycle and the start of the luteal phase.

Step 5 The Formation and Degeneration of the Corpus Luteum. The empty tertiary follicle initially collapses, and ruptured vessels bleed into the antrum. The remaining granulosa cells then invade the area, proliferating to create an endocrine structure known
as the **corpus luteum** (LOO-t -um), named for its yellow color (*lutea*, yellow). This process occurs under LH stimulation. The cholesterol contained in the corpus luteum is used to manufacture steroid hormones known as **progestins** (pr
¯e
¯o
-JES-tinz),
principally the steroid **progesterone** (pr
¯o
-JES-ter-

‾o

n). Although the corpus luteum also secretes moderate amounts of estrogens,

levels are not as high as they were at ovulation, and progesterone is the principal hormone in the luteal phase. Progesterone's primary function is to prepare the uterus for pregnancy by stimulating the maturation of the uterine lining and the secretions of uterine glands.

Step 6 Unless Fertilization Occurs, the Corpus Luteum Begins to Degenerate Roughly 12 Days after Ovulation. Progesterone and estrogen levels then fall markedly. Fibroblasts invade the nonfunctional corpus luteum, producing a knot of pale scar tissue called a **corpus albicans** (AL-bi-kanz). The disintegration, or *involution*, of the corpus luteum marks the end of the ovarian cycle. A new ovarian cycle then begins with the activation of another group of primordial follicles.

Age and Oogenesis

Although many primordial follicles may have developed into primary follicles, and several primary follicles may have been converted to secondary follicles, generally only a single oocyte is released into the pelvic cavity at ovulation. The rest undergo atresia. At puberty, each ovary contains about 200,000 primordial follicles. Forty years later, few if any follicles remain, although only about 500 will have been ovulated in the interim. AM: Ovarian Cancer

100 Keys | Oogenesis begins during embryonic development, and primary oocyte production is completed before birth. Each month after puberty, the ovarian cycle produces one or more secondary oocytes from the pre-existing population of primary oocytes. The number of viable and responsive primary oocytes declines markedly over time, until ovarian cycles end at age 45–55.

The Uterine Tubes

Each **uterine tube** (*Fallopian tube* or *oviduct*) is a hollow, muscular tube measuring roughly 13 cm (5.2 in.) in length (see Figures 28–13 and Figure 28–14•). Each uterine tube is divided into three segments (Figure 28–17a•):

1. *The Infundibulum.* The end closest to the ovary forms an expanded funnel, or **infundibulum**, with numerous fingerlike pro jections that extend into the pelvic cavity. The projections are called **fimbriae** (FIM-brē-ē). The inner surfaces of the infundibulum are lined with cilia that beat toward the middle segment of the uterine tube, called the *ampulla*.

1. **2.** *The Ampulla.* The thickness of the smooth muscle layers in the wall of the **ampulla**, the middle segment of the uterine tube, gradually increases as the tube approaches the uterus.

2. **3.** *The Isthmus.* The ampulla leads to the **isthmus** (IS-mus), a short segment connected to the uterine wall.

Histology of the Uterine Tube

The epithelium lining the uterine tube is composed of ciliated columnar epithelial cells with scattered mucin-secreting cells (Figure 28–17c•). The mucosa is surrounded by concentric layers of smooth muscle (Figure 28–17b•). Oocyte transport involves a combination of ciliary movement and peristaltic contractions in the walls of the uterine tube. A few hours before ovulation, sympathetic and parasympathetic nerves from the hypogastric plexus “turn on” this beating pattern and initiate peristalsis. It normally takes three to four days for an oocyte to travel from the infundibulum to the *uterine cavity*. If fertilization is to occur, the secondary oocyte must encounter spermatozoa during the first 12–24 hours of its passage. Fertilization typically occurs near the boundary between the ampulla and isthmus of the uterine tube.

In addition to its transport function, the uterine tube provides a nutrient-rich environment that contains lipids and glycogen. This mixture supplies nutrients to both spermatozoa and a developing *pre-embryo* (the cell cluster produced by the initial divisions following fertilization). Unfertilized oocytes degenerate in the terminal portions of the uterine tubes or within the uterus. AM: Pelvic Inflammatory Disease

The Uterus

The **uterus** provides mechanical protection, nutritional support, and waste removal for the developing *embryo* (weeks 1–8) and *fetus* (week 9 through delivery). In addition, contractions in the muscular wall of the uterus are important in ejecting the fetus at birth.

The uterus is a small, pear-shaped organ (Figure 28–18a•) about 7.5 cm (3 in.) long and with a maximum diameter of 5 cm (2 in.). It weighs 30–40 g (1–1.4 oz). In its normal position, the uterus bends anteriorly near its base (see Figure 28–13•, p. 1048),
a condition known as *anteflexion* (an-t -FLEK-shun). In this position, the uterus covers the superior and posterior surfaces of the urinary bladder. If the uterus bends backward toward the sacrum, the condition is termed *retroflexion* (re-tr
ē
ō
-FLEK-shun).

Retroflexion, which occurs in about 20 percent of adult women, has no clinical significance. (A retroflexed uterus generally becomes anteflexed spontaneously during the third month of pregnancy.)

Suspensory Ligaments of the Uterus

In addition to the broad ligament, three pairs of suspensory ligaments stabilize the position of the uterus and limit its range of movement (Figure 28–18b•). The **uterosacral**
(

ū
-te-r
ō
-S

Ā
-kral) **ligaments** extend from the lateral surfaces of the uterus to the anterior face of the

sacrum, keeping the body

of the uterus from moving inferiorly and anteriorly. The **round ligaments** arise on the lateral margins of the uterus just posterior and inferior to the attachments of the uterine tubes. These ligaments extend through the inguinal canal and end in the connective tissues of the external genitalia. The round ligaments restrict primarily posterior movement of the uterus. The **lateral** (*cardinal*) **ligaments** extend from the base of the uterus and vagina to the lateral walls of the pelvis. These ligaments tend to prevent inferior movement of the uterus. Additional mechanical support is provided by the muscles and fascia of the pelvic floor.

Internal Anatomy of the Uterus

We can divide the uterus into two anatomical regions (see Figure 28–18a•): the body and the cervix. The uterine **body**, or *corpus*, is the largest portion of the uterus. The **fundus** is the rounded portion of the body superior to the attachment of the uterine tubes. The body ends at a constriction known as the **isthmus** of the uterus. The **cervix** (SER-viks) is the inferior portion of the uterus that extends from the isthmus to the vagina.

The tubular cervix projects about 1.25 cm (0.5 in.) into the vagina. Within the vagina, the distal end of the cervix forms a curving surface that surrounds the **cervical os** (*os*, an opening or mouth), or *external orifice* of the uterus. The cervical os leads into the **cervical canal**, a constricted passageway that opens into the **uterine cavity** of the body at the **internal os**, or *internal orifice*.

The uterus receives blood from branches of the **uterine arteries**, which arise from branches of the *internal iliac arteries,* and from the *ovarian arteries,* which arise from the abdominal aorta inferior to the renal arteries. The arteries to the uterus are extensively interconnected, ensuring a reliable flow of blood to the organ despite changes in its position and shape during pregnancy. Numerous veins and lymphatic vessels also drain each portion of the uterus. The organ is innervated by autonomic fibers from the hypogastric plexus (sympathetic) and from sacral segments S3 and S4 (parasympathetic). Sensory information reaches the central nervous system within the dorsal roots of spinal nerves T11 and T12. The most delicate anesthetic procedures used dur ing labor and delivery, known as *segmental blocks*, target only spinal nerves T10

–

L1.

The Uterine Wall

The dimensions of the uterus are highly variable. In women of reproductive age who have not given birth, the uterine wall is about

¯E

1.5 cm (0.6 in.) thick. The wall has a thick, outer, muscular **myometrium** (m

–

ı -um), or *mucosa* (Figure 28–19•). The fundus and the posterior sur-

¯e

face of the uterine body and isthmus are covered by a serous membrane that is continuous with the peritoneal lining. This incomplete serosa is called the **perimetrium**.

The endometrium contributes about 10 percent to the mass of the uterus. The glandular and vascular tissues of the endometrium support the physiological demands of the growing fetus. Vast numbers of uterine glands open onto the endometrial surface and extend deep into the lamina propria, almost to the myometrium. Under the influence of estrogen, the uterine glands, blood vessels, and epithelium change with the phases of the monthly *uterine cycle*.

The myometrium, the thickest portion of the uterine wall, constitutes almost 90 percent of the mass of the uterus. Smooth muscle in the myometrium is arranged into longitudinal, circular, and oblique layers. The smooth muscle tissue of the myometrium provides much of the force needed to move a fetus out of the uterus and into the vagina.

Histology of the Uterus We can divide the endometrium into a **functional zone**—the layer closest to the uterine cavity—and a **basilar zone**, adjacent to the myometrium (see Figure 28–19b•). The functional zone contains most of the uterine glands and contributes most of the endometrial thickness. It is this zone that undergoes the dramatic changes in thickness and structure during the menstrual cycle. The basilar zone attaches the endometrium to the myometrium and contains the terminal branches of the tubular endometrial glands.

Within the myometrium, branches of the uterine arteries form **arcuate arteries**, which encircle the endometrium (see Figure 28–19a•). **Radial arteries** supply **straight arteries**, which deliver blood to the basilar zone of the endometrium, and **spiral arteries**, which supply the functional zone.

The structure of the basilar zone remains relatively constant over time, but that of the functional zone undergoes cyclical changes in response to sex hormone levels. These cyclical changes produce the characteristic histological features of the uterine cycle.

Cervical cancer is the most common cancer of the reproductive system in women ages 15–34. Each year roughly 13,000 U.S. women are diagnosed with invasive cervical cancer, and approximately one-third of them eventually die from the condition. Another 35,000 women are diagnosed with a less aggressive form of cervical cancer. Cervical and other uterine tumors and cancers are discussed in the *Applications Manual*. AM: Uterine Tumors and Cancers

The Uterine Cycle

The **uterine cycle**, or *menstrual* (MEN-stroo-al) *cycle*, is a repeating series of changes in the structure of the endometrium (Figure 28–20•). The uterine cycle averages 28 days in length, but it can range from 21 to 35 days in healthy women of reproductive age. We can divide the uterine cycle into three phases: (1) *menses*, (2) the *proliferative phase*, and (3) the *secretory phase*. The phases occur in response to hormones associated with the regulation of the ovarian cycle. Menses and the proliferative phase occur during the follicular phase of the ovarian cycle; the secretory phase corresponds to the luteal phase of the cycle. We will consider the regulatory mechanism involved in a later section.

Menses

¯e

The uterine cycle begins with the onset of **menses** (MEN-s z), an interval marked by the degeneration of the functional zone of the endometrium (Figure 28–20a•). This degeneration occurs in patches and is caused by constriction of the spiral arteries, which reduces blood flow to areas of endometrium. Deprived of oxygen and nutrients, the secretory glands and other tissues in the functional zone begin to deteriorate. Eventually, the weakened arterial walls rupture, and blood pours into the connective tissues of the functional zone. Blood cells and degenerating tissues then break away and enter the uterine lumen, to be lost by passage through the cervical os and into the vagina. Only the functional zone is affected, because the deeper, basilar zone is provided with blood from the straight arteries, which remain unconstricted.

The sloughing off of tissue is gradual, and at each site repairs begin almost at once. Nevertheless, before menses has ended,
the entire functional zone has been lost. The process of endometrial sloughing, called **menstruation** (men-stroo-
¯A

-shun), gen

erally lasts from one to seven days. Over this period roughly 35 to 50 ml of blood are lost. The process can be relatively painless. Painful menstruation, or **dysmenorrhea**, can result from uterine inflammation, myometrial contractions (“cramps”), or from conditions involving adjacent pelvic structures.

The Proliferative Phase The basilar zone, including the basal parts of the uterine glands, survives menses intact. In the days after menses, the epithelial cells of the uterine glands multiply and spread across the endometrial surface, restoring the integrity of the uterine epithelium (Figure 28–20b•). Further growth and vascularization result in the complete restoration of the functional zone. As this reorganization proceeds, the endometrium is in the **proliferative phase**. Restoration occurs at the same time as the enlargement of primary and secondary follicles in the ovary. The proliferative phase is stimulated and sustained by estrogens secreted by the developing ovarian follicles.

By the time ovulation occurs, the functional zone is several millimeters thick, and prominent mucous glands extend to the border with the basilar zone. At this time, the endometrial glands are manufacturing a mucus rich in glycogen. This specialized mucus appears to be essential for the survival of the fertilized egg through its earliest developmental stages. (These stages will be considered in Chapter 29.) The entire functional zone is highly vascularized, with small arteries spiraling toward the inner surface from larger arteries in the myometrium.

The Secretory Phase During the **secretory phase** of the uterine cycle, the endometrial glands enlarge, accelerating their rates of secretion, and the arteries that supply the uterine wall elongate and spiral through the tissues of the functional zone (Figure 28–20c•). This activity occurs under the combined stimulatory effects of progestins and estrogens from the corpus luteum. The secretory phase begins at the time of ovulation and persists as long as the corpus luteum remains intact.

Secretory activities peak about 12 days after ovulation. Over the next day or two, glandular activity declines, and the uterine cycle ends as the corpus luteum stops producing stimulatory hormones. A new cycle then begins with the onset of menses and the disintegration of the functional zone. The secretory phase generally lasts 14 days. As a result, you can identify the date of ovulation by counting backward 14 days from the first day of menses. AM: Endometriosis

Menarche and Menopause The uterine cycle begins at puberty. The first cycle, known as **menarche** (me-NAR-k
¯e
; *men*, month
+
arche beginning), typically occurs at age 11–12. The cycles continue until **menopause** (MEN-
¯o
-pawz), the termination of the
uterine cycle, at age 45–55. Over the interim, the regular appearance of uterine cycles is interrupted only by circumstances such as illness, stress, starvation, or pregnancy.

If menarche does not appear by age 16, or if the normal uterine cycle of an adult woman becomes interrupted for six months
or more, the condition of **amenorrhea** (
¯a
-men-
¯o
-R

¯E

-uh) exists. *Primary amenorrhea* is the failure to initiate menses. This condition may indicate developmental abnormalities, such as nonfunctional ovaries, the absence of a uterus, or an endocrine or genetic disorder. It can also result from malnutrition: Puberty is delayed if leptin levels are too low. l**p. 624** Transient *secondary amenorrhea* can be caused by severe physical or emotional stresses. In effect, the reproductive system gets “switched off.” Factors that cause either type of amenorrhea include drastic weight loss, anorexia nervosa, and severe depression or grief. Amenorrhea has also been observed in marathon runners and other women engaged in training programs that require sustained high levels of exertion and severely reduce body lipid reserves.

The Vagina

The **vagina** is an elastic, muscular tube extending between the cervix and the *vestibule*, a space bounded by the female external genitalia (see Figure 28–13•). The vagina is typically 7.5–9 cm (3–3.6 in.) long, but its diameter varies because it is highly distensible.

At the proximal end of the vagina, the cervix projects into the **vaginal canal**. The shallow recess surrounding the cervical protrusion is known as the **fornix** (FOR-niks). The vagina lies parallel to the rectum, and the two are in close contact posteriorly. Anteriorly, the urethra extends along the superior wall of the vagina from the urinary bladder to the external urethral orifice, which opens into the vestibule. The primary blood supply of the vagina is via the **vaginal branches** of the internal iliac (or uterine) arteries and veins. Innervation is from the hypogastric plexus, sacral nerves S2 –S4, and branches of the pudendal nerve. l**pp. 435, 745, 750**

The vagina has three major functions: It (1) serves as a passageway for the elimination of menstrual fluids, (2) receives the penis during sexual intercourse, and holds spermatozoa prior to their passage into the uterus, and (3) forms the inferior portion of the *birth canal*, through which the fetus passes during delivery.

Anatomy and Histology of the Vagina

In sectional view, the lumen of the vagina appears constricted, forming a rough H. The vaginal walls contain a network of blood vessels and layers of smooth muscle (Figure 28–21•). The lining is moistened by secretions of the cervical glands and by the movement of water across the permeable epithelium. Throughout childhood the vagina and vestibule are usually separated by the **hymen** (H -men), an elastic epithelial fold that partially or completely blocks the entrance to the vagina; an intact hymen is typically ruptured during sexual intercourse or tampon usage. The two *bulbospongiosus muscles* extend along either side of the vaginal entrance, which is constricted by their contractions. l**p. 349** These muscles cover the *vestibular bulbs*, masses of erectile tissue on either side of the vaginal entrance. The vestibular bulbs have the same embryological origins as the corpus spongiosum of the penis in males.

The vaginal lumen is lined by a nonkeratinized stratified squamous epithelium (see Figure 28–21•). In the relaxed state, this epithelium forms folds called *rugae*. The underlying lamina propria is thick and elastic, and it contains small blood vessels, nerves, and lymph nodes. The vaginal mucosa is surrounded by an elastic *muscularis* layer consisting of layers of smooth muscle fibers arranged in circular and longitudinal bundles continuous with the uterine myometrium. The portion of the vagina adjacent to the uterus has a serosal covering that is continuous with the pelvic peritoneum. Along the rest of the vagina, the muscularis layer is surrounded by an *adventitia* of fibrous connective tissue.

The vagina contains a population of resident bacteria, usually harmless, supported by nutrients in the cervical mucus. The metabolic activity of these bacteria creates an acidic environment, which restricts the growth of many pathogens. **Vaginitis** (vaj-

¯I —a

vaginal smear

¯I The hormonal changes associated with the ovarian cycle also affect the vaginal epithelium. By examining a

i-N -tis), an inflammation of the vaginal canal, is caused by fungi, bacteria, or parasites. In addition to any discomfort that may result, the condition may affect the survival of spermatozoa and thereby reduce fertility. An acidic environment also inhibits the motility of sperm; for this reason, the buffers in semen are important to successful fertilization. AM: Vaginitis

sample of epithelial cells shed at the surface of the vagina—a clinician can estimate the corresponding stage in the ovarian and uterine cycles. This diagnostic procedure is an example of *exfoliative cytology*. l**p. 114**

The External Genitalia

The area containing the female external genitalia is the **vulva** (VUL-vuh), or *pudendum* (pu-DEN-dum; Figure 28–22•). The vagina

opens into the **vestibule**, a central space bounded by small folds known as the **labia minora** (L

¯A

-b

¯e

-uh mi-NOR-uh; singular,

labium minus). The labia minora are covered with a smooth, hairless skin. The urethra opens into the vestibule just anterior to the vaginal entrance. The **paraurethral glands**, or *Skene's glands*, discharge into the urethra near the external urethral opening. Anterior to this opening, the **clitoris** (KLIT-o-ris) projects into the vestibule. A small, rounded tissue projection, the clitoris is derived from the same embryonic structures as the penis in males. Internally, it contains erectile tissue comparable to the corpora cavernosa of the penis. The clitoris engorges with blood during sexual arousal. A small erectile *glans* sits atop it; extensions of the labia minora encircle the body of the clitoris, forming its **prepuce**, or *hood*. ATLAS: Embryology Summary 21: The Development of the Reproductive System

A variable number of small **lesser vestibular glands** discharge their secretions onto the exposed surface of the vestibule, keeping it moist. During sexual arousal, a pair of ducts discharges the secretions of the **greater vestibular glands** (*Bartholin's glands*) into the vestibule near the posterolateral margins of the vaginal entrance. These mucous glands have the same embryological origins as the bulbourethral glands of males.

The outer limits of the vulva are established by the mons pubis and the labia majora. The bulge of the **mons pubis** is created by adipose tissue deep to the skin superficial to the pubic symphysis. Adipose tissue also accumulates within the **labia majora** (singular, *labium majus*), prominent folds of skin that encircle and partially conceal the labia minora and adjacent structures. The outer margins of the labia majora and the mons pubis are covered with coarse hair, but the inner surfaces of the labia majora are relatively hairless. Sebaceous glands and scattered apocrine sweat glands release their secretions onto the inner surface of the labia majora, moistening and lubricating them.

The Mammary Glands

A newborn infant cannot fend for itself, and several of its key systems have yet to complete development. Over the initial period of adjustment to an independent existence, the infant can gain nourishment from the milk secreted by the maternal **mammary glands**. Milk production, or **lactation** (lak-TA¯-shun), occurs in these glands. In females, mammary glands are specialized organs of the integumentary system that are controlled mainly by hormones of the reproductive system and by the *placenta*, a temporary structure that provides the embryo and fetus with nutrients.

On each side, a mammary gland lies in the subcutaneous tissue of the **pectoral fat pad** deep to the skin of the chest (Figure 28–23a•). Each breast bears a **nipple**, a small conical projection where the ducts of the underlying mammary gland open onto the body surface. The reddish-brown skin around each nipple is the **areola** (a-RE¯-o¯-luh). Large sebaceous glands deep to the areolar surface give it a grainy texture.

The glandular tissue of a mammary gland consists of separate lobes, each containing several secretory lobules. Ducts leaving the lobules converge, giving rise to a single **lactiferous** (lak-TIF-er-us) **duct** in each lobe. Near the nipple, that lactiferous duct enlarges, forming an expanded chamber called a **lactiferous sinus**. Typically, 15–20 lactiferous sinuses open onto the surface of each nipple. Dense connective tissue surrounds the duct system and forms partitions that extend between the lobes and the lobules. These bands of connective tissue, the *suspensory ligaments of the breast*, originate in the dermis of the overlying skin. A layer of areolar tissue separates the mammary gland complex from the underlying pectoralis muscles. Branches of the *internal thoracic artery* (see Figure 21–21•, p. 739) supply blood to each mammary gland.

Figure 28–23b,c• compares the histological organizations of inactive and active mammary glands. An inactive, or *resting*, mammary gland is dominated by a duct system rather than by active glandular cells. The size of the mammary glands in a nonpregnant woman reflects primarily the amount of adipose tissue present, not the amount of glandular tissue. The secretory apparatus normally does not complete its development unless pregnancy occurs. An active mammary gland is a tubuloalveolar gland, consisting of multiple glandular tubes that end in secretory alveoli. We will discuss the hormonal mechanisms involved in lactation in Chapter 29.

Anatomy 360 | Review the anatomy of the female reproductive system on the **Anatomy 360 CD-ROM: Reproductive Sys-tem/Female Reproductive System.**

Concept Check

As the result of infections such as gonorrhea, scar tissue can block the lumen of each uterine tube. How would this blockage affect a woman’s ability to conceive? What is the advantage of the acidic pH of the vagina?

Which layer of the uterus is sloughed off during menstruation?

Would the blockage of a single lactiferous sinus interfere with the delivery of milk to the nipple? Explain.

Answers begin on p. A–1

Hormones and the Female Reproductive Cycle

The activity of the female reproductive tract is under hormonal control that involves an interplay between secretions of both the pituitary gland and the gonads. But the regulatory pattern in females is much more complicated than in males, because it must coordinate the ovarian and uterine cycles. Circulating hormones control the **female reproductive cycle**, coordinating the ovarian and uterine cycles to ensure proper reproductive function. If the two cycles are not properly coordinated, infertility results. A woman who fails to ovulate cannot conceive, even if her uterus is perfectly normal. A woman who ovulates normally, but whose uterus is not ready to support an embryo, will also be infertile. Because the processes are complex and difficult to study, many of the biochemical details of the female reproductive cycle still elude us, but the general patterns are reasonably clear.

As in males, GnRH from the hypothalamus regulates reproductive function in females. However, in females, the GnRH pulse frequency and amplitude (amount secreted per pulse) change throughout the course of the ovarian cycle. If the hypothalamus were a radio station, the pulse frequency would correspond to the radio frequency it's transmitting on, and the amplitude would be the volume. We will consider changes in pulse frequency, as their effects are both dramatic and reasonably well understood. Changes in GnRH pulse frequency are controlled primarily by circulating levels of estrogens and progestins. Estrogens increase the GnRH pulse frequency, and progestins decrease it.

The endocrine cells of the anterior lobe of the pituitary gland respond as if each group of endocrine cells is monitoring different frequencies. As a result, each group of cells is sensitive to some GnRH pulse frequencies and insensitive to others. For example, consider the *gonadotropes,* the cells responsible for FSH and LH production. At one pulse frequency, the gonadotropes respond preferentially and secrete FSH, whereas at another frequency, LH is the primary hormone released. FSH and LH production also occurs in pulses that follow the rhythm of GnRH pulses. If GnRH is absent or is supplied at a constant rate (without pulses), FSH and LH secretion will stop in a matter of hours.

Hormones and the Follicular Phase

Follicular development begins under FSH stimulation; each month some of the primordial follicles begin to develop into primary follicles. As the follicles enlarge, thecal cells start producing *androstenedione*, a steroid hormone that is a key intermediate in the synthesis of estrogens and androgens. Androstenedione is absorbed by the granulosa cells and converted to estrogens. In addition, small quantities of estrogens are secreted by interstitial cells scattered throughout the ovarian stroma. Circulating estrogens are bound primarily to albumins, with lesser amounts carried by gonadal steroid-binding globulin (GBG).

Of the three estrogens circulating in the bloodstream—estradiol, estrone, and estriol—the

one that is most abundant and has the most pronounced effects on target tissues is **estradiol** (es-tra-D -ol). It is the dominant hormone prior to ovulation. In estra-
I¯diol synthesis (Figure 28–24•), androstenedione is first converted to testosterone, which the enzyme aromatase converts to estradiol. The synthesis of both *estrone* and *estriol* proceeds directly from androstenedione.

Estrogens have multiple functions that affect the activities of many tissues and organs throughout the body. Among the important general functions of estrogens are (1) stimulating bone and muscle growth, (2) maintaining female secondary sex characteristics, such as body hair distribution and the location of adipose tissue deposits, (3) affecting central nervous system (CNS) activity (especially in the hypothalamus, where estrogens increase the sexual drive), (4) maintaining functional accessory reproductive glands and organs, and (5) initiating the repair and growth of the endometrium. Figure 28–25•, which diagrams the hormonal regulation of ovarian activity, includes an overview of the effects of estrogens on various aspects of reproductive function.

Summary: Hormonal Regulation of the Female Reproductive Cycle

Figure 28–26• shows the changes in circulating hormone levels that accompany the ovarian cycle. Early in the follicular phase, estrogen levels are low and the GnRH pulse frequency is 16–24 per day (one pulse every 60–90 minutes) (Figure 28–26a•). At this frequency, FSH is the dominant hormone released by the anterior pituitary gland; the estrogens released by developing follicles inhibit LH secretion (Figure 28–26b•). As secondary follicles develop, FSH levels decline due to the negative feedback effects of inhibin. Follicular development and maturation continue, however, supported by the combination of estrogens, FSH, and LH.

As one or more tertiary follicles begin forming, the concentration of circulating estrogens rises steeply. As a result, the GnRH pulse frequency increases to about 36 per day (one pulse every 30–60 minutes). The increased pulse frequency stimulates LH secretion. In addition, at roughly day 10 of the cycle, the effect of estrogen on LH secretion changes from inhibition to stimulation. The switchover occurs only after rising estrogen levels have exceeded a specific threshold value for about 36 hours. (The threshold value and the time required vary among individuals.) High estrogen levels also increase gonadotrope sensitivity to GnRH. At about day 14, the estrogen level has peaked, the gonadotropes are at maximum sensitivity, and the GnRH pulses are arriving about every 30 minutes. The result is a massive release of LH from the anterior pituitary gland. This sudden surge in LH concentration triggers (1) the completion of meiosis I by the primary oocyte, (2) the rupture of the follicular wall, and (3) ovulation. Typically, ovulation occurs 34–38 hours after the LH surge begins, roughly 9 hours after the LH peak.

Hormones and the Luteal Phase

The high LH levels that trigger ovulation also promote progesterone secretion and the formation of the corpus luteum. As progesterone levels rise and estrogen levels fall, the GnRH pulse frequency declines sharply, soon reaching 1–4 pulses per day. This frequency of GnRH pulses stimulates LH secretion more than it does FSH secretion, and the LH maintains the structure and secretory function of the corpus luteum.

Although moderate amounts of estrogens are secreted by the corpus luteum, progesterone is the main hormone of the luteal phase. Its primary function is to continue the preparation of the uterus for pregnancy by enhancing the blood supply to the functional zone and stimulating the secretion of endometrial glands. Progesterone levels remain high for the next week, but unless pregnancy occurs, the corpus luteum begins to degenerate. Roughly 12 days after ovulation, the corpus luteum becomes nonfunctional, and progesterone and estrogen levels fall markedly. The blood supply to the functional zone is restricted, and the endometrial tissues begin to deteriorate. As progesterone and estrogen levels drop, the GnRH pulse frequency increases, stimulating FSH secretion by the anterior lobe of the pituitary gland, and the ovarian cycle begins again.

The hormonal changes involved with the ovarian cycle in turn affect the activities of other reproductive tissues and organs. At the uterus, the hormonal changes maintain the uterine cycle.

Hormones and the Uterine Cycle

Figure 28–26e• depicts the changes in the endometrium during a single uterine cycle. The declines in progesterone and estrogen levels that accompany the degeneration of the corpus luteum (see Figure 28–26c,d•) result in menses. The shedding of endometrial tissue continues for several days, until rising estrogen levels stimulate the repair and regeneration of the functional zone of the endometrium. The proliferative phase continues until rising progesterone levels mark the arrival of the secretory phase. The combination of estrogen and progesterone then causes the enlargement of the endometrial glands and an increase in their secretory activities.

Hormones and Body Temperature

The monthly hormonal fluctuations cause physiological changes that affect core body temperature. During the follicular phase, when estrogen is the dominant hormone, the *basal body temperature*, or the resting body temperature measured upon awakening in the morning, is about 0.3°C lower than it is during the luteal phase, when progesterone dominates (Figure 28–26d•). At the time of ovulation, the basal body temperature declines noticeably, making the rise in temperature over the next day even more noticeable (Figure 28–26f•). As a result, by keeping records of body temperature over a few uterine cycles, a woman can often determine the precise day of ovulation. This information can be important for individuals who wish to avoid or promote a pregnancy, because fertilization typically occurs within a day of ovulation. Thereafter, oocyte viability and the likelihood of successful fertilization decrease markedly. AM: PMS Premenstrual Syndrome

100 Keys | Cyclic changes in FSH and LH levels are responsible for the maintenance of the ovarian cycle; the hormones produced by the ovaries in turn regulate the uterine cycle. Inadequate hormone levels, inappropriate or inadequate responses to circulating hormones, or poor coordination and timing of hormone production or secondary oocyte release will reduce or eliminate the chances of pregnancy.

Concept Check

What changes would you expect to observe in the ovarian cycle if the LH surge did not occur?

What effect would a blockage of progesterone receptors in the uterus have on the endometrium?

What event in the uterine cycle occurs when the levels of estrogens and progesterone decline?

Answers begin on p. A–1

The Physiology of Sexual Intercourse

Objective

- Discuss the physiology of sexual intercourse as it affects the reproductive systems of males and females.

–

Sexual intercourse, also known as *coitus* (KO-i-tus) or *copulation*, introduces semen into the female reproductive tract. We will
now consider the process as it affects the reproductive systems of males and females. AM: Birth Control Strategies

Male Sexual Function

Sexual function in males is coordinated by complex neural reflexes that we do not yet understand completely. The reflex pathways utilize the sympathetic and parasympathetic divisions of the autonomic nervous system. During sexual **arousal**, erotic thoughts, the stimulation of sensory nerves in the genital region, or both lead to an increase in parasympathetic outflow over the pelvic nerves. This outflow in turn leads to erection of the penis (discussed on p. 1044). The integument covering the glans of the penis contains numerous sensory receptors, and erection tenses the skin and increases their sensitivity. Subsequent stimulation can initiate the secretion of the bulbourethral glands, lubricating the penile urethra and the surface of the glans.

During intercourse, the sensory receptors of the penis are rhythmically stimulated. This stimulation eventually results in the coordinated processes of emission and ejaculation. **Emission** occurs under sympathetic stimulation. The process begins when the peristaltic contractions of the ampulla push fluid and spermatozoa into the prostatic urethra. The seminal vesicles then begin contracting, and the contractions increase in force and duration over the next few seconds. Peristaltic contractions also appear in the walls of the prostate gland. The combination moves the seminal mixture into the membranous and penile portions of the urethra. While the contractions are proceeding, sympathetic commands also cause the contraction of the urinary bladder and the internal urethral sphincter. The combination of elevated pressure inside the bladder and the contraction of the sphincter effectively prevents the passage of semen into the bladder.

Ejaculation occurs as powerful, rhythmic contractions appear in the *ischiocavernosus* and *bulbospongiosus muscles,* two superficial skeletal muscles of the pelvic floor. The ischiocavernosus muscles insert along the sides of the penis; their contractions serve primarily to stiffen that organ. The bulbospongiosus muscle wraps around the base of the penis; the contraction of this muscle pushes semen toward the external urethral opening. The contractions of both muscles are controlled by somatic motor neurons in the inferior lumbar and superior sacral segments of the spinal cord. (The positions of these muscles are shown in Figure 11–12b•, p. 348.)

Ejaculation is associated with intensely pleasurable sensations, an experience known as male **orgasm** (OR-gazm). Several other noteworthy physiological changes occur at this time, including pronounced but temporary increases in heart rate and blood pressure. After ejaculation, blood begins to leave the erectile tissue, and the erection begins to subside. This subsidence, called **detumescence** (de-tu¯-MES-ens), is mediated by the sympathetic nervous system.

In sum, arousal, erection, emission, and ejaculation are controlled by a complex interplay between the sympathetic and parasympathetic divisions of the autonomic nervous system. Higher centers, including the cerebral cortex, can facilitate or inhibit many of the important reflexes, thereby modifying the patterns of sexual function. Any physical or psychological factor that affects a single component of the system can result in male sexual dysfunction, also called **impotence**.

Impotence is defined as an inability to achieve or maintain an erection. Various physical causes may be responsible for impotence, because erection involves vascular changes as well as neural commands. For example, low blood pressure in the arteries supplying the penis, due to a circulatory blockage such as a plaque, will reduce the ability to attain an erection. Drugs, alcohol, trauma, or illnesses that affect the autonomic nervous system or the central nervous system can have the same effect. But male sexual performance can also be strongly affected by the psychological state of the individual. Temporary periods of impotence are relatively common in healthy individuals who are experiencing severe stresses or emotional problems. Depression, anxiety, and fear of impotence are examples of emotional factors that can result in sexual dysfunction. The prescription drug Viagra, which enhances and prolongs the effects of nitric oxide on the erectile tissue of the penis, has proven useful in treating many cases of impotence.

Female Sexual Function

The phases of female sexual function are comparable to those of male sexual function. During sexual arousal, parasympathetic activation leads to engorgement of the erectile tissues of the clitoris and increased secretion of cervical mucous glands and the greater vestibular glands. Clitoral erection increases the receptors' sensitivity to stimulation, and the cervical and vestibular glands lubricate the vaginal walls. A network of blood vessels in the vaginal walls becomes filled with blood at this time, and the vaginal surfaces are also moistened by fluid that moves across the epithelium from underlying connective tissues. (This process accelerates during intercourse as the result of mechanical stimulation.) Parasympathetic stimulation also causes contraction of subcutaneous smooth muscle of the nipples, making them more sensitive to touch and pressure.

During sexual intercourse, rhythmic contact of the penis with the clitoris and vaginal walls—reinforced by touch sensations from the breasts and other stimuli (visual, olfactory, and auditory)—provides stimulation that leads to orgasm. Female orgasm is accompanied by peristaltic contractions of the uterine and vaginal walls and, by means of impulses traveling over the pudendal nerves, rhythmic contractions of the bulbospongiosus and ischiocavernosus muscles. The latter contractions give rise to the intensely pleasurable sensations of orgasm.

Sexual activity carries with it the risk of infection with a variety of microorganisms. The consequences of such an infection may range from merely inconvenient to potentially lethal. **Sexually transmitted diseases (STDs)** are transferred from individual to individual, primarily or exclusively by sexual intercourse. At least two dozen bacterial, viral, and fungal infections are currently recognized as STDs. The bacterium *Chlamydia* can cause

pelvic inflammatory disease (PID) and infertility; AIDS, caused by a virus, is deadly. The incidence of STDs has been increasing in the United States since 1984; an estimated 15 million new cases are diagnosed each year. Poverty, intravenous drug use, prostitution, and the appearance of drug-resistant pathogens all contribute to the problem. The *Applications Manual* contains a detailed discussion of the most common forms of STD, including *gonorrhea*, *syphilis*, *herpes*, *genital warts*, and *chancroid*. AM: Sexually Transmitted Diseases

Aging and the Reproductive System

Objective

- Describe the changes in the reproductive system that occur with aging.

The aging process affects all body systems, including the reproductive systems of men and women alike. As noted earlier in the chapter, these systems become fully functional at puberty. Thereafter, the most striking age-related changes in the female reproductive system occur at menopause. Comparable age-related changes in the male reproductive system occur more gradually and over a longer period of time.

Menopause

Menopause is usually defined as the time that ovulation and menstruation cease. Menopause typically occurs at age 45–55, but in the years immediately preceding it, the ovarian and uterine cycles become irregular. This interval is called *perimenopause*. A shortage of primordial follicles is the underlying cause of the irregular cycles. It has been estimated that almost 7 million potential oocytes are in fetal ovaries after five months of development, but the number drops to about 2 million at birth, and to a few hundred thousand at puberty. With the arrival of perimenopause, the number of follicles responding each month begins to drop markedly. As the number of available follicles decreases, estrogen levels decline and may not rise enough to trigger ovulation. By age 50, there are often no primordial follicles left to respond to FSH. In **premature menopause**, this depletion occurs before age 40.

Menopause is accompanied by a decline in circulating concentrations of estrogens and progesterone, and a sharp and sustained rise in the production of GnRH, FSH, and LH. The decline in estrogen levels leads to reductions in the size of the uterus and breasts, accompanied by a thinning of the urethral and vaginal epithelia. The reduced estrogen concentrations have also been linked to the development of osteoporosis, presumably because bone deposition proceeds at a slower rate. A variety of neural effects are reported as well, including "hot flashes," anxiety, and depression. Hot flashes typically begin while estrogen levels are declining, and cease when estrogen levels reach minimal values. These intervals of elevated body temperature are associated with surges in LH production. The hormonal mechanisms involved in other CNS effects of menopause are poorly understood. In addition, the risks of atherosclerosis and other forms of cardiovascular disease increase after menopause.

The majority of women experience only mild symptoms, but some individuals experience acutely unpleasant symptoms in perimenopause or during or after menopause. For most of those women, hormone replacement therapy (HRT) involving a combination of estrogens and progestins can control the unpleasant neural and vascular changes associated with menopause. The hormones are administered as pills, by injection, or by transdermal "estrogen patches." However, recent studies suggest that taking estrogen-replacement therapy for more than 5 years increases the risk of heart disease, breast cancer, Alzheimers disease, blood clots, and stroke; HRT should be prescribed with caution, only after a full discussion and assessment of the potential risks and benefits, and taken for as short a time as possible.

The Male Climacteric

Changes in the male reproductive system occur more gradually than do those in the female reproductive system. The period of declining reproductive function, which corresponds to perimenopause in women, is known as the **male climacteric** or *andropause*. Levels of circulating testosterone begin to decline between the ages of 50 and 60, and levels of circulating FSH and LH increase. Although sperm production continues (men well into their eighties can father children), older men experience a gradual reduction in sexual activity. This decrease may be linked to declining testosterone levels. Some clinicians suggest the use of testosterone replacement therapy to enhance the libido (sexual drive) of elderly men, but this may increase the risk of prostate disease.

100 Keys | Sex hormones have widespread effects on the body. They affect brain development and behavioral drives, muscle mass, bone mass and density, body proportions, and the patterns of hair and body fat distribution. As aging occurs, reductions in sex hormone levels affect appearance, strength, and a variety of physiological functions.

Concept Check

An inability to contract the ischiocavernosus and bulbospongiosus muscles would interfere with which part(s) of the male sex act?

What changes occur in females during sexual arousal as the result of increased parasympathetic stimulation?

Why does the level of FSH rise and remain high during menopause?

Answers begin on p. A–1

Integration with Other Systems

Normal human reproduction is a complex process that requires the participation of multiple systems. The hormones discussed in this chapter play a major role in coordinating reproductive events (Table 28–1). Physical factors also play a role. The man's sperm count must be adequate, the semen must have the correct pH and nutrients, and erection and ejaculation must occur in the proper sequence; the woman's ovarian and uterine cycles must be properly coordinated, ovulation and oocyte transport must occur normally, and her reproductive tract must provide a hospitable environment for the survival and movement of sperm, and for the subsequent fertilization of the oocyte. For these steps to occur, the reproductive, digestive, endocrine, nervous, cardiovascular, and urinary systems must all be functioning normally.

Even when all else is normal and fertilization occurs at the proper time and place, a healthy infant will not be produced unless the zygote—a single cell the size of a pinhead—manages to develop into a full-term fetus that typically weighs about 3 kg (6.6 lb). In Chapter 29 we will consider the process of development, focusing on the mechanisms that determine both the structure of the body and the distinctive characteristics of each individual.

Even though the reproductive system’s primary function—producing children—doesn’t play a role in maintaining homeostasis, reproduction depends on a variety of physical, physiological, and psychological factors, many of which require intersystem cooperation. In addition, the hormones that control and coordinate sexual function have direct effects on the organs and tissues of other systems. For example, testosterone and estradiol affect both muscular development and bone density. Figure 28–27• summarizes the relationships between the reproductive system and other physiological systems.

Clinical Patterns

The male and female reproductive systems are complex, and reproductive disorders are many and varied. Major categories of reproductive disorders include the following:

- Tumors, such as testicular, prostate, ovarian, or uterine cancers.
- Inflammation and infection, such as prostatitis, pelvic inflammatory disease, toxic shock syndrome, and the various sexually transmitted diseases.
- Uterine disorders such as endometriosis, and hormonally related problems such as amenorrhea.
- Trauma, such as testicular torsion and inguinal hernias.
- Congenital disorders, such as cryptorchidism.

Most reproductive disorders are primary disorders that reflect problems originating within the reproductive system. However, amenorrhea and premenstrual syndrome are examples of secondary disorders that can result from problems with the endocrine system, and impotence can result from neural, hormonal, or vascular problems. The *Applications Manual* discusses the diagnosis and treatment of the major classes of reproductive system disorders.

Chapter Review

Selected Clinical Terminology

amenorrhea: The failure of menarche to appear before age 16, or a cessation of menstruation for six months or more in an adult female of reproductive age. (p. 1057) **breast cancer:** A malignant, metastasizing tumor of the mammary gland that is the primary cause of death for women ages 35–45.

. (p. 1060) **cervical cancer:** A malignant, metastasizing tumor of the cervix, and the most common reproductive system cancer in women. (p. 1056) **cryptorchidism:** The failure of one or both testes to descend into the scrotum by the time of birth. (p. 1031) **dysmenorrhea:** Painful menstruation. (p. 1057) **endometriosis:** The growth of endometrial tissue outside the uterus. [AM] **fibrocystic disease:** Clusters of lobular cysts within the tissues of the mammary gland. (p. 1060) **gonorrhea:** A sexually transmitted bacterial disease. [AM] **impotence:** The inability to achieve or maintain an erection. (p. 1065) **mammography:** The use of x-rays to examine breast tissue. (p. 1060) **mastectomy:** The surgical removal of part or all of a breast containing cancerous glandular tissue. (p. 1030) **orchiectomy:** The surgical removal of a testis. (p. 1031) **ovarian cancer:** A malignant, metastasizing tumor of the ovaries, and the most dangerous reproductive system cancer in women. [AM] **pelvic inflammatory disease (PID):** An infection of the uterine tubes. (p. 1066) **prostate cancer:** A malignant, metastasizing tumor of the prostate gland, and the second most common cause of cancer deaths in males.

. (p. 1047) **prostatectomy:** The surgical removal of the prostate gland. (p. 1047) **prostate-specific antigen (PSA):** An antigen whose level in blood increases in men with prostate cancer. (p. 1047) **sexually transmitted diseases (STDs):** Diseases transferred from one individual to another primarily or exclusively through sexual

contact. Examples include gonorrhea, syphilis, herpes genitalis, and AIDS. (p. 1066 and [AM]) **vaginitis:** An infection of the vaginal canal by fungal or bacterial pathogens. (p. 1058 and [AM]) **vasectomy:** The surgical removal of a segment of the ductus deferens, making it impossible for spermatozoa to reach the distal portions
of the male reproductive tract. [AM]

Study Outline

Introduction to the Reproductive System p. 1030

1. 1. The human **reproductive system** produces, stores, nourishes, and transports functional **gametes** (reproductive cells). **Fertilization** is the fusion of male and female gametes.

2. 2. The reproductive system includes **gonads (testes** or **ovaries)**, ducts, accessory glands and organs, and the **external genitalia**.

3. 3. In males, the testes produce **spermatozoa**, which are expelled from the body in **semen** during *ejaculation*. The ovaries of a sexually mature female produce **oocytes** (immature **ova**) that travel along *uterine tubes* toward the *uterus*. The *vagina* connects the uterus with the exterior of the body.

The Reproductive System of the Male p. 1030

1. The spermatozoa travel along the *epididymis*, the *ductus deferens*, the *ejaculatory duct*, and the *urethra* before leaving the body. Accessory organs (notably the *seminal vesicles*, *prostate gland*, and *bulbourethral glands*) secrete fluids into the ejaculatory ducts and the urethra. The *scrotum* encloses the testes, and the *penis* is an erectile organ. *(Figure 28–1)*

The Testes p. 1030

1. 2. The **descent of the testes** through the *inguinal canals* occurs during fetal development. The testes remain connected to internal structures via the **spermatic cords**. The **raphe** marks the boundary between the two chambers in the **scrotum**. *(Figures 28–2, 28–3)*

2. 3. The **dartos** muscle tightens the scrotum, giving it a wrinkled appearance as it elevates the testes; the **cremaster muscles** are more substantial muscle that pull the testes close to the body.

3. 4. The **tunica albuginea** surrounds each testis. Septa extend from the tunica albuginea to the region of the testis closest to the entrance to the epididymis, creating a series of **lobules**. *(Figure 28–4)*

4. 5. **Seminiferous tubules** within each lobule are the sites of sperm production. From there, spermatozoa pass through the **rete testis**. **Efferent ductules** connect the rete testis to the epididymis. Between the seminiferous tubules are **interstitial cells**, which secrete sex hormones. *(Figures 28–4, 28–5)*

Spermatogenesis p. 1036

6. Seminiferous tubules contain **spermatogonia**, stem cells involved in **spermatogenesis** (the production of spermatozoa), and **sustentacular cells**, which sustain and promote the development of spermatozoa. *(Figures 28–6, 28–7)*

100 Keys | p. 1038

The Anatomy of a Spermatozoon p. 1038

7. Each **spermatozoon** has a **head** tipped by an **acrosomal cap**, a **middle piece**, and a **tail**. *(Figure 28–8)*

100 Keys | p. 1039

The Male Reproductive Tract p. 1040

1. **8.** From the testis, the spermatozoa enter the **epididymis**, an elongate tubule with **head**, **body**, and **tail** regions. The epididymis monitors and adjusts the composition of the fluid in the seminiferous tubules, serves as a recycling center for damaged spermatozoa, stores and protects spermatozoa, and facilitates their functional maturation. *(Figure 28–9)*

2. **9.** The **ductus deferens**, or *vas deferens*, begins at the epididymis and passes through the inguinal canal as part of the spermatic cord. Near the prostate gland, the ductus deferens enlarges to form the **ampulla**. The junction of the base of the seminal vesicle and the ampulla creates the **ejaculatory duct**, which empties into the urethra. *(Figures 28–9, 28–10)*

3. **10.** The **urethra** extends from the urinary bladder to the tip of the penis. The urethra can be divided into *prostatic, membranous,* and *spongy regions*.

The Accessory Glands p. 1041

11. Each **seminal vesicle** is an active secretory gland that contributes about 60 percent of the volume of semen; its secretions contain fructose (which is easily metabolized by spermatozoa), bicarbonate ions, prostaglandins, and fibrinogen. The **prostate gland**

secretes slightly acidic **prostatic fluid**. Alkaline mucus secreted by the **bulbourethral glands** has lubricating properties. *(Figures 28–10, 28–11)*

Semen p. 1043

12. A typical ejaculation releases 2–5 ml of semen (**ejaculate**), which contains 20–100 million spermatozoa per milliliter. The fluid component of semen is **seminal fluid**.

The External Genitalia p. 1044

13. The skin overlying the **penis** resembles that of the scrotum. Most of the **body** of the penis consists of three masses of **erectile tissue**. Beneath the superficial fascia are two **corpora cavernosa** and a single **corpus spongiosum**, which surrounds the urethra. Dilation of the blood vessels within the erectile tissue produces an **erection**. *(Figure 28–11)*

Anatomy 360 **|** Reproductive System/Male Reproductive System

Hormones and Male Reproductive Function p. 1045

14. Important regulatory hormones include **FSH** (*follicle-stimulating hormone*), **LH** (*luteinizing hormone*), and **GnRH** (*gonadotropinreleasing hormone*). *Testosterone* is the most important androgen. *(Figure 28–12)*

The Reproductive System of the Female p. 1048

1. **1.** Principal organs of the female reproductive system include the *ovaries, uterine tubes, uterus, vagina,* and external genitalia. *(Figure 28–13)*

2. **2.** The ovaries, uterine tubes, and uterus are enclosed within the **broad ligament**. The **mesovarium** supports and stabilizes each ovary.

(Figure 28–14)

The Ovaries p. 1049

1. **3.** The ovaries are held in position by the **ovarian ligament** and the **suspensory ligament**. Major blood vessels enter the ovary at the **ovarian hilum**. Each ovary is covered by a **tunica albuginea**. *(Figure 28–14)*

2. **4.** **Oogenesis** (ovum production) occurs monthly in **ovarian follicles** as part of the **ovarian cycle**, which is divided into a **follicular** (*preovulatory*) **phase** and a **luteal**

(*postovulatory*) **phase**. *(Figures 28–15, 28–16)*

3. **5.** As development proceeds, **primordial**, **primary**, **secondary**, and **tertiary follicles** are produced in turn. At **ovulation**, a **secondary oocyte** and the attached follicular cells of the **corona radiata** are released through the ruptured ovarian wall. The follicular cells remaining within the ovary form the **corpus luteum**, which later degenerates into scar tissue called a **corpus albicans**. *(Figure 28–16)*

100 Keys | p. 1052

The Uterine Tubes p. 1052

6. Each **uterine tube** has an **infundibulum** with **fimbriae** (fingerlike projections), an **ampulla**, and an **isthmus**. Each uterine tube opens into the *uterine cavity*. For fertilization to occur, a secondary oocyte must encounter spermatozoa during the first 12–24 hours of its passage from the infundibulum to the uterus. *(Figure 28–17)*

The Uterus p. 1053

1. **7.** The **uterus** provides mechanical protection, nutritional support, and waste removal for the developing embryo. Normally, the uterus bends anteriorly near its base (*anteflexion*). It is stabilized by the broad ligament, **uterosacral ligaments**, **round ligaments**, and **lateral ligaments**. *(Figure 28–18)*

2. **8.** Major anatomical landmarks of the uterus include the **body**, **isthmus**, **cervix**, **cervical os** (*external orifice*), **uterine cavity**, **cervical canal**, and **internal os** (*internal orifice*). The uterine wall consists of an inner **endometrium**, a muscular **myometrium**, and a superficial **perimetrium** (an incomplete serous layer). *(Figures 28–18, 28–19)*

3. **9.** A typical 28-day **uterine**, or *menstrual*, **cycle** begins with the onset of **menses** and the destruction of the **functional zone** of the endometrium. This process of **menstruation** continues from one to seven days. *(Figure 28–20)*

4. **10.** After menses, the **proliferative phase** begins, and the functional zone undergoes repair and thickens. The proliferative phase is followed by the **secretory phase**, during which endometrial glands enlarge. Menstrual activity begins at **menarche** and continues until **menopause**. *(Figure 28–20)*

The Vagina p. 1057

11. The **vagina** is a muscular tube extending between the uterus and the external genitalia. A thin epithelial fold, the **hymen**, partially blocks the entrance to the vagina until physical distortion (often associated with sexual intercourse) ruptures the membrane. *(Figure 28–21)*

The External Genitalia p. 1058

12. The components of the **vulva** are the **vestibule**, **labia minora**, **paraurethral glands**, **clitoris**, **labia majora**, and **lesser** and **greater vestibular glands**. *(Figure 28–22)*

The Mammary Glands p. 1059

13. A newborn infant can gain nourishment from milk secreted by maternal **mammary glands**. *(Figure 28–23)*

Anatomy 360 **|** Reproductive System/Female Reproductive System

Hormones and the Female Reproductive Cycle p. 1061

1. **14.** Hormonal regulation of the **female reproductive cycle** involves the coordination of the ovarian and uterine cycles.

2. **15. Estradiol**, the most important *estrogen*, is the dominant hormone of the follicular phase. Ovulation occurs in response to a midcycle surge in LH. *(Figures 28–24, 28–25)*

3. **16.** The hypothalamic secretion of GnRH occurs in pulses that trigger the pituitary secretion of FSH and LH. FSH initiates follicular development, and activated follicles and ovarian interstitial cells produce estrogens. High estrogen levels stimulate LH secretion, increase pituitary sensitivity to GnRH, and increase the GnRH pulse frequency. **Progesterone**, one of the **progestins**, is the principal hormone of the luteal phase. Changes in estrogen and progesterone levels are responsible for the maintenance of the uterine cycle.

(Figures 28–25, 28–26)

Summary: Hormonal Regulation of the Female Reproductive Cycle p. 1062

100 Keys | p. 1065

The Physiology of Sexual Intercourse p. 1065 Male Sexual Function p. 1065

1. During sexual **arousal** in males, erotic thoughts, sensory stimulation, or both lead to parasympathetic activity that produces erection. Stimuli accompanying **sexual intercourse** lead to **emission** and **ejaculation**. Contractions of the bulbospongiosus muscles are associated with **orgasm**.

Female Sexual Function p. 1066

2. The phases of female sexual function resemble those of male sexual function, with parasympathetic arousal and skeletal muscle contractions associated with orgasm.

Aging and the Reproductive System p. 1066 Menopause p. 1066

1. **1.** Menopause (the time that ovulation and menstruation cease) typically occurs at ages 45–55. The production of GnRH, FSH, and LH rise, whereas circulating concentrations of estrogen and progesterone decline.

2. **2.** During the **male climacteric**, at ages 50–60, circulating testosterone levels fall, and levels of FSH and LH rise.

The Male Climacteric p. 1067

100 Keys | p. 1067

Integration with Other Systems

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

. **1.** Developing spermatozoa are nourished by the

. **(a)** interstitial cells **(b)** seminal vesicles

. **(c)** sustentacular cells **(d)** Leydig cells

. **(e)** epididymis

. **2.** The ovaries are responsible for

. **(a)** the production of female gametes

. **(b)** the secretion of female sex hormones

. **(c)** the secretion of inhibin

. **(d)** a, b, and c are correct

. **3.** In females, meiosis is not completed until

. **(a)** birth

. **(b)** puberty

. **(c)** fertilization occurs

. **(d)** uterine implantation occurs

. **4.** A sudden surge in LH secretion causes the

. **(a)** onset of menses

. **(b)** rupture of the follicular wall and ovulation

. **(c)** beginning of the proliferative phase

. **(d)** end of the uterine cycle

. **5.** The principal hormone of the postovulatory phase is

. **(a)** progesterone **(b)** estradiol

. **(c)** estrogen **(d)** luteinizing hormone

2. **6.** Trace the duct system that the sperm traverses from the site of its production to the exterior of the body.

3. **7.** Which accessory organs and glands contribute to the composition of semen? What are the functions of each?

4. **8.** What are the primary cell populations in the testes that are responsible for functions related to reproductive activity? What are the functions of these cells?

5. **9.** Identify the three regions of the male urethra.

6. **10.** List the functions of testosterone in males.

7. **11.** List and summarize the important steps in the ovarian cycle.

8. **12.** Describe the histological composition of the uterine wall.

9. **13.** What is the role of the clitoris in the female reproductive system?

10. **14.** Trace the route that milk takes from its site of production to the outside of the female.

LEVEL 2 Reviewing Concepts

. **15.** All of the following are true of pelvic inflammatory disease, *except* that it

. **(a)** is frequently caused by sexually transmitted pathogens

. **(b)** causes fever and abdominal pain

. **(c)** can lead to a ruptured urinary bladder

. **(d)** can possibly lead to peritonitis

. **(e)** can cause sterility

. **16.** In the follicular phase of the ovarian cycle, the ovary is

. **(a)** undergoing atresia

. **(b)** forming a corpus luteum

. **(c)** releasing a mature egg

. **(d)** secreting progesterone

. **(e)** maturing a follicle

2. **17.** What are the main differences in gamete production between males and females?

3. **18.** Describe the erectile tissues of the penis. How does erection occur?

4. **19.** Using an average cycle of 28 days, describe each of the three phases of the uterine cycle.

5. **20.** Describe the hormonal events associated with the ovarian cycle.

6. **21.** Describe the hormonal events associated with the uterine cycle.

7. **22.** Summarize the steps that occur in sexual arousal and orgasm. Do these processes differ in males and females?

8. **23.** How does the aging process affect the reproductive systems of men and women?

LEVEL 3 Critical Thinking and Clinical Applications

1. **24.** Diane has peritonitis (an inflammation of the peritoneum), which her physician says resulted from a urinary tract infection. Why might this condition occur more readily in females than in males?

2. **25.** In a condition known as endometriosis, endometrial cells are believed to migrate from the body of the uterus into the uterine tubes or by way of the uterine tubes into the peritoneal cavity where they become established. A major symptom of endometriosis is periodic pain. Why do you think this occurs?

3. **26.** Contraceptive pills contain estradiol or estradiol and progesterone that are given at programmed doses during the ovarian cycle to prevent follicle maturation and ovulation. How would this happen?

4. **27.** Women bodybuilders and women with eating disorders such as anorexia nervosa commonly experience amenorrhea. What does this fact suggest about the relation between body fat and menstruation? What might be the benefit of amenorrhea under such circumstances?

Clinical Note

Prostatic Hypertrophy and Prostate Cancer

Enlargement of the prostate gland, or **benign prostatic hypertrophy**, typically occurs spontaneously in men over age 50. The increase in size occurs as testosterone production by the interstitial cells decreases. For unknown reasons, small masses called *prostatic concretions* may form within the glands (see photo). At the same time, the interstitial cells begin releasing small quantities of estrogens into the bloodstream. The combination of lower testosterone levels and the presence of estrogens probably stimulates prostatic growth. In severe cases, prostatic swelling constricts and blocks the urethra and constricts the rectum. If not corrected, the urinary obstruction can cause permanent kidney damage.1 Partial surgical removal is the most effective treatment. In the procedure known as a **TURP** (*transurethral prostatectomy*), an instrument pushed along the urethra restores normal function by cutting away the swollen prostatic tissue. Most of the prostate gland remains in place, and no external scars result.

Prostate cancer, a malignancy of the prostate gland, is the second most common cancer and the second most common cause of cancer deaths in males. In 2004, approximately 230,110 new cases of prostate cancer were diagnosed in the United States, and about 29,900 deaths resulted from the ailment. Most patients are elderly. (The average age at diagnosis is 72.) For reasons that are poorly understood, prostate cancer rates for Asian-American males are relatively low compared with those of either Caucasian-Americans or African-Americans. For all age and ethnic groups, the rates of prostate cancer are rising sharply. The reason for the increase is not known. Aggressive diagnosis and treatment of localized prostate cancer in elderly patients is controversial because many of these men have non-metastatic tumors, and even if untreated are more likely to die of some other disease.

Prostate cancer normally originates in one of the secretory glands. As the cancer progresses, it produces a nodular lump or swelling on the surface of the prostate gland. Palpation of this gland through the rectal wall—a procedure known as a *digital rectal exam* (DRE)—is the easiest diagnostic screening procedure. *Transrectal prostatic ultrasound* (TRUS) can be used to obtain more detailed information about the status of the prostate, but at significantly higher cost to the patient. Blood tests are also used for screening purposes. The most sensitive is a blood test for prostate-specific antigen (PSA). Elevated levels of this antigen, normally present in low concentrations, may indicate the presence of prostate cancer. The *serum enzyme assay*, which checks the level of the isozyme *prostatic acid phosphatase*, detects prostate cancer in later stages of development. Screening with periodic PSA tests is now being recommended for men over age 50.

If cancer is detected before it has spread to other organs, and the patient is elderly or has other serious health problems, “watchful waiting” is an option. In other cases, the usual treatment is localized radiation or surgical removal of the prostate gland. This operation, a **prostatectomy** (pros-ta-TEK-to-m e¯), can be effective in controlling the condition, but both surgery and radiation can have undesirable side effects, including urinary incontinence and loss of sexual function. Modified treatment procedures along with medications such as Viagra can reduce the risks and maintain normal sexual function in perhaps three out of four patients.

The prognosis is much worse for prostate cancer diagnosed after metastasis has occurred, because metastasis rapidly involves the lymphatic system, lungs, bone marrow, liver, or adrenal glands. Survival rates at this stage are relatively low. Treatments for metastasized prostate cancer include widespread irradiation, hormonal manipulation, lymph node removal, and aggressive chemotherapy. Because the cancer cells are stimulated by testosterone, treatment may involve castration or administering hormones that depress GnRH or LH production. There are three treatment options: (1) an *estrogen*, typically *diethylstilbestrol (DES)*; (2) *drugs that mimic GnRH,* which when given in high doses produce a surge in LH production followed by a sharp decline to very low levels (presumably as the endocrine cells adapt to the excessive stimulation); and (3) *drugs that block the binding of androgens* to the receptors on target cells (including the new drugs *flutamide* and *bicalutamide*), which prevent the stimulation of cancer cells by testosterone. The death rate for prostate cancer may be falling in some countries, perhaps from earlier detection and more effective treatment.

| SUMMARY TABLE 28–1 | HORMONES OF THE REPRODUCTIVE SYSTEM

Hormone	**Source**	**Regulation of Secretion**	**Primary Effects**
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	*Males*: inhibited by testosterone and possibly by inhibin *Females*: GnRH pulse frequency increased by estrogens, decreased by progestins	Stimulates FSH secretion and LH synthesis in males and females
Follicle-stimulating hormone (FSH)	Anterior lobe of pituitary gland	*Males*: stimulated by GnRH, inhibited by inhibin and *Females*: stimulated by GnRH,	*Males*: stimulates spermatogenesis and spermiogenesis through effects on sustentacular cells

inhibited by inhibin *Females*: stimulates follicle development, estrogen production, and oocyte maturation

Luteinizing Anterior lobe of pituitary *Males*: stimulated by GnRH *Males*: stimulates interstitial cells to

hormone (LH) gland *Females*: production stimulated by secrete testosterone

GnRH, secretion by the combination *Females*: stimulates ovulation,

of high GnRH pulse frequencies and formation of corpus luteum,

high estrogen levels and progestin secretion

Androgens (primarily Interstitial cells of testes Stimulated by LH Establish and maintain secondary

testosterone and sex characteristics and sexual

dihydrotestosterone) behavior; promote maturation

of spermatozoa; inhibit GnRH secretion

Estrogens (primarily Granulosa and thecal cells Stimulated by FSH Stimulate LH secretion (at high levels);

estradiol) of developing follicles; establish and maintain secondary sex

corpus luteum characteristics and sexual behavior; stimulate repair and growth of endometrium; increase frequency of GnRH pulses

Progestins (primarily Granulosa cells from

progesterone) midcycle through

functional life of corpus

luteum

Stimulated by LH Stimulate endometrial growth and glandular secretion; reduce frequency of GnRH pulses

Inhibin Sustentacular cells of Stimulated by factors released by Inhibits secretion of FSH (and possibly of testes and granulosa cells developing spermatozoa (male) GnRH) of ovaries and developing follicles (female)

An Overview of Topics in Development

Objective

- Explain the relationship between differentiation and development, and specify the various stages of development.

Time refuses to stand still; today's infant will be tomorrow's adult. The gradual modification of anatomical structures and physiological characteristics during the period from fertilization to maturity is called **development**. The changes that occur during development are truly remarkable. In a mere 9 months, all the tissues, organs, and organ systems we have studied thus far take shape and begin to function. What begins as a single cell slightly larger than the period at the end of this sentence becomes an individual whose body contains trillions of cells organized into a complex array of highly specialized structures. The creation of different types of cells required in this process is called **differentiation**. Differentiation occurs through selective changes in genetic activity. As development proceeds, some genes are turned off and others are turned on. The identities of these genes vary from one type of cell to another, and the patterns change over time.

Development begins at **fertilization**, or **conception**. We can divide development into periods characterized by specific anatomical changes. **Embryological development** comprises the events that occur during the first two months after fertilization. The

¯e ¯e

study of these events is called **embryology** (em-br -OL-o-j). **Fetal development** begins at the start of the ninth week and continues until birth. Embryological and fetal development are sometimes referred to collectively as **prenatal development**, the primary focus of this chapter. **Postnatal development** commences at birth and continues to **maturity**, when the aging process begins.

A basic understanding of human development provides important insights into anatomical structures. In addition, many of the mechanisms of development and growth are similar to those responsible for the repair of injuries. In this chapter, we will focus on major aspects of development. We will consider highlights of the developmental process rather than examine the events in great detail. We will also consider the regulatory mechanisms involved, and how developmental patterns can be modified—for good or ill. Few topics in the biological sciences are so fascinating, and fewer still confront investigators with so daunting an array of scientific, technological, and ethical challenges. The ongoing debate over fetal tissue research has brought several ethical issues into the public eye. The information presented in this final chapter should help you formulate your opinions on many difficult moral, legal, and public-policy questions.

Although all humans go through the same developmental stages, differences in their genetic makeup produce distinctive individual characteristics. The term **inheritance** refers to the transfer of genetically determined characteristics from generation to generation. The study of the mechanisms responsible for inheritance is called **genetics**. In this chapter, we will also consider basic genetics as it applies to inherited characteristics, such as sex, hair color, and various diseases.

Fertilization

Objectives

- Describe the process of fertilization.
- Explain how developmental processes are regulated.

Fertilization involves the fusion of two haploid gametes, each containing 23 chromosomes, producing a zygote that contains 46 chromosomes, the normal complement in a somatic cell. The functional roles and contributions of the male and female gametes are very different. The spermatozoon simply delivers the paternal chromosomes to the site of fertilization. It must travel a relatively large distance and is small, efficient, and highly streamlined. In contrast, the female gamete must provide all the cellular organelles and inclusions, nourishment, and genetic programming necessary to support development of the embryo for nearly a week after conception. The volume of this gamete is therefore much greater than that of the spermatozoon. Recall from Chapter 28 that ovulation releases a secondary oocyte suspended in metaphase of meiosis II. At fertilization, the diameter of the secondary oocyte is more than twice the entire length of the spermatozoon (Figure 29–1a•). The ratio of their volumes is even more striking— roughly 2000 : 1.

The spermatozoa deposited in the vagina are already motile, as a result of contact with secretions of the seminal vesicles—the first step of *capacitation*. l**p. 1040** (An unidentified substance secreted by the epididymis appears to prevent premature capacitation.) The spermatozoa, however, cannot accomplish fertilization until they have been exposed to conditions in the female reproductive tract. The mechanism responsible for this second step of capacitation remains unknown.

Fertilization typically occurs near the junction between the ampulla and isthmus of the uterine tube, generally within a day after ovulation. By this time, a secondary oocyte has traveled only a few centimeters, but spermatozoa must cover the distance between the vagina and the ampulla of the uterine tube. A spermatozoon can propel itself at speeds of only about 34 mm per second, roughly equivalent to 12.5 cm (5 in.) per hour, so in theory it should take spermatozoa several hours to reach the upper portions of the uterine tubes. The actual passage time, however, ranges from two hours to as little as 30 minutes. Contractions of the uterine musculature and ciliary currents in the uterine tubes have been suggested as likely mechanisms for accelerating the movement of spermatozoa from the vagina to the site of fertilization.

Even with transport assistance and available nutrients, the passage is not easy. Of the roughly 200 million spermatozoa introduced into the vagina in a typical ejaculation, only about 10,000 enter the uterine tube, and fewer than 100 reach the isthmus. In general, a male with a sperm count below 20 million per milliliter is functionally sterile because too few spermatozoa survive to reach and fertilize an oocyte. While it is true that only one spermatozoon fertilizes an oocyte, dozens of spermatozoa are required for successful fertilization. The additional sperm are essential because one sperm does not contain enough acrosomal enzymes to disrupt the *corona radiata*, the layer of follicle cells that surrounds the oocyte.

The Oocyte at Ovulation

Ovulation occurs before the oocyte is completely mature. The secondary oocyte leaving the follicle is in metaphase of meiosis II. The cell’s metabolic operations have been discontinued, and the oocyte drifts in a sort of suspended animation, awaiting the stimulus for further development. If fertilization does not occur, the oocyte disintegrates without completing meiosis.

Fertilization is complicated by the fact that when the secondary oocyte leaves the ovary, it is surrounded by the corona radiata. Fertilization and the events that follow are diagrammed in Figure 29–1b•. The cells of the corona radiata protect the secondary oocyte as it passes through the ruptured follicular wall, across the surface of the ovary, and into the infundibulum of the uterine tube. Although the physical process of fertilization requires that only a single spermatozoon contact the oocyte membrane, that spermatozoon must first penetrate the corona radiata. The acrosomal cap of each sperm contains several enzymes, including **hyaluronidase** (h -a-loo-RON-i-da¯s), which breaks down the bonds between adjacent follicle cells. Dozens of spermatozoa must

–

ı release hyaluronidase before the connections between the follicle cells break down enough to allow an intact spermatozoon to reach the oocyte.

No matter how many spermatozoa slip through the gap in the corona radiata, normally only a single spermatozoon accomplishes fertilization and activates the oocyte (STEP 1). That spermatozoon must have an intact acrosomal cap. The first step is the binding of the spermatozoon to *sperm receptors* in the zona pellucida. This step triggers the rupture of the acrosomal cap. The hyaluronidase and **acrosin**, another proteolytic enzyme, then digest a path through the zona pellucida toward the surface of the oocyte. When the sperm contacts that surface, the sperm and oocyte membranes begin to fuse. This step is the trigger for *oocyte activation*, a complex process we will discuss in the next section.

Oocyte Activation

Oocyte activation involves a series of changes in the metabolic activity of the oocyte. The trigger for activation is contact and fusion of the cell membranes of the sperm and oocyte. This process is accompanied by the depolarization of the oocyte membrane due to an increased permeability to sodium ions. The entry of sodium ions in turn causes the release of calcium ions from the smooth endoplasmic reticulum. The sudden rise in Ca^{2+} levels has important effects, including the following:

- **Exocytosis of Vesicles Located Just Interior to the Oocyte Membrane.** This process, called the *cortical reaction*, releases enzymes that both inactivate the sperm receptors and harden the zona pellucida. This combination prevents **polyspermy** (fertilization by more than one sperm), which would create a zygote that is incapable of normal development. (Prior to the completion of the cortical reaction, the depolarization of the oocyte membrane probably prevents fertilization by any sperm cells that penetrate the zona pellucida.)
- **Completion of Meiosis II and Formation of the Second Polar Body.**

- **Activation of Enzymes That Cause a Rapid Increase in the Cell’s Metabolic Rate.** The cytoplasm contains large numbers of mRNA strands that have been inactivated by special proteins. The mRNA strands are now activated, so protein synthesis accelerates rapidly. Most of the proteins synthesized are required for development to proceed.

After oocyte activation and the completion of meiosis, the nuclear material remaining within the ovum reorganizes as the **female pronucleus** (see STEP 2, Figure 29–1b•). While these changes are under way, the nucleus of the spermatozoon swells, and as it forms the **male pronucleus** the rest of the sperm breaks down (STEP 3). The male pronucleus then migrates toward the center of the cell, and spindle fibers form. The two pronuclei then fuse in a process called *amphimixis* (am-fi-MIK-sis; see STEP 4). The cell is now a zygote that contains the normal complement of 46 chromosomes, and fertilization is complete. This is the “moment of conception.” Almost immediately the chromosomes line up along a metaphase plate, and the cell prepares to divide. This is the start of the process of *cleavage*, a series of cell divisions that produce an ever-increasing number of smaller and smaller daughter cells. The first cleavage division is completed roughly 30 hours after fertilization, yielding two daughter cells, each one-half the size of the original zygote (STEP 5). These cells are called *blastomeres* (BLAS-tō-mērs).

The Stages of Prenatal Development

Objective

- List the three prenatal periods and describe the major events associated with each.

During prenatal development, a single cell ultimately forms a 3–4 kg (4.4–8.8 lb) infant, who in postnatal development will grow through adolescence and maturity toward old age and eventual death. One of the most fascinating aspects of development is its apparent order. Continuity exists at all levels and at all times. Nothing “leaps” into existence without apparent precursors; differentiation and increasing structural complexity occur hand in hand.

Differentiation involves changes in the genetic activity of some cells but not others. A continuous exchange of information occurs between the nucleus and the cytoplasm in a cell. Activity in the nucleus varies in response to chemical messages that arrive from the surrounding cytoplasm. In turn, ongoing nuclear activity alters conditions within the cytoplasm by directing the synthesis of specific proteins. In this way, the nucleus can affect enzyme activity, cell structure, and membrane properties.

In development, differences in the cytoplasmic composition of individual cells trigger changes in genetic activity. These changes in turn lead to further alterations in the cytoplasm, and the process continues in a sequential fashion. But if all the cells of the embryo are derived from cell divisions of a zygote, how do the cytoplasmic differences originate? What sets the process in motion? The important first step occurs before fertilization, while the oocyte is in the ovary.

Before ovulation, the growing oocyte accepts amino acids, nucleotides, and glucose, as well as more complex materials such as phospholipids, mRNA molecules, and proteins, from the surrounding granulosa cells. Because not all follicle cells manufacture and deliver the same nutrients and instructions to the oocyte, the contents of the cytoplasm are not evenly distributed. After fertilization, the zygote divides into ever-smaller cells that differ from one another in cytoplasmic composition. These differences alter the genetic activity of each cell, creating cell lines with increasingly diverse fates.

As development proceeds, some of the cells release chemical substances, including RNA molecules, polypeptides, and small proteins, that affect the differentiation of other embryonic cells. This type of chemical interplay among developing cells, called *induction* (in-DUK-shun), works over very short distances, such as when two types of cells are in direct contact. It may also operate over longer distances, with the inducing chemicals functioning as hormones.

This type of regulation, which involves an integrated series of interacting steps, can control highly complex processes. The mechanism is not always error-free, however: The appearance of an abnormal or inappropriate inducer can throw development off course. AM: Teratogens and Abnormal Development

The time spent in prenatal development is known as **gestation** (jes-T

¯A

-shun). For convenience, we usually think of the ges

tation period as consisting of three integrated **trimesters**, each three months in duration:

1. The **first trimester** is the period of embryological and early fetal development. During this period, the rudiments of all the major organ systems appear.

2. The **second trimester** is dominated by the development of organs and organ systems, a process that nears completion by the end of the sixth month. During this period, body shape and proportions change; by the end of this trimester, the fetus looks distinctively human.

3. The **third trimester** is characterized by rapid fetal growth and deposition of adipose tissue. Early in the third trimester, most of the fetus's major organ systems become fully functional. An infant born one month or even two months prematurely has a reasonable chance of survival.

The *Atlas* accompanying this text contains "Embryology Summaries" that introduce key steps in embryological and fetal development and trace the development of specific organ systems. The text will refer to those summaries in the discussions that follow. As you proceed, reviewing the material indicated will help you understand the "big picture" as well as the specific details. AM: Technology and the Treatment of Infertility

The First Trimester

Objectives

- Explain how the three germ layers participate in the formation of extraembryonic membranes.
- Discuss the importance of the placenta as an endocrine organ.

At the moment of conception, the fertilized ovum is a single cell about 0.135 mm (0.005 in.) in diameter and weighing approximately 150 mg. By the end of the first trimester (the 12th developmental week), the fetus is almost 75 mm (3 in.) long and weighs perhaps 14 g (0.5 oz).

Many important and complex developmental events occur during the first trimester. Here we will focus on four general processes: cleavage, implantation, placentation, and embryogenesis:

1. Cleavage (KLE¯V-ij) is a sequence of cell divisions that begins immediately after fertilization (see Figure 29–1b•). During cleavage, the zygote becomes a **pre-embryo**, which develops into a multicellular complex known as a *blastocyst*. Cleavage ends when the blastocyst first contacts the uterine wall. Cleavage and blastocyst formation are introduced in the *Atlas*. ATLAS: Embryology Summary 1: The Formation of Tissues

2. Implantation begins with the attachment of the blastocyst to the endometrium of the uterus and continues as the blastocyst invades maternal tissues. Important events during implantation set the stage for the formation of vital embryonic structures.

3. Placentation (plas-en-T

¯A

-shun) occurs as blood vessels form around the periphery of the blastocyst, and the placenta devel

ops. The **placenta** is a complex organ that permits exchange between the maternal and embryonic circulatory systems. It supports the fetus in the second and third trimesters, but it stops functioning and is ejected from the uterus just after birth. From that point on, the newborn is physically independent of the mother.

4. Embryogenesis (em-brē-ō-JEN-e-sis) is the formation of a viable embryo. This process establishes the foundations for all major organ systems.

The foregoing processes are both complex and vital to the survival of the embryo. Perhaps because the events in the first trimester are so complex, it is the most dangerous period in prenatal life. Only about 40 percent of conceptions produce embryos that survive the first trimester. For that reason, pregnant women are warned to take great care to avoid drugs and other disruptive stresses during the first trimester, in the hope of preventing an error in the delicate processes that are under way.

Cleavage and Blastocyst Formation

Cleavage is a series of cell divisions that subdivides the cytoplasm of the zygote (Figures 29–1b and 29–2•). The first cleavage produces a pre-embryo consisting of two identical cells. As noted earlier, the identical cells produced by cleavage divisions are called **blastomeres**. After the first division is completed roughly 30 hours after fertilization, subsequent divisions occur at intervals of 10–12 hours. During the initial divisions, all the blastomeres divide simultaneously. As the number of blastomeres increases, the timing becomes less predictable.

After three days of cleavage, the pre-embryo is a solid ball of cells resembling a mulberry. This stage is called the **morula** (MOR-ū-la; *morula*, mulberry). The morula typically reaches the uterus on day 4. Over the next two days, the blastomeres form a **blastocyst**, a hollow ball with an inner cavity known as the **blastocoele** (BLAS-t

¯o
-s
¯e
l). The blastomeres are now no longer identical
in size and shape. The outer layer of cells, which separates the outside world from the blastocoele, is called the **trophoblast** (TR
¯O

-f
¯o
-blast). As the word *trophoblast* implies, cells in this layer are responsible for providing nutrients to the developing embryo
(*trophos*, food + *blast*, precursor). A second group of cells, the **inner cell mass**, lies clustered at one end of the blastocyst. These cells are exposed to the blastocoele but are insulated from contact with the outside environment by the trophoblast. In time, the inner cell mass will form the embryo.

Implantation

During blastocyst formation, enzymes released by the trophoblast erode a hole through the zona pellucida, which is then shed in a process known as *hatching* (see Figure 29–2•). The blastocyst is now freely exposed to the fluid contents of the uterine cavity. This glycogen-rich fluid is secreted by the endometrial glands of the uterus. Over the previous few days, the pre-embryo and early blastocyst had been absorbing fluid and nutrients from its surroundings; the process now accelerates, and the blastocyst enlarges. When fully formed, the blastocyst contacts the endometrium, and implantation occurs (Figures 29–2 and 29–3•).

Implantation begins as the surface of the blastocyst closest to the inner cell mass touches and adheres to the uterine lining (see day 7 in Figure 29–3•) At the point of contact, the trophoblast cells divide rapidly, making the trophoblast several layers thick. The cells closest to the interior of the blastocyst remain intact, forming a layer of **cellular trophoblast**, or *cytotrophoblast*. Near the endometrial wall, the cell membranes separating the trophoblast cells disappear, creating a layer of cytoplasm containing multiple nuclei (day 8). This outer layer is called the **syncytial** (sin-SISH-al) **trophoblast**, or *syncytiotrophoblast*.

The syncytial trophoblast erodes a path through the uterine epithelium by secreting hyaluronidase. This enzyme dissolves the intercellular cement between adjacent epithelial cells, just as hyaluronidase released by spermatozoa dissolved the connections between cells of the corona radiata. At first, the erosion creates a gap in the uterine lining, but migration and divisions of maternal epithelial cells soon repair the surface. But by day 10 the repairs are complete, and the blastocyst has lost contact with the uterine cavity. Further development occurs entirely within the functional zone of the endometrium.

In most cases, implantation occurs in the fundus or elsewhere in the body of the uterus. In an **ectopic pregnancy**, implantation occurs somewhere other than within the uterus, such as in one of the uterine tubes. Approximately 0.6 percent of pregnancies are ectopic pregnancies, which do not produce a viable embryo and can be life-threatening. AM: Ectopic Pregnancies

As implantation proceeds, the syncytial trophoblast continues to enlarge and spread into the surrounding endometrium (see day 9, Figure 29–3•). The erosion of uterine glands releases nutrients that are absorbed by the syncytial trophoblast and distributed by diffusion through the underlying cellular trophoblast to the inner cell mass. These nutrients provide the energy needed to support the early stages of embryo formation. Trophoblastic extensions grow around endometrial capillaries. As the capillary walls are destroyed, maternal blood begins to percolate through trophoblastic channels known as **lacunae**. Fingerlike **villi** extend away from the trophoblast into the surrounding endometrium, gradually increasing in size and complexity until about day 21. As the syncytial trophoblast spreads, it begins breaking down larger endometrial veins and arteries, and blood flow through the lacunae accelerates.

Clinical Note

The trophoblast undergoes repeated nuclear divisions, shows extensive and rapid growth, has a very high demand for energy, invades and spreads through adjacent tissues, and fails to activate the maternal immune system—in short, the trophoblast has many of the characteristics of cancer cells. In about 0.1 percent of pregnancies, something goes wrong with the regulatory mechanisms, and instead of developing normally, the syncytial trophoblast behaves like a tumor. This condition is called *gestational trophoblastic neoplasia*. The least dangerous form, a *hydatidiform* (h ı -da-TID-i-form) *mole*, is not malignant. However, about 20 percent of gestational trophoblastic neoplasias metastasize to other tissues, with potentially fatal results. Consequently, prompt surgical removal of the mass is essential, and the surgery is sometimes followed by chemotherapy.

Formation of the Amniotic Cavity

The inner cell mass has little apparent organization early in the blastocyst stage. Yet by the time of implantation, the inner cell mass has separated from the trophoblast. The separation gradually increases, creating a fluid-filled chamber called the **amniotic** (am-n -OT-ik) **cavity** (see day 9 in Figure 29–3•; details from days 10–12 are shown in Figure 29–4•). The trophoblast will later be separated from the amniotic cavity by layers of cells that originate at the inner cell mass and line the amniotic cavity. These layers form the *amnion*, a membrane we will examine later in the chapter. When the amniotic cavity first appears, the cells of the inner cell mass are organized into an oval sheet that is two layers thick: a superficial layer that faces the amniotic cavity, and a deeper layer that is exposed to the fluid contents of the blastocoele.

Gastrulation and Germ Layer Formation

By day 12, a third layer begins to form through **gastrulation** (gas-troo-LA¯-shun) (day 12, Figure 29–4•). During gastrulation, cells in specific areas of the surface move toward a central line known as the **primitive streak**. At the primitive streak, the migrating cells leave the surface and move between the two existing layers. This movement creates three distinct embryonic layers:

(1) the **ectoderm**, consisting of superficial cells that did not migrate into the interior of the inner cell mass; (2) the **endoderm**, consisting of the cells that face the blastocoele; and (3) the **mesoderm**, consisting of the poorly organized layer of migrating cells between the ectoderm and the endoderm. Collectively, these three embryonic layers are called **germ layers**. The formation of mesoderm and the fates of each germ layer are summarized in the *Atlas*. ATLAS: Embryology Summary 4: The Development of Organ Systems

Table 29–1 contains a more comprehensive listing of the contributions each germ layer makes to the body systems described in earlier chapters.

¯e

Gastrulation produces an oval, three-layered sheet known as the **embryonic disc**. This disc will form the body of the embryo, whereas the rest of the blastocyst will be involved in forming the *extraembryonic membranes*.

The Formation of the Extraembryonic Membranes

Germ layers also participate in the formation of four **extraembryonic membranes**: (1) the *yolk sac* (endoderm and mesoderm),

(2) the *amnion* (ectoderm and mesoderm), (3) the *allantois* (endoderm and mesoderm), and (4) the *chorion* (mesoderm and trophoblast). Although these membranes support embryological and fetal development, few traces of their existence remain in adult systems. Figure 29–5• shows representative stages in the development of the extraembryonic membranes.

The Yolk Sac The **yolk sac** begins as a layer of cells spread out around the outer edges of the blastocoele to form a complete pouch. This pouch is already visible 10 days after fertilization (see Figure 29–4•). As gastrulation proceeds, mesodermal cells migrate around the pouch and complete the formation of the yolk sac (Week 2, Figure 29–5•). Blood vessels soon appear within the mesoderm, and the yolk sac becomes an important site of blood cell formation.

The Amnion The ectodermal layer enlarges, and ectodermal cells spread over the inner surface of the amniotic cavity. Mesodermal cells soon follow, creating a second, outer layer (see Week 2, Figure 29–5•). This combination of mesoderm and ectoderm is
¯e
the **amnion** (AM-n -on). As development proceeds, the amnion and the amniotic cavity continue to enlarge. The amniotic cavity contains **amniotic fluid**, which surrounds and cushions the developing embryo or fetus (Week 3 through Week 10, Figure 29–5•).

The Allantois The third extraembryonic membrane begins as an outpocketing of the endoderm near the base of the yolk sac (see Week 3, Figure 29–5•). The free endodermal tip then grows toward the wall of the blastocyst, surrounded by a mass of mesodermal cells. This sac of endoderm and mesoderm is the **allantois** (a-LAN-t
¯o
-is), the base of which later gives rise to the urinary bladder. The formation of the allantois and its relationship to the urinary bladder is illustrated in the *Atlas*. ATLAS: Embryology Summary 20: The Development of the Urinary System

The Chorion The mesoderm associated with the allantois spreads around the blastocyst, separating the cellular trophoblast from the blastocoele. This combination of mesoderm and trophoblast is the **chorion** (K
¯O

-r
¯e
-on) (see Weeks 2 and 3, Figure 29–5•).

When implantation first occurs, the nutrients absorbed by the trophoblast can easily reach the inner cell mass by simple diffusion. But as the embryo and the trophoblast enlarge, the distance between them increases, so diffusion alone can no longer keep pace with the demands of the developing embryo. Blood vessels now begin to develop within the mesoderm of the chorion, creating a rapid-transit system for nutrients that links the embryo with the trophoblast.

The appearance of blood vessels in the chorion is the first step in the creation of a functional placenta. By the third week of development, the mesoderm extends along the core of each trophoblastic villus, forming **chorionic villi** in contact with maternal tissues (see Figures 29–5 [Weeks 3 through 10] and 29–6•). These villi continue to enlarge and branch, creating an intricate network within the endometrium. Embryonic blood vessels develop within each villus. Blood flow through those chorionic vessels begins early in the third week of development, when the embryonic heart starts beating. The blood supply to the chorionic villi arises from the allantoic arteries and veins.

As the chorionic villi enlarge, more maternal blood vessels are eroded. Maternal blood now moves slowly through complex lacunae lined by the syncytial trophoblast. Chorionic blood vessels pass close by, and gases and nutrients diffuse between the embryonic and maternal circulations across the layers of the trophoblast. Recall that fetal hemoglobin has a higher affinity for oxy

gen than does maternal hemoglobin, enabling fetal hemoglobin to strip oxygen from maternal hemoglobin. l**p. 845** Maternal blood then reenters the venous system of the mother through the broken walls of small uterine veins. No mixing of maternal and fetal blood occurs, because the two are always separated by layers of trophoblast.

Placentation

At first, the entire blastocyst is surrounded by chorionic villi. The chorion continues to enlarge, expanding like a balloon within the endometrium. By week 4, the embryo, amnion, and yolk sac are suspended within an expansive, fluid-filled chamber (see Figure 29–5•). The **body stalk**, the connection between embryo and chorion, contains the distal portions of the allantois and blood vessels that carry blood to and from the placenta. The narrow connection between the endoderm of the embryo and the yolk sac is called the **yolk stalk**.

The formation of the yolk stalk and body stalk are illustrated in the *Atlas*. ATLAS: Embryology Summary

19: The Development of the Digestive System

The placenta does not continue to enlarge indefinitely. Regional differences in placental organization begin to develop as expansion of the placenta creates a prominent bulge in the endometrial surface. This relatively thin portion of the endometrium,

called the **decidua capsularis** (d

¯e

-SID-

¯u

-a kap-s

¯u

-LA-ris; *deciduus*, a falling off), no longer participates in nutrient exchange,

and the chorionic villi in the region disappear (see Figures 29–5 [Week 5] and 29–6a•). Placental functions are now concentrated in a disc-shaped area in the deepest portion of the endometrium, a region called the **decidua basalis** (ba-SA-lis). The rest of the uterine endometrium, which has no contact with the chorion, is called the **decidua parietalis**.

As the end of the first trimester approaches, the fetus moves farther from the placenta (see Weeks 5 and 10, Figure 29–5•). The fetus and placenta remain connected by the **umbilical cord**, or *umbilical stalk*, which contains the allantois, the placental blood vessels, and the yolk stalk.

Placental Circulation

Figure 29–6a• illustrates circulation at the placenta near the end of the first trimester. Blood flows to the placenta through the paired **umbilical arteries** and returns in a single **umbilical vein**. l**p. 753** The chorionic villi provide the surface area for active and passive exchanges of gases, nutrients, and waste products between the fetal and maternal bloodstreams. The blood in the umbilical arteries is deoxygenated and contains waste products generated by tissues; at the placenta, oxygen supplies are replenished, organic nutrients added, and carbon dioxide and other organic waste products removed.

The placenta places a considerable demand on the maternal cardiovascular system, and blood flow to the uterus and placenta is extensive. If the placenta is torn or otherwise damaged, the consequences may prove fatal to both fetus and mother. AM: Problems with Placentation

The Endocrine Placenta

In addition to its role in the nutrition of the fetus, the placenta acts as an endocrine organ. Several hormones—including *human chorionic gonadotropin*, *human placental lactogen*, *placental prolactin*, *relaxin*, *progesterone*, and *estrogens*— are synthesized by the syncytial trophoblast and released into the maternal bloodstream.

Human Chorionic Gonadotropin The hormone **human chorionic gonadotropin (hCG)** appears in the maternal bloodstream soon after implantation has occurred. The presence of hCG in blood or urine samples provides a reliable indication of pregnancy. Kits sold for the early detection of pregnancy are sensitive to the presence of this hormone.

In function, hCG resembles luteinizing hormone (LH), because it maintains the integrity of the corpus luteum and promotes the continued secretion of progesterone. As a result, the endometrial lining remains perfectly functional, and menses does not normally occur. In the absence of hCG, the pregnancy ends, because another uterine cycle begins and the functional zone of the endometrium disintegrates.

In the presence of hCG, the corpus luteum persists for three to four months before gradually decreasing in size and secretory function. The decline in luteal function does not trigger the return of uterine cycles, because by the end of the first trimester, the placenta actively secretes both estrogens and progesterone.

Human Placental Lactogen and Placental Prolactin **Human placental lactogen (hPL)**, or *human chorionic somatomammotropin (hCS)*, helps prepare the mammary glands for milk production. It also has a stimulatory effect on other tissues comparable to that of growth hormone (GH). At the mammary glands, the conversion from inactive to active status requires the presence of placental hormones (hPL, **placental prolactin**, estrogen, and progesterone) as well as several maternal hormones (GH, prolactin [PRL], and thyroid hormones). We will consider the hormonal control of the mammary gland function in a later section.

Relaxin **Relaxin** is a peptide hormone that is secreted by the placenta and the corpus luteum during pregnancy. Relaxin (1) increases the flexibility of the pubic symphysis, permitting the pelvis to expand during delivery; (2) causes the dilation of the cervix, making it easier for the fetus to enter the vaginal canal; and (3) suppresses the release of oxytocin by the hypothalamus and delays the onset of labor contractions.

Progesterone and Estrogens After the first trimester, the placenta produces sufficient amounts of progesterone to maintain the endometrial lining and continue the pregnancy. As the end of the third trimester approaches, estrogen production by the placenta accelerates. As we will see in a later section, the rising estrogen levels play a role in stimulating labor and delivery.

Embryogenesis

Shortly after gastrulation begins, the body of the embryo begins to separate itself from the rest of the embryonic disc. The body of the embryo and its internal organs now start to form. This process, called **embryogenesis**, begins as folding and differential growth of the embryonic disc produce a bulge that projects into the amniotic cavity (see Figure 29–5•). This projection is known as the **head fold**; similar movements lead to the formation of a **tail fold** (see Figure 29–5•).

The embryo is now physically as well as developmentally distinct from the embryonic disc and the extraembryonic membranes. The definitive orientation of the embryo can now be seen, complete with dorsal and ventral surfaces and left and right sides. Table 29–2 provides an overview of the subsequent development of the major organs and body systems. The changes in proportions and appearance that occur between the second developmental week and the end of the first trimester are summarized in Figure 29–7•.

The first trimester is a critical period for development, because events in the first 12 weeks establish the basis for **organogenesis**, the process of organ formation. The major features of organogenesis in each organ system are described in Embryology Summaries 6–21 in the *Atlas*. Important developmental milestones are indicated in Table 29–2.

Concept Check

What is the developmental fate of the inner cell mass of the blastocyst?

Improper development of which of the extraembryonic membranes would affect the cardiovascular system?

Sue's pregnancy test indicates the presence of elevated levels of the hormone hCG (human chorionic gonadotropin). Is she

pregnant?

What are two important functions of the placenta?

Answers begin on p. A–1

The Second and Third Trimesters

Objectives

- Describe the interplay between the maternal organ systems and the developing fetus.
- Discuss the structural and functional changes in the uterus during gestation.

By the end of the first trimester (see Figure 29–7d•), the rudiments of all the major organ systems have formed. Over the next three months, the fetus will grow to a weight of about 0.64 kg (1.4 lb). Encircled by the amnion, the fetus grows faster than the surrounding placenta during this second trimester. When the mesoderm on the outer surface of the amnion contacts the mesoderm on the inner surface of the chorion, these layers fuse, creating a compound *amniochorionic membrane*. Figure 29–8a• shows a four-month-old fetus; Figure 29–8b• shows a six-month-old fetus.

During the third trimester, most of the organ systems become ready to perform their normal functions without maternal assistance. The rate of growth starts to slow, but in absolute terms this trimester sees the largest weight gain. In the last three months of gestation, the fetus gains about 2.6 kg (5.7 lb), reaching a full-term weight of approximately 3.2 kg (7 lb). The Embryology Summaries in the *Atlas* illustrate organ system development in the second and third trimesters, and highlights are noted in Table 29–2.

At the end of gestation, a typical uterus will have undergone a tremendous increase in size. Figure 29–9a–c• shows the positions of the uterus, fetus, and placenta from 16 weeks to *full term* (nine months). When the pregnancy is at full term, the uterus and fetus push many of the maternal abdominal organs out of their normal positions (Figure 29–9c,d•).

100 Keys | The basic body plan, the foundations of all of the organ systems, and the four extraembryonic membranes appear during the first trimester. These are complex and delicate processes; not every zygote starts cleavage, and fewer than half of the zygotes that do begin cleavage survive until the end of the first trimester. The second trimester is a period of rapid growth, accompanied by the development of fetal organs that will then become fully functional by the end of the third trimester.

Pregnancy and Maternal Systems

The developing fetus is totally dependent on maternal organ systems for nourishment, respiration, and waste removal. These functions must be performed by maternal systems in addition to their normal operations. For example, the mother must absorb enough oxygen, nutrients, and vitamins for herself *and* for her fetus, and she must eliminate all the wastes that are generated. Although this is not a burden over the initial weeks of gestation, the demands placed on the mother become significant as the fetus grows. For the mother to survive under these conditions, maternal systems must compensate for changes introduced by the fetus. In practical terms, the mother must breathe, eat, and excrete for two. The major changes that occur in maternal systems include the following:

- **Maternal Respiratory Rate Goes Up and Tidal Volume Increases.** As a result, the mother’s lungs deliver the extra oxygen required, and remove the excess carbon dioxide generated, by the fetus.
- **Maternal Blood Volume Increases.** This increase occurs because blood flowing into the placenta reduces the volume in the rest of the systemic circuit, and because fetal metabolic activity both lowers blood PO_2 and elevates PCO_2. The latter combination stimulates the production of renin and erythropoietin, leading to an increase in maternal blood volume through mechanisms detailed in Chapter 21 (see Figure 21–17•, p. 734). By the end of gestation, maternal blood volume has increased by almost 50 percent.
- **Maternal Requirements for Nutrients and Vitamins Climb 10–30 Percent.** Pregnant women must nourish both themselves and their fetus and so tend to have increased hunger sensations.
- **Maternal Glomerular Filtration Rate Increases by Roughly 50 Percent.** This increase, which corresponds to the increase in blood volume, accelerates the excretion of metabolic wastes generated by the fetus. Because the volume of urine produced increases and the weight of the uterus presses down on the urinary bladder, pregnant women need to urinate frequently.
- **The Uterus Undergoes a Tremendous Increase in Size.** Structural and functional changes in the expanding uterus are so important that we will discuss them in a separate section.
- **The Mammary Glands Increase in Size, and Secretory Activity Begins.** Mammary gland development requires a combination of hormones, including human placental lactogen and placental prolactin from the placenta, and PRL, estrogens, progesterone, GH, and thyroxine from maternal endocrine organs. By the end of the sixth month of pregnancy, the mammary glands are fully developed and begin to produce clear secretions that are stored in the duct system of those glands and may be expressed from the nipple.

Clinical Note

Abortion is the termination of a pregnancy. Most references distinguish among spontaneous, therapeutic, and induced abortions.

Spontaneous abortions, or *miscarriages*, result from developmental problems (such as chromosomal defects in the embryo) or from

hormonal problems, including inadequate LH production by the maternal pituitary gland, reduced LH sensitivity at the corpus luteum,

inadequate progesterone sensitivity in the endometrium, or placental failure to produce adequate levels of hCG. Spontaneous abor

tions occur in at least 15 percent of recognized pregnancies. **Therapeutic abortions** are performed when continuing the pregnancy

poses a threat to the life of the mother. AM: Problems with the Maintenance of a Pregnancy

Induced abortions, or *elective abortions*, are performed at the woman's request. Induced abortions remain the focus of considerable controversy. Most induced abortions involve unmarried or adolescent women. The ratio of abortions to deliveries for married women is 1 : 10, whereas it is nearly 2 : 1 for unmarried women and adolescents. In most states, induced abortions are legal during the first three months after conception; under certain conditions, induced abortions may be permitted until the fifth or sixth month.

Structural and Functional Changes in the Uterus

At the end of gestation, a typical uterus has grown from 7.5 cm (3 in.) in length and 30–40 g (1–1.4 oz) in weight to 30 cm (12 in.) in length and 1100 g (2.4 lb) in weight. Because the uterus may then contain almost 5 liters of fluid, the organ plus its contents has a total weight of roughly 10 kg (22 lb). This remarkable expansion occurs through the enlargement (hypertrophy) of existing cells, especially smooth muscle fibers, rather than by an increase in the total number of cells.

The tremendous stretching of the uterus is associated with a gradual increase in the rate of spontaneous smooth muscle contractions in the myometrium. In the early stages of pregnancy, the contractions are weak, painless, and brief. Evidence indicates that progesterone released by the placenta has an inhibitory effect on uterine smooth muscle, preventing more extensive and more powerful contractions.

Three major factors oppose the calming action of progesterone:

1. *Rising Estrogen Levels.* Estrogens produced by the placenta increase the sensitivity of the uterine smooth muscles and make contractions more likely. Throughout pregnancy, progesterone exerts the dominant effect, but as delivery approaches, the production of estrogens accelerates and the myometrium becomes more sensitive to stimulation. Estrogens also increase the sensitivity of smooth muscle fibers to oxytocin.

2. *Rising Oxytocin Levels.* Rising oxytocin levels lead to an increase in the force and frequency of uterine contractions. Oxytocin release is stimulated by high estrogen levels and by distortion of the cervix. Uterine distortion, especially in the region of the cervix, occurs as the weight of the fetus increases.

3. *Prostaglandin Production.* Estrogens and oxytocin stimulate the production of prostaglandins in the endometrium. These prostaglandins further stimulate smooth muscle contractions.

Late in pregnancy, some women experience occasional spasms in the uterine musculature, but these contractions are neither regular nor persistent. Such contractions are called **false labor**. **True labor** begins when biochemical and mechanical factors reach a point of no return. After nine months of gestation, multiple factors interact to initiate true labor. Once **labor contractions** have begun in the myometrium, positive feedback ensures that they will continue until delivery has been completed.

Figure 29–10• diagrams important factors that stimulate and sustain labor. When labor commences, the fetal pituitary gland secretes oxytocin, which is then released into the maternal bloodstream at the placenta. This may be the actual trigger for the onset of true labor, as it increases myometrial contractions and prostaglandin production, on top of the priming effects of estrogens and maternal oxytocin.

Labor and Delivery

Objective

- List and discuss the events that occur during labor and delivery.

The goal of labor is **parturition** (par-tūr-ISH-un), the forcible expulsion of the fetus. During true labor, each contraction begins near the top of the uterus and sweeps in a wave toward the cervix. The contractions are strong and occur at regular intervals. As parturition approaches, the contractions increase in force and frequency, changing the position of the fetus and moving it toward the cervical canal.

Stages of Labor

Labor has traditionally been divided into three stages: the *dilation stage*, the *expulsion stage*, and the *placental stage* (Figure 29–11•).

The Dilation Stage

The **dilation stage** begins with the onset of true labor, as the cervix dilates and the fetus begins to shift toward the cervical canal (STAGE 1 in Figure 29–11•), moved by gravity and uterine contractions. This stage is highly variable in length but typically lasts eight or more hours. At the start of the dilation stage, labor contractions last up to half a minute and occur once every 10–30 minutes; their frequency increases steadily. Late in this stage, the amniochorionic membrane ruptures, an event sometimes referred to as “having one’s water break.” If this event occurs before other events of the dilation stage, the life of the fetus may be at risk from infection; if the risk is sufficiently great, labor can be induced.

The Expulsion Stage

The **expulsion stage** begins as the cervix, pushed open by the approaching fetus, completes its dilation (STAGE 2 in Figure 29–11•). In this stage, contractions reach maximum intensity, occurring at perhaps two- or three-minute intervals and lasting a full minute. Expulsion continues until the fetus has emerged from the vagina; in most cases, the expulsion stage lasts less than two hours. The arrival of the newborn infant into the outside world is **delivery**, or birth.

If the vaginal canal is too small to permit the passage of the fetus, posing acute danger of perineal tearing, a physician may temporarily enlarge the passageway by performing an **episiotomy** (e-p
¯e
z-
¯e
-OT-o-m
¯e
), an incision through the perineal musculature. After delivery, this surgical cut is repaired with sutures, a much simpler procedure than suturing the jagged edges associated with an extensive perineal tear. If complications arise during the dilation or expulsion stage, the infant can be removed by **cesarean section**, or “*C-section*.” In such cases, an incision is made through the abdominal wall, and the uterus is opened just enough to allow passage of the infant’s head. This procedure is performed during 15–25 percent of the deliveries in the United States—more often than necessary, according to some studies. Over the last decade, efforts have been made to reduce the frequency of both episiotomies and cesarean sections.

The Placental Stage

During the **placental stage** of labor, muscle tension builds in the walls of the partially empty uterus, which gradually decreases in size (STAGE 3 in Figure 29–11•). This uterine contraction tears the connections between the endometrium and the placenta. In general, within an hour of delivery, the placental stage ends with the ejection of the placenta, or *afterbirth*. The disruption of the placenta is accompanied by a loss of blood. Because maternal blood volume has increased greatly during pregnancy, this loss can be tolerated without difficulty.

Premature Labor

Premature labor occurs when true labor begins before the fetus has completed normal development. The newborn’s chances of surviving are directly related to its body weight at delivery. Even with massive supportive efforts, newborns weighing less than 400 g (14 oz) at birth will not survive, primarily because their respiratory, cardiovascular, and urinary systems are unable to support life without aid from maternal systems. As a result, the dividing line between spontaneous abortion and **immature delivery** is usually set at 500 g (17.6 oz), the normal weight near the end of the second trimester.

Most fetuses born at 25–27 weeks of gestation (a birth weight under 600 g) die despite intensive neonatal care; moreover, survivors have a high risk of developmental abnormalities. **Premature delivery** usually refers to birth at 28–36 weeks (a birth weight over 1 kg). With care, these newborns have a good chance of surviving and developing normally. AM: Complexity and Perfection

Difficult Deliveries

By the end of gestation in most pregnancies, the fetus has rotated within the uterus to transit the birth canal headfirst, facing the mother’s sacrum. In about 6 percent of deliveries, the fetus faces the mother’s pubis instead. These babies can be delivered normally, given enough time, but risks to infant and mother are reduced by a *forceps delivery*. Forceps resemble large, curved salad tongs that can be separated for insertion into the vaginal canal, one side at a time. Once in place, they are reunited and used to grasp the head of the fetus. An intermittent pull is applied, so that the forces on the head resemble those of normal delivery.

In 3–4 percent of deliveries, the legs or buttocks of the fetus enter the vaginal canal first. Such deliveries are **breech births**. Risks to the fetus are higher in breech births than in normal deliveries, because the umbilical cord can become constricted, cutting off placental blood flow. The head is normally the widest part of the fetus; the mother’s cervix may dilate enough to pass the baby’s legs and body, but not the head. This entrapment compresses the umbilical cord, prolongs delivery, and subjects the fetus to severe distress and potential injury. If attempts to reposition the fetus or promote further dilation are unsuccessful over the short term, delivery by cesarean section may be required.

Multiple Births

Multiple births (twins, triplets, quadruplets, and so forth) can occur for several reasons. The ratio of twin births to single births in the U.S. population is roughly 1 : 89. “Fraternal,” or **dizygotic** (d ¯ı-z ¯ı -GOT-ik), twins develop when two separate oocytes were ovulated and subsequently fertilized. Because chromosomes are shuffled during meiosis, the odds against any two zygotes from the same parents having identical genes exceed 1 in 8.4 million. Seventy percent of twins are dizygotic.

“Identical,” or **monozygotic**, twins result either from the separation of blastomeres early in cleavage or from the splitting of the inner cell mass before gastrulation. In either event, the genetic makeup of the twins is identical because both formed from the same pair of gametes. Triplets, quadruplets, and larger multiples can result from multiple ovulations, blastomere splitting, or some combination of the two. For unknown reasons, the rates of naturally occurring multiple births fall into a pattern: Twins occur in 1 of every 89 births, triplets in 1 of every 89^2 (or 7921) births, quadruplets in 1 of every 89^3 (704,969) births, and so forth. The incidence of multiple births can be increased by exposure to fertility drugs that stimulate the maturation of abnormally large numbers of oocytes. (See the discussion on “Technology and the Treatment of Infertility” in the *Applications Manual*.)

Multiple pregnancies pose special problems because the strains on the mother are multiplied. The chances of premature labor are increased, and the risks to the mother are higher than for single births. Increased risks also extend to the fetuses during gestation, and to the newborns, because even at full term such newborns have lower than average birth weights. They are also more likely to have problems during delivery. For example, in more than half of twin deliveries, one or both fetuses enter the vaginal canal in an abnormal position.

If the splitting of the blastomeres or of the embryonic disc is not complete, **conjoined** (*Siamese*) **twins** may develop. These genetically identical twins typically share some skin, a portion of the liver, and perhaps other internal organs as well. When the fusion is minor, the infants can be surgically separated with some success. Most conjoined twins with more extensive fusions fail to survive delivery.

Postnatal Development

Objective

- Identify the features and functions associated with the various life stages.

Developmental processes do not cease at delivery, because newborns have few of the anatomical, functional, or physiological characteristics of mature adults. In the course of postnatal development, every individual passes through five **life stages**: (1) the *neonatal period*, (2) *infancy*, (3) *childhood*, (4) *adolescence*, and (5) *maturity*. Each stage is typified by a distinctive combination of characteristics and abilities. These stages are familiar parts of human experience. Although each stage has distinctive features, the transitions between them are gradual, and the boundaries indistinct. At maturity, development ends and the process of aging, or *senescence*, begins.

The Neonatal Period, Infancy, and Childhood

The **neonatal period** extends from birth to one month thereafter. **Infancy** then continues to two years of age, and **childhood** lasts until **adolescence**, the period of sexual and physical maturation. Two major events are under way during these developmental stages:

1. The organ systems (except those associated with reproduction) become fully operational and gradually acquire the functional characteristics of adult structures.

2. The individual grows rapidly, and body proportions change significantly.

Pediatrics is the medical specialty that focuses on postnatal development from infancy through adolescence. Infants and young children cannot clearly describe the problems they are experiencing, so pediatricians and parents must be skilled observers. Standardized tests are used to assess developmental progress relative to average values. AM: Monitoring Postnatal Development

The Neonatal Period

Physiological and anatomical changes occur as the fetus completes the transition to the status of newborn, or **neonate**. Before delivery, dissolved gases, nutrients, wastes, hormones, and antibodies were transferred across the placenta. At birth, the neonate must become relatively self-sufficient, performing respiration, digestion, and excretion using its own specialized organs and organ systems. The transition from fetus to neonate can be summarized as follows:

- At birth, the lungs are collapsed and filled with fluid. Filling them with air requires a massive and powerful inhalation.

l**p. 853**

- When the lungs expand, the pattern of cardiovascular circulation changes due to alterations in blood pressure and flow rates.

The ductus arteriosus closes, isolating the pulmonary and systemic trunks. Closure of the foramen ovale separates the atria of the heart, completing the separation of the pulmonary and systemic circuits. l**p. 754**

- The typical neonatal heart rate (120–140 beats per minute) and respiratory rate (30 breaths per minute) are considerably higher than in adults. In addition, the metabolic rate per unit of body weight in neonates is roughly twice that in adults.
- Before birth, the digestive system remains relatively inactive, although it does accumulate a mixture of bile secretions, mucus, and epithelial cells. This collection of debris is excreted during the first few days of life. Over that period, the newborn begins to nurse.
- As waste products build up in the arterial blood, they are excreted at the kidneys. Glomerular filtration is normal, but the neonate cannot concentrate urine to any significant degree. As a result, urinary water losses are high, and neonatal fluid requirements are much greater than those of adults.

- The neonate has little ability to control its body temperature, particularly in the first few days after delivery. As the infant grows

larger and its insulating subcutaneous adipose “blanket” gets thicker, its metabolic rate also rises. Daily and even hourly shifts in body temperature continue throughout childhood. l**p. 945**

Over the entire neonatal period, the newborn is dependent on nutrients contained in milk, typically breast milk secreted by the maternal mammary glands.

Lactation and the Mammary Glands By the end of the sixth month of pregnancy, the mammary glands are fully developed, and the gland cells begin to produce a secretion known as **colostrum** (ko-LOS-trum). Ingested by the infant during the first two or three days of life, colostrum contains more proteins and far less fat than breast milk. Many of the proteins are antibodies that may help the infant ward off infections until its own immune system becomes fully functional. In addition, the mucins present in both colostrum and milk can inhibit the replication of a family of viruses (*rotaviruses*) that can cause dangerous forms of gastroenteritis and diarrhea in infants.

As colostrum production drops, the mammary glands convert to milk production. Breast milk consists of water, proteins, amino acids, lipids, sugars, and salts. It also contains large quantities of *lysozymes*—enzymes with antibiotic properties. Human milk provides roughly 750 Calories per liter. The secretory rate varies with the demand, but a 5–6-kg (11–13-lb) infant usually requires about 850 ml of milk per day. (The production of milk throughout this period is maintained through the combined actions of several hormones, as detailed in Chapter 18. l**pp. 603–604**)

Milk becomes available to infants through the **milk let-down reflex** (Figure 29–12•). Mammary gland secretion is triggered when the infant sucks on the nipple (STEP 1). The stimulation of tactile receptors there leads to the stimulation of secretory neurons in the paraventricular nucleus of the mother’s hypothalamus (STEPS 2 and 3). These neurons release oxytocin at the posterior lobe of the pituitary gland (STEP 4). When circulating oxytocin reaches the mammary gland, this hormone causes the contraction of *myoepithelial* *cells*, contractile cells in the walls of the lactiferous ducts and sinuses. The result is milk ejection (STEP 5), or *milk let-down*.

The milk let-down reflex continues to function until *weaning*, typically one to two years after birth. Milk production ceases soon after, and the mammary glands gradually return to a resting state. Earlier weaning is a common practice in the United States, where women take advantage of commercially prepared milk- or soy-based infant formulas that closely approximate the composition of natural breast milk. The major difference between such substitutes and natural milk is that the substitutes lack antibodies and lysozymes, which play important roles in maintaining the health of the infant. Consequently, early weaning is associated with an increased risk of infections and allergies in the infant.

Infancy and Childhood

The most rapid growth occurs during prenatal development, and the growth rate declines after delivery. Growth during infancy and childhood occurs under the direction of circulating hormones, notably growth hormone, adrenal steroids, and thyroid hormones. These hormones affect each tissue and organ in specific ways, depending on the sensitivities of the individual cells. As a result, growth does not occur uniformly, so the body proportions gradually change. The head, for example, is relatively large at birth but decreases in proportion with the rest of the body as the child grows to adulthood (Figure 29–13•).

Adolescence and Maturity

Adolescence begins at **puberty**, the period of sexual maturation, and ends when growth is completed. Three major hormonal events interact at the onset of puberty:

1. The hypothalamus increases its production of gonadotropin-releasing hormone (GnRH). Evidence indicates that this increase is dependent on adequate levels of *leptin*, a hormone released by adipose tissues. l**p. 624**

2. Endocrine cells in the anterior lobe of the pituitary gland become more sensitive to the presence of GnRH, and circulating levels of FSH and LH rise rapidly.

3. Ovarian or testicular cells become more sensitive to FSH and LH, initiating (1) gamete production, (2) the secretion of sex hormones that stimulate the appearance of secondary sex characteristics and behaviors, and (3) a sudden acceleration in the growth rate, culminating in closure of the epiphyseal cartilages.

The age at which puberty begins varies. In the United States today, puberty generally starts at about age 12 in boys and 11 in girls, but the normal ranges are broad (10–15 in boys, 9–14 in girls). Many body systems alter their activities in response to circulating sex hormones and to the presence of growth hormone, thyroid hormones, PRL, and adrenocortical hormones, so sex-specific differences in structure and function develop. At puberty, endocrine system changes induce characteristic changes in various body systems:

- **Integumentary System.** Testosterone stimulates the development of terminal hairs on the face and chest, whereas under estrogen stimulation those follicles continue to produce fine hairs. The hairline recedes under testosterone stimulation. Both testosterone and estrogen stimulate terminal hair growth in the axillae and in the genital area. Androgens, which are present in both sexes, also stimulate sebaceous gland secretion and may cause acne. Adipose tissues respond differently to testosterone than to estrogens, and this difference produces changes in the distribution of subcutaneous body fat. In women, the combination of estrogens, PRL, growth hormone, and thyroid hormones promotes the initial development of the mammary glands. Although the duct system becomes more elaborate, true secretory alveoli do not develop, and much of the growth of the breasts during this period reflects increased deposition of fat rather than glandular tissue.
- **Skeletal System.** Both testosterone and estrogen accelerate bone deposition and skeletal growth. In the process, they promote closure of the epiphyses and thus place a limit on growth in height. Estrogens cause more rapid epiphyseal closure than does testosterone. In addition, the period of skeletal growth is shorter in girls than in boys, and girls generally

do not grow as tall as boys. Girls grow most rapidly between ages 10 and 13, whereas boys grow most rapidly between ages 12 and 15.

- **Muscular System.** Sex hormones stimulate the growth of skeletal muscle fibers, increasing strength and endurance. The effects of testosterone greatly exceed those of the estrogens, and the increased muscle mass accounts for significant sex differences in body mass, even for males and females of the same height. The stimulatory effects of testosterone on muscle mass have produced an interest in anabolic steroids among competitive athletes of both sexes.
- **Nervous System.** Sex hormones affect central nervous system centers concerned with sexual drive and sexual behaviors. These centers differentiated in sex-specific ways during the second and third trimesters, when the fetal gonads secrete either testosterone (in males) or estrogens (in females). The surge in sex hormone secretion at puberty activates the CNS centers.
- **Cardiovascular System.** Testosterone stimulates erythropoiesis, thereby increasing the blood volume and the hematocrit. In females whose uterine cycles have begun, the iron loss associated with menses increases the risk of developing iron-deficiency anemia. Late in each uterine cycle, estrogens and progesterone promote the movement of water from plasma into interstitial fluid, leading to an increase in tissue water content. Estrogens decrease plasma cholesterol levels and slow the formation of plaque. As a result, premenopausal women have a lower risk of atherosclerosis than do adult men.
- **Respiratory System.** Testosterone stimulates disproportionate growth of the larynx and a thickening and lengthening of the vocal cords. These changes cause a gradual deepening of the voice of males compared with that of females.
- **Reproductive System.** In males, testosterone stimulates the functional development of the accessory reproductive glands, such as the prostate gland and seminal vesicles, and helps promote spermatogenesis. In females, estrogens target the uterus, promoting a thickening of the myometrium, increasing blood flow to the endometrium, and stimulating cervical mucus production. Estrogens also promote the functional development of

accessory reproductive organs in females. The first few uterine cycles may or may not be accompanied by ovulation. After the initial stage, the woman will be fertile, even though growth and physical maturation will continue for several years.

After puberty, the continued background secretion of estrogens or androgens maintains the foregoing sex-specific differences. In both sexes, growth continues at a slower pace until age 18–21, by which time most of the epiphyseal cartilages have closed. The boundary between adolescence and maturity is hazy, because it has physical, emotional, and behavioral components. Adolescence is often said to be over when growth stops, in the late teens or early twenties. The individual is then considered physically mature.

Senescence

Although physical growth may cease at maturity, physiological changes continue. The sex-specific differences produced at puberty are retained, but further changes occur when sex hormone levels decline at menopause or the male climacteric. l**pp. 1066–1067** All these changes are part of the process of **senescence**, or aging, which reduces the functional capabilities of the individual. Even in the absence of such factors as disease or injury, senescence-related changes at the molecular level ultimately lead to death.

Table 29–3 summarizes the age-related changes in physiological systems discussed in earlier chapters. Taken together, these changes both reduce the functional abilities of the individual and affect homeostatic mechanisms. As a result, the elderly are less able to make homeostatic adjustments in response to internal or environmental stresses. The risks of contracting a variety of infectious diseases are proportionately increased as immune function deteriorates. This deterioration leads to drastic physiological changes that affect all internal systems. Death ultimately occurs when some combination of stresses cannot be countered by the body’s existing homeostatic mechanisms.

Physicians attempt to forestall death by adjusting homeostatic mechanisms or removing the sources of stress. **Geriatrics** is the medical specialty that deals with the problems associated with aging; physicians trained in geriatrics are known as **geriatricians**.

Problems commonly encountered by geriatricians include infections, cancers, heart disease, strokes, arthritis, senile dementia, and anemia—conditions directly related to age-induced changes in vital systems. AM: Death and Dying

Concept Check

Why does a mother's blood volume increase during pregnancy?

What effect would a decrease in progesterone have on the uterus during late pregnancy?

Increases in the levels of GnRH, FSH, LH, and sex hormones in blood mark the onset of which stage of development?

Answers begin on p. A–1

Genetics, Development, and Inheritance

Objective

- Relate basic principles of genetics to the inheritance of human traits.

Genes and Chromosomes

Chromosomes contain DNA, and genes are functional segments of DNA. Each gene carries the information needed to direct the synthesis of a specific polypeptide. Chromosome structure and the functions of genes were introduced in Chapter 3. l**pp. 79–84** Every nucleated somatic cell in your body carries copies of the original 46 chromosomes present when you were a zygote. Those

chromosomes and their component genes constitute your **genotype** (JE¯N

–

ı

Through development and differentiation, the instructions contained in the genotype are expressed in many ways. No single cell or tissue uses all the information and instructions contained in the genotype. For example, in muscle fibers, the genes involved in the formation of excitable membranes and contractile proteins are active, whereas in cells of the pancreatic islets, a different set of genes operates. Collectively, however, the instructions contained in your genotype determine the anatomical and physiological characteristics that make you a unique individual. Those anatomical and physiological characteristics constitute your **phenotype**

¯o

p).-t

¯E

(F

–

ı in your phenotype, such as hair and eye color, skin tone, and foot size, are called phenotypic *characters*, or *traits*.

¯o

p). In architectural terms, the genotype is a set of plans, and the phenotype is the finished building. Specific elements

-t

-n

Your genotype is derived from the genotypes of your parents. Yet you are not an exact copy of either parent; nor are you an easily identifiable mixture of their characteristics. Our discussion of genetics will begin with the basic patterns of inheritance and their implications. We will then examine the mechanisms responsible for regulating the activities of the genotype during prenatal development.

Patterns of Inheritance

The 46 chromosomes carried by each somatic cell occur in pairs: Every somatic cell contains 23 pairs of chromosomes. At amphimixis, one member of each pair is contributed by the spermatozoon, and the other by the ovum. The two members of each pair are known as **homologous** (hō-MOL-o-gus) **chromosomes**. Twenty-two of those pairs are called **autosomal** (aw-tō-SŌ-mal) **chromosomes**. Most of the genes of the autosomal chromosomes affect somatic characteristics, such as hair color and skin pigmentation. The chromosomes of the 23rd pair are called the **sex chromosomes**; one of their functions is to determine whether the individual is genetically male or female. Figure 29–14• shows the **karyotype**, or entire set of chromosomes, of a normal male. The discussion that follows concerns the inheritance of traits carried on the autosomal chromosomes; we will examine the patterns of inheritance via the sex chromosomes in a later section.

The two chromosomes in a homologous autosomal pair have the same structure and carry genes that affect the same traits. Suppose that one member of the pair contains three genes in a row, with the first gene determining hair color, the second eye color, and the third skin pigmentation. The other chromosome carries genes that affect the same traits, and the genes are in the same sequence. The genes are also located at equivalent positions on their respective chromosomes. A gene's position on a chromosome is called a **locus** (LŌ-kus; plural, *loci*).

The two chromosomes in a pair may not carry the same *form* of each gene, however. The various forms of a given gene are

called **alleles** (a-L

¯E

LZ). These *alternate forms* determine the precise effect of the gene on your phenotype. If the two chromosomes

of a homologous pair carry the same allele of a particular gene, you are **homozygous** (h

¯o

-m

¯o

-Z -gus) for the trait affected by that

I¯

gene. That allele will then indeed be expressed in your phenotype. For example, if you receive a gene for curly hair from your father and a gene for curly hair from your mother, you will be homozygous for curly hair—and you will have curly hair. About 80 percent of an individual's genome consists of homozygous alleles. In **simple inheritance**, the phenotype is determined by interactions between a single pair of alleles.

Interactions between Alleles

Because the chromosomes of a homologous pair have different origins, one paternal and the other maternal, they do not neces-

¯I

-Z -gus) for the trait determined by that gene. The phenotype that results from a heterozygous genotype depends on the nature of the interaction between the corresponding alleles. For example, if you received a gene for curly hair from your father, but a gene for straight hair from your mother, whether *you* will have curly hair, straight hair, or even wavy hair depends on the relationship between the alleles for those traits:

- In **strict dominance**, an allele that is **dominant** will be expressed in the phenotype, *regardless of any conflicting instructions carried by the other allele*. For instance, an individual with only one allele for freckles will have freckles, because that allele is dominant over the “nonfreckle” allele. An allele that is **recessive** will be expressed in the phenotype only if that same allele is present on *both chromosomes* of a homologous pair. For example, in Chapter 5 we learned that albino individuals cannot synthesize the yellow-brown pigment *melanin*. l**p. 158** The presence of one allele that directs melanin production will result in normal color. Two recessive alleles must be present to produce an albino individual. A single gene can have many different alleles, some dominant and others recessive.

- In **incomplete dominance**, heterozygous alleles produce a phenotype that is distinct from the phenotypes of individuals who are homozygous for one allele or the other. A good example is a gene that affects the shape of red blood cells. Individuals with homozygous alleles that carry instructions for normal adult hemoglobin A have red blood cells of normal shape. Individuals with homozygous alleles for hemoglobin S, an abnormal form, have red blood cells that become sickle–shaped in peripheral capillaries when the P_{O_2} decreases. These individuals develop *sickle cell anemia*. l**p. 665** Individuals who are heterozygous for this trait do not develop anemia; instead, they have red blood cells that sickle only when tissue oxygen levels are extremely low.
- In **codominance**, an individual who is heterozygous (has different alleles) for a given trait exhibits both the dominant and recessive phenotypes for that trait. Blood type in humans is determined by codominance. The alleles for type A and type B blood are dominant over the allele for type O blood, but a person with one type A allele and one type B allele has type AB blood, not A or B. Type AB blood has *both* type A antigens and type B antigens. The distinction between incomplete dominance and codominance is not always clear-cut. For example, a person who has alleles for hemoglobin A and hemoblogin S shows incomplete dominance for RBC shape, but codominance for hemoglobin; each red blood cell contains a mixture of hemoglobin A and hemoglobin S.

Penetrance and Expressivity

Differences in genotype lead to distinct variations in phenotype, but the relationships are not always predictable. The presence of a particular pair of alleles does not affect the phenotype in the same way in every individual. **Penetrance** is the percentage of individuals with a particular genotype that show the "expected" phenotype. The effects of that genotype in other individuals may

sarily carry the same alleles. When you have two different alleles for the same gene, you are **heterozygous** (het-er-

¯o

be overridden by the activity of other genes or by environmental factors. For example, *emphysema*, a respiratory disorder discussed in Chapter 23, has been linked to a specific abnormal genotype. l**p. 853** However, roughly 20 percent of the individuals with this genotype do not develop emphysema, and thus the penetrance of this genotype is approximately 80 percent. The effects of environmental factors are apparent: Most people who develop emphysema are cigarette smokers.

If a given genotype *does* affect the phenotype, it can do so to various degrees, again depending on the activity of other genes or environmental stimuli. For example, even though identical twins have the same genotype, they do not have exactly the same fingerprints. The extent to which a particular allele is expressed when it is present is termed its **expressivity**.

Environmental effects on genetic expression are particularly evident during embryological and fetal development. Drugs, including certain antibiotics, alcohol, and nicotine in cigarette smoke, can disrupt fetal development. Factors that result in abnormal development are called **teratogens** (TER-a-to¯-jenz). AM: Teratogens and Abnormal Development

Predicting Inheritance

When an allele can be neatly characterized as dominant or recessive, you can predict the characteristics of individuals on the basis of their parents' alleles.

In such calculations, dominant alleles are traditionally indicated by capitalized abbreviations, and recessive alleles by lowercase abbreviations. For a given trait, the possibilities are indicated by *AA* (homozygous dominant), *Aa* (heterozygous), or *aa* (homozygous recessive). Each gamete involved in fertilization contributes a single allele for a given trait. That allele must be one of the two alleles contained by all cells in the parent's body. Consider, for example, the possible offspring of an albino mother and a father with normal skin pigmentation. Because albinism is a recessive trait, the maternal alleles are abbreviated *aa*. No matter which of her oocytes is fertilized, it will carry the recessive *a* allele. The father has normal pigmentation, a dominant trait. He is therefore either homozygous *or* heterozygous for this trait, because both *AA* and *Aa* will produce the same phenotype: normal skin pigmentation. Every sperm produced by a homozygous father will carry the *A* allele. In contrast, half the sperm produced by a heterozygous father will carry the dominant allele *A*, and the other half will carry the recessive allele *a*.

A simple box diagram known as a **Punnett square** enables us to predict the probabilities that children will have particular characteristics by showing the various combinations of parental alleles they can inherit. In the Punnett squares shown in Figure 29–15•, the maternal alleles for skin pigmentation are listed along the horizontal axis, and the paternal ones along the vertical axis. The combinations of alleles are indicated in the small boxes. Figure 29–15a• shows the possible offspring of an *aa* mother and an *AA* father. All the children must have the genotype *Aa*, so all will have normal skin pigmentation. Compare these results with those of Figure 29–15b•, for a heterozygous father (*Aa*) and an *aa* mother. The heterozygous male produces two types of gametes, *A* and *a*, and the secondary oocyte may be fertilized by either one. As a result, the probability is 50 percent that a child of such a father will inherit the genotype *Aa* and so have normal skin pigmentation. The probability of inheriting the genotype *aa*, and thus having the albino phenotype, is also 50 percent.

A Punnett square can also be used to draw conclusions about the identity and genotype of a parent. For example, a man with the genotype *AA* cannot be the father of an albino child (*aa*).

We can predict the frequency of appearance of any inherited disorder that results from simple inheritance by using a Punnett square. Although they are rare in terms of overall numbers, more than 1200 inherited disorders have been identified that reflect the presence of one or two abnormal alleles for a single gene. Figure 29–16• diagrams the relationships among the various forms of inheritance and gives examples of representative phenotypic characters, both normal and abnormal. The majority of characters listed develop through simple inheritance.

However, many phenotypic characters are determined by interactions among several genes. Such interactions constitute **polygenic inheritance**. Because the resulting phenotype depends not only on the nature of the alleles but how those alleles interact, you cannot predict the presence or absence of phenotypic characters using a simple Punnett square. In *suppression,* one gene suppresses the other, so that the second gene has no effect on the phenotype. In *complementary gene action,* dominant alleles on two genes interact to produce a phenotype different from that seen when one gene contains recessive alleles. The risks of developing several important adult disorders, including hypertension and coronary artery disease, are linked to polygenic inheritance.

Many of the developmental disorders responsible for fetal deaths and congenital malformations result from polygenic inheritance. In these cases, an individual’s genetic composition does not by itself determine the onset of the disease. Instead, the conditions regulated by these genes establish a susceptibility to particular environmental influences. Thus, not every individual with the genetic tendency for a certain condition will develop that condition. It is therefore difficult to track polygenic conditions through successive generations. However, because many inherited polygenic conditions are *likely* (but not *guaranteed*) to occur, steps can be taken to prevent a crisis. For example, you can reduce hypertension by controlling your diet and fluid volume, and you can prevent coronary artery disease by lowering your serum cholesterol levels.

Sources of Individual Variation

Just as you are not a copy of either of your parents, neither are you a 50 > 50 mixture of their characteristics. One reason for this was noted in Chapter 28: During meiosis, maternal and paternal chromosomes are randomly distributed, so each gamete has a unique combination of maternal and paternal chromosomes. Thus, you may have an allele for curly hair from your father and an allele for straight hair from your mother, even though your sister received an allele for straight hair from each of your parents. Only in very rare cases will an individual receive both alleles from one parent. The few documented cases appear to have resulted when duplicate maternal chromatids failed to separate during meiosis II and the corresponding chromosome provided by the sperm did not participate in amphimixis. This condition, called *uniparental disomy*, generally remains undetected, because the individuals are phenotypically normal.

Genetic Recombination

During meiosis, various changes can occur in chromosome structure, producing gametes with chromosomes that differ from those of each parent. This phenomenon, called **genetic recombination**, greatly increases the range of possible variation among gametes, and thus among members of successive generations, whose genotypes are formed by the combination of gametes in fertilization. Genetic recombination can also complicate the tracing of the inheritance of genetic disorders.

In one normal form of recombination, parts of chromosomes become rearranged during synapsis (Figure 29–17•). When tetrads form, adjacent chromatids may overlap, an event called **crossing over**. The chromatids may then break, and the overlapping segments trade places. This reshuffling process is known as **translocation**.

During recombination, portions of chromosomes may also break away and be lost, or *deleted*. The effects of a deletion on a zygote depend on the nature of the lost genes. In a phenomenon called **genomic imprinting**, the effects depend on whether the abnormal gamete is produced through oogenesis or spermatogenesis. For example, the deletion of a specific segment of chromosome 15 in humans can cause two very different disorders. In *Angelman syndrome*, which results when the abnormal chromosome is provided by the oocyte, hyperactivity, severe mental retardation, and seizures occur. In *Prader–Willi* *syndrome*, which results when the abnormal chromosome is delivered by the sperm, individuals have short stature, reduced muscle tone and skin pigmentation, underdeveloped gonads, and mental retardation varying from slight to severe.

Recombination that produces abnormal chromosome shapes or numbers is lethal for the zygote in almost all cases. Roughly 10 percent of zygotes have **chromosomal abnormalities**—that is, damaged, broken, missing, or extra copies of chromosomes— but only about 0.5 percent of newborns have such abnormalities. Few individuals with chromosomal abnormalities survive to full term; Down syndrome (trisomy 21) is an exception. In addition to contributing to prenatal mortality, chromosomal abnormalities produce a variety of serious clinical conditions. The high mortality rate and the severity of the problems reflect the fact that large numbers of genes have been added or deleted. Women who become pregnant later in life run a higher risk of birth defects and miscarriage due to chromosomal abnormalities in the oocyte. It seems that the longer the oocyte remains suspended in meiosis I, the more likely are recombination errors when meiosis is completed.

Mutation

Variations at the level of the individual gene can result from *mutations*—changes in the nucleotide sequence of an allele. **Spontaneous mutations** are the result of random errors in DNA replication. Such errors are relatively common, but in most cases the error is detected and repaired by enzymes in the nucleus. Those errors that go undetected and unrepaired have the potential to change the phenotype in some way.

Mutations occurring during meiosis can produce gametes that contain abnormal alleles. These alleles may be dominant or recessive, and they may occur on autosomal chromosomes or on sex chromosomes. The vast majority of mutations make the zygote incapable of completing normal development. Mutation, rather than chromosomal abnormalities, is probably the primary cause of the high mortality rate among pre-embryos and embryos. (Roughly 50 percent of all zygotes fail to complete cleavage, and another 10 percent fail to reach the fifth month of gestation.) AM: Complexity and Perfection

If the abnormal allele is dominant but does not affect gestational survival, the individual's phenotype will show the effects of the mutation. If the abnormal allele is recessive and is on an autosomal chromosome, it will not affect the individual's phenotype as long as the zygote contains a normal allele contributed by the other parent at fertilization. Over generations, a recessive autosomal allele can spread through the population, remaining undetected until a fertilization occurs in which the two gametes contribute identical recessive alleles. This individual, who will be homozygous for the abnormal allele, will be the first to show the phenotypic effects of the original mutation. Individuals who are heterozygous for the abnormal allele but do not show the effects of the mutation are called **carriers**. Available genetic tests can determine whether an individual is a carrier for any of several autosomal recessive disorders, including Tay–Sachs disease. The information obtained from these tests can be useful in counseling prospective parents. For example, if both parents are carriers of the same disorder, they have a 25 percent probability of producing a child with the disease. This information may affect their decision to conceive.

Sex-Linked Inheritance

Unlike the other 22 chromosomal pairs, the sex chromosomes may not be identical in appearance and gene content. There are two types of sex chromosomes: an **X chromosome** and a **Y chromosome**. X chromosomes are considerably larger and have more genes than do Y chromosomes. The Y chromosome includes dominant alleles specifying that an individual with that chromosome will be male. The normal pair of sex chromosomes in males is XY. Females do not have a Y chromosome; their sex chromosome pair is XX.

All oocytes carry an X chromosome, because the only sex chromosomes females have are X chromosomes. But each sperm carries either an X or a Y chromosome, because males have one of each and can pass along either one. As a Punnett square shows, the ratio of males to females in offspring should be 1 : 1. The birth statistics differ slightly from that prediction, with 106 males born for every 100 females. It has been suggested that more males are born because a sperm that carries the Y chromosome can reach the oocyte first, because that sperm does not have to carry the extra weight of the larger X chromosome.

The X chromosome also carries genes that affect somatic structures. These characteristics are called **X-linked** (or *sex linked*), because in most cases there are no corresponding alleles on the Y chromosome. The inheritance of characteristics regulated by these genes does not follow the pattern of alleles on autosomal chromosomes. The best known single-allele characteristics are those associated with identifiable diseases or functional deficits.

The inheritance of color blindness exemplifies the differences between sex-linked inheritance and autosomal inheritance. The presence of a dominant allele, *C*, on the X chromosome results in normal color vision; a recessive allele, *c*, on the X chromosome results in red–green color blindness. A woman, with her two X chromosomes, can be either homozygous dominant (*CC*) or heterozygous (*Cc*) and still have normal color vision. She will be unable to distinguish reds from greens only if she carries two recessive alleles, *cc*. But a male has only one X chromosome, so whichever allele that chromosome carries determines whether he has normal color vision or is red–green color blind. The Punnett square in Figure 29–18• reveals that the sons produced by a father with normal vision and a heterozygous (carrier) mother have a 50 percent chance of being red–green color blind, whereas any daughters have normal color vision.

A number of other clinical disorders noted earlier in the text are X-linked traits, including certain forms of hemophilia, diabetes insipidus, and muscular dystrophy. In several instances, advances in molecular genetics techniques have enabled geneticists to localize the specific genes on the X chromosome. These techniques provide a relatively direct method of screening for the presence of a particular condition before any symptoms appear, and even before birth.

The Human Genome Project

Few of the genes responsible for inherited disorders have been identified or even associated with a specific chromosome. That situation is changing rapidly, however, due to the **Human Genome Project**. Funded by the National Institutes of Health and the Department of Energy, the project’s goal was to transcribe the entire human **genome**—that is, the full complement of genetic material—chromosome by chromosome, gene by gene, and nucleotide by nucleotide. The work began in October 1990 and was expected to take 15 years. Progress has been more rapid than expected. A working draft of the entire genome was published in 2001, and 99 percent of the entire genome was listed as finished, “high-quality sequence” as of May 2003. A high-quality sequence is defined as a complete sequence of nucleotides, with no gaps or ambiguities and an error rate of no more than one base per 10,000. The first step in understanding the human genome was to prepare a map of the individual chromosomes. **Karyotyping** (KAR-

ı in Figure 29–15•. Each chromosome has characteristic banding patterns when stained with special dyes. The patterns are useful as reference points for the preparation of more detailed genetic maps, such as those shown in Figure 29–19•. The banding patterns themselves can be useful, as abnormal patterns are characteristic of some genetic disorders and several cancers. AM: Chromosomal Abnormalities and Genetic Analysis

As of 2004, a progress report included the following:

- Thirteen chromosomes—chromosomes 3, 5, 6, 7, 11, 12, 14, 16, 19, 20, 21, 22, and the Y chromosome—have been mapped completely, and several have been completely sequenced. Preliminary maps have been made of all the other chromosomes.
- Roughly 38,000 genes have been tentatively identified, and more than 15,000 have been mapped. The first number may represent most of the genes in the human genome.
- The genes responsible for roughly 1500 disorders, including those causing 60 inherited disorders, have been identified. Examples are included in Figure 29–19•. Genetic screening is now performed for many of these disorders.

It was originally thought that the relationship between genes and proteins was 1 : 1, and as a result, investigators were anticipating the discovery of as many as 140,000 genes in the human genome. Instead, the total number of protein-coding genes appears to be fewer than 40,000, representing just 2 percent of the total genome. This stands in stark contrast with the estimated 2 million different proteins found in the human body. The realization that one gene can carry instructions for more than one protein has revolutionized thinking about genetic diseases and potential therapies. A whole new set of questions has arisen as a result. For example, what factors and enzymes control mRNA processing? How are these factors regulated? Although we may be close to unraveling the human genome, we are still many years from the answers to these questions—and they must be answered

–

if we are to manipulate genes effectively to treat many congenital diseases.

Of course, controversy remains over the advisability of tinkering with our genetic makeup. The Human Genome Project is attempting to determine the normal genetic composition of a “typical” human. Yet we all are variations on a basic theme. How do we decide what set of genes to accept as “normal”? Moreover, as we improve our abilities to manipulate our own genetic foundations, we will face many additional troubling ethical and legal decisions. For example, few people object to the insertion of a “correct” gene into somatic cells to cure a specific disease. (See “Genetic Engineering and Gene Therapy” in the *Applications Manual*.) But what if we could insert that modified gene into a gamete and change not only that individual, but all of his or her descendants as well? And what if the goal of manipulating the gene was not to correct or prevent any disorder, but instead to “improve” the individual by increasing his or her intelligence, height, or vision, or by altering some other phenotypic characteristic? Such difficult questions will not go away. In the years to come, we will have to find answers that are acceptable to us all.

Concept Check

Curly hair is an autosomal dominant trait. What would be the phenotype of a person who is heterozygous for this trait?

Why are children not identical copies of their parents?

Selected Clinical Terminology

amniocentesis: A genetic analysis of fetal cells collected from a sample of amniotic fluid. [AM]

breech birth: A delivery in which the legs or buttocks of the fetus enter the vaginal canal first. (p. 1094)

chorionic villus sampling: A genetic analysis of cells usually collected from the chorionic villi during the first trimester. [AM]

ectopic pregnancy: A pregnancy in which implantation occurs somewhere other than the uterus. (p. 1080 and [AM])

gestational trophoblastic neoplasia: A tumor formed by undifferentiated, rapid growth of the syncytial trophoblast; if untreated, the

neoplasm may become malignant. (p. 1080) **infertility:** The inability to achieve pregnancy after one year of appropriately timed intercourse. [AM] **in vitro fertilization:** Fertilization outside the body, generally in a petri dish. [AM]

Study Outline

An Overview of Topics in Development p. 1075

1. **Development** is the gradual modification of anatomical structures and physiological characteristics from **conception** to maturity. The creation of different types of cells is **differentiation**.

2. **Prenatal development** occurs before birth; **postnatal development** begins at birth and continues to **maturity**, when aging begins. **Inheritance** is the transfer of genetically determined characteristics from generation to generation. **Genetics** is the study of the mechanisms of inheritance.

Fertilization p. 1075

1. **Fertilization**, or *conception*, normally occurs in the uterine tube within a day after ovulation. Spermatozoa cannot fertilize a secondary oocyte until they have undergone *capacitation*. *(Figure 29–1)*

The Oocyte at Ovulation p. 1076

2. The acrosomal caps of the spermatozoa release **hyaluronidase** and **acrosin**, enzymes required to penetrate the corona radiata and zona pellucida of the oocyte. When a single spermatozoon contacts the oocyte membrane, fertilization begins and **oocyte activation** follows. *(Figure 29–1)*

Oocyte Activation p. 1077

3. During activation, the oocyte completes meiosis II and thus becomes a functionally mature ovum. **Polyspermy** is prevented by membrane depolarization and the *cortical reaction*.

4. After activation, the **female pronucleus** and the **male pronucleus** fuse in a process called *amphimixis*. *(Figure 29–1)*

The Stages of Prenatal Development p. 1077

1. During prenatal development, differences in the cytoplasmic composition of individual cells trigger changes in genetic activity. The chemical interplay among developing cells is **induction**.

2. The nine-month **gestation** period can be divided into three **trimesters**.

The First Trimester p. 1078

1. In the **first trimester**, **cleavage** subdivides the cytoplasm of the zygote in a series of mitotic divisions; the zygote becomes a **pre-embryo** and then a **blastocyst**. During **implantation**, the blastocyst burrows into the uterine endometrium. **Placentation** occurs as blood vessels form around the blastocyst and the **placenta** develops. **Embryogenesis** is the formation of a viable embryo.

Cleavage and Blastocyst Formation p. 1078

2. The blastocyst consists of an outer **trophoblast** and an **inner cell mass**. *(Figure 29–2)*

Implantation p. 1079

3. Implantation occurs about seven days after fertilization as the blastocyst adheres to the uterine lining. *(Figure 29–3)*

4. As the trophoblast enlarges and spreads, maternal blood flows through open **lacunae**. After **gastrulation**, there is an **embryonic disc** composed of **endoderm**, **ectoderm**, and an intervening **mesoderm**. It is from these **germ layers** that the body systems differentiate.

(Figure 29–4; Summary Table 29–1)

5. Germ layers help form four **extraembryonic membranes**: the yolk sac, amnion, allantois, and chorion. *(Figure 29–5)*

6. The **yolk sac** is an important site of blood cell formation. The **amnion** encloses fluid that surrounds and cushions the developing embryo. The base of the **allantois** later gives rise to the urinary bladder. Circulation within the vessels of the **chorion** provides a rapid-transit system that links the embryo with the trophoblast. *(Figures 29–5, 29–6)*

Placentation p. 1082

7. **Chorionic villi** extend outward into the maternal tissues, forming an intricate, branching network through which maternal blood flows. As development proceeds, the **umbilical cord** connects the fetus to the placenta. The syncytial trophoblast synthesizes

human chorionic gonadotropin (hCG), estrogens, progesterone, **human placental lactogen (hPL)**, **placental prolactin**, and **relaxin**.

(Figure 29–6)

Embryogenesis p. 1085

8. The first trimester is critical, because events in the first 12 weeks establish the basis for **organogenesis** (organ formation). *(Figure 29–7; Summary Table 29–2)*

The Second and Third Trimesters p. 1089

1. In the **second trimester**, the organ systems increase in complexity. During the **third trimester**, many of the organ systems become fully functional. *(Figure 29–8; Summary Table 29–2)*

2. The fetus undergoes its largest weight gain in the third trimester. At the end of gestation, the fetus and the enlarged uterus displace many of the mother’s abdominal organs. *(Figure 29–9)*

100 Keys | p. 1089

Pregnancy and Maternal Systems p. 1089

3. The developing fetus is totally dependent on maternal organs for nourishment, respiration, and waste removal. Maternal adaptations include increases in respiratory rate, tidal volume, blood volume, nutrient and vitamin intake, and glomerular filtration rate, as well as changes in the size of the uterus and mammary glands.

Structural and Functional Changes in the Uterus p. 1091

4. Progesterone produced by the placenta has an inhibitory effect on uterine muscles; its calming action is opposed by estrogens, oxytocin, and prostaglandins. At some point, multiple factors interact to produce **labor contractions** in the uterine wall. *(Figure 29–10)*

Labor and Delivery p. 1092

1. The goal of **true labor** is **parturition**, the forcible expulsion of the fetus.

Stages of Labor p. 1092

2. Labor can be divided into three stages: the **dilation stage**, the **expulsion stage**, and the **placental stage**. *(Figure 29–11)*

Premature Labor p. 1093

3. **Premature labor** may result in **premature delivery**.

Difficult Deliveries p. 1094

4. Difficult deliveries can include *forceps deliveries* and **breech births**—deliveries in which the legs or buttocks of the fetus, rather than the head, enter the vaginal canal first.

Multiple Births p. 1094

5. Twin births are either **dizygotic** (fraternal) or **monozygotic** (identical).

Postnatal Development p. 1094

1. Postnatal development involves a series of five **life stages**: the neonatal period, infancy, childhood, adolescence, and maturity. *Senescence* (aging) begins at maturity and ends in the death of the individual.

The Neonatal Period, Infancy, and Childhood p. 1094

2. The **neonatal period** extends from birth to one month after. In the transition from fetus to **neonate**, the respiratory, circulatory, digestive, and urinary systems of the infant begin functioning independently. The newborn must also begin thermoregulation.

3. Mammary gland cells produce protein-rich **colostrum** during the neonate’s first few days of life and then convert to milk production. These secretions are released as a result of the **milk let-down reflex**. *(Figure 29–12)*

4. Body proportions gradually change during **infancy** (from age one month to two years) and during **childhood** (from two years to puberty). *(Figure 29–13)*

Adolescence and Maturity p. 1097

5. **Adolescence** begins at **puberty**, when (1) the hypothalamus increases its production of GnRH, (2) circulating levels of FSH and LH rise rapidly, and (3) ovarian or testicular cells become more sensitive to FSH and LH. These changes initiate gamete formation, the production of sex hormones, and a sudden rise in the growth rate. The hormonal changes at puberty, especially changes in sex hormone levels, produce sex-specific differences in the structure and function of many systems; these differences will be retained. Adolescence continues until growth is completed. Further changes occur when sex hormone levels decline at menopause or the male climacteric.

Senescence p. 1098

6. **Senescence** then begins, producing gradual reductions in the functional capabilities of all systems. *(Summary Table 29–3)*

Genetics, Development, and Inheritance p. 1098 Genes and Chromosomes p. 1098

1. Every somatic cell carries copies of the original 46 chromosomes in the zygote; these chromosomes and their component genes constitute the individual's **genotype**. The physical expression of the genotype is the individual's **phenotype**.

Patterns of Inheritance p. 1099

2. Every somatic human cell contains 23 pairs of chromosomes; each pair consists of **homologous chromosomes**. Twenty-two pairs are **autosomal chromosomes**. The chromosomes of the twenty-third pair are the **sex chromosomes**; they differ between the sexes.

(Figure 29–14)

3. Chromosomes contain DNA, and genes are functional segments of DNA. The various forms of a given gene are called **alleles**. If both homologous chromosomes carry the same allele of a particular gene, the individual is **homozygous**; if they carry different alleles, the individual is **heterozygous**.

4. Alleles are either **dominant** or **recessive**, depending on how their traits are expressed.

5. Combining maternal and paternal alleles in a **Punnett square** diagram helps us predict the characteristics of offspring. *(Figure 29–15)*

6. In **simple inheritance**, phenotypic characters are determined by interactions between a single pair of alleles. **Polygenic inheritance** involves interactions among alleles on several genes. *(Figure 29–16)*

Sources of Individual Variation p. 1102

7. **Genetic recombination**, the gene reshuffling (**crossing over** and **translocation)** that occurs during meiosis, increases the genetic variation of male and female gametes. *(Figure 29–17)*

8. **Spontaneous mutations** are the result of random errors in DNA replication. Such mutations can cause the production of abnormal alleles.

Sex-Linked Inheritance p. 1103

9. The two types of sex chromosomes are an **X chromosome** and a **Y chromosome**. The normal sex chromosome complement of males is XY; that of females is XX. The X chromosome carries **X-linked** (*sex-linked*) **genes**, which affect somatic structures but have no corresponding alleles on the Y chromosome. *(Figure 29–18)*

The Human Genome Project p. 1104

10. The **Human Genome Project** has mapped more than 38,000 human genes, including some of those responsible for inherited disorders. *(Figure 29–19)*

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The chorionic villi

(a) form the umbilical cord

(b) form the umbilical vein

(c) form the umbilical arteries

(d) increase the surface area available for exchange between the placenta and the maternal blood

(e) form the portion of the placenta called the decidua capsularis

2. The hormone that is the basis for a pregnancy test is

(a) LH

(b) progesterone

(c) human chorionic gonadotropin (hCG)

(d) human placental lactogen (hPL)

(e) either c or d depending on the type of test

3. Recessive X-linked traits

(a) are passed from fathers to their sons

(b) are more likely to be expressed in males

(c) always affect some aspect of the reproductive system

(d) are never expressed in females

(e) cannot be passed from mothers to daughters

4. The stage of development that follows cleavage is the

(a) blastocyst **(b)** morula

(c) trophoblast **(d)** blastocoele

5. What begins as a zygote arrives in the uterine cavity as a

(a) blastocyst **(b)** trophoblast

(c) lacuna **(d)** blastomere

6. The surface that provides for active and passive exchange between the fetal and maternal bloodstreams is the

(a) yolk stalk

(b) chorionic villi

(c) umbilical veins

(d) umbilical arteries

7. If an allele must be present on both the maternal and paternal chromosomes to affect the phenotype, the allele is said to be

(a) dominant **(b)** recessive

(c) complementary **(d)** heterozygous

8. Describe the changes that occur in the oocyte immediately after fertilization.

9. (a) What are the four extraembryonic membranes?

(b) How do these membranes form, and what are their functions?

10. Identify the three stages of labor, and describe the events that characterize each stage.

11. List the factors involved in initiating labor contractions.

12. Identify the three life stages that occur between birth and approximately age 10. Describe the characteristics of each stage and when it occurs.

13. What hormonal events are responsible for puberty? Which life stage does puberty initiate?

LEVEL 2 Reviewing Concepts

14. A normally pigmented woman whose father was an albino marries a normally pigmented man whose mother was an albino. What is the probability that they would have an albino child?

(a) 12 **(b)** 14 **(c)** 18 **(d)** 116 **(e)** 100%

>>> >

15. If a sperm cell lacked sufficient quantities of hyaluronidase, it would *not* be able to

(a) move its flagellum

(b) penetrate the corona radiata

(c) become capacitated

(d) survive the environment of the female reproductive tract

(e) metabolize fructose

16. Problems involving the formation of the chorion would affect

(a) the embryo's ability to produce blood cells

(b) the formation of limbs

(c) the embryo's ability to derive nutrition from the mother

(d) lung formation

(e) the urinary system

17. After implantation, how does the developing embryo obtain nutrients? What structures and processes are involved?

18. In addition to its role in the nutrition of the fetus, what are the primary endocrine functions of the placenta?

19. Discuss the changes that occur in maternal systems during pregnancy. Why are these changes functionally significant?

20. During true labor, what physiological mechanisms ensure that uterine contractions continue until delivery has been completed?

21. What physiological adjustments must an infant make during the neonatal period in order to survive?

22. Distinguish between the following paired terms:

(a) genotype and phenotype

(b) heterozygous and homozygous

(c) simple inheritance and polygenic inheritance

23. What would you conclude about a trait in each of the following situations?

(a) Children who exhibit the trait have at least one parent who exhibits it also.

(b) Children exhibit the trait even though neither parent exhibits it.

(c) The trait is expressed more commonly in sons than in daughters.

(d) The trait is expressed equally in daughters and sons.

24. Explain the goals and possible benefits of the Human Genome Project.

LEVEL 3 Critical Thinking and Clinical Applications

25. Hemophilia A, a condition in which blood does not clot properly, is a recessive trait located on the X chromosome (X^h). Suppose

that a woman who is heterozygous for this trait (XX^h) mates with a normal male (XY). What is the probability that the couple will have hemophiliac daughters? What is the probability that the couple will have hemophiliac sons?

26. Joan is a 27-year-old nurse who is in labor with her first child. She remembers from her anatomy and physiology class that calcium ions can increase the force of smooth muscle contractions, and because the labor is prolonged, she asks her physician for a calcium injection. The surprised physician informs Joan that such an injection is definitely out of the question. Why?

27. Joe and Jane desperately want to have children, and although they have tried for two years, they have not been successful. Finally, each of them consults a physician, and it turns out that Joe suffers from oligospermia (a low sperm count). He confides to you that he doesn’t understand why this would interfere with his ability to have children since he remembers from biology class that it only takes one sperm to fertilize an egg. What would you tell him?

28. Cathy has just given birth to a little girl. When the nurses take the infant back to the nursery and try to feed her, she becomes cyanotic (turns blue). The episode passes, but when the infant is bathed, she becomes cyanotic again. Blood gas levels are taken and they show the arterial blood is only 60% saturated. Physical examination indicates that there are no structural deformities involving the respiratory or digestive system. What might be causing the problem?

29. Sally gives birth to a baby with a congenital deformity of the stomach. Sally believes that her baby’s affliction is the result of a viral infection that she suffered during her third trimester. Is this a possibility? Explain.

| SUMMARY TABLE 29–1 | THE FATES OF THE GERM LAYERS

ECTODERMAL CONTRIBUTIONS

Integumentary system: epidermis, hair follicles and hairs, nails, and glands communicating with the skin (sweat glands, mammary glands,

and sebaceous glands)

Skeletal system: pharyngeal cartilages and their derivatives in adults (portion of sphenoid bone, the auditory ossicles, the styloid processes of the temporal bones, the cornu and superior rim of the hyoid bone)*

Nervous system: all neural tissue, including brain and spinal cord

Endocrine system: pituitary gland and adrenal medullae

Respiratory system: mucous epithelium of nasal passageways

Digestive system: mucous epithelium of mouth and anus, salivary glands

MESODERMAL CONTRIBUTIONS Integumentary system: dermis (and hypodermis) **Skeletal system:** all components except some pharyngeal derivatives **Muscular system:** all components **Endocrine system:** adrenal cortex, endocrine tissues of heart, kidneys, and gonads **Cardiovascular system:** all components **Lymphatic system:** all components **Urinary system:** the kidneys, including the nephrons and the initial portions of the collecting system **Reproductive system:** the gonads and the adjacent portions of the duct systems **Miscellaneous:** the lining of the body cavities (pleural, pericardial, and peritoneal) and the connective tissues that support all organ systems

ENDODERMAL CONTRIBUTIONS Endocrine system: thymus, thyroid gland, and pancreas **Respiratory system:** respiratory epithelium (except nasal passageways) and associated mucous glands **Digestive system:** mucous epithelium (except mouth and anus), exocrine glands (except salivary glands), liver, and pancreas **Urinary system:** urinary bladder and distal portions of the duct system **Reproductive system:** distal portions of the duct system, stem cells that produce gametes

* The neural crest is derived from ectoderm and contributes to the formation of the skull and the skeletal derivatives of the embryonic pharyngeal arches.

| SUMMARY TABLE 29–3 | EFFECTS OF AGING ON ORGAN SYSTEMS

The characteristic physical and functional changes that are part of the aging process affect all organ systems. Examples discussed in previous chapters include the following:

- A loss of elasticity in the skin that produces sagging and wrinkling. l**p. 173**
- A decline in the rate of bone deposition, leading to weak bones, and degenerative changes in joints that make them less mobile. l**pp. 199, 278**
- Reductions in muscular strength and ability. l**p. 371**
- Impairment of coordination, memory, and intellectual function. l**p. 542**
- Reductions in the production of, and sensitivity to, circulating hormones. l**p. 628**
- Appearance of cardiovascular problems and a reduction in peripheral blood flow that can affect a variety of vital organs. l**p. 756**

- Reduced sensitivity and responsiveness of the immune system, leading to infection, cancer, or both. l**p. 802**
- Reduced elasticity in the lungs, leading to decreased respiratory function. l**p. 853**
- Decreased peristalsis and muscle tone along the digestive tract. l**p. 907**
- Decreased peristalsis and muscle tone in the urinary system, coupled with a reduction in the glomerular filtration rate. l**p. 987**
- Functional impairment of the reproductive system, which eventually becomes inactive when menopause or the male climacteric occurs.

l**pp. 1066–1067**

- **FIGURE 29–1** Fertilization. **(a)** An oocyte and numerous sperm at the time of fertilization. Notice the difference in size between the gametes.

(b) Fertilization and the preparations for cleavage.

- **FIGURE 29–2** Cleavage and Blastocyst Formation
- **FIGURE 29–3** Stages in Implantation
- **FIGURE 29–4** The Inner Cell Mass and Gastrulation
- **FIGURE 29–5** Extraembryonic Membranes and Placenta Formation
- **FIGURE 29–6** A Three-Dimensional View of Placental Structure. **(a)** A view of the uterus after the embryo has been removed and the umbilical cord cut. Arrows in the enlarged view indicate the direction of blood flow. Blood flows into the placenta through ruptured maternal arteries and then flows around chorionic villi, which contain fetal blood vessels. **(b)** A cross section through a chorionic villus, showing the syncytial trophoblast exposed to the maternal blood space.
- **FIGURE 29–7** The First Trimester. **(a)** An SEM of the superior surface of a monkey embryo at 2 weeks of development. A human embryo at this stage would look essentially the same. **(b–d)** Fiber-optic views of human embryos at 4, 8, and 12 weeks. For actual sizes, see *Figure 29–13*,

p. 1096. ATLAS: Plate 90a

- **FIGURE 29–8** The Second and Third Trimesters. **(a)** A four-month-old fetus, seen through a fiber-optic endoscope. **(b)** Head of a six-month-old fetus, seen through ultrasound. ATLAS: Plate 90b
- **FIGURE 29–9** Growth of the Uterus and Fetus. **(a)** Pregnancy at 16 weeks, showing the positions of the uterus, fetus, and placenta.

(b) Pregnancy at three months to nine months (full term), showing the superior-most position of the uterus within the abdomen. **(c)** Pregnancy at full term. Note the positions of the uterus and full-term fetus within the abdomen, and the displacement of abdominal organs; compare with **(d)**, a sectional view through the abdominopelvic cavity of a woman who is not pregnant.

- **FIGURE 29–10** Factors Involved in the Initiation of Labor and Delivery
- **FIGURE 29–11** The Stages of Labor
- **FIGURE 29–12** The Milk Let-Down Reflex
- **FIGURE 29–13** Growth and Changes in Body Form and Proportion. The views at 4, 8, and 16 weeks of gestation are presented at actual size. Notice the changes in body form and proportions as development proceeds. Such changes do not stop at birth. For example, the head, which contains the brain and sense organs, is relatively large at birth.
- **FIGURE 29–14** A Human Karyotype. The 23 pairs of somatic-cell chromosomes from a normal male.
- **FIGURE 29–15** Predicting Phenotypic Characters by Using Punnett Squares. **(a)** All the offspring of a homozygous dominant father (*AA*) and a homozygous recessive mother (*aa*) will be heterozygous (*Aa*) for that trait. Their phenotype for the trait will be the same as that of the father.

(b) The offspring of a heterozygous father (*Aa*) and a homozygous recessive mother (*aa*) will be either heterozygous or homozygous for the recessive trait. In this example, half the offspring will have normal skin color, and the other half will be albinos.

- **FIGURE 29–16**

The Major Forms of Inheritance

- **FIGURE 29–17** Crossing Over and Translocation. **(a)** Synapsis, with the formation of a tetrad during meiosis. **(b)** Crossing over of homologous portions of two chromosomes. **(c)** The breakage and exchange of corresponding sections on the chromosomes in part (b).
- **FIGURE 29–18** Inheritance of an X-Linked Trait. Because they have two X chromosomes, females with a dominant normal allele on at least one X chromosome will have normal phenotypes. By contrast, a male with an X chromosome bearing a recessive allele for a genetic disorder will develop that disorder (in this case, red–green color blindness). Thus recessive alleles on X chromosomes produce genetic disorders in males at a higher frequency than in females.
- **FIGURE 29–19** A Map of Human Chromosomes. The banding patterns of typical chromosomes in a male, and the locations of the genes responsible for specific inherited disorders. The chromosomes are not drawn to scale.

Five Supplements Are Included with Your New Textbook!

These media and print supplements are referenced throughout the chapters of your textbook. The references are called out with distinctive designs and colors for easy integration with your studies.

InterActive Physiology® CD-ROM

This award-winning tutorial software program for physiology uses detailed animations and engaging quizzes to help you learn the most difficult concepts in your A&P course.

Anatomy 360º™ CD-ROM

Featuring highly realistic, rotatable images with a wide variety of interactive exercises and self-review questions, this engaging anatomy media program will guide you through hundreds of anatomy terms, locations, and concepts.

Student Access Kit for MyA&P™ online resource center and The Anatomy & Physiology Place companion website

The access code in this kit opens the door to the one-stop location for all of the great media available with this program. If your instructor does not have a Course ID for MyA&P, you may use the same access code to register instead for The Anatomy & Physiology Place companion website.

Martini’s Atlas of the Human Body

Spiral bound for ease of use and in full color, the atlas contains vivid anatomical photographs, radiological images, and embryology summaries.

A&P Applications Manual

This guide includes clinical topics — such as disorders, diagnostics, and case studies — related to the chapter content.

Get the Kit!

TO ACTIVATE YOUR PRE-PAID SUBSCRIPTION TO MyA&P:

1. Locate the MyA&P Student Access Kit that came packaged with your Benjamin Cummings textbook.

2. Ask your instructor for the Course ID.*

3. Go to: www.myaandp.com

4. Click "Student Registration" and follow the on-screen instructions, referring to the MyA&P Student Access Kit booklet, as needed.

*** If your instructor does not provide you with a Course ID for the MyA&P site, you can instead access the companion website to *Fundamentals of Anatomy & Physiology*, Seventh Edition. Go to www.anatomyandphysiology.com select your textbook, and follow the on-screen instructions for accessing The Anatomy & Physiology Place.**

The same code includes access to The Anatomy & Physiology Place companion website!

RAISE YOUR TEST SCORES WITH POWERFUL STUDY TOOLS FROM MyA&P

With your purchase of a new copy of Martini's ***Fundamentals of Anatomy & Physiology*, Seventh Edition,** you received a Student Access Kit for MyA&P. The kit contains instructions and a code for you to access MyA&P online.

If you did not purchase a new textbook or cannot locate the Student Access Kit and would like to access MyA&P, you may purchase your subscription online with a major credit card. Go to www.myaandp.com and click “Student Registration” and then “Purchase Online Access.”

WHAT IS MyA&P?

MyA&P is your one-stop online location for accessing the great media that will help you increase your understanding of anatomy & physiology and raise your test scores.

Turn the page to learn more about MyA&P!

Your convenient online MAP to

SELF-STUDY QUIZZES

We’ve done the work for you!

Easy to navigate Chapter Contents organize the following media tools to coincide with the chapter topics in Martini’s ***Fundamentals of Anatomy & Physiology*****, Seventh Edition.**

DOZENS OF INTERACTIVE EXERCISES

REAL-WORLD CASE STUDIES

MEDIA LIBRARY

all of the most trusted, successful media resources for A&P!

INTERACTIVE PHYSIOLOGY®

Tutorials and animations from *InterActive Physiology*® continue to help thousands of students advance beyond memorization to a genuine understanding of complex topics. And now, students can assess their comprehension of IP topics with new IP quizzes. Assigned by instructors, these quizzes are available through the Assessment Manager, and results can be recorded in the instructor's grade book.

ANATOMY 360°™

New Anatomy 360°™ media program helps students learn hundreds of anatomy terms, locations, and concepts.The program features accurate, high-quality, rotatable images, engaging interactive exercises, and self-review questions.

LIVE TUTOR CENTER

Experienced instructors are available 5 days a week to provide tutoring services via internet whiteboard, email, telephone, and fax.

Included at no additional charge!

ADDITIONAL RESOURCES FOR INSTRUCTORS

The Instructor Access Kit provides convenient links to the entire Test Bank, the Instructor's Manual, and all of the electronic art files for the text. For each chapter instructors can also assign a graded test, which can be recorded in the instructor's grade book.

INFORMATION FOR INSTRUCTORS

Choose from 2 ways to access online resources

As illustrated in the preceding pages, MyA&P organizes all of the most trusted, successful media resources for anatomy & physiology in one convenient online location. Students and instructors can easily access over 100 tutorials and animations, dozens of interactive learning activities and self-assessment quizzes, the *InterActive Physiology*® and Anatomy 360°™ media products, and much more. All of the content is organized into easy-to-navigate Chapter Contents that follow the presentation of topics within each chapter of

Martini's ***Fundamentals of Anatomy & Physiology,* Seventh Edition.** And, best of all, MyA&P is fully customizable, offering the ultimate in flexibility for creating your own online course with the best technology available.

IMPORTANT: After registration and course creation, you will receive a Course ID (specific to your course). **Your students MUST have this Course ID to access MyA&P. Please distribute this Course ID to your students.**

The Anatomy & Physiology Place (the companion web-site formerly known as "Martini Online") is a dynamic online review and reference tool that extends the three-level learning system from the end-of-chapter material in the textbook. Featuring 60–100 quiz questions per chapter, the site also includes case studies, tutorials, flashcards, and a glossary.

IMPORTANT: Please advise your students to follow the instructions for accessing The Anatomy & Physiology Place companion website.Your students will not need a Course ID unless you create a MyA&P course.

Get the Kit and Start Today!

Locate the Instructor Access Kit that is packaged with your professional copy of this textbook.To access either the MyA&P online resource center or The Anatomy & Physiology Place companion website, you will need the access code in this kit. Contact your Benjamin Cummings sales rep if you don't have a professional copy of the textbook or the accompanying Instructor Access Kit.

For access you will also need a valid email address and your school's zip code.

Text and Illustration Team

Frederic (Ric) H. Martini, Ph.D.

Author

Dr. Frederic H. Martini received his Ph.D. from Cornell University in comparative and functional anatomy for work on the comparative pathophysiology of stress. His publications include journal articles, technical reports, magazine articles, and a book for naturalists about the biology and geology of tropical islands. He is the coauthor of seven other undergraduate texts on anatomy and physiology or anatomy. He is on the faculty of the University of Hawaii— Hilo and remains affiliated with the Shoals Marine Laboratory, a joint venture between Cornell University and the University of New Hampshire. Dr.

Martini is President-Elect of the Human Anatomy and Physiology Society, and he is a member of the American Physiological Society, the American Association of Anatomists, the Society for Integrative and Comparative Biology, the Western Society of Naturalists, and the International Society of Vertebrate Morphologists.

William C. Ober, M.D.

Art Coordinator and Illustrator

Dr. William C. Ober received his undergraduate degree from Washington and Lee University and his

M.D. from the University of Virginia. While in medical school, he also studied in the Department of Art as Applied to Medicine at Johns Hopkins University. After graduation, Dr. Ober completed a residency in Family Practice and later was on the faculty at the University of Virginia in the Department of Family Medicine. He is an Instructor in the Division of Sports Medicine at the University of Virginia and is part of the Core Faculty at Shoals Marine Laboratory, where he teaches Biological Illustration every summer. The textbooks illustrated by his company, Medical & Scientific Illustration, have won numerous design and illustration awards.

Claire W. Garrison, R.N.

Illustrator

Claire W. Garrison, R.N., B.A., practiced pediatric and obstetric nursing before turning to medical illustration as a full-time career. She returned to school at Mary Baldwin College, where she received her degree with distinction in studio art. Following a five-year apprenticeship, she has worked as Dr. Ober's partner in Medical & Scientific Illustration since 1986. She is on the Core Faculty at Shoals Marine Laboratory and co-teaches the Biological Illustration course with Dr. Ober.

Kathleen Welch, M.D.

Clinical Consultant

Dr. Kathleen Welch received her M.D. from the University of Washington in Seattle and did her residency at the University of North Carolina in Chapel Hill. For two years, she served as Director of Maternal and Child Health at the LBJ Tropical Medical Center in American Samoa and subsequently was a member of the Department of Family Practice at the Kaiser Permanente Clinic in Lahaina, Hawaii. She has been in private practice since 1987. Dr. Welch is a Fellow of the American Academy of Family Practice and a member of the Hawaii Medical Association, the Maui County Medical Society, and the Human Anatomy and Physiology Society. She is coauthor of the *A&P Applications Manual* and an undergraduate textbook on health and disease.

Ralph T. Hutchings

Biomedical Photographer

Ralph T. Hutchings was associated with the Royal College of Surgeons for 20 years. An engineer by training, he has focused for years on photographing the structure of the human body. The result has been a series of color atlases, including the *Color Atlas of Human Anatomy*, the *Color Atlas of Surface Anatomy*, and *The Human Skeleton* (all published by Mosby-Yearbook Publishing). For his anatomical portrayal of the human body, the International Photographers Association has chosen Mr. Hutchings as the best photographer of humans in the twentieth century. He lives in North London, where he tries to balance the demands of his photographic assignments with his hobbies of early motor cars and airplanes.

Brief Contents

UNIT 1:LEVELS OF ORGANIZATION

Chapter 1 An Introduction to Anatomy and Physiology 3
Chapter 2 The Chemical Level of Organization 26
Chapter 3 The Cellular Level of Organization 62
Chapter 4 The Tissue Level of Organization 106

UNIT 2:SUPPORT AND MOVEMENT

Chapter 5 The Integumentary System 153

Chapter 6 Osseous Tissue and Bone Structure 179

Chapter 7 The Axial Skeleton 205

Chapter 8 The Appendicular Skeleton 238

Chapter 9 Articulations 258

Chapter 10 Muscle Tissue 283

Chapter 11 The Muscular System 326

UNIT 3:CONTROL AND REGULATION

Chapter 12 Neural Tissue 379

Chapter 13 The Spinal Cord, Spinal Nerves, and Spinal Reflexes 421

Chapter 14 The Brain and Cranial Nerves 451

Chapter 15 Neural Integration I: Sensory Pathways and the Somatic Nervous System 495

Chapter 16 Neural Integration II: The Autonomic Nervous System and Higher-Order Functions 517

Chapter 17 The Special Senses 549

Chapter 18 The Endocrine System 590

UNIT 4:FLUIDS AND TRANSPORT

Chapter 19 Blood 639

Chapter 20 The Heart 669

Chapter 21 Blood Vessels and Circulation 708

Chapter 22 The Lymphatic System and Immunity 763

UNIT 5:ENVIRONMENTAL EXCHANGE

Chapter 23 The Respiratory System 813

Chapter 24 The Digestive System 862

Chapter 25 Metabolism and Energetics 915

Chapter 26 The Urinary System 951

Chapter 27 Fluid, Electrolyte, and Acid–Base Balance 994

UNIT 6:CONTINUITY OF LIFE

Chapter 28 The Reproductive System 1029
Chapter 29 Development and Inheritance 1074 Contents

Preface xxx

UNIT 1:LEVELS OF ORGANIZATION

Chapter 1

An Introduction to Anatomy and Physiology 3
An Introduction to Studying the Human Body 4
The Relationship between Anatomy and Physiology 4
Anatomy 5
Physiology 5
Levels of Organization 6
Homeostasis 11
The Role of Negative Feedback in Homeostasis 12
Systems Integration, Equilibrium,
and Homeostasis 14
Frames of Reference for Anatomical Studies 15
Superficial Anatomy 15
Sectional Anatomy 18
Body Cavities 19
Chapter Review 23

Chapter 2

The Chemical Level of Organization 26
Atoms, Molecules, and Bonds 27
Atomic Structure 27
Chemical Bonds 30
Chemical Notation 34
Chemical Reactions 35

Basic Energy Concepts 35

Types of Chemical Reactions 35

Reversible Reactions 36

Enzymes, Energy, and Chemical Reactions 36

Inorganic Compounds 37

Water and its Properties 37

Inorganic Acids and Bases 41

Salts 41

Buffers and pH Control 41

Organic Compounds 42

Carbohydrates 42

Lipids 44

Proteins 49

Nucleic Acids 54

High-Energy Compounds 56

Chemicals and Cells 57

Chapter Review 58

Chapter 3

The Cellular Level of Organization 62

An Introduction to Cells 63

The Cell Membrane 63

Membrane Lipids 66

Membrane Proteins 66

Membrane Carbohydrates 67

The Cytoplasm 68

The Cytosol 68

The Organelles 68

The Nucleus 77

Contents of the Nucleus 78
Information Storage in the Nucleus 79
Gene Activation and Protein Synthesis 80
How the Nucleus Controls Cell Structure and Function 84
How Things Get Into and Out of Cells 84
Diffusion 85
Carrier-Mediated Transport 89
Vesicular Transport 92
The Transmembrane Potential 94
The Cell Life Cycle 95
Interphase 95
Mitosis 96
Cytokinesis 98
The Mitotic Rate and Energy Use 98
Regulation of the Cell Life Cycle 99
Cell Division and Cancer 99
Cell Diversity and Differentiation 100
Chapter Review 101

Chapter 4
The Tissue Level of Organization 106
Tissues of the Body: An Introduction 107
Epithelial Tissue 107
Functions of Epithelial Tissue 107
Specializations of Epithelial Cells 108
Maintaining the Integrity of Epithelia 108
Classification of Epithelia 111
Glandular Epithelia 114
Connective Tissues 118

Classification of Connective Tissues 118

Connective Tissue Proper 119

Fluid Connective Tissues 123

Supporting Connective Tissues 125

Membranes 129

Mucous Membranes 129

Serous Membranes 129

The Cutaneous Membrane 130

Synovial Membranes 131

The Connective Tissue Framework of the Body 131

Muscle Tissue 132

Skeletal Muscle Tissue 132

Cardiac Muscle Tissue 134

Smooth Muscle Tissue 134

Neural Tissue 134

Tissue Injuries and Repair 135

Inflammation and Regeneration 135

Aging and Tissue Structure 137

Aging and Cancer Incidence 137

Chapter Review 138

SYSTEMS OVERVIEW 142

UNIT 2:SUPPORT AND MOVEMENT

Chapter 5

The Integumentary System 153

The Integumentary System:

An Overview 154

The Epidermis 155

Layers of the Epidermis 155

The Basis of Skin Color 158

The Epidermis and Steroid Production 159

The Roles of Epidermal Growth Factor 161

The Dermis 161

Dermal Organization 161

The Subcutaneous Layer 163

Accessory Structures 164

Hair and Hair Follicles 164

Glands in the Skin 167

Nails 169

The Response of the Integument to Injury 170

Repair of Localized Injuries to the Skin 170

Aging and the Integumentary System 173

Integration with Other Systems 174

Clinical Patterns 174

Chapter Review 174

Chapter 6

Osseous Tissue and Bone Structure 179

An Introduction to the Skeletal System 180

The Gross Anatomy of Bones 180

Bone Shapes 180

Bone Markings (Surface Features) 181

Bone Structure 183

Bone Histology 183

The Matrix of Bone 184

The Cells of Bone 184

The Structure of Compact Bone 185

The Structure of Spongy Bone 185

The Periosteum and Endosteum 188
Bone Formation and Growth 189
Endochondral Ossification 189
Intramembranous Ossification 192
The Blood and Nerve Supplies 193
The Dynamic Nature of Bone 194
Effects of Exercise on Bone 194
Hormonal and Nutritional Effects on Bone 194
The Skeleton as a Calcium Reserve 196
Fracture Repair 198
Aging and the Skeletal System 199
Types of Fractures 200
Chapter Review 201

Chapter 7

The Axial Skeleton 205
The Axial Division of the Skeletal System 206
The Skull 206
The Individual Bones of the Skull 212
Summary: Foramina and Fissures of the Skull 220
The Orbital and Nasal Complexes 220
The Skulls of Infants and Children 222
The Vertebral Column 224
Spinal Curvature 224
Vertebral Anatomy 225
Vertebral Regions 226
The Thoracic Cage 231
The Ribs 233
The Sternum 234

Chapter Review 235

Chapter 8

The Appendicular Skeleton 238

The Pectoral Girdle and Upper Limbs 240

The Pectoral Girdle 240

The Upper Limbs 242

The Pelvic Girdle and Lower Limbs 245

The Pelvic Girdle 245

The Lower Limbs 249

Individual Variation in the Skeletal System 253

Chapter Review 255

Chapter 9

Articulations 258

The Classification of Joints 259

Synarthroses (Immovable Joints) 260

Amphiarthroses (Slightly Movable Joints) 260

Diarthroses (Freely Movable Joints) 260

Form and Function of Synovial Joints 263

Describing Dynamic Motion 263

Types of Movements at Synovial Joints 264

A Structural Classification of Synovial Joints 267

Representative Articulations 269

Intervertebral Articulations 269

The Shoulder Joint 272

The Elbow Joint 273

The Hip Joint 274

The Knee Joint 276

Aging and Articulations 278
Integration with Other Systems 278
Clinical Patterns 278
Chapter Review 280

Chapter 10

Muscle Tissue 283
Skeletal Muscle Tissue and the Muscular System 284
Functional Anatomy of Skeletal Muscle 284
Organization of Connective Tissues 284
Blood Vessels and Nerves 285
Skeletal Muscle Fibers 286
Sliding Filaments and Muscle Contraction 291
The Contraction of Skeletal Muscle 292
The Control of Skeletal Muscle Activity 293
Excitation–Contraction Coupling 295
Relaxation 298
Tension Production 300
Tension Production by Muscle Fibers 300
Tension Production by Skeletal Muscles 304
Energy Use and Muscular Activity 308
ATP and CP Reserves 309
ATP Generation 309
Energy Use and the Level of Muscular Activity 310
Muscle Fatigue 310
The Recovery Period 312
Hormones and Muscle Metabolism 312
Muscle Performance 313
Types of Skeletal Muscle Fibers 313

Muscle Performance and the Distribution of Muscle Fibers 314
Muscle Hypertrophy and Atrophy 314
Physical Conditioning 315
Cardiac Muscle Tissue 316
Structural Characteristics of Cardiac Muscle Tissue 316
Functional Characteristics of Cardiac Muscle Tissue 317
Smooth Muscle Tissue 318
Structural Characteristics of Smooth Muscle Tissue 319
Functional Characteristics of Smooth Muscle Tissue 319
Chapter Review 321

Chapter 11

The Muscular System 326
Muscle Organization and Function 327
Organization of Skeletal Muscle Fibers 327
Levers 328
Muscle Terminology 330
Origins and Insertions 330
Actions 330
Names of Skeletal Muscles 331
Axial and Appendicular Muscles 333
The Axial Muscles 336
Muscles of the Head and Neck 336
Muscles of the Vertebral Column 344
Oblique and Rectus Muscles 346
Muscles of the Pelvic Floor 348
The Appendicular Muscles 350
Muscles of the Shoulders and Upper Limbs 351
Muscles of the Pelvis and Lower Limbs 363

Aging and the Muscular System 371
Integration with Other Systems 372
Chapter Review 374

UNIT 3:CONTROL AND REGULATION

Chapter 12

Neural Tissue 379
An Overview of the Nervous System 380
The Anatomical Divisions of the Nervous System 380
The Functional Divisions of the Nervous System 380
Neurons 380
The Structure of Neurons 381
The Classification of Neurons 383
Neuroglia 384
Neuroglia of the Central Nervous System 384
Neuroglia of the Peripheral Nervous System 387
Neural Responses to Injuries 387
Ion Movements and Electrical Signals 390
The Transmembrane Potential 390
Changes in the Transmembrane Potential 394
Graded Potentials 396
Action Potentials 398
Synaptic Activity 404
General Properties of Synapses 404
Cholinergic Synapses 405
The Activities of Other Neurotransmitters 408
Neuromodulators 408
How Neurotransmitters and Neuromodulators Work 409
Information Processing by Individual Neurons 412

Postsynaptic Potentials 412
Presynaptic Inhibition and Presynaptic Facilitation 414
The Rate of Generation of Action Potentials 415
Chapter Review 416

Chapter 13
The Spinal Cord, Spinal Nerves, and Spinal Reflexes 421
General Organization of the Nervous System 422
Gross Anatomy of the Spinal Cord 423
Spinal Meninges 425
Sectional Anatomy of the Spinal Cord 427
Spinal Nerves 429
Peripheral Distribution of Spinal Nerves 430
Nerve Plexuses 431
Principles of Functional Organization 437
Neuronal Pools 438
An Introduction to Reflexes 439
Spinal Reflexes 441
Monosynaptic Reflexes 441
Polysynaptic Reflexes 443
Integration and Control of Spinal Reflexes 445
Voluntary Movements and Reflex Motor Patterns 445
Reinforcement and Inhibition 445
Chapter Review 447

Chapter 14
The Brain and Cranial Nerves 451
An Introduction to the Organization of the Brain 452
A Preview of Major Regions and Landmarks 452

Embryology of the Brain 452

Ventricles of the Brain 453

Protection and Support of the Brain 455

The Cranial Meninges 455

Cerebrospinal Fluid 456

The Blood Supply to the Brain 458

The Medulla Oblongata 459

Preface

TO THE INSTRUCTOR

You may or may not be familiar with earlier editions of this book, so I will focus on things that I'd want to know if I were considering a text for use in one of my classes.

What Sets This Text Apart from the Others?

I have often heard people say, "All A&P books are the same." Well, certainly the available texts are about the same size and length, and they all have a similar organization, feature colorful illustrations, and include an assortment of supplements. But they differ widely in the way they organize information and present complex concepts. I will cite four specifics that set this text apart from all that are available:

#1: The Consistent and Highly-Effective Art Program

Most texts are illustrated by a dozen or more different artists and studios, all working in relative isolation. There are no common conventions, no consistent presentation or theme. This is the only text that has all of the art done by a pair of medical illustrators—William C. Ober, M.D., and Claire W. Garrison, R.N. (see the biographical notes on p. vii). Bill and Claire have worked with me since the start of the First-Edition illustration program in 1986. They know the material, they know the text, and, as they work, they know how they will illustrate related topics in later chapters. As a result, the art flows as smoothly as the text. Please turn to the Visual Introduction (pp. xxiv–xxxiv) for an illustrated tour of the art program, including details on how figures have been enhanced for the Seventh Edition.

#2: The Clear and Direct Narrative Style

I believe that it is important to organize material so that it can easily be studied, understood, and reviewed for exams. This is not a novel that will be read for fun. This textbook is a resource that helps students accomplish a specific task—mastering the material—as efficiently as possible. The narrative in this new edition has been revised with special attention paid to those features that have proven to aid in the actual learning process:

- Overviews that help students see the big picture
- Navigator Figures that provide a road map through complex discussions
- Lists that make it easier to organize information and focus on key facts and concepts
- Tables that summarize information concisely, in a format that makes it easy to memorize when memorization is required

#3: The Thorough and Time-Saving Pedagogical Framework

This focus on the needs of students is reflected in many pedagogical devices used throughout the text:

- Students can check their progress periodically by answering short Concept Check questions at the ends of major sections.
- When material relates to topics presented earlier, Concept Links signaled with icons l provide specific page numbers that facilitate review.
- The end-of-chapter Study Outlines are unusually comprehensive.
- The end-of-chapter Review Questions are organized in increasing levels of difficulty and sophistication, so that students can test their mastery first of facts and terminology, then of concepts, and finally of critical thinking and clinical applications.
- A new feature called 100 Keys has been added. These are basic concepts and principles that I would like students to remember five years after the course is

over, regardless of their ultimate career paths. Signaled with icons, the keys are factual statements that function as organizers of central information in A&P.

#4: The Helpful and Practical Ancillaries Provided with the Text

Today, no single text, no matter how good or how comprehensive, can provide all the resources that students should be able to draw on for help in mastering this demanding subject. Accordingly, this book has been designed as the central component of a fully integrated learning system that includes both media and print components. The complete package includes five additional components, all of which are automatically packaged with new copies of the text:

- ***InterActive Physiology® CD-ROM***, a media program that has helped thousands of students improve their grades in A&P with animations, tutorials, and quizzes to teach the most difficult physiological concepts.
- The ***A&P Applications Manual***, organized to parallel the text, and including discussions of clinically important disorders for each of the body's organ systems, together with information about the relevant diagnostic techniques, laboratory tests, and treatment options.
- ***Martini's Atlas of the Human Body***, expanded and enhanced, now with 252 photographs, clinical images, and scans, including anatomical photographs by Ralph T. Hutchings, a renowned biomedical photographer.

- **New *Anatomy 360 ™ CD-ROM***, featuring three-dimensional rotatable and layered visualizations derived from the Visible Human Project, along with labeling activities, interactive exercises, and self-review questions.
- ***A Student Access Kit*** for ***MyA&P™***, an online resource site where students will find a variety of interactive exercises and self-quizzes for each chapter.

All of these components are completely integrated with the text through icons and specific references that appear both within the chapters and in the Chapter Reviews. More complete descriptions appear in the Visual Introduction section (pp. xxiv–xxxiv).

What’s Different about the Seventh Edition?

The basic chapter sequence and organization of the text remain largely unchanged. However, you will find several new organizational features within the narrative, as well as refinements to (and more generous use of) features that have been highly praised by students and instructors, including Navigator Figures, the Systems Overview section, and integrative sections that discuss the interactions among the various organ systems.

#1: Improvements to Text Readability

A thorough and complete line-by-line edit was applied to the entire book to tighten the writing and improve the consistency and coordination between the text prose and the art figures. The combination of more succinct writing, a noticeably larger text font size, and a fresh clear, and open design provides students with a more inviting, “readable” textbook.

#2: Enhancements to the Art Program

Bill Ober and Claire Garrison have made substantial improvements to the already superb art program of previous editions. Virtually every figure has been altered to some degree to make the use of colors, arrow conventions, and design features consistent at all levels. Please turn to the Visual Introduction (pp. xxiv–xxxiv) for an illustrated overview of the upgraded “Stepped” Art Figures, Macro-to-Micro Views, Compound Art, and Navigator figures.

#3: Re-Organization of the Clinical Material

The clinical material has been further integrated within the text to increase its pedagogical value. Short Clinical Notes deal with pathologies that shed light on the principles of normal physiological function. Longer, boxed versions of the Clinical Notes deal with topics of particular medical or social importance (such as cancer and AIDS) that require more extended exploration.

The revised *A&P Application Manual* contains an abundance of supplementary clinical material, including a number of topics that were previously included in the text. It includes authoritative discussions of a broad range of diseases with extensive information about relevant laboratory tests, diagnostic procedures, and treatments. With an organization that parallels the text, system by system and chapter by chapter, the *A&P Application Manual* can be used as a supplement to the text, as a reference, or as a resource for those students who want to learn more about clinical topics. See the Visual Introduction (pp. xxiv–xxxiv) for an illustrated presentation of the clinical material in the program.

#4: Improved Pedagogy and Media References

Along with the new 100 Keys feature (see page xxvi in the Visual Introduction), new labels and design improvements have been added to the Concept Check, Clinical Notes, Systems Overview, and System in Perspective features. The Seventh Edition makes it easier than ever to connect the two accompanying CD-ROMs and the website with the core material in the text. The *InterActive Physiology*® CD-ROM, Anatomy 360 ™. CDROM, the MyA&P™ online course management system and website are referenced with distinctive icons at appropriate points throughout the book.

To let me know what you think of the Seventh Edition or give suggestions to be considered for the Eighth Edition, please e-mail me at the following address.

Frederic H. Martini
martini@maui.net

TO THE STUDENT

How to Get the Most Out of This Program

You probably have several reasons for taking this course. You might have questions about your own body and its functions. You may be curious about the origins of health problems or diseases. Perhaps you need a course in anatomy and physiology to further your career plans.

If you are like most college students, you have two short-term goals in mind: (1) to learn and understand the material, and (2) to be able to demonstrate your mastery to the satisfaction of the instructor. I've tried to build features into the text that will help you reach both of these goals. In many respects, I've assembled this text like an owner's manual for the human body—it not only has the important information, but it is also designed to help you find that information quickly. As a result, you may find that it is different from the texts you've used for other classes. In this section, I've tried to give you some advice on how to use the features and unique organization of this text to your advantage. If you charge off into the text without reading further, you may miss some suggestions that could help you succeed.

Learn the Terminology

You will find that there are a lot of new words to learn. The faster you can learn the terminology, the easier it will be for you to master the concepts. Throughout the text, the most important terms appear in **boldface** print so they are easy to spot. Any time there's a chance of confusion regarding how a new term is pronounced, I've included a pronunciation guide. Accented syllables are in capital letters, and for the vowels:

as in tray	a as in track
as in tree	e as in help
as in spine	i as in ink
as in bone	o as in Tom
as in use	u as in run

Witch the Big Picture

Although there is a lot of detailed information in anatomy and physiology, don't lose sight of the big picture.

. • Each chapter begins with an *outline*. Use it to get a sense of the scope and organization of the chapter as a whole.

. • Each of the major sections in the chapter starts with a list of Objectives. The list will give you a preview of the main points that you can expect to learn as you work through the material in the section.

- Many of the chapters include Navigator Figures, clearly labeled as such, which function as a kind of road map. Use them to help keep track of where you are in a complex discussion without getting lost in the details.
- Many of the chapters include Summary Tables that integrate large blocks of information in a format that makes the material easier to review. Make sure you understand the information before moving ahead in the chapter.

Organize Important Information

You’ve got to have a study plan and a method of organizing your notes. Don’t try to memorize everything. Organize the material, focus on the key points, and look for common themes and patterns.

- Take advantage of the many lists in the text as well as the abundance of tables. Both of these formats summarize important information in a way that will make it easier for you to grasp and memorize.
- The material in each chapter builds on the material presented in earlier chapters. Often you will want to review the relevant discussions. To make this easier, I’ve inserted a symbol with a page reference: l **p. 000**. To help you proceed directly to the proper page, you will find that the page numbers appear in bold in the upper margin of each page of narrative, or at the bottom margin of each page of artwork.

Keep an Eye on the Art

I’ve provided a lot of visual support in this package because, whether you are considering processes or structures, you need to be able to visualize what’s being described in the narrative.

- There are a LOT of illustrations in the text, and I work closely with the artists, an M.D. and an R.N., who review the text before creating the images. Because the text and art are developed together, you will find yourself moving back and forth between the text and the art as you read the chapter. At each spot in the narrative where you are sent to the art, a red dot serves as a place holder—use it to help you find your way back to the point in the text that you left.

- Many of the figures show dynamic processes underway in a series of steps; these same steps are also clearly identified and explained in the narrative. Breaking a complex process into stages is one way to make it easier to follow and understand.
- Some figures are accompanied by an ATLAS citation, which directs you to another view of the same structure in *Martini's Atlas of the Human Body*, packaged with your text. You'll find that looking at a single anatomical feature from different perspectives or visualized using different techniques is a powerful way of enhancing your understanding of what you are seeing.

Consider What the Information Means

You probably would not be taking this course if you did not have at least some interest in health and medicine. The text and its ancillaries contain a wealth of clinical material, organized so that you can easily focus on precisely what is relevant to your own or your instructor's concerns:

- Short Clinical Notes embedded in the text deal with many kinds of pathologies. These topics have been selected to help you understand the principles of normal function by showing what happens when something goes wrong.
- Topics of great general importance or that require more extended treatment are considered in longer boxed Clinical Notes.
- Information about a variety of diseases not discussed in the text, as well as additional details about many that are, can be found in the *A&P Applications Manual* that came with your new text, together with information about the diagnosis and treatment of these conditions. The *A&P Applications Manual* is organized in exactly the same way as the text to make it as easy as possible for you to consult. Use it as a supplement to the text, as a reference, or just to satisfy your individual curiosity. Look for the red icon, AM, that will direct you to relevant topics in the *A&P Applications Manual*.

Put It All Together

The human body is an integrated whole, not a collection of isolated systems, so it's important that you be able to see information pertaining to specific systems in a larger context.

- For each body system, you'll find a System in Perspective art figure that focuses on its interactions with every other body system and outlines relevant clinical aspects of the system. These figures can be an important part of your study, because they integrate the contents of the entire book.
- You will find 100 important concepts and principles flagged in the text. These concepts are identified by the icon . Commit the 100 Keys to long-term memory, as many of them will prove useful in your studies as well as in your daily life.

Pace Yourself

It is usually a bad idea to read a chapter in this textbook as if it were a chapter in a novel—from beginning to end, with no breaks. It's much more efficient to pace yourself and take a few pauses along the way to test your understanding of the material presented thus far. You are building your knowledge base, and there's no use reading the *next* section until you understand what was covered in *this* section.

- At the end of each major section, you will find a few short review questions in the Concept Check section. Take a moment to answer them. If you find them easy to answer, you can go on to the next section. If you find them difficult to answer, go back and reread the material. It's like building a house—it's not wise to start working on the second floor if the first floor is shaky.
- Throughout the chapter are references to tutorials or three-dimensional anatomical views on the *InterActive Physiology® CD-ROM* or the Anatomy 360 ™ CD-ROM, which are packaged with your text. Don't hesitate to take advantage of these resources if you feel that you need to reinforce or deepen your understanding of the material you have just covered.

Review the Chapter after You Complete It

It might take you a week to work through a chapter, and by the time you reach the end, you may not have a clear perspective on the presentation as a whole. That's the time to review the end-of-chapter material.

- The Study Outline at the end of each chapter gives you an opportunity to review all the chapter's key information and concepts. You can also use it as a jumping-off point for the CD-based tutorials and visualizations referenced within the chapter (*InterActive Physiology*® and Anatomy 360 ™), because those references are repeated here.
- The Review Questions are organized so that you can assess your mastery of the chapter on three levels. You can test your grasp of facts and terminology (Level 1), your understanding of concepts (Level 2), and your ability to apply the material to realistic clinical situations (Level 3). If you need additional practice, there are more self-assessment quizzes in various formats at MyA&P (http://www.myaandp.com) or on the Anatomy and Physiology Place Website (www.anatomyandphysiology.com).

I wrote this book to give you the information you need as clearly as possible. If you find certain sections especially difficult, if you don't find information that you or your instructor would really like to cover, or if you have other comments or suggestions for future editions, please let me know using the e-mail address below.

Good luck and best wishes, Ric

martini@maui.net

Visual Introduction

THE ART PROGRAM

An Award-Winning Presentation of Anatomy & Physiology

Compound Art

pairs an artist's drawing with a photograph to encourage students to compare a detailed rendering with the "real thing" as they would see it in a laboratory.

Martini's Atlas of the Human Body is packaged with every new book, and references to it are marked with an "ATLAS."

Navigator Figures

present a “big picture” overview at the beginning of complex discussions and are repeated at appropriate intervals with specific details highlighted to break the material into smaller, clearer units.

NEW! Navigator Figures are now called out with a Navigator heading and a compass icon so students can clearly see that the figure relates to later figures.

“Stepped”Art Figures

break down multifaceted processes into step-by-step illustrations that coordinate with the author’s narrative descriptions.These easy-to-follow sequences in the book are also featured in the new Media Manager CD-ROMs for instructors to use in classroom presentations.

NEW! Re-designed “Stepped”Art Figures provide clearer step headings to help students follow the sequence of events.

Macro-to-Micro Views

bridge the gap between familiar and unfamiliar structures of the body by illustrating smaller anatomical structures within larger ones.A large-scale orienting image is followed by corresponding smaller-scale sectional views.

NEW! Macro-to-Micro Views have been substantially re-designed and re-arranged to present a more intuitive “flow,” and arrows are more strongly used to show progressions.

TEXT FEATURES

Save Time and Raise Test Scores!

NEW! 100 Keys

offer 100 important concepts and principles over the course of the chapters. Signaled with an icon, the Keys are factual statements that function as organizers of central information in anatomy & physiology.

Concept Check Questions
appear at the end of chapter sections and help students test their comprehension before moving on to the next topic.

Concept Links
are used when material relates to topics presented earlier and offer specific page numbers to facilitate review.

Figure Locator Dots
appear with every figure reference in the narrative and function as placeholders to help students return to reading after viewing a figure.

Learn Applications to the Real World!

An *A&P Applications Manual* that extends the clinical information in the chapters is packaged with every new book, and references to it are marked with an "AM."

Clinical Notes
present relevant clinical information throughout the text.Those embedded in the narrative deal with pathologies and their relation to normal physiological function, while the larger boxed versions address important medical or social topics.
NEW! Core clinical topics are now more prominent in the chapters.

Focus Boxes

include concentrated coverage of a particular topic with clear text explanations and many illustrations or photographs.

TEXT FEATURES

See the Big Picture!

Systems Overview Section

appears between Chapters 4 and 5—after the introductory material on chemical, cellular, and tissue levels of organization—to prepare students for the body systems chapters and to serve as a convenient "big picture" summary for easy reference.

System in Perspective Summaries

provide an excellent, illustrated review of the basic functions of each body system and help students understand that the body functions as an integrated unit rather than as a set of isolated, independent systems.

INSTRUCTOR SUPPLEMENTS

Dynamic Lectures in Half the Time!

NEW! Media Manager

combines all instructor and student media for ***Fundamentals of Anatomy & Physiology,*** **Seventh Edition** into the ultimate chapter-by-chapter resource.The package includes seven CDs plus a foldout Quick Reference Guide.The CDs contain all of the art from the book. A special collection of Precision Art has Figure Edit and Text Edit capabilities that allow instructors to customize the art and labels to the needs of their students. Other resources include powerful animations, three-dimensional images and movies, links to the *InterActive Physiology*® and Anatomy 360º ™ media programs, PowerPoint® lecture presentations, the Test Bank, and much more!

MEDIA MANAGER INCLUDES CUSTOMIZABLE ART!

Precision Art

lets you tailor the art from the book to your classroom needs in two ways:

Figure Edit art facilitates step-by-step presentation of complex topics.

Text Edit art allows you to edit terms and labels in the figure.

In addition to the features displayed on this screen, the Media Manager offers:

- All images from the text, in labeled, unlabeled, and leadered-only versions
- Over 120 animations
- More than 50 three-dimensional anatomical presentations with peel-away, flythrough, and panoramic views
- Chapter-specific links to the *InterActive Physiology* and Anatomy 360º media programs
- Active Lecture Questions, for in-class projection, that students can respond to using personal response systems (in H-ITT or PRS formats), for easy checking of comprehension
- An Additional Resources section, including MRI and CT Scans, Histology images, the Instructor's Manual, the *A&P Applications Manual*, and more.

INSTRUCTOR SUPPLEMENTS

Everything You Need to Teach Your Course Your Way

Transparency Acetates

package includes more than 800 high-quality acetates with all of the art from the text in enhanced colors with enlarged figure labels for use in lecture halls.

Instructor's Manual

includes lecture sugges tions, vocabulary aids, applications, and classroom demonstrations to help you prepare for the classroom.A chapter-by-chapter Quick Reference Guide of all available media helps you organize your presentations.

Test Bank and Computerized Test Bank

include more than 3,000 questions organized into the text's three-level learning system for designing a variety of tests and quizzes. Available in both a print version and TestGen software.

MyA&P,™ WebCT,™ and Blackboard

provide ready-to-as-sign materials in the most widely used course management systems. See the very beginning pages of this text for an overview of MyA&P. ™

Instructor's Visual Guide

lets you see all of the art and PowerPoint® slides that are available on the Media Manager CD-ROMs in a convenient printed reference guide that you can use when selecting visuals for classroom presentation.

STUDENT SUPPLEMENTS

A Superb Student Learning Package

Included with every new copy of the text:

- *InterActive Physiology*® CD-ROM
- Anatomy 360º ™ CD-ROM
- MyA&P™
- Martini’s Atlas of the Human Body
- A&P Applications Manual

See descriptions of these components on the inside front cover of this text.

Study Guide

by Charles Seiger provides additional review of basic facts and concepts and practice for developing problem-solving skills.A wide variety of questions, including labeling and concept mapping, are keyed to every learning objective in the textbook and are organized around the text’s three-level learning system.

ISBN: 0-8053-7294-6

The Anatomy Coloring Book

by Wynn Kapit and Lawrence M. Elson helps students memorize structures of the body by coloring in line drawings. Use of the coloring book sharpens concentration and increases attention to detail, thereby aiding students in retention of material.

ISBN: 0-8053-7282-2

FOR THE LAB

Manuals That Meet Your Needs

Benjamin Cummings publishes a variety of best-selling laboratory manuals to meet the diverse needs of lab courses.

Laboratory Manual for Anatomy & Physiology

by Michael G.Wood This full-color lab manual has been designed to complement F*undamentals of Anatomy & Physiology,* Seventh Edition and includes much of the same high-quality art by illustrators Bill Ober and Claire Garrison.

- . • Main Version,Third Edition ISBN: 0-8053-7368-3
- . • Cat Version,Third Edition ISBN: 0-8053-7369-1
- . • Pig Version,Third Edition ISBN: 0-8053-7370-5

Human Anatomy & Physiology Laboratory Manual

by Elaine N. Marieb

This full-color lab manual guides students through well-planned
lab activities to aid in mastery of the subject.

. • Main Version, Seventh Edition Update ISBN: 0-8053-5514-6

. • Cat Version, Eighth Edition Update ISBN: 0-8053-5516-2

. • Pig Version, Eighth Edition Update ISBN: 0-8053-5518-9

Integrate

Create your own A&P laboratory manual tailored to your specific needs on the Integrate database, which includes all of the Benjamin Cummings laboratory manuals from which you can select the individual laboratory exercises you want. Your own laboratory exercises can also be added to your custom-built laboratory manual.

Acknowledgments

This textbook is not the product of any single individual. It represents a group effort, and the members of the group deserve to be acknowledged.

Foremost on my thank you list are the instructors who reviewed the published text of the Sixth Edition and the manuscript for the Seventh Edition to offer the suggestions that helped guide me through the revision process. To them, I express my sincere thanks and best wishes:

Mary E. Allen-Martin, *San Antonio College*

Nishi Bryska, *University of North Carolina—Charlotte*

Sarah Caruthers Jackson, *Florida Community College—Jacksonville*

Clifford L. Fontenot, *Southeastern Louisiana University*

Karen Hart, *Peninsula College*

Martin F. Hicks, *Community College of Southern Nevada*

Bonnie Kalison, *Mesa Community College*

Marie L. Kotter, *Weber State University Circle*
Charles Matsuda, *Kapi'olani Community College*
Karen McCourt, *El Paso Community College*
Robert McMullen, *Pikes Peak Community College*
Colin A. Morris, *Pensacola Junior College*
Christopher Nicolay, *University of North Carolina—Asheville*
Amy Griffin Ouchley, *University of Louisiana—Monroe*
Chuck Robinson, *Mississippi Gulf Coast Community College*
Dee Sato, *Goldenwest College*
Tamara McNutt Scott, *Clemson University*
Robert R. Speed, *Wallace Community College*
Ralph W. Stevens III, *Old Dominion University*
Janis G. Thompson, D.V.M., *Lorain County Community College*
Don Wager, *Broome Community College*
Jyoti R. Wagle, *Houston Community College—Central*
David Ward, *Modesto Junior College*

After the initial drafts were completed, five dedicated instructors functioned as technical editors, assisting with the review and correction of page proofs. They have been immensely helpful to me during the revision of this edition:

Gillian Bice, *Michigan State University*
Kelly J. Johnson, *University of Kansas*
Alan Magid, *Durham Technical Community College*
Judi Nath, *Lourdes College*
Marilyn Shannon, *Indiana University—Purdue University Indianapolis*

Focus groups and meetings with students helped me concentrate on students' needs. Every day I receive e-mails from faculty members and students who have comments, questions, and suggestions. Their interest in the subject, concern for the accuracy and method of presentation, and wide range of abilities and backgrounds made the revision process an engaging and educational experience for me.

Over time, a textbook evolves. As with organisms, each evolutionary step builds on a preexisting framework. Thus, I also thank the individuals who helped with the development of previous editions:

Maxine A'Hearn, *Prince George's Community College*
Shylaja Akkaraju, *College of DuPage*
Ahmed Naguy Ali, *Alexandria, Egypt*
John Aliff, *Georgia Perimeter College*

Bruce Wingerd, *San Diego State University*

Eric Wise, *University of California—Santa Barbara*

Michael G. Wood, *Del Mar College*

Jamie Young, *Chattanooga State Technical Community College*

Nancy L. Young, *Seattle Pacific University*

The accuracy and currency of the clinical material in this edition of the textbook and in the *A&P Applications Manual* in large part reflect the work of my wife, Kathleen Welch, M.D. Her professionalism and concern for practicality and common sense make the clinical information especially relevant for today's students.

Virtually without exception, reviewers stressed the importance of accurate, integrated, and visually attractive illustrations in helping students understand the content of anatomy and physiology. The revision of the art program was directed by William C. Ober, M.D., and Claire W. Garrison,

R.N. Their suggestions about topics of clinical importance, presentation sequence, and revisions to the proposed art were of incalculable value to me and the project. The illustration program for this edition was further enhanced by the efforts of two other talented individuals. Jim Gibson designed most of the new features in the art program and consulted on the design and layout of individual figures. His talents have helped produce an illustration program that is attractive, cohesive, and easy to understand. Anita Hylton helped to create the new photo/art combinations which provide a greater sense of realism in important anatomical figures.

Many of the text’s illustrations include color photographs or micrographs collected from a variety of sources. The striking anatomical photos in the text, in *Martini’s Atlas of the Human Body*, and in the *Laboratory Manual for Anatomy & Physiology* by Michael G. Wood are the work of Ralph T. Hutchings, whose efforts on this project are deeply appreciated. Dr. Eugene C. Wasson III and the staff of Maui Radiology Consultants, Inc., provided valuable assistance in the selection and printing of many of the CT and MRI scans included in the revised *Atlas*.

I also express my appreciation to the editors and support staff at Benjamin Cummings. First on the list is Nicole George, Project Editor for my texts, who somehow managed to handle every crisis and kept things moving in the right direction. Her support, hard work, and patience are deeply appreciated.

I owe special thanks to my editor, Leslie Berriman, for her creativity and dedication. Her vision helped shape this book in countless ways. I also owe thanks to Kim Neumann for her creative efforts on the media supplements and for generating new media components for incorporation into the MyA&P course management program, the Media Manager instructor presentation CDs, and the Anatomy and Physiology Place website for Martini.

Alan Titche, my Development Editor, played a vital role in fashioning the Seventh Edition. I could not have survived this process without him, and his unfailing attention to detail and quality made a tremendous difference in the final package.

Thanks are also due to the rest of the editorial team, including Michael Roney and Blythe Robbins, for their assistance with the integrated supplements package.

This book would not exist without the extraordinary dedication of the production team, including Debbie Cogan, Corinne Benson, and Heather Johnson, who solved many problems under pressure with unfailing good cheer.

Thanks to Mark Ong, Kathleen Cunningham, and Yvo Riezebos for this edition’s stunning and effective interior and cover designs. I am grateful to Lillian Carr, Creative Director, for her spectacular designs of the media packages and this book’s Visual Introduction. I would also like to express my gratitude to Linda Davis, President of Benjamin Cummings; Daryl Fox, Publisher; Lauren Fogel, Director of Media Development and Publishing Technology;

Stacy Treco, Director of Marketing; and Lauren Harp, Executive Marketing Manager, for their continuing support of this project.

No one person could expect to produce a flawless textbook of this scope and complexity. Any errors or oversights are strictly my own rather than those of the reviewers, artists, or editors. To help improve future editions, I encourage you to send any pertinent information, suggestions, or comments about the organization or content of this textbook to me directly, using the following e-mail address. I will deeply appreciate any and all comments and suggestions and will carefully consider them in the preparation of the Eighth Edition.

Frederic H. Martini

Glossary

Eponyms in Common Use

Eponym Equivalent Term(s) Individual Referenced

THE CELLULAR LEVEL OF ORGANIZATION *(CHAPTER 3)*

Golgi apparatus
Krebs cycle Tricarboxylic, or citric acid,
cycle

Camillo Golgi (1844–1926), Italian histologist; shared Nobel Prize in 1906 Hans Adolph Krebs (1900–1981), British biochemist; shared Nobel Prize in 1953

THE SKELETAL SYSTEM *(CHAPTERS 6–9)*

Colles' fracture
Haversian canals Central canals
Haversian systems Osteons
Pott's fracture
Sharpey's fibers Perforating fibers

Volkmann's canals Perforating canals
Wormian bones Sutural bones

Abraham Colles (1773–1843), Irish surgeon Clopton Havers (1650–1702), English anatomist and microscopist Clopton Havers Percivall Pott (1713–1788), English surgeon William Sharpey (1802–1880), Scottish histologist and
physiologist Alfred Wilhelm Volkmann (1800–1877), German surgeon Olas Worm (1588–1654), Danish anatomist

THE MUSCULAR SYSTEM *(CHAPTERS 10, 11)*

Achilles' tendon Calcaneal tendon Achilles, hero of Greek mythology

Cori cycle Carl Ferdinand Cori (1896–1984) and Gerty Theresa Cori (1896–1957), American biochemists; shared Nobel Prize in 1947

THE NERVOUS SYSTEM *(CHAPTERS 12–16)*

Broca’s center Speech center
Foramen of Lushka Lateral foramina
Meissner’s corpuscles Tactile corpuscles
Merkel’s discs Tactile discs
Foramen of Munro Interventricular foramen
Nissl bodies
Pacinian corpuscles Lamellated corpuscles
Purkinje cells
Nodes of Ranvier Nodes
Island of Reil Insula
Fissure of Rolando Central sulcus
Ruffini’s corpuscles
Schwann cells Neurolemmocytes
Aqueduct of Sylvius Mesencephalic aqueduct
Sylvian fissure Lateral sulcus
Pons varolii Pons

Pierre Paul Broca (1824–1880), French surgeon Hubert von Lushka (1820–1875), German anatomist Georg Meissner (1829–1905), German physiologist Friedrich Siegismund Merkel (1845–1919), German anatomist John Cummings Munro (1858–1910), American surgeon Franz Nissl (1860–1919), German neurologist Fillippo Pacini (1812–1883), Italian anatomist Johannes E. Purkinje (1781–1869), Czechoslovakian physiologist Louis Antoine Ranvier (1835–1922), French physiologist Johann Christian Reil (1759–1813), German anatomist Luigi Rolando (1773–1831), Italian anatomist Angelo Ruffini (1864–1929), Italian anatomist Theodor Schwann (1810–1882), German anatomist Jacobus Sylvius (Jacques Dubois, 1478–1555), French anatomist Franciscus Sylvius (Franz de le Boë, 1614–1672), Dutch anatomist Costanzo Varolio (1543–1575), Italian anatomist

SENSORY FUNCTION *(CHAPTER 17)*

Organ of Corti Spiral organ
Eustachian tube Auditory tube
Golgi tendon organs Tendon organs

Hertz (Hz)
Meibomian glands Tarsal glands
Canal of Schlemm Scleral venous sinus

Alfonso Corti (1822–1888), Italian anatomist Bartolomeo Eustachio (1520–1574), Italian anatomist Camillo Golgi (1844–1926), Italian histologist; shared
Nobel Prize in 1906 Heinrich Hertz (1857–1894), German physicist Heinrich Meibom (1638–1700), German anatomist Friedrich S. Schlemm (1795–1858), German anatomist

THE ENDOCRINE SYSTEM *(CHAPTER 18)*

Islets of Langerhans Pancreatic islets Paul Langerhans (1847–1888), German pathologist
Interstitial cells of Leydig Interstitial cells Franz von Leydig (1821–1908), German anatomist

Eponym Equivalent Term(s)	**Individual Referenced**
THE CARDIOVASCULAR SYSTEM *(CHAPTERS 19–21)*	
Bundle of His	Wilhelm His (1863–1934), German physician
Purkinje fibers	Johannes E. Purkinje (1781–1869), Czechoslovakian

Starling’s law	Ernest Henry Starling (1866–1927), English physiologist
Circle of Willis Cerebral arterial circle	Thomas Willis (1621–1675), English physician

THE LYMPHATIC SYSTEM *(CHAPTER 22)*

Hassall’s corpuscles	Arthur Hill Hassall (1817–1894), English physician
Kupffer cells Stellate reticuloendothelial cells	Karl Wilhelm Kupffer (1829–1902), German anatomist
Langerhans cells	Paul Langerhans (1847–1888), German pathologist
Peyer’s patches Aggregated lymphoid nodules	Johann Conrad Peyer (1653–1712), Swiss anatomist

THE RESPIRATORY SYSTEM *(CHAPTER 23)*

Bohr effect	Christian Bohr (1855–1911), Danish physiologist
Boyle’s law	Robert Boyle (1621–1691), English physicist
Charles’ law	Jacques Alexandre César Charles (1746–1823), French physicist
Dalton’s law	John Dalton (1766–1844), English physicist
Henry’s law	William Henry (1775–1837), English chemist

THE DIGESTIVE SYSTEM *(CHAPTER 24)*

Plexus of Auerbach Myenteric plexus	Leopold Auerbach (1827–1897), German anatomist

Brunner’s glands Duodenal glands	Johann Conrad Brunner (1653–1727), Swiss anatomist
Kupffer cells Stellate reticuloendothelial cells	Karl Wilhelm Kupffer (1829–1902), German anatomist
Crypts of Lieberkühn Intestinal glands	Johann Nathaniel Lieberkuhn (1711–1756), German anatomist
Plexus of Meissner Submucosal plexus	Georg Meissner (1829–1905), German physiologist
Sphincter of Oddi Hepatopancreatic sphincter	Ruggero Oddi (1864–1913), Italian physician
Peyer’s patches Aggregated lymphoid ducts	Johann Conrad Peyer (1653–1712), Swiss anatomist
Duct of Santorini Accessory pancreatic duct	Giovanni Domenico Santorini (1681–1737), Italian anatomist
Stensen’s duct Parotid duct	Niels Stensen (1638–1686), Danish physician/priest
Ampulla of Vater Duodenal ampulla	Abraham Vater (1684–1751), German anatomist
Wharton’s duct Submandibular duct	Thomas Wharton (1614–1673), English physician
Duct of Wirsung Pancreatic duct	Johann Georg Wirsung (1600–1643), German physician

THE URINARY SYSTEM *(CHAPTER 26)*

Bowman’s capsule Glomerular capsule	Sir William Bowman (1816–1892), English physician
Loop of Henle Nephron loop	Friedrich Gustav Jakob Henle (1809–1885), German histologist

THE REPRODUCTIVE SYSTEM *(CHAPTERS 28, 29)*

Bartholin’s glands Greater vestibular glands	Casper Bartholin, Jr. (1655–1738), Danish anatomist
Cowper’s glands Bulbourethral glands	William Cowper (1666–1709), English surgeon
Fallopian tube Uterine tube/oviduct	Gabriele Fallopio (1523–1562), Italian anatomist
Graafian follicle Tertiary follicle	Reijnier de Graaf (1641–1673), Dutch physician
Interstitial cells of Leydig Interstitial cells	Franz von Leydig (1821–1908), German anatomist
Glands of Littré Lesser vestibular glands	Alexis Littré (1658–1726), French surgeon
Sertoli cells Sustentacular cells	Enrico Sertoli (1842–1910), Italian histologist

Glossary of Key Terms

A

abdomen: The region of the trunk bounded by the diaphragm and pelvis. (1)

abdominopelvic cavity: The portion of the ventral body cavity that contains abdominal and pelvic subdivisions; also contains the peritoneal cavity. (1)

abducens: Cranial nerve VI, which innervates the lateral rectus muscle of the eye. (14)

abduction: Movement away from the midline of the body, as viewed in the anatomical position. (9)

abortion: The premature loss or expulsion of an embryo or fetus. (29)

abscess: A localized collection of pus within a damaged tissue. (4, 22)

absorption: The active or passive uptake of gases, fluids, or solutes. (25)

accommodation: An alteration in the curvature of the lens of the eye to focus an image on the retina. (17)

acetabulum: The fossa on the lateral aspect of the pelvis that accommodates the head of the femur. (8)

acetylcholine (ACh): A chemical neurotransmitter in the brain and peripheral nervous system; the dominant neurotransmitter in the peripheral nervous system, released at neuromuscular junctions and synapses of the parasympathetic division. (10, 12, 16)

acetylcholinesterase (AChE): An enzyme found in the synaptic cleft, bound to the postsynaptic membrane, and in tissue fluids; breaks down and inactivates acetylcholine molecules. (10, 12)

acetyl-CoA: An acetyl group bound to coenzyme A, a participant in the anabolic and catabolic pathways for carbohydrates, lipids, and many amino acids. (25)

acetyl group: ¬ CH3CO. (25)

Achilles tendon: *See* **calcaneal tendon**.

acid: A compound whose dissociation in solution releases a hydrogen ion and an anion; an acidic solution has a pH below 7.0 and contains an excess of hydrogen ions.

(2, 27)

acidosis (as-i-D O sis): An abnormal physiological state characterized by a plasma pH below 7.35. (2, 25, 26, 27)

–

acinus/acini: A histological term referring to a blind pocket, pouch, or sac.

acoustic: Pertaining to sound or the sense of hearing. (17)

acquired immune deficiency syndrome (AIDS): A disease caused by the human immunodeficiency virus (HIV); characterized by the destruction of helper T cells and a resulting severe impairment of the immune response. (22)

acromegaly: A condition caused by the overproduction of growth hormone in adults, characterized by a thickening of bones and an enlargement of cartilages and other soft tissues. (6, 18)

acromion: A continuation of the scapular spine that projects superior to the capsule of the scapulohumeral joint. (8)

acrosomal cap: A membranous sac at the tip of a spermatozoon that contains hyaluronidase. (28)

actin: The protein component of microfilaments that forms thin filaments in skeletal muscles and produces contractions of all muscles through interaction with thick (myosin) filaments; *see also* **sliding filament theory**. (3, 10)

action potential: A propagated change in the transmembrane potential of excitable cells, initiated by a change in the membrane permeability to sodium ions; *see also* **nerve impulse**. (10, 12)

active transport: The ATP-dependent absorption or secretion of solutes across a cell membrane. (3, 26)

acute: Sudden in onset, severe in intensity, and brief in duration.

adaptation: A change in pupillary size in response to changes in light intensity (17); a decrease in receptor sensitivity or perception after chronic stimulation (15); physiological responses that produce acclimatization (25)

Addison's disease: A condition resulting from the hyposecretion of glucocorticoids; characterized by lethargy, weakness, hypotension, and increased skin pigmentation. (5, 18)

adduction: Movement toward the axis or midline of the body, as viewed in the anatomical position. (9)

adenine: A purine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

adenohypophysis: The anterior lobe of the pituitary gland. (18)

adenoids: The pharyngeal tonsil. (22, 23)

adenosine: A combination of adenine and ribose. (2)

adenosine diphosphate (ADP): A compound consisting of adenosine with two phosphate groups attached. (2, 25)

adenosine monophosphate (AMP): A nucleotide consisting of adenine plus a phosphate group ($PO4^{3-}$); also called *adenosine phosphate*. (AM)

adenosine triphosphate (ATP): A high-energy compound consisting of adenosine with three phosphate groups attached; the third is attached by a high-energy bond. (2, 10, 25)

adenylate cyclase: An enzyme bound to the inner surfaces of cell membranes that can convert ATP to cyclic-AMP; also called *adenylyl cyclase*. (12)

adhesion: The fusion of two mesenterial layers after damage or irritation of their opposing surfaces; this process restricts relative movement of the organs involved (4); the binding of a phagocyte to its target (22)

adipocyte: A fat cell. (4)

adipose tissue: Loose connective tissue dominated by adipocytes. (4, 18)

adrenal cortex: The superficial portion of the adrenal gland that produces steroid hormones. (18)

adrenal gland: A small endocrine gland that secretes steroids and catecholamines and is located superior to each kidney; also called *suprarenal gland*. (18)

adrenal medulla: The core of the adrenal gland (18); a modified sympathetic ganglion that secretes catecholamines into the blood during sympathetic activation (16)

adrenergic: A synaptic terminal that, when stimulated, releases norepinephrine. (12)

adrenocortical hormone: Any steroid produced by the adrenal cortex. (18)

adrenocorticotropic hormone (ACTH): The hormone that stimulates the production and secretion of glucocorticoids by the zona fasciculata of the adrenal cortex; released by the anterior lobe of the pituitary gland in response to corticotropin-releasing hormone. (18)

adventitia: The superficial layer of connective tissue surrounding an internal organ; fibers are continuous with those of surrounding tissues, providing support and stabilization. (24)

aerobic: Requiring the presence of oxygen.

aerobic metabolism: The complete breakdown of organic substrates into carbon dioxide and water, via pyruvic acid; a process that yields large amounts of ATP but requires mitochondria and oxygen. (3, 10, 25)

afferent: Toward.

afferent arteriole: An arteriole that carries blood to a glomerulus of the kidney. (26)

afferent fiber: An axon that carries sensory information to the central nervous system. (12)

agglutination: The aggregation of red blood cells due to interactions between surface antigens and plasma antibodies. (19, 22)

agglutinins: Immunoglobulins in plasma that react with antigens on the surfaces of foreign red blood cells when donor and recipient differ in blood type. (19)

agglutinogens: Surface antigens on red blood cells whose presence and structure are genetically determined. (19)

aggregated lymphoid nodules: Lymphoid nodules beneath the epithelium of the small intestine; also called *Peyer's patches*. (22)

agonist: A muscle responsible for a specific movement; a.k.a. prime mover. (11)

agranular: Without granules; *agranular leukocytes* are monocytes and lymphocytes. (19)

AIDS: *See* **acquired immune deficiency syndrome**.

alba: White.

albicans: White.

albuginea: White.

aldosterone: A mineralocorticoid produced by the zona glomerulosa of the adrenal cortex; stimulates sodium and water conservation at the kidneys; secreted in response to the presence of angiotensin II. (18, 26, 27)

alkalosis: The condition characterized by a plasma pH greater than 7.45; associated with a relative deficiency of hydrogen ions or an excess of bicarbonate ions. (2, 27)

alpha receptors: Membrane receptors sensitive to norepinephrine or epinephrine; stimulation normally results in the excitation of the target cell. (16)

alveolar sac: An air-filled chamber that supplies air to several alveoli. (23)

alveolus/alveoli: Blind pockets at the end of the respiratory tree, lined by a simple squamous epithelium and surrounded by a capillary network; sites of gas exchange with the blood (23); a bony socket that holds the root of a tooth (24)

Alzheimer’s disease: A disorder resulting from degenerative changes in populations of neurons in the cerebrum, causing dementia characterized by problems with attention, short-term memory, and emotions. (16)

amination: The attachment of an amino group to a carbon chain; performed by a variety of cells and important in the synthesis of amino acids. (25)

amino acids: Organic compounds whose chemical structure can be summarized as R ¬ CHNH2 ¬ COOH. (2, 25)

amino group: ¬ NH2 . (2)

amnion: One of the four extraembryonic membranes; surrounds the developing embryo or fetus. (29)

amniotic fluid: Fluid that fills the amniotic cavity; cushions and supports the embryo or fetus. (4, 29)

amphiarthrosis: An articulation that permits a small degree of independent movement; *see* **interosseous membrane** (8) and **pubic symphysis**. (9)

ampulla/ampullae: A localized dilation in the lumen of a canal or passageway. (17, 24, 28)

amygdaloid body: A basal nucleus that is a component of the limbic system and acts as an interface between that system, the cerebrum, and sensory systems. (14)

amylase: An enzyme that breaks down polysaccharides; produced by the salivary glands and pancreas. (24)

anabolism: The synthesis of complex organic compounds from simpler precursors. (2, 25)

anaerobic: Without oxygen. **analgesic:** A substance that relieves pain. (15)

anal triangle: The posterior subdivision of the perineum. (11)

anaphase: The mitotic stage in which the paired chromatids separate and move toward opposite ends of the spindle apparatus. (3)

anaphylaxis: A hypersensitivity reaction due to the binding of antigens to immunoglobulins (IgE) on the surfaces of mast cells; the release of histamine, serotonin, and prostaglandins by mast cells then causes widespread inflammation; a sudden decline in blood pressure may occur, producing anaphylactic shock. (22)

anastomosis: The joining of two tubes, usually referring to a connection between two peripheral vessels without an intervening capillary bed. (21)

anatomical position: An anatomical reference position; the body viewed from the anterior surface with the palms facing forward. (1)

anatomy: The study of the structure of the body. (1)

androgen: A steroid sex hormone primarily produced by the interstitial cells of the testis and manufactured in small quantities by the adrenal cortex in either gender. (18, 28)

anemia: The condition marked by a reduction in the hematocrit, the hemoglobin content of the blood, or both. (19)

angiotensin I: The hormone produced by the activation of angiotensinogen by renin (18); angiotensin-converting enzyme converts angiotensin I into angiotensin II in lung capillaries. (26)

angiotensin II: A hormone that causes an elevation in systemic blood pressure, stimulates the secretion of aldosterone, promotes thirst, and causes the release of antidi

uretic hormone (18); angiotensin-converting enzyme in lung capillaries converts angiotensin I into angiotensin II. (21, 26)

angiotensinogen: The blood protein produced by the liver that is converted to angiotensin I by the enzyme renin. (18)

anion: An ion bearing a negative charge. (2, 27)

anoxia (an-ok-s

¯e

-a): Tissue oxygen deprivation. (23)

antagonist: A muscle that opposes the movement of an agonist. (10)

antebrachium: The forearm. (8)

anterior: On or near the front, or ventral surface, of the body.

antibiotic: A chemical agent that selectively kills pathogens. (20)

antibody: A globular protein produced by plasma cells that will bind to specific antigens and promote their destruction or removal from the body. (19, 22)

antibody-mediated immunity: The form of immunity resulting from the presence of circulating antibodies produced by plasma cells; also called *humoral immunity*. (22)

anticholinesterase: A chemical compound that blocks the action of acetylcholine and causes prolonged and intensive stimulation of post-synaptic membranes. (12)

anticodon: Three nitrogenous bases on a tRNA molecule that interact with an appropriate codon on a strand of mRNA. (3)

antidiuretic hormone (ADH): A hormone synthesized in the hypothalamus and secreted at the posterior lobe of the pituitary gland; causes water retention at the kidneys and an elevation of blood pressure. (18, 21, 26, 27)

antigen: A substance capable of inducing the production of antibodies. (22)

antigen–antibody complex: The combination of an antigen and a specific antibody. (22)

antigenic determinant site: A portion of an antigen that can interact with an antibody molecule. (22)

antigen-presenting cell (APC): A cell that processes antigens and displays them, bound to MHC proteins; essential to the initiation of a normal immune response. (22)

antihistamines: A chemical agent that blocks the action of histamine on peripheral tissues. (22)

antrum: A chamber or pocket. (28, for example) **anulus:** A cartilage or bone shaped like a ring; also spelled *annulus*. (9)

anus: The external opening of the anal canal. (24)

aorta: The large, elastic artery that carries blood away from the left ventricle and into the systemic circuit. (20)

apocrine secretion: A mode of secretion in which the glandular cell sheds portions of its cytoplasm. (4, 5)

aponeurosis/aponeuroses: A broad tendinous sheet that may serve as the origin or insertion of a skeletal muscle. (4, 6, 10)

appendicular: Pertaining to the upper or lower limbs. (8)

appendix: A blind tube connected to the cecum of the large intestine. (24)

appositional growth: The enlargement of a bone by the addition of cartilage or bony matrix at its surface. (4)

aqueous humor: A fluid similar to perilymph or cerebrospinal fluid that fills the anterior chamber of the eye. (17)

arachidonic acid: One of the essential fatty acids. (2, 18)

arachnoid mater: The middle meninx that encloses cerebrospinal fluid and protects the central nervous system. (13, 14)

arachnoid granulations: Processes of the arachnoid mater that project into the superior sagittal sinus; sites where cerebrospinal fluid enters the venous circulation. (14)

arbor vitae: The central, branching mass of white matter inside the cerebellum. (14)

arcuate (AR-k

ū

-

ā

t): Curving.

areolar: Containing minute spaces, as in areolar tissue.

areolar tissue: Loose connective tissue with an open framework. (4)

arrector pili: Smooth muscles whose contractions force hairs to stand erect. (5)

arrhythmias: Abnormal patterns of cardiac contractions. (20)

arteriole: A small arterial branch that delivers blood to a capillary network. (21)

artery: A blood vessel that carries blood away from the heart and toward a peripheral capillary. (4, 20, 21)

articular: Pertaining to a joint.

articular capsule: The dense collagen fiber sleeve that surrounds a joint and provides protection and stabilization. (6, 9)

articular cartilage: The cartilage pad that covers the surface of a bone inside a joint cavity. (6, 9)

articulation: A joint (9); the formation of words (23)

arytenoid cartilages: A pair of small cartilages in the larynx. (23)

ascending tract: A tract carrying information from the spinal cord to the brain. (13, 14)

association areas: Cortical areas of the cerebrum that are responsible for the integration of sensory inputs and/or motor commands. (14)

association neuron: *See* **interneuron**.

astrocyte: One of the four types of neuroglia in the central nervous system; responsible for maintaining the blood–brain barrier by the stimulation of endothelial cells. (12)

atherosclerosis: The formation of fatty plaques in the walls of arteries, restricting blood flow to deep tissues. (21)

atom: The smallest stable unit of matter. (2)

atomic number: The number of protons in the nucleus of an atom. (2)

atomic weight: Roughly, the average total number of protons and neutrons in the atoms of a particular element. (2)

atria: Thin-walled chambers of the heart that receive venous blood from the pulmonary or systemic circuit atrial natriuretic peptide (ANP): See **natriuretic peptides**. (20)

atrial reflex: The reflexive increase in heart rate after an increase in venous return; due to mechanical and neural factors; also called *Bainbridge reflex*. (20, 21)

atrioventricular (AV) node: Specialized cardiocytes that relay the contractile stimulus to the bundle of His, the bundle branches, the Purkinje fibers, and the ventricular myocardium; located at the boundary between the atria and ventricles. (20)

atrioventricular (AV) valve: One of the valves that prevents backflow into the atria during ventricular systole. (20)

atrophy: The wasting away of tissues from a lack of use, ischemia, or nutritional abnormalities. (10)

auditory: Pertaining to the sense of hearing. (17)

auditory ossicles: The bones of the middle ear: malleus, incus, and stapes. (7, 17)

auditory tube: A passageway that connects the nasopharynx with the middle ear cavity; also called *Eustachian tube* or *pharyngotympanic tube*. (17)

auricle: A broad, flattened process that resembles the external ear; in the ear, the expanded, projecting portion that surrounds the external auditory canal, also called *pinna* (17); in the heart, the externally visible flap formed by the collapse of the outer wall of a relaxed atrium (20)

autoantibodies: Antibodies that react with antigens on the surfaces of a person’s own cells and tissues. (22)

autoimmunity: The immune system’s sensitivity to normal cells and tissues, resulting in the production of autoantibodies. (22)

autolysis: The destruction of a cell due to the rupture of lysosomal membranes in its cytoplasm. (3)

automaticity: The spontaneous depolarization to threshold, characteristic of cardiac pacemaker cells. (10, 20)

autonomic ganglion: A collection of visceral motor neurons outside the central nervous system. (16)

autonomic nerve: A peripheral nerve consisting of preganglionic or postganglionic autonomic fibers. (16)

autonomic nervous system (ANS): Centers, nuclei, tracts, ganglia, and nerves involved in the unconscious regulation of visceral functions; includes components of the central nervous system and the peripheral nervous system. (12, 16)

autopsy: The detailed examination of a body after death. (AM)

autoregulation: Changes in activity that maintain homeostasis in direct response to changes in the local environment; does not require neural or endocrine control. (1, 21, 26)

autosomal: Chromosomes other than the X or Y chromosome. (29)

avascular: Without blood vessels. (4)

axilla: The armpit. (1, 8)

axolemma: The cell membrane of an axon, continuous with the cell membrane of the cell body and dendrites and distinct from any neuroglial coverings. (12)

axon: The elongate extension of a neuron that conducts an action potential. (4, 12)

axon hillock: In a multipolar neuron, the portion of the cell body adjacent to the initial segment. (12)

axoplasm: The cytoplasm within an axon. (12)

B

bacteria: Single-celled microorganisms, some pathogenic, that are common in the environment and in and on the body. (22)

Bainbridge reflex: *See* **atrial reflex**.

baroreception: The ability to detect changes in pressure. (15, 23)

baroreceptor reflex: A reflexive change in cardiac activity in response to changes in blood pressure. (21)

baroreceptors: The receptors responsible for baroreception. (15, 21)

basal lamina: A layer of filaments and fibers that attach an epithelium to the underlying connective tissue. (4)

basal nuclei: Nuclei of the cerebrum that are important in the subconscious control of skeletal muscle activity. (14, 15)

base: A compound whose dissociation releases a hydroxide ion (OH^-) or removes a hydrogen ion (H^+) from the solution. (2, 27)

basophils: Circulating granulocytes (white blood cells) similar in size and function to tissue mast cells. (19)

B cells: Lymphocytes capable of differentiating into plasma cells, which produce antibodies. (19, 22)

benign: Not malignant. (3)

beta cells: Cells of the pancreatic islets that secrete insulin in response to elevated blood sugar concentrations. (18)

beta oxidation: Fatty acid catabolism that produces molecules of acetyl-CoA. (25)

beta receptors: Membrane receptors sensitive to epinephrine; stimulation may result in the excitation or inhibition of the target cell. (16)

bicarbonate ions: $HCO3^-$; anion components of the carbonic acid–bicarbonate buffer system. (26, 27)

bicuspid: Having two cusps or leafs; refers to a premolar tooth, which has two roots, or to the left AV valve, which has two cusps. (24)

bicuspid valve: The left atrioventricular (AV) valve, also called *mitral valve*. (20)

bifurcate: To branch into two parts.

bile: The exocrine secretion of the liver; stored in the gallbladder and ejected into the duodenum. (24)

bile salts: Steroid derivatives in bile; responsible for the emulsification of ingested lipids. (2)

bilirubin: A pigment that is the by-product of hemoglobin catabolism. (19)

biopsy: The removal of a small sample of tissue for pathological analysis. (4, 13)

bladder: A muscular sac that distends as fluid is stored and whose contraction ejects the fluid at an appropriate time; used alone, the term usually refers to the urinary bladder. (26)

blastocyst: An early stage in the developing embryo, consisting of an outer trophoblast and an inner cell mass. (29)

blockers/blocking agents: Drugs that block membrane pores or prevent binding to membrane receptors. (16)

blood–brain barrier: The isolation of the central nervous system from the general circulation; primarily the result of astrocyte regulation of capillary permeabilities. (12, 14)

blood clot: *See* **clot**.

blood–CSF barrier: The isolation of the cerebrospinal fluid from the capillaries of the choroid plexus; primarily the result of specialized ependymal cells. (14)

blood pressure: A force exerted against vessel walls by the blood in the vessels, due to the push exerted by cardiac contraction and the elasticity of the vessel walls; usually measured along one of the muscular arteries, with systolic pressure measured during ventricular systole and diastolic pressure during ventricular diastole. (21)

blood–testis barrier: The isolation of the interior of the seminiferous tubules from the general circulation, due to the activities of the sustentacular cells. (28)

Bohr effect: The increased oxygen release by hemoglobin in the presence of elevated carbon dioxide levels. (23)

bolus: A compact mass; usually refers to compacted ingested material on its way to the stomach. (23, 24)

bone: *See* **osseous tissue**.

bowel: The intestinal tract. (24)

Bowman's capsule: The cup-shaped initial portion of the renal tubule; surrounds the glomerulus and receives the glomerular filtrate. (26)

brachial: Pertaining to the arm.

brachial plexus: A network formed by branches of spinal nerves C5 -T1 en route to innervating the upper limb. (13)

brachium: The arm. (11)

bradycardia: An abnormally slow heart rate, usually below 50 bpm. (20)

brain natural peptide (BNP): *See* **natriuretic peptides**.

brain stem: The brain minus the cerebrum, diencephalon, and cerebellum. (14)

brevis: Short.

Broca's area: The speech center of the brain, normally located on the neural cortex of the left cerebral hemisphere. (14)

bronchial tree: The trachea, bronchi, and bronchioles. (23)

bronchodilation: The dilation of the bronchial passages; can be caused by sympathetic stimulation. (23)

bronchus/bronchi: A branch of the bronchial tree between the trachea and bronchioles. (23)

buccal: Pertaining to the cheeks. (24)

buffer: A compound that stabilizes the pH of a solution by removing or releasing hydrogen ions. (2, 27)

buffer system: Interacting compounds that prevent increases or decreases in the pH of body fluids; includes the carbonic acid–bicarbonate buffer system, the phosphate

buffer system, and the protein buffer system. (27)

bulbar: Pertaining to the brain stem. (14)

bulbourethral glands: Mucous glands at the base of the penis that secrete into the penile urethra; the equivalent of the greater vestibular glands of females; also called *Cowper's glands*. (28)

bundle branches: Specialized conducting cells in the ventricles that carry the contractile stimulus from the bundle of His to the Purkinje fibers. (20)

bundle of His: Specialized conducting cells in the interventricular septum that carry the contracting stimulus from the AV node to bundle branches and then to Purkinje fibers. (20)

bursa: A small sac filled with synovial fluid that cushions adjacent structures and reduces friction. (9)

calcaneal tendon: The large tendon that inserts on the calcaneus; tension on this tendon produces extension (plantar flexion) of the foot; also called *Achilles tendon*. (8, 11)

calcaneus: The heelbone, the largest of the tarsal bones. (8)

calcification: The deposition of calcium salts within a tissue. (4, 6)

calcitonin: The hormone secreted by C cells of the thyroid when calcium ion concentrations are abnormally high; restores homeostasis by increasing the rate of bone dep osition and the rate of calcium loss at the kidneys. (6, 18)

calculus/calculi: Concretions of insoluble materials that form within body fluids, especially the gallbladder, kidneys, or urinary bladder. (26)

callus: A localized thickening of the epidermis due to chronic mechanical stresses (5); a thickened area that forms at the site of a bone break as part of the repair process (6)

calorigenic effect: The stimulation of energy production and heat loss by thyroid hormones. (18)

canaliculi: Microscopic passageways between cells; bile canaliculi carry bile to bile ducts in the liver (24); in bone, canaliculi permit the diffusion of nutrients and wastes

to and from osteocytes (4, 6)

cancellous bone: Spongy bone, composed of a network of bony struts. (6)

cancer: An illness caused by mutations leading to the uncontrolled growth and replication of the affected cells. (3)

cannula: A tube that can be inserted into the body; commonly placed in blood vessels prior to transfusion or dialysis. (19)

capacitation: The activation process that must occur before a spermatozoon can successfully fertilize an oocyte; occurs in the vagina after ejaculation. (28, 29)

capillary: A small blood vessel, located between an arteriole and a venule, whose thin wall permits the diffusion of gases, nutrients, and wastes between plasma and in terstitial fluids.

(4, 19, 20, 21)

capitulum: A general term for a small, elevated articular process; refers to the rounded distal surface of the humerus that articulates with the head of the radius. (8)

caput: The head. (7)

carbaminohemoglobin: Hemoglobin bound to carbon dioxide molecules. (19, 23)

carbohydrase: An enzyme that breaks down carbohydrate molecules. (24)

carbohydrate: An organic compound containing carbon, hydrogen, and oxygen in a ratio that approximates 1:2:1. (2, 25)

carbon dioxide: CO_2 ; a compound produced by the decarboxylation reactions of aerobic metabolism. (2, 23)

carbonic anhydrase: An enzyme that catalyzes the reaction $H_2O + CO_2$ ¡ H_2CO_3 ; important in carbon dioxide transport (23), gastric acid secretion (24), and renal pH regulation (26)

carcinogenic: Stimulating cancer formation in affected tissues. (3)

cardia: The area of the stomach surrounding its connection with the esophagus. (24)

cardiac: Pertaining to the heart. (10, 20)

cardiac cycle: One complete heartbeat, including atrial and ventricular systole and diastole. (20)

cardiac output: The amount of blood ejected by the left ventricle each minute; normally about 5 liters. (20)

cardiac reserve: The potential percentage increase in cardiac output above resting levels. (20)

cardiac tamponade: A compression of the heart due to fluid accumulation in the pericardial cavity. (20)

cardiocyte: A cardiac muscle cell. (4, 10, 20)

cardiovascular: Pertaining to the heart, blood, and blood vessels. (19, 20, 21)

cardiovascular centers: Poorly localized centers in the reticular formation of the medulla oblongata of the brain; includes cardioacceleratory, cardioinhibitory, and vaso motor centers. (14, 21)

cardium: The heart. (20)

carotene: A yellow-orange pigment, found in carrots and in green and orange leafy vegetables, that the body can convert to vitamin A. (5)

carotid artery: The principal artery of the neck, servicing cervical and cranial structures; one branch, the internal carotid, provides a major blood supply to the brain. (21)

carotid body: A group of receptors, adjacent to the carotid sinus, that are sensitive to changes in the carbon dioxide levels, pH, and oxygen concentrations of arterial blood. (15, 21)

carotid sinus: A dilated segment at the base of the internal carotid artery whose walls contain baroreceptors sensitive to changes in blood pressure. (21)

carotid sinus reflex: Reflexive changes in blood pressure that maintain homeostatic pressures at the carotid sinus, stabilizing blood flow to the brain. (21)

carpus/carpal: The wrist. (8, 11)

cartilage: A connective tissue with a gelatinous matrix that contains an abundance of fibers. (4)

catabolism: The breakdown of complex organic molecules into simpler components, accompanied by the release of energy. (2, 25)

catalyst: A substance that accelerates a specific chemical reaction but that is not altered by the reaction. (2)

catecholamine: Epinephrine, norepinephrine, dopamine, and related compounds. (18)

catheter: A tube surgically inserted into a body cavity or along a blood vessel or excretory passageway for the collection of body fluids, monitoring of blood pressure, or introduction of medications or radiographic dyes. (20)

cation: An ion that bears a positive charge. (2, 27)

cauda equina: Spinal nerve roots distal to the tip of the adult spinal cord; they extend caudally inside the vertebral canal en route to lumbar and sacral segments. (13)

caudal/caudally: Closest to or toward the tail (coccyx). **caudate nucleus:** One of the basal nuclei involved with the subconscious control of skeletal muscular activity. (14)

cavernous tissue: Erectile tissue that can be engorged with blood; located in the penis (males) and clitoris (females). (28)

cell: The smallest living unit in the human body. (3)

cell body: Body; the body of a neuron; also called *soma*. (4, 12)

cell-mediated immunity: Resistance to disease through the activities of sensitized T cells that destroy antigen-bearing cells by direct contact or through the release of lymphotoxins; also called *cellular immunity*. (22)

center of ossification: The site in a connective tissue where bone formation begins. (6)

central canal: Longitudinal canal in the center of an osteon that contains blood vessels and nerves, also called *Haversian canal* (6); a passageway along the longitudinal axis of the spinal cord that contains cerebrospinal fluid (13, 14)

central nervous system (CNS): The brain and spinal cord. (12)

centriole: A cylindrical intracellular organelle composed of nine groups of microtubules, three in each group; functions in mitosis or meiosis by organizing the micro tubules of the spindle apparatus. (3)

centromere: The localized region where two chromatids remain connected after the chromosomes have replicated; site of spindle fiber attachment. (3)

centrosome: A region of cytoplasm that contains a pair of centrioles oriented at right angles to one another. (3)

cephalic: Pertaining to the head.

cerebellum: The posterior portion of the metencephalon, containing the cerebellar hemispheres; includes the arbor vitae, cerebellar nuclei, and cerebellar cortex. (14, 15)

cerebral cortex: An extensive area of neural cortex covering the surfaces of the cerebral hemispheres. (14)

cerebral hemispheres: A pair of expanded portions of the cerebrum covered in neural cortex. (14)

cerebrospinal fluid (CSF): Fluid bathing the internal and external surfaces of the central nervous system; secreted by the choroid plexus. (12, 13, 14)

cerebrovascular accident (CVA): The occlusion of a blood vessel that supplies a portion of the brain, resulting in damage to the dependent neurons; also called *stroke*. (14)

cerebrum: The largest portion of the brain, composed of the cerebral hemispheres; includes the cerebral cortex, the basal nuclei, and the internal capsule. (14)

cerumen: The waxy secretion of the ceruminous glands along the external acoustic canal. (5, 17)

ceruminous glands: Integumentary glands that secrete cerumen. (5, 17)

cervix: The inferior portion of the uterus. (28)

chemoreception: The detection of changes in the concentrations of dissolved compounds or gases. (15, 17, 21, 23, 25)

chemotaxis: The attraction of phagocytic cells to the source of abnormal chemicals in tissue fluids. (22)

chemotherapy: The treatment of illness through the administration of specific chemicals. (AM) **chloride shift:** The movement of plasma chloride ions into red blood cells in exchange for bicarbonate ions generated by the intracellular dissociation of carbonic acid.

(23, 27)

cholecystokinin (CCK): A duodenal hormone that stimulates the contraction of the gallbladder and the secretion of enzymes by the exocrine pancreas; also called *panc*

reozymin. (24)

cholesterol: A steroid component of cell membranes and a substrate for the synthesis of steroid hormones and bile salts. (2, 25)

choline: A breakdown product or precursor of acetylcholine. (12)

cholinergic synapse: A synapse where the presynaptic membrane releases acetylcholine on stimulation. (12, 16)

cholinesterase (ko-lin-es-ter-as): The enzyme that breaks down and inactivates acetylcholine. (12)

chondrocyte: A cartilage cell. (4)

chondroitin sulfate (kon-dro-i-tin): The predominant proteoglycan in cartilage, responsible for the gelatinous consistency of the matrix. (4)

chordae tendineae: Fibrous cords that stabilize the position of the AV valves in the heart, preventing backflow during ventricular systole. (20)

chorion/chorionic (ko-re-on): An extraembryonic membrane, consisting of the trophoblast and underlying mesoderm, that forms the placenta. (29)

choroid: The middle, vascular layer in the wall of the eye. (17)

choroid plexus: The vascular complex in the roof of the third and fourth ventricles of the brain, responsible for the production of cerebrospinal fluid. (14)

chromatid: One complete copy of a DNA strand and its associated nucleoproteins. (3, 28, 29)

chromatin: A histological term referring to the grainy material visible in cell nuclei during interphase; the appearance of the DNA content of the nucleus when the chromosomes are uncoiled. (3)

chromosomes: Dense structures, composed of tightly coiled DNA strands and associated histones, that become visible in the nucleus when a cell prepares to undergo mitosis or meiosis; normal human somatic cells contain 46 chromosomes apiece. (3, 28, 29)

chronic: Habitual or long term.

chylomicrons: Relatively large droplets that may contain triglycerides, phospholipids, and cholesterol in association with proteins; synthesized and released by intestinal cells and transported to the venous blood by the lymphatic system. (24, 25)

ciliary body: A thickened region of the choroid that encircles the lens of the eye; includes the ciliary muscle and the ciliary processes that support the suspensory ligaments of the lens. (17)

cilium/cilia: A slender organelle that extends above the free surface of an epithelial cell and generally undergoes cycles of movement; composed of a basal body and microtubules in a 9 * 12 array. (3)

circulatory system: The network of blood vessels and lymphatic vessels that facilitate the distribution and circulation of extracellular fluid. (21, 22)

circumduction: A movement at a synovial joint in which the distal end of the bone describes a circle but the shaft does not rotate. (9)

circumvallate papilla: One of the large, dome-shaped papillae on the superior surface of the tongue that form a V, separating the body of the tongue from the root. (17)

cisterna: An expanded or flattened chamber derived from and associated with the endoplasmc reticulum. (3, 10)

citric acid cycle: *See* **TCA cycle**.

clot: A network of fibrin fibers and trapped blood cells; also called a *thrombus* if it occurs within the cardiovascular system. (19)

clotting factors: Plasma proteins, synthesized by the liver, that are essential to the clotting response. (19)

clotting response: The series of events that results in the formation of a clot. (19)

coccygeal ligament: The fibrous extension of the dura mater and filum terminale; provides longitudinal stabilization to the spinal cord. (13)

coccyx: The terminal portion of the spinal column, consisting of relatively tiny, fused vertebrae. (7)

cochlea: The spiral portion of the bony labyrinth of the inner ear that surrounds the organ of hearing. (17)

cochlear duct: The central membranous tube within the cochlea that is filled with endolymph and contains the organ of Corti; also called *scala media*. (17)

codon: A sequence of three nitrogenous bases along an mRNA strand that will specify the location of a single amino acid in a peptide chain. (3)

coelom: The ventral body cavity, lined by a serous membrane and subdivided during fetal development into the pleural, pericardial, and abdominopelvic (peritoneal) cavities. (1)

coenzymes: Complex organic cofactors; most are structurally related to vitamins. (2, 25)

cofactor: Ions or molecules that must be attached to the active site before an enzyme can function; examples include mineral ions and several vitamins. (2)

collagen: A strong, insoluble protein fiber common in connective tissues. (4)

collateral ganglion: A sympathetic ganglion situated anterior to the spinal column and separate from the sympathetic chain. (12, 16)

colliculus/colliculi: A little mound; in the brain, refers to one of the thickenings in the roof of the mesencephalon; the superior colliculus is associated with the visual system, and the inferior colliculi with the auditory system. (14, 15, 17)

colloid/colloidal suspension: A solution containing large organic molecules in suspension. (2, 26)

colon: The large intestine. (24)

coma: An unconscious state from which an individual cannot be aroused, even by strong stimuli. (16)

comminuted: Broken or crushed into small pieces.

commissure: A crossing over from one side to another.

common bile duct: The duct formed by the union of the cystic duct from the gallbladder and the bile ducts from the liver; terminates at the duodenal ampulla, where it meets the pancreatic duct. (24)

compact bone: Dense bone that contains parallel osteons. (6)

complement: A system of 11 plasma proteins that interact in a chain-reaction after exposure to activated antibodies or the surfaces of certain pathogens; complement proteins promote cell lysis, phagocytosis, and other defense mechanisms. (22)

compliance: Distensibility; the ability of certain organs to tolerate changes in volume; indicates the presence of elastic fibers and smooth muscles. (23, lungs)

compound: A molecule containing two or more elements in combination. (2)

concentration: The amount (in grams) or number of atoms, ions, or molecules (in moles) per unit volume. (2, 3, 25, 26)

concentration gradient: Regional differences in the concentration of a particular substance. (3, 25, 26)

conception: Fertilization. (29)

concha/conchae: Three pairs of thin, scroll-like bones that project into the nasal cavities; the superior and medial conchae are part of the ethmoid, and the inferior conchae are separate bones. (7)

condyle: A rounded articular projection on the surface of a bone. (8)

congenital: Present at birth. **congestive heart failure (CHF):** The failure to maintain adequate cardiac output due to cardiovascular problems or myocardial damage. (23)

conjunctiva: A layer of stratified squamous epithelium that covers the inner surfaces of the eyelids and the anterior surface of the eye to the edges of the cornea. (17)

connective tissue: One of the four primary tissue types; provides a structural framework that stabilizes the relative positions of the other tissue types; includes connec tive tissue proper, cartilage, bone, and blood; contains cell products, cells, and ground substance. (4)

continuous propagation: The propagation of an action potential along an unmyelinated axon or a muscle cell membrane, wherein the action potential affects every portion of the membrane surface. (12)

contractility: The ability to contract; possessed by skeletal, smooth, and cardiac muscle cells. (4, 20)

contralateral reflex: A reflex that affects the opposite side of the body from the stimulus. (13)

conus medullaris: The conical tip of the spinal cord that gives rise to the filum terminale. (13)

convergence: In the nervous system, the innervation of a single neuron by axons from several neurons; most common along motor pathways. (13)

coracoid process: A hook-shaped process of the scapula that projects above the anterior surface of the capsule of the shoulder joint. (8)

Cori cycle: The metabolic exchange of lactic acid from skeletal muscle for glucose from the liver; performed during the recovery period after muscular exertion. (10)

cornea: The transparent portion of the fibrous tunic of the anterior surface of the eye. (17)

corniculate cartilages: A pair of small laryngeal cartilages. (23)

cornu: Horn-shaped. **coronoid:** Hooked or curved. (8)

corpora quadrigemina: The superior and inferior colliculi of the mesencephalic tectum (roof) in the brain. (14)

corpus/corpora: Body. **corpus callosum:** The bundle of axons that links centers in the left and right cerebral hemispheres. (14)

corpus luteum: The progestin-secreting mass of follicle cells that develops in the ovary after ovulation. (18, 28)

cortex: The outer layer or portion of an organ (5)

or bone (6)

corticobulbar tracts: Descending tracts that carry information or commands from the cerebral cortex to nuclei and centers in the brain stem. (15)

corticospinal tracts: Descending tracts that carry motor commands from the cerebral cortex to the anterior gray horns of the spinal cord. (15)

corticosteroid: A steroid hormone produced by the adrenal cortex. (2, 18)

corticosterone: A corticosteroid secreted by the zona fasciculata of the adrenal cortex; a glucocorticoid. (18)

corticotropin-releasing hormone (CRH): The releasing hormone, secreted by the hypothalamus, that stimulates secretion of adrenocorticotropic hormone by the anterior lobe of the pituitary. (18)

cortisol: A corticosteroid secreted by the zona fasciculata of the adrenal cortex; a glucocorticoid. (18)

costa/costae: A rib. (7, 23)

cotransport: The membrane transport of a nutrient, such as glucose, in company with the movement of an ion, normally sodium; transport requires a carrier protein but does not involve direct ATP expenditure and can occur regardless of the concentration gradient for the nutrient. (3, 24, 26)

countercurrent exchange: The diffusion between two solutions that travel in opposite directions. (25, 26)

countercurrent multiplication: Active transport between two limbs of a loop that contains a fluid moving in one direction; responsible for the concentration of urine in the kidney tubules. (26)

covalent bond: A chemical bond between atoms that involves the sharing of electrons. (2)

cranial: Pertaining to the head. (7)

cranial nerves: Peripheral nerves originating at the brain. (12)

craniosacral division: *See* **parasympathetic division**. **cranium:** The braincase; the skull bones that surround and protect the brain. (7)

creatine: A nitrogenous compound, synthesized in the body, that can form a high-energy bond by connecting to a phosphate group and that serves as an energy reserve.

(10)

creatine phosphate: A high-energy compound in muscle cells; during muscle activity, the phosphate group is donated to ADP, regenerating ATP; also called *phosphorylc*

reatine. (10)

creatinine: A breakdown product of creatine metabolism. (26)

crenation: Cellular shrinkage due to an osmotic movement of water out of the cytoplasm. (3)

cribriform plate: A portion of the ethmoid that contains the foramina used by the axons of olfactory receptors en route to the olfactory bulbs of the cerebrum. (7)

cricoid cartilage: A ring-shaped cartilage that forms the inferior margin of the larynx. (23)

crista/cristae: A ridge-shaped collection of hair cells in the ampulla of a semicircular duct; the crista and cupula form a receptor complex sensitive to movement along

the plane of the canal. (17)

cross-bridge: A myosin head that projects from the surface of a thick filament and that can bind to an active site of a thin filament in the presence of calcium ions. (10)

cuneiform cartilages: A pair of small cartilages in the larynx. (23)

cupula: A gelatinous mass that is located in the ampulla of a semicircular duct in the inner ear and whose movement stimulates the hair cells of the crista. (17)

Cushing’s disease: A condition caused by the oversecretion of adrenal steroids. (18)

cutaneous membrane: The epidermis and papillary layer of the dermis. (4, 5)

cuticle: The layer of dead, keratinized cells that surrounds the shaft of a hair; for nails, *see* **eponychium**. (5)

cyanosis: A bluish coloration of the skin due to the presence of deoxygenated blood in vessels near the body surface. (5)

cystic duct: A duct that carries bile between the gallbladder and the common bile duct. (24)

cytochrome: A pigment component of the electron transport system; a structural relative of heme. (25)

cytokinesis: The cytoplasmic movement that separates two daughter cells at the completion of mitosis. (3)

cytology: The study of cells. (1, 3)

cytoplasm: The material between the cell membrane and the nuclear membrane; cell contents. (3)

cytosine: A pyrimidine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

cytoskeleton: A network of microtubules and microfilaments in the cytoplasm. (3)

cytosol: The fluid portion of the cytoplasm. (3, 27)

cytotoxic: Poisonous to cells. (22)

cytotoxic T cells: Lymphocytes involved in cell-mediated immunity that kill target cells by direct contact or by the secretion of lymphotoxins; also called *killer T cells* and

TC cells. (22)

D

daughter cells: Genetically identical cells produced by somatic cell division. (3, 28)

deamination: The removal of an amino group from an amino acid. (25, 26)

decomposition reaction: A chemical reaction that breaks a molecule into smaller fragments. (2)

decussate: To cross over to the opposite side, usually referring to the crossover of the descending tracts of the corticospinal pathway on the ventral surface of the medulla

oblongata. (15)

defecation: The elimination of fecal wastes. (24)

degradation: Breakdown, catabolism. (2, 25)

dehydration: A reduction in the water content of the body that threatens homeostasis. (27)

dehydration synthesis: The joining of two molecules associated with the removal of a water molecule. (2)

demyelination: The loss of the myelin sheath of an axon, normally due to chemical or physical damage to Schwann cells or oligodendrocytes. (12)

denaturation: A temporary or permanent change in the three-dimensional structure of a protein. (2)

dendrite: A sensory process of a neuron. (4, 12)

deoxyribonucleic acid (DNA): A nucleic acid consisting of a chain of nucleotides that contain the sugar deoxyribose and the nitrogenous bases adenine, guanine, cytosine, and thymine. (2)

deoxyribose: A five-carbon sugar resembling ribose but lacking an oxygen atom. (2)

depolarization: A change in the transmembrane potential from a negative value toward 0 mV. (12, 20)

depression: Inferior (downward) movement of a body part.

dermatitis: An inflammation of the skin. (5)

dermatome: A sensory region monitored by the dorsal rami of a single spinal segment. (13)

dermis: The connective tissue layer beneath the epidermis of the skin. (5)

detrusor muscle: A smooth muscle in the wall of the urinary bladder. (26)

detumescence: The loss of a penile erection. (28)

development: Growth and the acquisition of increasing structural and functional complexity; includes the period from conception to maturity.

diabetes insipidus: Polyuria due to inadequate production of antidiuretic hormone. (18)

diabetes mellitus: Polyuria and glycosuria, most commonly due to the inadequate production of insulin with a resulting elevation of blood glucose levels. (18)

diapedesis: The movement of white blood cells through the walls of blood vessels by migration between adjacent endothelial cells. (19, 22)

diaphragm: Any muscular partition; the respiratory muscle that separates the thoracic cavity from the abdominopelvic cavity. (1, 11, 23)

diaphysis: The shaft of a long bone. (6)

diarthrosis: A synovial joint. (9)

diastolic pressure: Pressure measured in the walls of a muscular artery when the left ventricle is in diastole. (20)

diencephalon: A division of the brain that includes the epithalamus, thalamus, and hypothalamus. (14)

differential count: The determination of the relative abundance of each type of white blood cell on the basis of a random sampling of 100 white blood cells. (19)

differentiation: The gradual appearance of characteristic cellular specializations during development as the result of gene activation or repression. (3)

diffusion: Passive molecular movement from an area of higher concentration to an area of lower concentration. (3, 21, 23, 26)

digestion: The chemical breakdown of ingested materials into simple molecules that can be absorbed by the cells of the digestive tract. (24)

digestive system: The digestive tract and associated glands. (24)

digestive tract: An internal passageway that begins at the mouth, ends at the anus, and is lined by a mucous membrane; also called *gastrointestinal tract*. (24)

dilate: To increase in diameter; to enlarge or expand.

disaccharide: A compound formed by the joining of two simple sugars by dehydration synthesis. (2)

dissociation: *See* **ionization**.

distal: Movement away from the point of attachment or origin; for a limb, away from its attachment to the trunk. (8)

distal convoluted tubule (DCT): The portion of the nephron closest to the connecting tubules and collecting duct; an important site of active secretion. (26)

diuresis: Fluid loss at the kidneys; the production of urine. (26)

divergence: In neural tissue, the spread of information from one neuron to many neurons; an organizational pattern common along sensory pathways of the central nervous system. (13)

diverticulum: A sac or pouch in the wall of the colon or other organ. (24)

DNA molecule: Two DNA strands wound in a double helix and held together by weak bonds between complementary nitrogenous base pairs. (3)

dopamine: An important neurotransmitter in the central nervous system. (12)

dorsal: Toward the back, posterior.

dorsal root ganglion: A peripheral nervous system ganglion containing the cell bodies of sensory neurons. (13)

dorsiflexion: The elevation of the superior surface of the foot through flexion at the ankle. (9)

Down syndrome: A genetic abnormality resulting from the presence of three copies of chromosome 21; individuals with this condition have characteristic physical and intellectual deficits. (16)

duct: A passageway that delivers exocrine secretions to an epithelial surface. (4)

ductus arteriosus: A vascular connection between the pulmonary trunk and the aorta that functions throughout fetal life; normally closes at birth or shortly thereafter and persists as the ligamentum arteriosum. (21, 23)

ductus deferens: A passageway that carries spermatozoa from the epididymis to the ejaculatory duct. (28)

duodenal ampulla: A chamber that receives bile from the common bile duct and pancreatic secretions from the pancreatic duct. (24)

duodenal papilla: A conical projection from the inner surface of the duodenum that contains the opening of the duodenal ampulla. (24)

duodenum: The proximal 25 cm of the small intestine that contains short villi and submucosal glands. (24)

dura mater: The outermost component of the cranial and spinal meninges. (13, 14)

E

eccrine glands: Sweat glands of the skin that produce a watery secretion. (5)

ectoderm: One of the three primary germ layers; covers the surface of the embryo and gives rise to the nervous system, the epidermis and associated glands, and a variety of other structures. (29)

ectopic: Outside the normal location.

effector: A peripheral gland or muscle cell innervated by a motor neuron. (1, 12)

efferent: Away from.

efferent arteriole: An arteriole carrying blood away from a glomerulus of the kidney. (26)

efferent fiber: An axon that carries impulses away from the central nervous system. (12)

ejaculation: The ejection of semen from the penis as the result of muscular contractions of the bulbospongiosus and ischiocavernosus muscles. (28)

ejaculatory ducts: Short ducts that pass within the walls of the prostate gland and connect the ductus deferens with the prostatic urethra. (28)

elastase: A pancreatic enzyme that breaks down elastin fibers. (24)

elastin: Connective tissue fibers that stretch and recoil, providing elasticity to connective tissues. (4, 5)

electrical coupling: A connection between adjacent cells that permits the movement of ions and the transfer of graded or conducted changes in the transmembrane potential from cell to cell. (12)

electrocardiogram (ECG, EKG): A graphic record of the electrical activities of the heart, as monitored at specific locations on the body surface. (20)

electroencephalogram (EEG): A graphic record of the electrical activities of the brain. (14)

electrolytes: Soluble inorganic compounds whose ions will conduct an electrical current in solution. (2, 27)

electron: One of the three fundamental subatomic particles; bears a negative charge and normally orbits the protons of the nucleus. (2, 25)

electron transport system (ETS): The cytochrome system responsible for most of the energy production in cells; a complex bound to the inner mitochondrial membrane.

(25)

element: All the atoms with the same atomic number. (2)

elevation: Movement in a superior, or upward, direction. **elimination:** The ejection of wastes from the body through urination or defecation. (24, 26)

embolism: The obstruction or closure of a vessel by an embolus. (19)

embolus: An air bubble, fat globule, or blood clot drifting in the bloodstream. (19)

embryo: The developmental stage beginning at fertilization and ending at the start of the third developmental month. (29)

embryology: The study of embryonic development, focusing on the first 2 months after fertilization. (1, 28)

endocardium: The simple squamous epithelium that lines the heart and is continuous with the endothelium of the great vessels. (20)

endochondral ossification: The conversion of a cartilaginous model to bone; the characteristic mode of formation for skeletal elements other than the bones of the cranium, the clavicles, and sesamoid bones. (6)

endocrine gland: A gland that secretes hormones into the blood. (4, 18)

endocrine system: The endocrine glands of the body. (18)

endocytosis: The movement of relatively large volumes of extracellular material into the cytoplasm via the formation of a membranous vesicle at the cell surface; includes pinocytosis and phagocytosis. (3)

endoderm: One of the three primary germ layers; the layer on the undersurface of the embryonic disc; gives rise to the epithelia and glands of the digestive system, the respiratory system, and portions of the urinary system. (29)

endogenous: Produced within the body.

endolymph: The fluid contents of the membranous labyrinth (the saccule, utricle, semicircular ducts, and cochlear duct) of the inner ear. (17)

endometrium: The mucous membrane lining the uterus. (28)

endomysium: A delicate network of connective tissue fibers that surrounds individual muscle cells. (10)

endoneurium: A delicate network of connective tissue fibers that surrounds individual nerve fibers. (13)

endoplasmic reticulum: A network of membranous channels in the cytoplasm of a cell that function in intracellular transport, synthesis, storage, packaging, and secretion. (3)

endorphins: Neuromodulators, produced in the central nervous system, that inhibit activity along pain pathways. (12)

endosteum: An incomplete cellular lining on the inner (medullary) surfaces of bones. (6)

endothelium: The simple squamous epithelium cells that line blood and lymphatic vessels. (4, 19, 21)

enkephalins: Neuromodulators, produced in the central nervous system, that inhibit activity along pain pathways. (12)

enterocrinin: A hormone secreted by the lining of the duodenum after exposure to chyme; stimulates the secretion of the submucosal glands. (24)

enteroendocrine cells: Endocrine cells scattered among the epithelial cells that line the digestive tract. (24)

enterogastric reflex: The reflexive inhibition of gastric secretion; initiated by the arrival of chyme in the small intestine. (24)

enterohepatic circulation: The excretion of bile salts by the liver, followed by the absorption of bile salts by intestinal cells for return to the liver by the hepatic portal vein. (24)

enterokinase: An enzyme in the lumen of the small intestine that activates the proenzymes secreted by the pancreas. (24)

enzyme: A protein that catalyzes a specific biochemical reaction. (2)

eosinophil: A microphage (white blood cell) with a lobed nucleus and red-staining granules; participates in the immune response and is especially important during allergic reactions. (19)

ependyma: The layer of cells lining the ventricles and central canal of the central nervous system. (12)

epicardium: A serous membrane covering the outer surface of the heart; also called *visceral pericardium*. (20)

epidermis: The epithelium covering the surface of the skin. (5)

epididymis: A coiled duct that connects the rete testis to the ductus deferens; site of functional maturation of spermatozoa. (28)

epidural space: The space between the spinal dura mater and the walls of the vertebral foramen; contains blood vessels and adipose tissue; a common site of injection for regional anesthesia. (13)

epiglottis: A blade-shaped flap of tissue, reinforced by cartilage, that is attached to the dorsal and superior surface of the thyroid cartilage; folds over the entrance to the larynx during swallowing. (23)

epimysium: A dense layer of collagen fibers that surrounds a skeletal muscle and is continuous with the tendons/aponeuroses of the muscle and with the perimysium.

(10)

epineurium: A dense layer of collagen fibers that surrounds a peripheral nerve. (13)

epiphyseal cartilage: The cartilaginous region between the epiphysis and diaphysis of a growing bone. (6)

epiphysis: The head of a long bone. (6)

epithelium: One of the four primary tissue types; a layer of cells that forms a superficial covering or an internal lining of a body cavity or vessel. (4, 24)

equilibrium: A dynamic state in which two opposing forces or processes are in balance. (1, 15, 17: and hearing) **erection:** The stiffening of the penis due to the engorgement of the erectile tissues of the corpora cavernosa and corpus spongiosum. (28)

erythema: Redness and inflammation at the surface of the skin. (5, 22)

erythrocyte: A red blood cell; has no nucleus and contains large quantities of hemoglobin. (4, 19)

erythropoietin: A hormone released by tissues, especially the kidneys, exposed to low oxygen concentrations; stimulates erythropoiesis (red blood cell formation) in bone marrow. (18, 19, 21)

Escherichia coli: A normal bacterial resident of the large intestine. (24)

esophagus: A muscular tube that connects the pharynx to the stomach. (24)

essential amino acids: Amino acids that cannot be synthesized in the body in adequate amounts and must be obtained from the diet. (25)

essential fatty acids: Fatty acids that cannot be synthesized in the body and must be obtained from the diet. (25)

estrogens: A class of steroid sex hormones that includes estradiol. (2, 18)

evaporation: A movement of molecules from the liquid state to the gaseous state. **eversion:** A turning outward. (9)

excitable membranes: Membranes that propagate action potentials, a characteristic of muscle cells and nerve cells. (10, 12)

excitatory postsynaptic potential (EPSP): The depolarization of a post-synaptic membrane by a chemical neurotransmitter released by the presynaptic cell. (12)

excretion: A removal from body fluids. **exocrine gland:** A gland that secretes onto the body surface or into a passageway connected to the exterior. (4)

exocytosis: The ejection of cytoplasmic materials by the fusion of a membranous vesicle with the cell membrane. (3)

expiration: Exhalation; breathing out. **extension:** An increase in the angle between two articulating bones; the opposite of flexion. (8, 9)

external acoustic canal: A passageway in the temporal bone that leads to the tympanic membrane of the inner ear. (17)

external ear: The auricle, external acoustic canal, and tympanic membrane. (17)

external nares: The nostrils; the external openings into the nasal cavity. (23)

external respiration: The diffusion of gases between the alveolar air and the alveolar capillaries and between the systemic capillaries and peripheral tissues. (23)

exteroceptors: General sensory receptors in the skin, mucous membranes, and special sense organs that provide information about the external environment and about our position within it. (12)

extracellular fluid: All body fluids other than that contained within cells; includes plasma and interstitial fluid. (3, 27)

extraembryonic membranes: The yolk sac, amnion, chorion, and allantois. (29)

extrafusal fibers: Contractile muscle fibers (as opposed to the sensory intrafusal fibers, or muscle spindles). (13)

extrinsic pathway: A clotting pathway that begins with damage to blood vessels or surrounding tissues and ends with the formation of tissue thromboplastin. (19)

F

fabella: A sesamoid bone commonly located in the gastrocnemius muscle. (11)

facilitated: Brought closer to threshold, as in the depolarization of a nerve cell membrane toward threshold; making the cell more sensitive to depolarizing stimuli. (12)

facilitated diffusion: The passive movement of a substance across a cell membrane by means of a protein carrier. (3, 24, 26)

falciform ligament: A sheet of mesentery that contains the ligamentum teres, the fibrous remains of the umbilical vein of the fetus. (29)

falx: Sickle-shaped.

falx cerebri: The curving sheet of dura mater that extends between the two cerebral hemispheres; encloses the superior sagittal sinus. (7, 14)

fasciae: Connective tissue fibers, primarily collagenous, that form sheets or bands beneath the skin to attach, stabilize, enclose, and separate muscles and other internal organs. (4)

fasciculus: A small bundle; usually refers to a collection of nerve axons or muscle fibers. (10, 15)

fatty acids: Hydrocarbon chains that end in a carboxylic acid group. (2)

fauces: The passage from the mouth to the pharynx, bounded by the palatal arches, the soft palate, and the uvula. (24)

febrile: Characterized by or pertaining to a fever. (22, 25)

feces: Waste products eliminated by the digestive tract at the anus; contains indigestible residue, bacteria, mucus, and epithelial cells. (24)

fenestra: An opening.

fertilization: The fusion of a secondary oocyte and a spermatozoon to form a zygote. (28)

fetus: The developmental stage lasting from the start of the third developmental month to delivery. (28, 29)

fibrin: Insoluble protein fibers that form the basic framework of a blood clot. (19)

fibrinogen: A plasma protein that is the soluble precursor of the fibrous protein fibrin. (19)

fibroblasts: Cells of connective tissue proper that are responsible for the production of extracellular fibers and the secretion of the organic compounds of the extracellular matrix. (4)

fibrocartilage: Cartilage containing an abundance of collagen fibers; located around the edges of joints, in the intervertebral discs, the menisci of the knee, and so on. (4)

fibrous tunic: The outermost layer of the eye, composed of the sclera and cornea. (17)

fibula: The lateral, slender bone of the leg. (8)

filariasis: A condition resulting from infection by mosquito-borne parasites; can cause elephantiasis. (21, 22)

filiform papillae: Slender conical projections from the dorsal surface of the anterior two-thirds of the tongue. (17)

filtrate: The fluid produced by filtration at a glomerulus in the kidney. (26)

filtration: The movement of a fluid across a membrane whose pores restrict the passage of solutes on the basis of size. (21, 26)

filtration pressure: The hydrostatic pressure responsible for filtration. (21, 26)

filum terminale: A fibrous extension of the spinal cord, from the conus medullaris to the coccygeal ligament. (13)

fimbriae: Fringes; the fingerlike processes that surround the entrance to the uterine tube. (28)

fissure: An elongate groove or opening. (7, 14)

fistula: An abnormal passageway between two organs or from an internal organ or space to the body surface. **flaccid:** Limp, soft, flabby; a muscle without muscle tone. **flagellum/flagella:** An organelle that is structurally similar to a cilium but is used to propel a cell through a fluid. (28)

flatus: Intestinal gas. (24)

flexion: A movement that reduces the angle between two articulating bones; the opposite of extension. (8, 9)

flexor: A muscle that produces flexion. (11)

flexor reflex: A reflex contraction of the flexor muscles of a limb in response to an unpleasant stimulus. (13)

flexure: A bending. **folia:** Leaflike folds; the slender folds in the surface of the cerebellar cortex. (14)

follicle: A small secretory sac or gland. **follicle-stimulating hormone (FSH):** A hormone secreted by the anterior pituitary; stimulates oogenesis (female) and spermatogenesis (male). (18, 28)

fontanel: A relatively soft, flexible, fibrous region between two flat bones in the developing skull; also spelled *fontanelle*. (7)

foramen/foramina: An opening or passage through a bone. (7, 20)

forearm: The distal portion of the upper limb between the elbow and wrist. (8)

forebrain: The cerebrum. (14)

fornix: An arch or the space bounded by an arch; in the brain, an arching tract that connects the hippocampus with the mamillary bodies (14); in the eye, a slender pocket situated where the epithelium of the ocular conjunctiva folds back on itself as the palpebral conjunctiva (17); in the vagina, the shallow recess surrounding the protrusion of the cervix (28)

fossa: A shallow depression or furrow in the surface of a bone. (8, 20)

fourth ventricle: An elongate ventricle of the metencephalon (pons and cerebellum) and the myelencephalon (medulla oblongata) of the brain; the roof contains a region

of choroid plexus. (14)

fovea: The portion of the retina that provides the sharpest vision because it has the highest concentration of cones; also called *macula lutea*. (17)

fracture: A break or crack in a bone. (6)

frenulum: A bridle;usually referring to a band of tissue that restricts movement, e.g. *lingual frenulum* (24)

frontal plane: A sectional plane that divides the body into an anterior portion and a posterior portion; also called *coronal plane*. (1)

fructose: A hexose (six-carbon simple sugar) in foods and in semen. (2, 28)

fundus: The base of an organ.

G

gallbladder: The pear-shaped reservoir for bile after it is secreted by the liver. (24)

gametes: Reproductive cells (spermatozoa or oocytes) that contain half the normal chromosome complement. (28, 29)

gametogenesis: The formation of gametes. (28)

gamma aminobutyric acid (GABA): A neurotransmitter of the central nervous system whose effects are generally inhibitory. (12)

gamma motor neurons: Motor neurons that adjust the sensitivities of muscle spindles (intrafusal fibers). (13)

ganglion/ganglia: A collection of neuron cell bodies outside the central nervous system. (12, 16)

gangliosides: Glycolipids that are important components of cell membranes in the central nervous system. (12)

gap junctions: Connections between cells that permit electrical coupling. (4)

gaster: The stomach (24); the body, or belly, of a skeletal muscle (11)

gastric: Pertaining to the stomach. (24)

gastric glands: The tubular glands of the stomach whose cells produce acid, enzymes, intrinsic factor, and hormones. (24)

gastrointestinal (GI) tract: *See* **digestive tract**.

gene: A portion of a DNA strand that functions as a hereditary unit, is located at a particular site on a specific chromosome, and codes for a specific protein. (3, 29)

genetic engineering: Research and experiments involving the manipulation of the genetic makeup of an organism. (29)

genetics: The study of mechanisms of heredity. (29)

geniculate: Like a little knee; the medial geniculates and the lateral geniculates are nuclei in the thalamus of the brain. (14)

genitalia: The reproductive organs. (28)

germinal centers: Pale regions in the interior of lymphoid tissues or nodules, where cell divisions are under way. (22)

gestation: The period of intrauterine development. (29)

gland: Cells that produce exocrine or endocrine secretions. (4)

glenoid cavity: A rounded depression that forms the articular surface of the scapula at the shoulder joint. (8)

glial cells: *See* **neuroglia**.

globular proteins: Proteins whose tertiary structure makes them rounded and compact. (2)

glomerular capsule: The expanded initial portion of the nephron that surrounds the glomerulus. (26)

glomerular filtration rate: The rate of filtrate formation at the glomerulus. (26)

glomerulus: A ball or knot; in the kidneys, a knot of capillaries that projects into the enlarged, proximal end of a nephron; the site of filtration, the first step in the production of urine. (26)

glossopharyngeal nerve: Cranial nerve IX. (14)

glucagon: A hormone secreted by the alpha cells of the pancreatic islets; elevates blood glucose concentrations. (18)

glucocorticoids: Hormones secreted by the zona fasciculata of the adrenal cortex to modify glucose metabolism; cortisol and corticosterone are important examples. (18)

gluconeogenesis: The synthesis of glucose from protein or lipid precursors. (25)

glucose: A six-carbon sugar, $C_6H_{12}O_6$; the preferred energy source for most cells and normally the only energy source for neurons. (2, 10, 18, 25)

glycerides: Lipids composed of glycerol bound to fatty acids. (2)

glycogen: A polysaccharide that is an important energy reserve; a polymer consisting of a long chain of glucose molecules. (2, 10)

glycogenesis: The synthesis of glycogen from glucose molecules. (25)

glycogenolysis: Glycogen breakdown and the liberation of glucose molecules. (25)

glycolipids: Compounds created by the combination of carbohydrate and lipid components. (2)

glycolysis: The anaerobic cytoplasmic breakdown of glucose into lactic acid by way of pyruvic acid, with a net gain of two ATP molecules. (3, 10, 25)

glycoprotein: A compound containing a relatively small carbohydrate group attached to a large protein. (2, 18)

glycosuria: The presence of glucose in urine. (18, 26)

goblet cell: A goblet-shaped, mucus-producing, unicellular gland in certain epithelia of the digestive and respiratory tracts. (4)

Golgi apparatus: A cellular organelle consisting of a series of membranous plates that give rise to lysosomes and secretory vesicles. (3)

gomphosis: A fibrous synarthrosis that binds a tooth to the bone of the jaw; *see* **periodontal ligament**. (24)

gonadotropin-releasing hormone (GnRH): A hypothalamic releasing hormone that causes the secretion of both follicle-stimulating hormone and luteinizing hormone

by the anterior pituitary gland. (18, 28)

gonadotropins: Follicle-stimulating hormone and luteinizing hormone, hormones that stimulate gamete development and sex hormone secretion. (18, 28)

gonads: Reproductive organs that produce gametes and hormones. (28)

granulocytes: White blood cells containing granules that are visible with the light microscope; includes eosinophils, basophils, and neutrophils; also called *granular leukocytes*. (19)

gray matter: Areas in the central nervous system that are dominated by neuron cell bodies, neuroglia, and unmyelinated axons. (12, 13, 14)

gray ramus: A bundle of postganglionic sympathetic nerve fibers that are distributed to effectors in the body wall, skin, and limbs by way of a spinal nerve. (13)

greater omentum: A large fold of the dorsal mesentery of the stomach; hangs anterior to the intestines. (24)

groin: The inguinal region. (11)

gross anatomy: The study of the structural features of the body without the aid of a microscope. **growth hormone (GH):** An anterior pituitary hormone that stimulates tissue growth and anabolism when nutrients are abundant and restricts tissue glucose dependence when nutrients are in short supply. (18)

growth hormone–inhibiting hormone (GH-IH): A hypothalamic regulatory hormone that inhibits growth hormone secretion by the anterior pituitary; also called *somatostatin*. (18)

guanine: A purine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

gustation: Taste. (15, 17)

gyrus: A prominent fold or ridge of neural cortex on the surfaces of the cerebral hemispheres. (14)

H

hair: A keratinous strand produced by epithelial cells of the hair follicle. (5)

hair cells: Sensory cells of the inner ear. (17)

hair follicle: An accessory structure of the integument; a tube lined by a stratified squamous epithelium that begins at the surface of the skin and ends at the hair papilla.

(5)

hallux: The big toe. (8)

haploid: Possessing half the normal number of chromosomes; a characteristic of gametes. (28, 29)

hard palate: The bony roof of the oral cavity, formed by the maxillary and palatine bones. (23, 24)

helper T cells: Lymphocytes whose secretions and other activities coordinate cell-mediated and antibody-mediated immunities; also called *TH cells*. (22)

hematocrit: The percentage of the volume of whole blood contributed by cells; also called *volume of packed red cells (VPRC)* or *packed cell volume (PCV).* (19)

hematoma: A tumor or swelling filled with blood. (AM) **hematuria:** The presence of abnormal numbers of red blood cells in urine. (19, 26)

heme: A porphyrin ring containing a central iron atom that can reversibly bind oxygen molecules; a component of the hemoglobin molecule. (19)

hemocytoblasts: Stem cells whose divisions produce each of the various populations of blood cells. (19)

hemoglobin: A protein composed of four globular subunits, each bound to a heme molecule; gives red blood cells the ability to transport oxygen in the blood. (5, 19, 23, 27)

hemolysis: The breakdown of red blood cells. (3)

hemopoiesis: Blood cell formation and differentiation. (19)

hemorrhage: Blood loss. (21)

hemostasis: The cessation of bleeding. (19)

heparin: An anticoagulant released by activated basophils and mast cells. (4, 19)

hepatic duct: The duct that carries bile away from the liver lobes and toward the union with the cystic duct. (24)

hepatic portal vein: The vessel that carries blood between the intestinal capillaries and the sinusoids of the liver. (21)

hepatocyte: A liver cell. (24)

heterotopic: Ectopic; outside the normal location. **heterozygous:** Possessing two different alleles at corresponding sites on a chromosome pair; the individual's phenotype is determined by one or both of the alleles. (29)

hexose: A six-carbon simple sugar. (2)

hiatus: A gap, cleft, or opening. **high-density lipoprotein (HDL):** A lipoprotein with a relatively small lipid content; thought to be responsible for the movement of cholesterol from peripheral tissues to

the liver. (25)

hilum/hilus: A localized region where blood vessels, lymphatic vessels, nerves, and/or other anatomical structures are attached to an organ. (22, 23, 26)

hippocampus: A region, beneath the floor of a lateral ventricle, involved with emotional states and the conversion of short-term to long-term memories. (12, 14)

histamine: The chemical released by stimulated mast cells or basophils to initiate or enhance an inflammatory response. (4, 12)

histology: The study of tissues. (1, 4)

histones: Proteins associated with the DNA of the nucleus; the DNA strands are wound around them. (3)

holocrine: A form of exocrine secretion in which the secretory cell becomes swollen with vesicles and then ruptures. (4)

homeostasis: The maintenance of a relatively constant internal environment. (1)

hormone: A compound that is secreted by one cell and travels through the circulatory system to affect the activities of cells in another portion of the body. (2, 4, 6, 18, 21, 24, 28, 29)

human chorionic gonadotropin (hCG): The placental hormone that maintains the corpus luteum for the first 3 months of pregnancy. (29)

human immunodeficiency virus (HIV): The infectious agent that causes acquired immune deficiency syndrome (AIDS). (22)

human leukocyte antigen (HLA): *See* **MHC protein**. **human placental lactogen (hPL):** The placental hormone that stimulates the functional development of the mammary glands. (29)

humoral immunity: *See* **antibody-mediated immunity**. **hyaluronan:** A carbohydrate component of proteoglycans in the matrix of many connective tissues. (4)

hyaluronidase: An enzyme that breaks down the bonds between adjacent follicle cells; produced by some bacteria and found in the acrosomal cap of a spermatozoon.

(29)

hydrogen bond: A weak interaction between the hydrogen atom on one molecule and a negatively charged portion of another molecule. (2)

hydrolysis: The breakage of a chemical bond through the addition of a water molecule; the reverse of dehydration synthesis. (2)

hydrophilic: Freely associating with water; readily entering into solution. (2)

hydrophobic: Incapable of freely associating with water molecules; insoluble. (2)

hydrostatic pressure: Fluid pressure. (21, 26)

-

hydroxide ion: OH. (2)

hypercapnia: High plasma carbon dioxide concentrations, commonly as a result of hypoventilation or inadequate tissue perfusion. (23, 27)

hyperplasia: An abnormal enlargement of an organ due to an increase in the number of cells. (3)

hyperpolarization: The movement of the transmembrane potential away from the normal resting potential and farther from 0 mV. (12)

hypersecretion: The overactivity of glands that produce exocrine or endocrine secretions. (18)

hypertension: Abnormally high blood pressure. (21)

hypertonic: In comparing two solutions, the solution with the higher osmolarity. (3)

hypertrophy: An increase in the size of tissue without cell division. (10)

hyperventilation: A rate of respiration sufficient to reduce plasma PCO_2 to levels below normal. (23, 27)

hypocapnia: An abnormally low plasma PCO_2 commonly as a result of hyperventilation. (27)

hypodermic needle: A needle inserted through the skin to introduce drugs into the subcutaneous layer. (5)

hypodermis: *See* **subcutaneous layer**. **hypophyseal portal system:** The network of vessels that carry blood from capillaries in the hypothalamus to capillaries in the anterior lobe of the pituitary gland. (18)

hypophysis: The pituitary gland. (18)

hyposecretion: Abnormally low rates of exocrine or endocrine secretion. (18)

hypothalamus: The floor of the diencephalon; the region of the brain containing centers involved with the subconscious regulation of visceral functions, emotions, drives, and the coordination of neural and endocrine functions. (14)

hypothermia: An abnormally low body temperature. (25)

hypothesis: A prediction that can be subjected to scientific analysis and review. **hypotonic:** In comparing two solutions, the solution with the lower osmolarity. (3)

hypoventilation: A respiratory rate that is insufficient to keep plasma PCO_2 within normal levels. (23, 27)

hypoxia: A low tissue oxygen concentration. (19, 23)

ileum: The distal 2.5 m of the small intestine. (24)

ilium: The largest of the three bones whose fusion creates an os coxae. (8)

immunity: Resistance to injuries and diseases caused by foreign compounds, toxins, or pathogens. (22)

immunization: The production of immunity by the deliberate exposure to antigens under conditions that prevent the development of illness but stimulate the production of memory B cells. (22)

immunoglobulin: A circulating antibody. (19, 22)

implantation: The erosion of a blastocyst into the uterine wall. (29)

inclusions: Aggregations of insoluble pigments, nutrients, or other materials in cytoplasm. (3)

incus: The central auditory ossicle, situated between the malleus and the stapes in the middle ear cavity. (17)

inducer: A stimulus that promotes the activity of a specific gene. (29)

inexcitable: Incapable of propagating an action potential. (12)

infarct: An area of dead cells that results from an interruption of blood flow. (19, 20)

infection: The invasion and colonization of body tissues by pathogens. (4)

inferior: Below, in reference to a particular structure, with the body in the anatomical position.

inferior vena cava: The vein that carries blood from the parts of the body inferior to the heart to the right atrium. (20, 21)

infertility: The inability to conceive; also called *sterility*.(28. 29)

inflammation: A nonspecific defense mechanism that operates at the tissue level; characterized by swelling, redness, warmth, pain, and some loss of function. (4, 22)

infundibulum: A tapering, funnel-shaped structure; in the brain, the connection between the pituitary gland and the hypothalamus (14, 18); in the uterine tube, the entrance bounded by fimbriae that receives the oocytes at ovulation (28)

ingestion: The introduction of materials into the digestive tract by way of the mouth. (24)

inguinal canal: A passage through the abdominal wall that marks the path of testicular descent and that contains the testicular arteries, veins, and ductus deferens. (11, 28)

inguinal region: The area near the junction of the trunk and the thighs that contains the external genitalia; a.k.a. groin. (28)

inhibin: A hormone, produced by sustentacular cells of the testes and follicular cells of the ovaries, that inhibits the secretion of follicle-stimulating hormone by the anterior lobe of the pituitary gland. (18, 28)

inhibitory postsynaptic potential (IPSP): A hyperpolarization of the postsynaptic membrane after the arrival of a neurotransmitter. (12)

initial segment: The proximal portion of the axon where an action potential first appears. (12)

injection: The forcing of fluid into a body part or organ.

inner cell mass: Cells of the blastocyst that will form the body of the embryo. (29)

inner ear: *See* **internal ear**.

innervation: The distribution of sensory and motor nerves to a specific region or organ. (11, 16)

insensible perspiration: Evaporative water loss by diffusion across the epithelium of the skin or evaporation across the alveolar surfaces of the lungs. (5, 27)

insertion: A point of attachment of a muscle; the end that is easily movable. (11)

insoluble: Incapable of dissolving in solution. (2)

inspiration: Inhalation; the movement of air into the respiratory system. (23)

insulin: A hormone secreted by the beta cells of the pancreatic islets; causes a reduction in plasma glucose concentrations. (18)

integument: The skin. (5)

intercalated discs: Regions where adjacent cardiocytes interlock and where gap junctions permit electrical coupling between the cells. (4, 10, 20)

intercellular cement: Proteoglycans situated between adjacent epithelial cells. (4)

intercellular fluid: *See* **interstitial fluid**.

interferons: Peptides released by virus-infected cells, especially lymphocytes, that slow viral replication and make other cells more resistant to viral infection. (22)

interleukins: Peptides, released by activated monocytes and lymphocytes, that assist in the coordination of cell-mediated and antibody-mediated immunities. (22)

internal capsule: The collection of afferent and efferent fibers of the white matter of the cerebral hemispheres, visible on gross dissection of the brain. (14)

internal ear: The membranous labyrinth that contains the organs of hearing and equilibrium. (17)

internal nares: The entrance to the nasopharynx from the nasal cavity. (23)

internal respiration: The diffusion of gases between interstitial fluid and cytoplasm. (23)

interneuron: An association neuron; central nervous system neurons that are between sensory and motor neurons. (12)

interoceptors: Sensory receptors monitoring the functions and status of internal organs and systems. (12)

interosseous membrane: The fibrous connective tissue membrane between the shafts of the tibia and fibula and between the radius and ulna; an example of a fibrous amphiarthrosis. (8)

interphase: The stage in the life cycle of a cell during which the chromosomes are uncoiled and all normal cellular functions except mitosis are under way. (29)

intersegmental reflex: A reflex that involves several segments of the spinal cord. (13)

interstitial fluid: The fluid in the tissues that fills the spaces between cells. (3)

interstitial growth: A form of cartilage growth through the growth, mitosis, and secretion of chondrocytes in the matrix. (4)

interventricular foramen: The opening that permits fluid movement between the lateral and third ventricles of the brain. (14)

intervertebral disc: A fibrocartilage pad between the bodies of successive vertebrae that absorbs shocks. (7, 9)

intestinal crypt: A tubular epithelial pocket that is lined by secretory cells and opens into the lumen of the digestive tract; also called *intestinal gland*. (24)

intestine: The tubular organ of the digestive tract. (18, 24)

intracellular fluid: The cytosol. (27)

intrafusal fibers: Muscle spindle fibers. (13)

intramembranous ossification: The formation of bone within a connective tissue without the prior development of a cartilaginous model. (6)

intrinsic factor: A glycoprotein, secreted by the parietal cells of the stomach, that facilitates the intestinal absorption of vitamin B12 . (19, 24, 25)

intrinsic pathway: A pathway of the clotting system that begins with the activation of platelets and ends with the formation of platelet thromboplastin. (19)

inversion: A turning inward. (9)

in vitro: Outside the body, in an artificial environment.

in vivo: In the living body.

involuntary: Not under conscious control.

ion: An atom or molecule bearing a positive or negative charge due to the donation or acceptance, respectively, of an electron. (2, 26, 27)

ionic bond: A molecular bond created by the attraction between ions with opposite charges. (2)

ionization: Dissociation; the breakdown of a molecule in solution to form ions. (2)

ipsilateral: A reflex response that affects the same side as the stimulus. (13)

iris: A contractile structure, made up of smooth muscle, that forms the colored portion of the eye. (17)

ischemia: An inadequate blood supply to a region of the body. (11)

ischium: One of the three bones whose fusion creates an os coxae. (8)

islets of Langerhans: *See* **pancreatic islets.**

isotonic: A solution with an osmolarity that does not result in water movement across cell membranes. (10)

isotopes: Forms of an element whose atoms contain the same number of protons but different numbers of neutrons (and thus differ in atomic weight). (2)

isthmus: A narrow band of tissue connecting two larger masses.

J

jejunum: The middle part of the small intestine. (24)

joint: An area where adjacent bones interact; also called *articulation*. (9)

juxtaglomerular apparatus: The macula densa and the juxtaglomerular cells; a complex responsible for the release of renin and erythropoietin. (26)

juxtaglomerular cells: Modified smooth muscle cells in the walls of the afferent and efferent arterioles adjacent to the glomerulus and the macula densa. (26)

K

keratin: The tough, fibrous protein component of nails, hair, calluses, and the general integumentary surface. (5)

keto acid: A molecule that ends in— COCOOH; the carbon chain that remains after the deamination or transamination of an amino acid. (25)

ketoacidosis: A reduction in the pH of body fluids due to the presence of large numbers of ketone bodies. (25, 26, 27)

ketone bodies: Keto acids produced during the catabolism of lipids and ketogenic amino acids; specifically, acetone, acetoacetate, and beta-hydroxybutyrate. (25)

kidney: A component of the urinary system; an organ functioning in the regulation of plasma composition, including the excretion of wastes and the maintenance of normal fluid and electrolyte balances. (18, 26)

killer T cells: *See* **cytotoxic T cells**. **Krebs cycle:** *See* **TCA cycle**. **Kupffer cells:** Stellate reticular cells of the liver; phagocytic cells of the liver sinusoids. (22, 24)

labium/labia: Lips; the labia majora and labia minora are components of the female external genitalia. (28)

labrum: A lip or rim.

labyrinth: A maze of passageways; the structures of the inner ear. (17)

lacrimal gland: A tear gland on the dorsolateral surface of the eye. (17)

lactase: An enzyme that breaks down milk proteins. (24)

lactation: The production of milk by the mammary glands. (28)

lacteal: A terminal lymphatic within an intestinal villus. (24)

lactic acid: A compound produced from pyruvic acid under anaerobic conditions. (10)

lacuna: A small pit or cavity. (4, 6)

lambdoid suture: The synarthrosis between the parietal and occipital bones of the cranium. (7)

lamellae: Concentric layers; the concentric layers of bone within an osteon. (6)

lamellated corpuscle: A receptor sensitive to vibration. (15)

lamina: A thin sheet or layer.

lamina propria: The reticular tissue that underlies a mucous epithelium and forms part of a mucous membrane. (4, 23, 24)

Langerhans cells: Cells in the epithelium of the skin (15)

and digestive tract (24)

that participate in the immune response by presenting antigens to T cells.

large intestine: The terminal portions of the intestinal tract, consisting of the colon, the rectum, and the anal canal. (24)

laryngopharynx: The division of the pharynx that is inferior to the epiglottis and superior to the esophagus. (23)

larynx: A complex cartilaginous structure that surrounds and protects the glottis and vocal cords; the superior margin is bound to the hyoid bone, and the inferior margin is bound to the trachea. (23)

latent period: The time between the stimulation of a muscle and the start of the contraction phase. (10)

lateral: Pertaining to the side. **lateral apertures:** Openings in the roof of the fourth ventricle that permit the circulation of cerebrospinal fluid into the subarachnoid space. (14)

lateral ventricle: A fluid-filled chamber within a cerebral hemisphere. (14)

lens: The transparent body that is inferior to the iris and pupil and superior to the vitreous humor. (17)

lesion: A localized abnormality in tissue organization. (4)

lesser omentum: A small pocket in the mesentery that connects the lesser curvature of the stomach to the liver. (24)

leukocyte: A white blood cell. (4, 19)

ligament: A dense band of connective tissue fibers that attaches one bone to another. (4, 9)

ligamentum arteriosum: The fibrous strand in adults that is the remnant of the ductus arteriosus of the fetal stage. (21)

ligamentum nuchae: An elastic ligament between the vertebra prominens and the occipital bone. (7)

ligamentum teres: The fibrous strand in the falciform ligament of adults that is the remnant of the umbilical vein of the fetal stage. (24)

ligate: To tie off. **limbic system:** The group of nuclei and centers in the cerebrum and diencephalon that are involved with emotional states, memories, and behavioral drives. (14)

lingual: Pertaining to the tongue. (17, 24)

lipid: An organic compound containing carbons, hydrogens, and oxygens in a ratio that does not approximate 1:2:1; includes fats, oils, and waxes. (2, 24, 25)

lipogenesis: The synthesis of lipids from nonlipid precursors. (25)

lipoids: Prostaglandins, steroids, phospholipids, glycolipids, and so on. (25)

lipolysis: The catabolism of lipids as a source of energy. (25)

lipoprotein: A compound containing a relatively small lipid bound to a protein. (25)

liver: An organ of the digestive system that has varied and vital functions, including the production of plasma proteins, the excretion of bile, the storage of energy reserves, the detoxification of poisons, and the interconversion of nutrients. (24)

lobule: Histologically, the basic organizational unit of the liver. (24)

local hormone: *See* **prostaglandin**. **loop of Henle:** The portion of the nephron that creates the concentration gradient in the renal medulla. (26)

loose connective tissue: A loosely organized, easily distorted connective tissue that contains several fiber types, a varied population of cells, and a viscous ground substance. (4)

lumbar: Pertaining to the lower back. (7, 13)

lumen: The central space within a duct or other internal passageway. (4)

lungs: The paired organs of respiration, situated in the pleural cavities. (23)

luteinizing hormone (LH): Also called *lutropin*; a hormone produced by the anterior lobe of the pituitary gland. In females, it assists FSH in follicle stimulation, triggers ovulation, and promotes the maintenance and secretion of endometrial glands. In males, it was formerly called *interstitial cell-stimulating hormone* because it stimulates testosterone secretion by the interstitial cells of the testes. (18, 28)

lymph: The fluid contents of lymphatic vessels, similar in composition to interstitial fluid. (4, 22)

lymphatic vessels: The vessels of the lymphatic system; also called *lymphatics*. (4, 22)

lymph nodes: Lymphoid organs that monitor the composition of lymph. (22)

lymphocyte: A cell of the lymphatic system that participates in the immune response. (4, 19, 22)

lymphokines: Chemicals secreted by activated lymphocytes. (22)

lymphopoiesis: The production of lymphocytes from lymphoid stem cells. (19, 22)

lymphotoxin: A secretion of lymphocytes that kills the target cells. (22)

lysis: The destruction of a cell through the rupture of its cell membrane. (3)

lysosome: An intracellular vesicle containing digestive enzymes. (3)

lysozyme: An enzyme, present in some exocrine secretions, that has antibiotic properties. (17)

M

macrophage: A phagocytic cell of the monocyte–macrophage system. (4, 22)

macula: A receptor complex, located in the saccule or utricle of the inner ear, that responds to linear acceleration or gravity. (17)

macula densa: A group of specialized secretory cells that is located in a portion of the distal convoluted tubule, adjacent to the glomerulus and the juxtaglomerular cells; a component of the juxtaglomerular apparatus. (26)

macula lutea: *See* **fovea**.

major histocompatibility complex: *See* **MHC protein**.

malignant tumor: A form of cancer characterized by rapid cell growth and the spread of cancer cells throughout the body. (3)

malleus: The first auditory ossicle, bound to the tympanic membrane and the incus. (17)

malnutrition: An unhealthy state produced by inadequate dietary intake of nutrients, calories, and/or vitamins. (25)

mamillary bodies: Nuclei in the hypothalamus that affect eating reflexes and behaviors; a component of the limbic system. (14)

mammary glands: Milk-producing glands of the female breast. (5, 28)

manus: The hand. (8, 11)

marrow: A tissue that fills the internal cavities in bone; dominated by hemopoietic cells (red bone marrow) or by adipose tissue (yellow bone marrow). (6, 19)

mast cell: A connective tissue cell that, when stimulated, releases histamine, serotonin, and heparin, initiating the inflammatory response. (4)

mastication: Chewing. (11, 24)

mastoid sinus: Air-filled spaces in the mastoid process of the temporal bone. (7)

matrix: The extracellular fibers and ground substance of a connective tissue. (4)

maxillary sinus: One of the paranasal sinuses; an air-filled chamber lined by a respiratory epithelium that is located in a maxillary bone and opens into the nasal cavity.

(7)

meatus: An opening or entrance into a passageway. (23, 26)

mechanoreception: The detection of mechanical stimuli, such as touch, pressure, or vibration. (15)

medial: Toward the midline of the body. **mediastinum:** The central tissue mass that divides the thoracic cavity into two pleural cavities (1, 20); includes the aorta and other great vessels, the esophagus, trachea,
thymus, the pericardial cavity and heart, and a host of nerves, small vessels, and lymphatic vessels; in males, the area of connective tissue attaching a testis to the epididymis, proximal portion of ductus deferens, and associated vessels (28)

medulla: The inner layer or core of an organ. **medulla oblongata:** The most caudal of the brain regions, also called the *myelencephalon*. (14)

medullary cavity: The space within a bone that contains the marrow. (6)

medullary rhythmicity center: The center in the medulla oblongata that sets the background pace of respiration; includes inspiratory and expiratory centers. (14)

megakaryocytes: Bone marrow cells responsible for the formation of platelets. (19)

meiosis: Cell division that produces gametes with half the normal somatic chromosome complement. (3, 28)

melanin: The yellow-brown pigment produced by the melanocytes of the skin. (5)

melanocyte: A specialized cell in the deeper layers of the stratified squamous epithelium of the skin; responsible for the production of melanin. (4, 5, 18)

melanocyte-stimulating hormone (MSH): A hormone, produced by the pars intermedia of the anterior lobe of the pituitary gland, that stimulates melanin production.

(18)

melatonin: A hormone secreted by the pineal gland; inhibits secretion of MSH and GnRH. (14, 18)

membrane: Any sheet or partition; a layer consisting of an epithelium and the underlying connective tissue. (2)

membrane flow: The movement of sections of membrane surface to and from the cell surface and components of the endoplasmic reticulum, the Golgi apparatus, and

vesicles. (3)

membrane potential: *See* **transmembrane potential**.

membranous labyrinth: Endolymph-filled tubes that enclose the receptors of the inner ear. (17)

memory: The ability to recall information or sensations; can be divided into short-term and long-term memories (16)

(22, immunologic memory)

meninges: Three membranes that surround the surfaces of the central nervous system; the dura mater, the pia mater, and the arachnoid. (13)

meniscus: A fibrocartilage pad between opposing surfaces in a joint. (9)

menses: The first portion of the uterine cycle, the portion in which the endometrial lining sloughs away. (28)

merocrine: A method of secretion in which the cell ejects materials through exocytosis of the midbrain. (4, 5)

mesencephalon: The midbrain; the region between the diencephalon and pons. (14)

mesenchyme: Embryonic or fetal connective tissue. (4)

mesentery: A double layer of serous membrane that supports and stabilizes the position of an organ in the abdominopelvic cavity and provides a route for the associated blood vessels, nerves, and lymphatic vessels. (24)

mesoderm: The middle germ layer, between the ectoderm and endoderm of the embryo.

(29)

mesothelium: A simple squamous epithelium that lines one of the divisions of the ventral body cavity. (4)

messenger RNA (mRNA): RNA formed at transcription to direct protein synthesis in the cytoplasm. (2, 3)

metabolic turnover: The continuous breakdown and replacement of organic materials within cells. (2, 25)

metabolism: The sum of all biochemical processes under way within the human body at any moment; includes anabolism and catabolism. (25)

metabolites: Compounds produced in the body as a result of metabolic reactions. (2)

metacarpal bones: The five bones of the palm of the hand. (8)

metalloproteins: Plasma proteins that transport metal ions. (19)

metaphase: The stage of mitosis in which the chromosomes line up along the equatorial plane of the cell. (3)

metaphysis: The region of a long bone between the epiphysis and diaphysis, corresponding to the location of the epiphyseal cartilage of the developing bone. (6)

metarteriole: A vessel that connects an arteriole to a venule and that provides blood to a capillary plexus. (21)

metastasis: The spread of cancer cells from one organ to another, leading to the establishment of secondary tumors. (3)

metatarsal bone: One of the five bones of the foot that articulate with the tarsal bones (proximally) and the phalanges (distally). (8)

metencephalon: The pons and cerebellum of the brain. (14)

MHC protein: A surface antigen that is important to the recognition of foreign antigens and that plays a role in the coordination and activation of the immune response;

also called *human leukocyte antigen (HLA)*. (22)

micelle: A droplet with hydrophilic portions on the outside; a spherical aggregation of bile salts, monoglycerides, and fatty acids in the lumen of the intestinal tract. (2, 24)

microfilaments: Fine protein filaments visible with the electron microscope; components of the cytoskeleton. (3)

microglia: Phagocytic neuroglia in the central nervous system. (12, 22)

microphages: Neutrophils and eosinophils. (4, 19, 22)

microtubules: Microscopic tubules that are part of the cytoskeleton and are a component in cilia, flagella, the centrioles, and spindle fibers. (3)

microvilli: Small, fingerlike extensions of the exposed cell membrane of an epithelial cell. (3)

micturition: Urination. (26)

midbrain: The mesencephalon. (14)

middle ear: The space between the external and internal ears that contains auditory ossicles. (17)

midsagittal plane: A plane passing through the midline of the body that divides it into left and right halves. (1)

mineralocorticoid: Corticosteroids produced by the zona glomerulosa of the adrenal cortex; steroids such as aldosterone that affect mineral metabolism. (18)

mitochondrion: An intracellular organelle responsible for generating most of the ATP required for cellular operations. (3, 25)

mitosis: The division of a single cell nucleus that produces two identical daughter cell nuclei; an essential step in cell division. (3, 28)

mitral valve: *See* **bicuspid valve**.

mixed gland: A gland that contains exocrine and endocrine cells, or an exocrine gland that produces serous and mucous secretions. (4)

mixed nerve: A peripheral nerve that contains sensory and motor fibers. (13)

mole: A quantity of an element or compound having a mass in grams equal to the element's atomic weight or to the compound's molecular weight. (2)

molecular weight: The sum of the atomic weights of all the atoms in a molecule. (3)

molecule: A chemical structure containing two or more atoms that are held together by chemical bonds. (3)

monoclonal antibodies: Antibodies produced by genetically identical cells under laboratory conditions. (22)

monocytes: Phagocytic agranulocytes (white blood cells) in the circulating blood. (19)

monoglyceride: A lipid consisting of a single fatty acid bound to a molecule of glycerol. (2)

monokines: Secretions released by activated cells of the monocyte–macrophage system to coordinate various aspects of the immune response. (22)

monosaccharide: A simple sugar, such as glucose or ribose. (2, 24)

monosynaptic reflex: A reflex in which the sensory afferent neuron synapses directly on the motor efferent neuron. (13)

motor unit: All of the muscle cells controlled by a single motor neuron. (10)

mucins: Proteoglycans responsible for the lubricating properties of mucus. (2, 24)

mucosa: A mucous membrane; the epithelium plus the lamina propria. (4, 24)

mucosa-associated lymphoid tissue (MALT): The extensive collection of lymphoid tissues linked with the digestive system. (22)

mucous (adjective): Indicating the presence or production of mucus.

mucous membrane: *See* **mucosa**.

mucus (noun): A lubricating fluid that is composed of water and mucins and is produced by unicellular and multicellular glands along the digestive, respiratory, urinary, and reproductive tracts. (2, 4)

multipolar neuron: A neuron with many dendrites and a single axon; the typical form of a motor neuron. (12)

multiunit smooth muscle: A smooth muscle tissue whose muscle cells are innervated in motor units. (10)

muscarinic receptors: Membrane receptors sensitive to acetylcholine and to muscarine, a toxin produced by certain mushrooms; located at all parasympathetic neuromuscular and neuroglandular junctions and at a few sympathetic neuromuscular and neuroglandular junctions. (16)

muscle: A contractile organ composed of muscle tissue, blood vessels, nerves, connective tissues, and lymphatic vessels. (10, 11)

muscle tissue: A tissue characterized by the presence of cells capable of contraction; includes skeletal, cardiac, and smooth muscle tissues. (4, 10)

muscularis externa: Concentric layers of smooth muscle responsible for peristalsis. (24)

muscularis mucosae: The layer of smooth muscle beneath the lamina propria; responsible for moving the mucosal surface. (24)

mutagens: Chemical agents that induce mutations and may be carcinogenic. (3)

mutation: A change in the nucleotide sequence of the DNA in a cell. (3)

myelencephalon: *See* **medulla oblongata**. **myelin:** An insulating sheath around an axon; consists of multiple layers of neuroglial membrane; significantly increases the impulse propagation rate along the axon. (12)

myelination: The formation of myelin. (12)

myenteric plexus: :Parasympathetic motor neurons and sympathetic postganglionic fibers located between the circular and longitudinal layers of the muscularis externa.

(24)

myocardial infarction: A heart attack; damage to the heart muscle due to an interruption of regional coronary circulation. (20)

myocardium: The cardiac muscle tissue of the heart. (20)

myofibril: Organized collections of myofilaments in skeletal and cardiac muscle cells. (10)

myofilaments: Fine protein filaments composed primarily of the proteins actin (thin filaments) and myosin (thick filaments). (10)

myoglobin: An oxygen-binding pigment that is especially common in slow skeletal muscle fibers and cardiac muscle cells. (2, 10)

myogram: A recording of the tension produced by muscle fibers on stimulation. (10)

myometrium: The thick layer of smooth muscle in the wall of the uterus. (28)

myosepta: Connective tissue partitions that separate adjacent skeletal muscles. (11)

myosin: The protein component of thick filaments. (3, 10)

N

nail: A keratinous structure produced by epithelial cells of the nail root. (5)

nares, external: The entrance from the exterior to the nasal cavity. (23)

nares, internal: The entrance from the nasal cavity to the nasopharynx. (23)

nasal cavity: A chamber in the skull that is bounded by the internal and external nares. (7)

nasolacrimal duct: The passageway that transports tears from the nasolacrimal sac to the nasal cavity. (7, 17)

nasolacrimal sac: A chamber that receives tears from the lacrimal ducts. (17)

nasopharynx: A region that is posterior to the internal nares and superior to the soft palate and ends at the oropharynx. (23)

natriuretic peptides (NP): Hormones released by specialized cardiocytes when they are stretched by an abnormally large venous return; promotes fluid loss and reduc

tions in blood pressure and in venous return. Includes atrial natural peptide (ANP) and brain natriuretic (BNP). (18, 21, 26, 27)

N compound: An organic compound containing nitrogen atoms. (25)

necrosis: The death of cells or tissues from disease or injury. (4, 22)

negative feedback: A corrective mechanism that opposes or negates a variation from normal limits. (18)

neonate: A newborn infant, or baby. (29)

neoplasm: A tumor, or mass of abnormal tissue. (3)

nephron: The basic functional unit of the kidney. (26)

nerve impulse: An action potential in a neuron cell membrane. (12)

neural cortex: An area of gray matter at the surface of the central nervous system. (13)

neurilemma: The outer surface of a neuroglia that encircles an axon. (12)

neurofibrils: Microfibrils in the cytoplasm of a neuron. (12)

neurofilaments: Microfilaments in the cytoplasm of a neuron. (12)

neuroglandular junction: A cell junction at which a neuron controls or regulates the activity of a secretory (gland) cell. (12)

neuroglia: Cells of the central nervous system and peripheral nervous system that support and protect neurons; also called *glial cells. (4, 12)*

neurohypophysis: The posterior pituitary, or pars nervosa. (18)

neuromodulator: A compound, released by a neuron, that adjusts the sensitivities of another neuron to specific neurotransmitters. (12)

neuromuscular junction: A synapse between a neuron and a muscle cell. (10, 12)

neuron or **neurone:** A cell in neural tissue that is specialized for intercellular communication through (1)

changes in membrane potential and (2)

synaptic connections.

(4, 12, 15, 16)

neurotransmitter: A chemical compound released by one neuron to affect the transmembrane potential of another. (12, 16)

neurotubules: Microtubules in the cytoplasm of a neuron. (12)

neurulation: The embyrological process responsible for the formation of the central nervous system. (29)

neutron: A fundamental particle that does not carry a positive or a negative charge. (2)

neutrophil: A microphage that is very numerous and normally the first of the mobile phagocytic cells to arrive at an area of injury or infection. (19)

nicotinic receptors: Acetylcholine receptors on the surfaces of sympathetic and parasympathetic ganglion cells; respond to the compound nicotine. (16)

nipple: An elevated epithelial projection on the surface of the breast; contains the openings of the lactiferous sinuses. (28)

Nissl bodies: The ribosomes, Golgi apparatus, rough endoplasmic reticulum, and mitochondria of the perikaryon of a typical neuron. (12)

nitrogenous wastes: Organic waste products of metabolism that contain nitrogen, such as urea, uric acid, and creatinine. (25)

nociception: Pain perception. (15)

node of Ranvier: The area between adjacent neuroglia where the myelin covering of an axon is incomplete. (12)

nodose ganglion: A sensory ganglion of cranial nerve X. (14)

noradrenaline: *See* **norepinephrine**.

norepinephrine (NE): A catecholamine neurotransmitter in the peripheral nervous system and central nervous system, released at most sympathetic neuromuscular and neuroglandular junctions, and a hormone secreted by the adrenal medulla; also called *noradrenaline*. (12, 18)

nucleic acid: A polymer of nucleotides that contains a pentose sugar, a phosphate group, and one of four nitrogenous bases that regulate the synthesis of proteins and make up the genetic material in cells. (2)

nucleolus: The dense region in the nucleus that is the site of RNA synthesis. (3)

nucleoplasm: The fluid content of the nucleus. (3)

nucleoproteins: Proteins of the nucleus that are generally associated with DNA. (3)

nucleotide: A compound consisting of a nitrogenous base, a simple sugar, and a phosphate group. (2)

nucleus: A cellular organelle that contains DNA, RNA, and proteins; in the central nervous system, a mass of gray matter. (3)

nucleus pulposus: The gelatinous central region of an intervertebral disc. (9)

nutrient: An inorganic or organic compound that can be broken down in the body to produce energy. (2, 25)

nystagmus: An unconscious, continuous movement of the eyes as if to adjust to constant motion. (17)

O

obesity: Body weight 10–20 percent above standard values as a result of body fat accumulation. (25)

occlusal surface: The opposing surfaces of the teeth that come into contact when processing food. (24)

ocular: Pertaining to the eye. (17)

oculomotor nerve: Cranial nerve III, which controls the extra-ocular muscles other than the superior oblique and the lateral rectus muscles. (14)

olecranon: The proximal end of the ulna that forms the prominent point of the elbow. (8)

olfaction: The sense of smell. (15, 17, 23)

olfactory bulb: The expanded ends of the olfactory tracts (17); the sites where the axons of the first cranial nerves (I) synapse on central nervous system interneurons that lie inferior to the frontal lobes of the cerebrum (14)

oligodendrocytes: Central nervous system neuroglia that maintain cellular organization within gray matter and provide a myelin sheath in areas of white matter. (12)

oligopeptide: A short chain of amino acids. (2)

oocyte: A cell whose meiotic divisions will produce a single ovum and three polar bodies (3,28)

oogenesis: Ovum production. (28)

ooplasm: The cytoplasm of the ovum. (28)

opsonization: An effect of coating an object with antibodies; the attraction and enhancement of phagocytosis. (22)

optic chiasm: The crossing point of the optic nerves. (14)

optic nerve: The second cranial nerve (II), which carries signals from the retina of the eye to the optic chiasm. (14)

optic tract: The tract over which nerve impulses from the retina are transmitted between the optic chiasm and the thalamus. (14)

orbit: The bony recess of the skull that contains the eyeball. (7)

organelle: An intracellular structure that performs a specific function or group of functions. (3)

organic compound: A compound containing carbon, hydrogen, and in most cases oxygen. (2)

organogenesis: The formation of organs during embryological and fetal development. (29)

organs: Combinations of tissues that perform complex functions. (1)

origin: In a skeletal muscle, the point of attachment which does not change position when the muscle contracts; usually defined in terms of movements from the anatomical position. (11)

oropharynx: The middle portion of the pharynx, bounded superiorly by the nasopharynx, anteriorly by the oral cavity, and inferiorly by the laryngopharynx. (23)

os coxae/ossa coxae: The hip bone(s). (8)

osmolarity: The total concentration of dissolved materials in a solution, regardless of their specific identities, expressed in moles; also called *osmotic concentration*. (3, 26, 27)

osmoreceptor: A receptor sensitive to changes in the osmolarity of plasma. (27)

osmosis: The movement of water across a selectively permeable membrane from one solution to another solution that contains a higher solute concentration. (3, 21, 26, 27)

osmotic pressure: The force of osmotic water movement; the pressure that must be applied to prevent osmosis across a membrane. (3, 21, 26, 27)

osseous tissue: A strong connective tissue containing specialized cells and a mineralized matrix of crystalline calcium phosphate and calcium carbonate; also called **bone**. (4, 6)

ossicles: Small bones. (17, in the ear)

ossification: The formation of bone. (6)

osteoblast: A cell that produces the fibers and matrix of bone. (6)

osteoclast: A cell that dissolves the fibers and matrix of bone. (6)

osteocyte: A bone cell responsible for the maintenance and turnover of the mineral content of the surrounding bone. (4, 6)

osteogenic layer: The inner, cellular layer of the periosteum that participates in bone growth and repair. (6)

osteolysis: The breakdown of the mineral matrix of bone. (6)

osteon: The basic histological unit of compact bone, consisting of osteocytes organized around a central canal and separated by concentric lamellae. (6)

otic: Pertaining to the ear. (17)

otolith: A complex formed by the combination of a gelatinous matrix and statoconia, aggregations of calcium carbonate crystals; located above one of the maculae of the vestibule. (17)

oval window: An opening in the bony labyrinth where the stapes attaches to the membranous wall of the vestibular duct. (17)

ovarian cycle: The monthly chain of events that leads to ovulation. (28)

ovary: The female reproductive organ that produces gametes. (18, 28)

ovulation: The release of a secondary oocyte, surrounded by cells of the corona radiata, after the rupture of the wall of a tertiary follicle (29); in females, the periodic release of an oocyte from an ovary (28)

ovum/ova: The functional product of meiosis II, produced after the fertilization of a secondary oocyte (28, 29)

oxytocin: A hormone produced by hypothalamic cells and secreted into capillaries at the posterior lobe of the pituitary gland; stimulates smooth muscle contractions of the uterus or mammary glands in females and the prostate gland in males. (18)

P

pacemaker cells: Cells of the sinoatrial node that set the pace of cardiac contraction. (4, 10, 20)

palate: The horizontal partition separating the oral cavity from the nasal cavity and nasopharynx; divided into an anterior bony (hard) palate and a posterior fleshy (soft) palate. (7, 24)

palatine: Pertaining to the palate. (24)

palpate: To examine by touch.

palpebrae: Eyelids. (17)

pancreas: A digestive organ containing exocrine and endocrine tissues; the exocrine portion secretes pancreatic juice, and the endocrine portion secretes hormones, including insulin and glucagon. (18, 24)

pancreatic duct: A tubular duct that carries pancreatic juice from the pancreas to the duodenum. (18, 24)

pancreatic islets: Aggregations of endocrine cells in the pancreas; also called *islets of Langerhans*. (18, 24)

pancreatic juice: A mixture of buffers and digestive enzymes that is discharged into the duodenum under the stimulation of the enzymes secretin and cholecystokinin. (18, 24)

Papanicolaou (Pap) test: A test for the detection of malignancies based on the cytological appearance of epithelial cells, especially those of the cervix and uterus. (28)

papilla: A small, conical projection.

paralysis: The loss of voluntary motor control over a portion of the body. (13)

paranasal sinuses: Bony chambers, lined by respiratory epithelium, that open into the nasal cavity; the frontal, ethmoidal, sphenoidal, and maxillary sinuses. (7)

parasagittal: A section or plane that parallels the midsagittal plane but that does not pass along the midline. (1)

parasympathetic division: One of the two divisions of the autonomic nervous system; also called *craniosacral division*; generally responsible for activities that conserve energy and lower the metabolic rate. (16)

parathyroid glands: Four small glands embedded in the posterior surface of the thyroid gland; secrete parathyroid hormone. (6, 18)

parathyroid hormone (PTH): A hormone secreted by the parathyroid glands when plasma calcium levels fall below the normal range; causes increased osteoclast activity, increased intestinal calcium uptake, and decreased calcium ion loss at the kidneys. (6, 18)

parenchyma: The cells of a tissue or organ that are responsible for fulfilling its functional role; distinguished from the stroma of that tissue or organ. (4)

paresthesia: A sensory abnormality that produces a tingling sensation. (AM)

parietal: Referring to the body wall or outer layer. (7, parietal bones; 23, pleura)

parietal cells: Cells of the gastric glands that secrete hydrochloric acid and intrinsic factor. (24)

parotid salivary glands: Large salivary glands that secrete a saliva containing high concentrations of salivary (alpha) amylase. (24)

pars distalis: The large, anterior portion of the anterior lobe of the pituitary gland. (18)

pars intermedia: The portion of the anterior lobe of the pituitary gland that is immediately adjacent to the posterior lobe and the infundibulum. (18)

pars nervosa: The posterior lobe of the pituitary gland. (18)

pars tuberalis: The portion of the anterior lobe of the pituitary gland that wraps around the infundibulum superior to the posterior lobe. (18)

patella: The sesamoid bone of the kneecap. (8)

pathogen: A disease-causing organism. (1, 22)

pathogenic: Disease-causing.

pathologist: An M.D. specializing in the identification of diseases on the basis of characteristic structural and functional changes in tissues and organs.

pelvic cavity: The inferior subdivision of the abdominopelvic cavity; encloses the urinary bladder, the sigmoid colon and rectum, and male or female reproductive organs. (1, 8)

pelvis: A bony complex created by the articulations among the ossa coxae, the sacrum, and the coccyx. (8, 11)

penis: A component of the male external genitalia; a copulatory organ that surrounds the urethra and serves to introduce semen into the female vagina; the developmental equivalent of the female clitoris. (28)

peptide: A chain of amino acids linked by peptide bonds. (2, 18)

peptide bond: A covalent bond between the amino group of one amino acid and the carboxyl group of another. (2)

pericardial cavity: The space between the parietal pericardium and the epicardium (visceral pericardium) that covers the outer surface of the heart. (20)

pericardium: The fibrous sac that surrounds the heart; its inner, serous lining is continuous with the epicardium. (4, 20)

perichondrium: The layer that surrounds a cartilage, consisting of an outer fibrous region and an inner cellular region. (4)

perikaryon: The cytoplasm that surrounds the nucleus in the cell body of a neuron. (12)

perilymph: A fluid similar in composition to cerebrospinal fluid; located in the spaces between the bony labyrinth and the membranous labyrinth of the inner ear. (17)

perimysium: A connective tissue partition that separates adjacent fasciculi in a skeletal muscle. (10)

perineum: The pelvic floor and its associated structures. (11)

perineurium: A connective tissue partition that separates adjacent bundles of nerve fibers in a peripheral nerve. (13)

periodontal ligament: Collagen fibers that bind the cementum of a tooth to the periosteum of the surrounding alveolus. (24)

periosteum: The layer that surrounds a bone, consisting of an outer fibrous region and inner cellular region. (4, 6)

peripheral nervous system (PNS): All neural tissue outside the central nervous system. (12)

peripheral resistance: The resistance to blood flow; primarily caused by friction with the vascular walls. (21)

peristalsis: A wave of smooth muscle contractions that propels materials along the axis of a tube such as the digestive tract (24)

, the ureters (26)

, or the ductus deferens (28)

peritoneal cavity: *See* **abdominopelvic cavity**.

peritoneum: The serous membrane that lines the peritoneal cavity. (4, 28)

peritubular capillaries: A network of capillaries that surrounds the proximal and distal convoluted tubules of the kidneys. (26)

permeability: The ease with which dissolved materials can cross a membrane; if the membrane is freely permeable, any molecule can cross it; if impermeable, nothing can cross; most biological membranes are selectively permeable. (3)

peroxisome: A membranous vesicle containing enzymes that break down hydrogen peroxide (H2O2)

(3)

pes: The foot. (8, 11)

petrosal ganglion: A sensory ganglion of the glossopharyngeal nerve (IX). (14, 15)

petrous: Stony; usually refers to the thickened portion of the temporal bone that encloses the inner ear. (17)

pH: The negative exponent of the hydrogen ion concentration, expressed in moles per liter. (2, 27)

phagocyte: A cell that performs phagocytosis. (22)

phagocytosis: The engulfing of extracellular materials or pathogens; the movement of extracellular materials into the cytoplasm by enclosure in a membranous vesicle. (3, 19, 22)

phalanx/phalanges: Bones of the fingers or toes. (8)

pharmacology: The study of drugs, their physiological effects, and their clinical uses.

pharynx: The throat; a muscular passageway shared by the digestive and respiratory tracts. (11, 23, 24)

phasic response: A pattern of response to stimulation by sensory neurons that are normally inactive; stimulation causes a burst of neural activity that ends when the stimulus either stops or stops changing in intensity. (15)

phenotype: Physical characteristics that are genetically determined. (29)

phosphate group: $\mathbf{PO4}^{3-}$; a functional group that can be attached to an organic molecule; required for the formation of high-energy bonds. (2, 25, 27)

phospholipid: An important membrane lipid whose structure includes both hydrophilic and hydrophobic regions. (2, 3)

phosphorylation: The addition of a high-energy phosphate group to a molecule. (2, 25)

photoreception: Sensitivity to light. (17)

physiology: The study of function; deals with the ways organisms perform vital activities. (1)

pia mater: The tough, outer meningeal layer that surrounds the central nervous system. (13, 14)

pineal gland: Neural tissue in the posterior portion of the roof of the diencephalon; secretes melatonin. (14, 18)

pinna: *See* **auricle**.

pinocytosis: The introduction of fluids into the cytoplasm by enclosing them in membranous vesicles at the cell surface. (3)

pituitary gland: An endocrine organ that is situated in the sella turcica of the sphenoid and is connected to the hypothalamus by the infundibulum; includes the posterior lobe (pars nervosa) and the anterior lobe (adenohypophysis). (14, 18)

placenta: A temporary structure in the uterine wall that permits diffusion between the fetal and maternal circulatory systems**.** (29)

plantar: Referring to the sole of the foot. (11, muscles; 13, plantar reflex) **plantar flexion:** Ankle extension (8, 11)

plasma: The fluid ground substance of whole blood; what remains after the cells have been removed from a sample of whole blood. (4, 19)

plasma cell: An activated B cell that secretes antibodies. (4, 19, 22)

plasmalemma: A cell membrane. (3)

platelets: Small packets of cytoplasm that contain enzymes important in the clotting response; manufactured in bone marrow by megakaryocytes. (4, 19)

pleura: The serous membrane that lines the pleural cavities. (4, 23)

pleural cavities: Subdivisions of the thoracic cavity that contain the lungs. (1, 23)

plexus: A network or braid. **polar body:** A nonfunctional packet of cytoplasm that contains chromosomes eliminated from an oocyte during meiosis. (28, 29)

polar bond: A covalent bond in which electrons are shared unequally. (2)

polarized: Referring to cells that have regional differences in organelle distribution or cytoplasmic composition along a specific axis, such as between the basement membrane and free surface of an epithelial cell. (4)

pollex: The thumb. (8)

polymer: A large molecule consisting of a long chain of subunits. (2)

polypeptide: A chain of amino acids strung together by peptide bonds; those containing more than 100 peptides are called *proteins*. (2)

polyribosome: Several ribosomes linked by their translation of a single mRNA strand. (3)

polysaccharide: A complex sugar, such as glycogen or a starch. (2)

polysynaptic reflex: A reflex in which interneurons are interposed between the sensory fiber and the motor neuron(s). (13)

polyunsaturated fats: Fatty acids containing carbon atoms that are linked by double bonds. (1, 2)

pons: The portion of the metencephalon that is anterior to the cerebellum. (14)

popliteal: Pertaining to the back of the knee. (9, 11, 21)

porphyrins: Ring-shaped molecules that form the basis of important respiratory and metabolic pigments, including heme and the cytochromes. (23)

positive feedback: A mechanism that increases a deviation from normal limits after an initial stimulus. (1)

postcentral gyrus: The primary sensory cortex, where touch, vibration, pain, temperature, and taste sensations arrive and are consciously perceived. (14)

posterior: Toward the back; dorsal. **postganglionic neuron:** An autonomic neuron in a peripheral ganglion, whose activities control peripheral effectors. (16)

postsynaptic membrane: The portion of the cell membrane of a post-synaptic cell that is part of a synapse. (12)

potential difference: The separation of opposite charges; requires a barrier that prevents ion migration. (3, 12)

precentral gyrus: The primary motor cortex of a cerebral hemisphere, located anterior to the central sulcus. (14)

prefrontal cortex: The anterior portion of each cerebral hemisphere; thought to be involved with higher intellectual functions, predictions, calculations, and so forth. (14)

preganglionic neuron: A visceral motor neuron in the central nervous system whose output controls one or more ganglionic motor neurons in the peripheral nervous

system. (16)

premotor cortex: The motor association area between the precentral gyrus and the prefrontal area. (14)

preoptic nucleus: The hypothalamic nucleus that coordinates thermoregulatory activities. (14)

presynaptic membrane: The synaptic surface where neurotransmitter release occurs. (12)

prevertebral ganglion: *See* **collateral ganglion**. **prime mover:** A muscle that performs a specific action. (11)

proenzyme: An inactive enzyme secreted by an epithelial cell. (19)

progesterone: The most important progestin secreted by the corpus luteum after ovulation. (18, 28)

progestins: Steroid hormones structurally related to cholesterol; progesterone is an example. (18, 28)

prognosis: A prediction about the possibility or time course of recovery from a specific disease. **projection fibers:** Axons carrying information from the thalamus to the cerebral cortex. (14)

prolactin: The hormone that stimulates functional development of the mammary gland in females; a secretion of the anterior lobe of the pituitary gland. (18)

pronation: The rotation of the forearm that makes the palm face posteriorly. (9)

prone: Lying face down with the palms facing the floor. (1)

pronucleus: An enlarged ovum or spermatozoon nucleus that forms after fertilization but before amphimixis. (29)

prophase: The initial phase of mitosis; characterized by the appearance of chromosomes, the breakdown of the nuclear membrane, and the formation of the spindle apparatus. (3)

proprioception: The awareness of the positions of bones, joints, and muscles. (15)

prostaglandin: A fatty acid secreted by one cell that alters the metabolic activities or sensitivities of adjacent cells; also called *local hormone*. (2, 18)

prostate gland: An accessory gland of the male reproductive tract, contributing roughly one-third of the volume of semen. (28)

prosthesis: An artificial substitute for a body part. **protease:** *See* **proteinase**. **protein:** A large polypeptide with a complex structure, (2, 25)

proteinase: An enzyme that breaks down proteins into peptides and amino acids. (2, 3)

proteoglycan: A compound containing a large polysaccharide complex attached to a relatively small protein; examples include hyaluronan and chondroitin sulfate. (2)

proton: A fundamental particle bearing a positive charge. (2)

protraction: Movement anteriorly in the horizontal plane. **proximal:** Toward the attached base of an organ or structure. (8)

proximal convoluted tubule (PCT): The portion of the nephron that is situated between Bowman’s capsule and the loop of Henle; the major site of active reabsorption

from filtrate. (26)

pseudopodia: Temporary cytoplasmic extensions typical of mobile or phagocytic cells. (3)

pseudostratified epithelium: An epithelium that contains several layers of nuclei but whose cells are all in contact with the underlying basement membrane. (4)

puberty: A period of rapid growth, sexual maturation, and the appearance of secondary sexual characteristics; normally occurs at ages 10–15 years. (18, 28)

pubic symphysis: The fibrocartilaginous amphiarthrosis between the pubic bones of the ossa coxae. (8, 9)

pubis: The anterior, inferior component of the os coxae. (8)

pudendum: The external genitalia. (28)

pulmonary circuit: Blood vessels between the pulmonary semilunar valve of the right ventricle and the entrance to the left atrium; the blood flow through the lungs. (20)

pulmonary ventilation: The movement of air into and out of the lungs. (23)

pulvinar: The thalamic nucleus involved in the integration of sensory information prior to projection to the cerebral hemispheres. (14)

pupil: The opening in the center of the iris through which light enters the eye. (17)

purine: A nitrogen compound with a double ring-shaped structure; examples include adenine and guanine, two nitrogenous bases that are common in nucleic acids. (2, 12)

Purkinje cell: A large, branching neuron of the cerebellar cortex. (14)

Purkinje fibers: Specialized conducting cardiocytes in the ventricles of the heart. (20)

pus: An accumulation of debris, fluid, dead and dying cells, and necrotic tissue. (4, 20, 22)

pyloric sphincter: A sphincter of smooth muscle that regulates the passage of chyme from the stomach to the duodenum. (24)

pylorus: The gastric region between the body of the stomach and the duodenum; includes the pyloric sphincter. (24)

pyrimidine: A nitrogen compound with a single ring-shaped structure; examples include cytosine, thymine, and uracil, nitrogenous bases that are common in nucleic acids. (2)

pyruvic acid: A three-carbon compound produced by glycolysis. (25)

Q

quaternary structure: The three-dimensional protein structure produced by interactions between protein subunits. (2)

R

radiodensity: The relative resistance to the passage of X-rays. (1)

radiographic techniques: Methods of visualizing internal structures by using various forms of radiational energy. (1)

radiopaque: Having a high radiodensity. (1)

rami communicantes: Axon bundles that link the spinal nerves with the ganglia of the sympathetic chain. (8)

ramus/rami: A branch.

raphe: A seam. (11, 28)

receptive field: The area monitored by a single sensory receptor. (15)

rectum: The inferior 15 cm (6 in.) of the digestive tract. (24)

rectus: Straight.

red blood cell (RBC): *See* **erythrocyte**.

reduction: The gain of hydrogen atoms or electrons or the loss of an oxygen molecule. (25)

reductional division: The first meiotic division, which reduces the chromosome number from 46 to 23. (28)

reflex: A rapid, automatic response to a stimulus. (12, 13, 16, 18, 21)

reflex arc: The receptor, sensory neuron, motor neuron, and effector involved in a particular reflex; interneurons may be present, depending on the reflex considered. (13)

refractory period: The period between the initiation of an action potential and the restoration of the normal resting potential; during this period, the membrane will not respond normally to stimulation. (12)

relaxation phase: The period after a contraction when the tension in the muscle fiber returns to resting levels. (10)

relaxin: A hormone that loosens the pubic symphysis; secreted by the placenta. (29)

renal: Pertaining to the kidneys. (26)

renal corpuscle: The initial portion of the nephron, consisting of an expanded chamber that encloses the glomerulus. (26)

renin: The enzyme released by cells of the juxtaglomerular apparatus when renal blood flow declines; converts angiotensinogen to angiotensin I. (18, 26)

rennin: A gastric enzyme that breaks down milk proteins. (24)

replication: Duplication. (29)

repolarization: The movement of the transmembrane potential away from a positive value and toward the resting potential. (12, 20)

respiration: The exchange of gases between cells and the environment; includes pulmonary ventilation, external respiration, internal respiration, and cellular respiration.

(23, 27)

respiratory minute volume (VE:): The amount of air moved into and out of the respiratory system each minute. (23)

respiratory pump: A mechanism by which changes in the intrapleural pressures during the respiratory cycle assist the venous return to the heart; also called

thoracoabdominal pump. (21, 23)

resting potential: The transmembrane potential of a normal cell under homeostatic conditions. (3, 12)

rete: An interwoven network of blood vessels or passageways. (28)

reticular activating system (RAS): The mesencephalic portion of the reticular formation;

responsible for arousal and the maintenance of consciousness. (16)

reticular formation: A diffuse network of gray matter that extends the entire length of the brain stem. (14)

reticulospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by neurons of the reticular formation. (15)

retina: The innermost layer of the eye, lining the vitreous chamber; also called *neural tunic*. (17)

retinal: A visual pigment derived from vitamin A. (17)

retraction: Movement posteriorly in the horizontal plane. **retroperitoneal:** Behind or outside the peritoneal cavity. (1)

reverberation: A positive feedback along a chain of neurons such that they remain active once stimulated. (13)

rheumatism: A condition characterized by pain in muscles, tendons, bones, or joints. (9)

Rh factor: A surface antigen that may be present (Rh-positive) or absent (Rh-negative) from the surfaces of red blood cells. (19)

rhodopsin: The visual pigment in the membrane disks of the distal segments of rods. (17)

rhythmicity center: A medullary center responsible for the pace of respiration; includes inspiratory and expiratory centers. (23)

ribonucleic acid: A nucleic acid consisting of a chain of nucleotides that contain the sugar ribose and the nitrogenous bases adenine, guanine, cytosine, and uracil. (2, 3)

ribose: A five-carbon sugar that is a structural component of RNA. (2, 3)

ribosome: An organelle that contains rRNA and proteins and is essential to mRNA translation and protein synthesis. (2, 3)

rod: A photoreceptor responsible for vision in dim lighting. (17)

rough endoplasmic reticulum (RER): A membranous organelle that is a site of protein synthesis and storage. (3)

round window: An opening in the bony labyrinth of the inner ear that exposes the membranous wall of the tympanic duct to the air of the middle ear cavity. (17)

rubrospinal tracts: Descending tracts of the lateral pathway that carry involuntary motor commands issued by the red nucleus of the mesencephalon. (15)

rugae: Mucosal folds in the lining of the empty stomach that disappear as gastric distension occurs (24); folds in the urinary bladder (26)

S

saccule: A portion of the vestibular apparatus of the inner ear; contains a macula important for static equilibrium. (17)

sagittal plane: A sectional plane that divides the body into left and right portions. (1)

salt: An inorganic compound consisting of a cation other than H^+ and an anion other than OH^- (2)

saltatory propagation: The relatively rapid propagation of an action potential between successive nodes of a myelinated axon. (12)

sarcolemma: The cell membrane of a muscle cell. (10)

sarcomere: The smallest contractile unit of a striated muscle cell. (10)

sarcoplasm: The cytoplasm of a muscle cell. (10)

satellite cells: *See* **amphicytes**.

scala media: *See* **cochlear duct**.

scala tympani: *See* **tympanic duct**.

scala vestibuli: *See* **vestibular duct**.

scar tissue: The thick, collagenous tissue that forms at an injury site. (5)

Schwann cells: Neuroglia responsible for the neurilemma that surrounds axons in the peripheral nervous system. (12)

sciatic nerve: A nerve innervating the posteromedial portions of the thigh and leg. (13)

sclera: The fibrous, outer layer of the eye that forms the white area of the anterior surface;

a portion of the fibrous tunic of the eye. (17)

sclerosis: A hardening and thickening that commonly occurs secondary to tissue inflammation. (4)

scrotum: The loose-fitting, fleshy pouch that encloses the testes of the male. (28)

sebaceous glands: Glands that secrete sebum; normally associated with hair follicles. (5)

sebum: A waxy secretion that coats the surfaces of hairs. (5)

secondary sex characteristics: Physical characteristics that appear at puberty in response to sex hormones but are not involved in the production of gametes. (28)

secretin: A hormone, secreted by the duodenum, that stimulates the production of buffers by the pancreas and inhibits gastric activity. (24)

semen: The fluid ejaculate that contains spermatozoa and the secretions of accessory glands of the male reproductive tract. (28)

semicircular ducts: The tubular components of the membranous labyrinth of the inner ear; responsible for dynamic equilibrium. (17)

semilunar valve: A three-cusped valve guarding the exit from one of the cardiac ventricles; the pulmonary and aortic valves. (20)

seminal vesicles: Glands of the male reproductive tract that produce roughly 60 percent of the volume of semen. (28)

seminiferous tubules: Coiled tubules where spermatozoon production occurs in the testis. (28)

senescence: Aging.

sensible perspiration: Water loss due to secretion by sweat glands. (5, 27)

septae: Partitions that subdivide an organ. (20, heart; 22, thymus)

serosa: *See* **serous membrane**.

serotonin: A neurotransmitter in the central nervous system; a compound that enhances inflammation and is released by activated mast cells and basophils. (12)

serous cell: A cell that produces a serous secretion. (4)

serous membrane: A squamous epithelium and the underlying loose connective tissue; the lining of the pericardial, pleural, and peritoneal cavities. (4, 24)

serous secretion: A watery secretion that contains high concentrations of enzymes; produced by serous cells. (4)

serum: The ground substance of blood plasma from which clotting agents have been removed. (19)

sesamoid bone: A bone that forms within a tendon. (6)

sigmoid colon: The S-shaped 18-cm-long portion of the colon between the descending colon and the rectum. (24)

sign: The visible evidence of the presence of a disease.

simple epithelium: An epithelium containing a single layer of cells above the basal lamina. (4)

sinoatrial (SA) node: The natural pacemaker of the heart; situated in the wall of the right atrium. (20)

sinus: A chamber or hollow in a tissue; a large, dilated vein.

sinusoid: An exchange vessel that is similar in general structure to a fenestrated capillary. The two differ in size (sinusoids are larger and more irregular in cross-section), continuity (sinusoids have gaps between endothelial cells), and support (sinusoids have thin basal laminae, if they have them at all). (20)

skeletal muscle: A contractile organ of the muscular system. (10)

skeletal muscle tissue: A contractile tissue dominated by skeletal muscle fibers; characterized as striated, voluntary muscle. (4, 10)

sliding filament theory: The concept that a sarcomere shortens as the thick and thin filaments slide past one another. (10)

small intestine: The duodenum, jejunum, and ileum; the digestive tract between the stomach and the large intestine. (24)

smooth endoplasmic reticulum (SER): A membranous organelle in which lipid and carbohydrate synthesis and storage occur. (3)

smooth muscle tissue: Muscle tissue in the walls of many visceral organs; characterized as nonstriated, involuntary muscle. (4, 10, 24, 26)

soft palate: The fleshy posterior extension of the hard palate, separating the nasopharynx from the oral cavity. (24)

solute: Any materials dissolved in a solution. (2, 21, 26)

solution: A fluid containing dissolved materials. (2, 21)

solvent: The fluid component of a solution. (2, 21)

somatic: Pertaining to the body. **somatic nervous system (SNS):** The efferent division of the nervous system that innervates skeletal muscles. (12, 15, 16)

somatomedins: Compounds stimulating tissue growth; released by the liver after the secretion of growth hormone; also called *insulin-like growth factors*. (18)

somatotropin: Growth hormone; produced by the anterior pituitary in response to growth hormone–releasing hormone (GH-RH). (18)

sperm: *See* **spermatozoon**. **spermatic cord:** Collectively, the spermatic vessels, nerves, lymphatic vessels, and the ductus deferens, extending between the testes and the proximal end of the inguinal

canal. (28)

spermatocyte: A cell of the seminiferous tubules that is engaged in meiosis. (28)

spermatogenesis: Spermatozoon production. (28)

spermatozoon/spermatozoa: A male gamete; also called *sperm*. (3, 28)

sphincter: A muscular ring that contracts to close the entrance or exit of an internal passageway. (10, 11, 26)

spinal nerve: One of 31 pairs of nerves that originate on the spinal cord from anterior and posterior roots. (12, 13)

spindle apparatus: A muscle spindle (intrafusal fibers) and its sensory and motor innervation. (3)

spinocerebellar tracts: Ascending tracts that carry sensory information to the cerebellum. (15)

spinothalamic tracts: Ascending tracts that carry poorly localized touch, pressure, pain, vibration, and temperature sensations to the thalamus. (15)

spinous process: The prominent posterior projection of a vertebra; formed by the fusion of two laminae. (7)

spleen: A lymphoid organ important for the phagocytosis of red blood cells, the immune response, and lymphocyte production. (22)

squama: A broad, flat surface. **squamous:** Flattened. **squamous epithelium:** An epithelium whose superficial cells are flattened and platelike. (4)

stapes: The auditory ossicle attached to the tympanic membrane. (17)

stenosis: A constriction or narrowing of a passageway. **stereocilia:** Elongate microvilli characteristic of the epithelium of the epididymis, portions of the ductus deferens (28)

, and the inner ear (17)

steroid: A ring-shaped lipid structurally related to cholesterol. (2, 18)

stimulus: An environmental change that produces a change in cellular activities; often used to refer to events that alter the transmembrane potentials of excitable cells.

(15)

stratified: Containing several layers. (4, epithelium, for example) **stratum:** A layer. **stretch receptors:** Sensory receptors that respond to stretching of the surrounding tissues. (13)

stroma: The connective tissue framework of an organ; distinguished from the functional cells (parenchyma) of that organ. **subarachnoid space:** A meningeal space containing cerebrospinal fluid; the area between the arachnoid membrane and the pia mater. (13)

subclavian: Pertaining to the region immediately posterior and inferior to the clavicle. **subcutaneous layer:** The layer of loose connective tissue below the dermis; also called *hypodermis* or *superficial fascia*. (4, 5)

submucosa: The region between the muscularis mucosae and the muscularis externa. (23, 24)

subserous fascia: The loose connective tissue layer beneath the serous membrane that lines the ventral body cavity. (4)

substrate: A participant (product or reactant) in an enzyme-catalyzed reaction. (2)

sulcus: A groove or furrow. (14)

summation: The temporal or spatial addition of stimuli. (10, 12)

superficial fascia: *See* **subcutaneous layer**. **superior:** Above, in reference to a portion of the body in the anatomical position. **superior vena cava (SVC):** The vein that carries blood to the right atrium from parts of the body that are superior to the heart. (20, 21)

supination: The rotation of the forearm such that the palm faces anteriorly. (9)

supine: Lying face up, with palms facing anteriorly. (1)

suppressor T cells: Lymphocytes that inhibit B cell activation and the secretion of antibodies by plasma cells. (22)

suprarenal gland: *See* **adrenal gland**. **surfactant:** A lipid secretion that coats the alveolar surfaces of the lungs and prevents their collapse. (23)

sustentacular cells: Supporting cells of the seminiferous tubules of the testis; responsible for the differentiation of spermatids, the maintenance of the blood–testis barrier, and the secretion of inhibin, androgen-binding protein, and Müllerian-inhibiting factor. (18, 28)

sutural bones: Irregular bones that form in fibrous tissue between the flat bones of the developing cranium; also called *Wormian bones*. (6)

suture: A fibrous joint between flat bones of the skull. (7, 9)

sympathetic division: The division of the autonomic nervous system that is responsible for "fight or flight" reactions; primarily concerned with the elevation of metabolic rate and increased alertness. (12, 16)

symphysis: A fibrous amphiarthrosis, such as that between adjacent vertebrae or between the pubic bones of the ossa coxae. (9)

symptom: An abnormality of function as a result of disease. **synapse:** The site of communication between a nerve cell and some other cell; if the other cell is not a neuron, the term *neuromuscular* or *neuroglandular junction* is often used. (12, 16, 18)

synaptic delay: The period between the arrival of an impulse at the presynaptic membrane and the initiation of an action potential in the postsynaptic membrane. (12)

syncytium: A multinucleate mass of cytoplasm, produced by the fusion of cells or repeated mitoses without cytokinesis. (29)

syndrome: A discrete set of symptoms that occur together. **synergist:** A muscle that assists a prime mover in performing its primary action. (11)

synovial cavity: A fluid-filled chamber in a synovial joint. (4, 9)

synovial fluid: The substance secreted by synovial membranes that lubricates joints. (4, 9)

synovial joint: A freely movable joint where the opposing bone surfaces are separated by synovial fluid; a diarthrosis. (4, 9)

synovial membrane: An incomplete layer of fibroblasts confronting the synovial cavity, plus the underlying loose connective tissue. (4)

synthesis: Manufacture; anabolism. (23)

system: An interacting group of organs that performs one or more specific functions. **systemic circuit:** The vessels between the aortic valve and the entrance to the right atrium; the system other than the vessels of the pulmonary circuit. (20)

systole: A period of contraction in a chamber of the heart, as part of the cardiac cycle. (20)

systolic pressure: The peak arterial pressure measured during ventricular systole. (20)

T

tactile: Pertaining to the sense of touch. (15)

tarsal bones: The bones of the ankle (the talus, calcaneus, navicular, and cuneiform bones). (8)

tarsus: The ankle. (8)

TCA (tricarboxylic acid) cycle: The aerobic reaction sequence that occurs in the matrix of mitochondria; in the process, organic molecules are broken down, carbon dioxide molecules are released, and hydrogen molecules are transferred to coenzymes that deliver them to the electron transport system; also called *citric acid cycle* or *Krebs cycle*. (3, 10, 25)

T cells: Lymphocytes responsible for cell-mediated immunity and for the coordination and regulation of the immune response; includes regulatory T cells (helpers and suppressors) and cytotoxic (killer) T cells. (19, 22)

tectospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by the colliculi. (15)

telodendria: Terminal axonal branches that end in synaptic knobs. (12)

telophase: The final stage of mitosis, characterized by the disappearance of the spindle apparatus, the reappearance of the nuclear membrane, the disappearance of the chromosomes, and the completion of cytokinesis. (3)

temporal: Pertaining to time (temporal summation) or to the temples (temporal bone). (7)

tendon: A collagenous band that connects a skeletal muscle to an element of the skeleton. (4, 10)

teres: Long and round. **terminal:** Toward the end. **tertiary structure:** The protein structure that results from interactions among distant portions of the same molecule; complex coiling and folding. (2)

testes: The male gonads, sites of gamete production and hormone secretion. (18, 28)

testosterone: The principal androgen produced by the interstitial cells of the testes. (2, 18, 28)

tetraiodothyronine: T4 , or thyroxine, a thyroid hormone. (18)

thalamus: The walls of the diencephalon. (14)

theory: A hypothesis that makes valid predictions, as demonstrated by evidence that is testable, unbiased, and repeatable. **therapy:** The treatment of disease. **thermoreception:** Sensitivity to temperature changes. (15)

thermoregulation: Homeostatic maintenance of body temperature. (1, 25)

thick filament: A cytoskeletal filament in a skeletal or cardiac muscle cell; composed of myosin, with a core of titin. (3, 10)

thin filament: A cytoskeletal filament in a skeletal or cardiac muscle cell; consists of actin, troponin, and tropomyosin. (3, 10)

thoracolumbar division: The sympathetic division of the autonomic nervous system. (16)

thorax: The chest. (7)

threshold: The transmembrane potential at which an action potential begins. (12)

thrombin: The enzyme that converts fibronogen to fibrin. (19)

thymine: A pyrimidine; one of the nitrogenous bases in the nucleic acid DNA. (2)

thymosins: Thymic hormones essential to the development and differentiation of T cells. (18, 22)

thymus: A lymphoid organ, the site of T cell formation. (18, 22)

thyroglobulin: A circulating transport globulin that binds thyroid hormones. (18)

thyroid gland: An endocrine gland whose lobes are lateral to the thyroid cartilage of the larynx. (18)

thyroid hormones: Thyroxine (T4)

and triiodothyronine (T3)

, hormones of the thyroid gland; stimulate tissue metabolism, energy utilization, and growth. (18)

thyroid-stimulating hormone (TSH): The hormone, produced by the anterior lobe of the pituitary gland, that triggers the secretion of thyroid hormones by the thyroid

gland. (18)

thyroxine: A thyroid hormone; also called *T*4 or *tetraiodothyronine*. (18)

tidal volume: The volume of air moved into and out of the lungs during a normal quiet respiratory cycle. (23)

tissue: A collection of specialized cells and cell products that performs a specific function. (1, 4)

tonic response: An increase or decrease in the frequency of action potentials by sensory receptors that are chronically active. (15)

tonsil: A lymphoid nodule in the wall of the pharynx; the palatine, pharyngeal, and lingual tonsils. (22)

topical: Applied to the body surface. **toxic:** Poisonous. **trabecula:** A connective tissue partition that subdivides an organ. (22)

trachea: The windpipe, an airway extending from the larynx to the primary bronchi. (23)

tract: A bundle of axons in the central nervous system. (13, 14)

transcription: The encoding of genetic instructions on a strand of mRNA. (3)

transection: The severing or cutting of an object in the transverse plane. **translation:** The process of peptide formation from the instructions carried by an mRNA strand. (3)

transmembrane potential: The potential difference, measured across a cell membrane and expressed in millivolts, that results from the uneven distribution of positive

and negative ions across the cell membrane. (3, 12)

transudate: A fluid that diffuses across a serous membrane and lubricates opposing surfaces. (4)

transverse tubules: The transverse, tubular extensions of the sarcolemma that extend deep into the sarcoplasm, contacting cisternae of the sarcoplasmic reticulum; also called *T tubules*. (10)

tricarboxylic acid cycle: *See* **TCA cycle**. **tricuspid valve:** The right atrioventricular valve, which prevents the backflow of blood into the right atrium during ventricular systole. (20)

trigeminal nerve: Cranial nerve V, which provides sensory information from the lower portions of the face (including the upper and lower jaws) and delivers motor commands to the muscles of mastication. (14)

triglyceride: A lipid that is composed of a molecule of glycerol attached to three fatty acids. (2, 25)

triiodothyronine: T3 , a thyroid hormone. (18)

trisomy: The abnormal possession of three copies of a chromosome; trisomy 21 is responsible for Down syndrome. (16)

trochanter: Large processes near the head of the femur. (8)

trochlea: A pulley; the spool-shaped medial portion of the condyle of the humerus. (8)

trochlear nerve: Cranial nerve IV, controlling the superior oblique muscle of the eye. (14)

trunk: The thoracic and abdominopelvic regions (1); a major arterial branch (21)

T tubules: *See* **transverse tubules**.

tuberculum: A small, localized elevation on a bony surface. (7)

tuberosity: A large, roughened elevation on a bony surface. (6)

tumor: A tissue mass formed by the abnormal growth and replication of cells. (3)

tunica: A layer or covering.

twitch: A single stimulus–contraction–relaxation cycle in a skeletal muscle. (10)

tympanic duct: The perilymph-filled chamber of the inner ear, adjacent to the basilar membrane; pressure changes there distort the round window; also called *scala tympani*. (17)

tympanic membrane: The membrane that separates the external acoustic canal from the middle ear; the membrane whose vibrations are transferred to the auditory ossicles and ultimately to the oval window; also called *eardrum* or *tympanum*. (17)

type A axons: Large myelinated axons. (12)

type B axons: Small myelinated axons. (12)

type C axons: Small unmyelinated axons. (12)

U

umbilical cord: The connecting stalk between the fetus and the placenta; contains the allantois, the umbilical arteries, and the umbilical vein. (21, 29)

umbilicus: The navel. (29)

unicellular gland: Goblet cells. (4)

unipolar neuron: A sensory neuron whose cell body is in a dorsal root ganglion or a sensory ganglion of a cranial nerve. (12)

unmyelinated axon: An axon whose neurilemma does not contain myelin and across which continuous propagation occurs. (12)

uracil: A pyrimidine; one of the nitrogenous bases in the nucleic acid RNA. (2)

ureters: Muscular tubes, lined by transitional epithelium, that carry urine from the renal pelvis to the urinary bladder. (26)

urethra: A muscular tube that carries urine from the urinary bladder to the exterior. (26)

urinary bladder: The muscular, distensible sac that stores urine prior to micturition. (26)

urination: The voiding of urine; micturition. (26)

uterus: The muscular organ of the female reproductive tract in which implantation, placenta formation, and fetal development occur. (28)

utricle: The largest chamber of the vestibular apparatus of the inner ear; contains a macula important for static equilibrium. (17)

V

vagina: A muscular tube extending between the uterus and the vestibule. (28)

vascular: Pertaining to blood vessels. (19)

vasoconstriction: A reduction in the diameter of arterioles due to the contraction of smooth muscles in the tunica media; elevates peripheral resistance; may occur in response to local factors, through the action of hormones, or from the stimulation of the vasomotor center. (21)

vasodilation: An increase in the diameter of arterioles due to the relaxation of smooth muscles in the tunica media; reduces peripheral resistance; may occur in response to local factors, through the action of hormones, or after decreased stimulation of the vasomotor center. (21)

vasomotion: Changes in the pattern of blood flow through a capillary bed in response to changes in the local environment. (21)

vasomotor center: The center in the medulla oblongata whose stimulation produces vasoconstriction and an elevation of peripheral resistance. (14)

vein: A blood vessel carrying blood from a capillary bed toward the heart. (20, 21)

vena cava: One of the major veins delivering systemic blood to the right atrium; superior and inferior venae cavae. (20, 21)

ventilation: Air movement into and out of the lungs. (23)

ventral: Pertaining to the anterior surface.

ventricle: A fluid-filled chamber; in the heart, one of the large chambers discharging blood into the pulmonary or systemic circuits (20); in the brain, one of four fluid-filled interior chambers (14)

venule: Thin-walled veins that receive blood from capillaries. (21)

vermiform appendix: *See* **appendix**.

vertebral canal: The passageway that encloses the spinal cord; a tunnel bounded by the neural arches of adjacent vertebrae. (7)

vertebral column: The cervical, thoracic, and lumbar vertebrae, the sacrum, and the coccyx. (7, 11)

vesicle: A membranous sac in the cytoplasm of a cell. (3)

vestibular nucleus: The processing center for sensations that arrive from the vestibular apparatus of the inner ear, located near the border between the pons and the medulla oblongata. (17)

vestibulospinal tracts: Descending tracts of the medial pathway that carry involuntary motor commands issued by the vestibular nucleus to stabilize the position of the head. (15)

villus/villi: A slender projection of the mucous membrane of the small intestine. (24)

virus: A noncellular pathogen. (22)

viscera: Organs in the ventral body cavity. (1)

visceral: Pertaining to viscera or their outer coverings. (1)

visceral smooth muscle: A smooth muscle tissue that forms sheets or layers in the walls of visceral organs; the cells may not be innervated, and the layers often show automaticity (rhythmic contractions). (10, 24)

viscosity: The resistance to flow that a fluid exhibits as a result of molecular interactions within the fluid. (21)

viscous: Thick, syrupy.

vitamin: An essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. (25)

vitreous humor: The gelatinous mass in the vitreous chamber of the eye. (17)

voluntary: Controlled by conscious thought processes.

W

white blood cells (WBCs): the granulocytes and agranulocytes of blood. (4, 19)

white matter: Regions in the central nervous system that are dominated by myelinated axons. (12, 13, 14)

white ramus: A nerve bundle containing the myelinated preganglionic axons of sympathetic motor neurons en route to the sympathetic chain or to a collateral ganglion.

(13)

Wormian bones: *See* sutural bones.

X

xiphoid process: The slender, inferior extension of the sternum. (7)

Y

Y chromosome: The sex chromosome whose presence indicates that the individual is a genetic male. (29)

Z

zona fasciculata: f the adrenal cortex that secretes glucocorticoids. (18)

zona glomerulosa: The region of the adrenal cortex that secretes mineralocorticoids. (18)

zona reticularis: The region of the adrenal cortex that secretes androgens. (18)

zygote: The fertilized ovum, prior to the start of cleavage. (28)

Appendix I

Answers to Concept Check and End-of-Chapter Questions

Chapter 1

Page 8

1. A histologist investigates the structure and properties of the tissue level of organization.

2. The study of the physiology of specific organs is called special physiology. In this particular case, the field of study is cardiac physiology (the study of heart function). Because heart failure is typically caused by disease, this specialty would overlap or be closely related to pathological physiology.

Page 15

1. Physiological systems can function normally only under carefully controlled conditions. Homeostatic regulation prevents potentially disruptive changes in the body's internal environment.

2. When homeostasis fails, organ systems function less efficiently or malfunction. The result is the state that we call disease. If the situation is not corrected, death can result.

3. Positive feedback is useful in processes, such as blood clotting, that must move quickly to completion once they have begun. It is harmful in situations in which a stable condition must be maintained, because it tends to increase any departure from the desired condition. For example, positive feedback in the regulation of body temperature would cause a slight fever to spiral out of control, with fatal results. For this reason, physiological systems normally exhibit negative feedback, which tends to oppose any departure from the norm.

Page 22

1. The two eyes would be separated by a midsagittal section.

2. The body cavity inferior to the diaphragm is the abdominopelvic cavity.

Page 25 *Level 1 Reviewing Facts and Terms*

Level 2 Reviewing Concepts

23. **(a)** Anatomy is the study of internal and external structures and the physical relationships among body parts. **(b)** Physiology is the study of how organisms perform their vital functions.

24. d

25. Autoregulation occurs when the activities of a cell, tissue, organ, or organ system change automatically (that is, without neural or endocrine input) when faced with some environmental change. Extrinsic regulation results from the activities of the nervous or endocrine system. It causes more extensive and potentially more effective adjustments in activities.

26. The body is erect, and the hands are at the sides with the palms facing forward.

27. b 28. c

Level 3 Critical Thinking and Clinical Applications

29. Calcitonin is released when calcium levels are elevated. This hormone should bring about a decrease in blood calcium levels, thus decreasing the stimulus for its own release.

30. There are several reasons why your body temperature may have dropped. Your body may be losing heat faster than it is being produced. This, however, is more likely to occur on a cool day. Various chemical factors, such as hormones, may have caused a decrease in your metabolic rate and thus your body is not producing as much heat as it normally would. Alternatively, you may be suffering from an infection that has temporarily changed the setpoint of the body’s “thermostat.” This would seem to be the most likely explanation considering the circumstances of the question.

Chapter 2

Page 33

1. Atoms combine with each other so as to gain a complete set of eight electrons in their outer energy level. Oxygen atoms do not have a full outer energy level, so they readily react with many other elements to attain this stable arrangement. Neon already has a full outer energy level and thus has little tendency to combine with other elements.

2. Hydrogen has three isotopes: hydrogen-1, with a mass of 1; deuterium, with a mass of 2; and tritium, with a mass of 3. The heavier sample must contain a higher proportion of one or both of the heavier isotopes.

3. The atoms in a water molecule are held together by polar covalent bonds. Water molecules are attracted to one another by hydrogen bonds.

Page 37

1. Because this reaction involves a large molecule being broken down into two smaller ones, it is a decomposition reaction. Because energy is released in the process, the reaction can also be classified as exergonic.

2. Enzymes in our cells promote chemical reactions by lowering the activation energy requirements. Enzymes make it possible for chemical reactions to proceed under conditions compatible with life.

Page 41

1. When it dissolves in water, salt dissociates into ions, charged particles that are capable of conducting an electrical current. Sugar molecules are held together by covalent bonds and so do not dissociate in solution; thus there are no ions to carry a current.

2. Stomach discomfort is commonly the result of excess stomach acidity (“acid indigestion”). Antacids contain a weak base that neutralizes the excess acid.

Page 48

1. A compound with a C:H:O ratio of 1:2:1 is a carbohydrate. The body uses carbohydrates chiefly as an energy source.

2. When two monosaccharides undergo a dehydration synthesis reaction, they form a disaccharide.

3. The most abundant lipid in a sample taken from beneath the skin would be a triglyceride.

4. An analysis of the lipid content of human cell membranes would reveal the presence of mostly phospholipids and small amounts of cholesterol and glycolipids.

Page 54

1. Proteins are chains of small organic molecules called amino acids.

2. An agent that breaks hydrogen bonds would affect the secondary level of protein structure.

3. The heat of boiling breaks bonds that maintain the protein’s tertiary structure, quaternary structure, or both. The resulting change in shape affects the ability of the protein molecule to perform its normal biological functions. These changes are known as denaturation.

4. If the active site of an enzyme changes so that the site better fits its substrate, the level of enzyme activity will increase. But if the change alters the active site to the extent that the enzyme’s substrate can no longer bind or binds poorly, the enzyme’s activity will decrease or be inhibited.

Page 56

1. The nucleic acid RNA (ribonucleic acid) contains the sugar ribose. The nucleic acid DNA (deoxyribonucleic acid) contains the sugar deoxyribose instead; both contain nitrogenous bases and phosphate groups.

2. Phosphorylation of an ADP molecule yields a molecule of ATP.

Page 60 *Level 1 Reviewing Facts and Terms*

1. a 2. b 3. d 4. d 5. b 6. c 7. d 8. d 9. b

10. d 11. a 12. d 13. b

14. protons, neutrons, and electrons

15. carbohydrates, lipids, proteins, and nucleic acids

16. (1) They provide a significant energy reserve. (2) They serve as insulation and thus act in heat preservation. (3) They protect organs by cushioning them.

17. (1) support (structural proteins); (2) movement (contractile proteins); (3) transport (transport proteins); (4) buffering; (5) metabolic regulation; (6) coordination and control (hormones and neurotransmitters); and (7) defense (antibodies)

18. **(a)** DNA: deoxyribose, phosphate, and nitrogenous bases (A, T, C, G); **(b)** RNA: ribose, phosphate, and nitrogenous bases (A, U, C, G)

19. (1) adenosine, (2) phosphate groups, and (3) appropriate enzymes

Level 2 Reviewing Concepts

20. d 21. c

22. Enzymes are specialized protein catalysts that lower the activation energy for chemical reactions. Enzymes speed up chemical reactions but are not used up or changed in the process.

23. A salt is an ionic compound consisting of any cations other than hydrogen ions and any anions other than hydroxide ions. Acids dissociate and release hydrogen ions, while bases remove hydrogen ions from solution (usually by releasing hydroxide ions)

24. Nonpolar covalent bonds have an equal sharing of electrons. Polar covalent bonds have an unequal sharing of electrons. Ionic bonds lose and/or gain electrons.

25. e 26. c

27. The molecule is a nucleic acid. Carbohydrates and lipids do not contain nitrogen. Although both proteins and nucleic acids contain nitrogen, only nucleic acids normally contain phosphorus.

Level 3 Critical Thinking and Clinical Applications

28. calcium electrons = 20; atomic number = 20; atomic weight = 40; 2 electrons in shell 1, 8 in shell 2; 8 in shell three and 2 in shell 4

29. Decreasing the amount of enzyme at the second step would slow down the remaining steps of the pathway because less substrate would be available for the next two steps. The net result would be a decrease in the amount of product.

30. If a person exhales large amounts of CO2, the equilibrium will shift to the left, and the level of H^+ in the blood will decrease. A decrease

in the amount of H^+ will cause the pH to rise.

Chapter 3

Page 68

1. The phospholipid bilayer of the cell membrane form a physical barrier between the internal environment of the cell and the external environment.

2. Channel proteins are integral proteins that allow water and small ions to pass through the cell membrane.

Page 72

1. The fingerlike projections on the surface of the intestinal cells are microvilli. They increase the cells’ surface area, enhancing their ability to absorb nutrients.

2. The cytosol has a higher concentration of potassium ions and suspended proteins and a lower concentration of sodium ions than the extracellular fluid. The cytosol also includes small quantities of carbohydrates, and larger reserves of amino acids and lipids.

Page 77

The SER functions in the synthesis of lipids such as steroids. Ovaries and testes produce large amounts of steroid hormones, which are lipids, and thus need large amounts of SER.

Mitochondria produce energy, in the form of ATP molecules, for the cell. A large number of mitochondria in a cell indicates a high demand for energy.

Page 84

1. The nucleus of a cell contains DNA, which codes for the production of all the cell’s polypeptides and proteins. Some of these proteins are structural proteins, which are responsible for the shape and other physical characteristics of the cell. Other proteins are enzymes, which govern cellular metabolism, direct the production of cell proteins, and control all the cell’s activities.

2. If a cell lacked the enzyme RNA polymerase, the cell would not be able to transcribe RNA from DNA.

Page 89

1. Diffusion is driven by a concentration gradient. The larger the concentration gradient, the faster the rate of diffusion; the smaller the concentration gradient, the slower the rate of diffusion. If the concentration of oxygen in the lungs were to decrease, the concentration gradient between oxygen in the lungs and oxygen in the blood would decrease (as long as the oxygen level of the blood remained constant). Thus oxygen would diffuse more slowly into the blood.

2. The 10 percent salt solution is hypertonic with respect to the cells lining the nasal cavity, because this solution contains a higher concentration of salt than do the cells. The hypertonic solution would draw water out of the cells, causing the cells to shrink and adding water to the mucus, thus relieving the congestion.

Page 95

1. To transport hydrogen ions against their concentration gradient—that is, from a region where they are less concentrated (the cells lining the stomach) to a region where they are more concentrated (the interior of the stomach)—energy must be expended. An active transport process must be involved.

2. If the cell membrane were freely permeable to sodium ions, more of these positively charged ions would move into the cell and the transmembrane potential would move closer to zero.

3. This process is an example of phagocytosis.

Page 101

1. This cell is likely in the G1 phase of its life cycle.
2. The deletion of a single nucleotide from a coding sequence of DNA would alter the entire base sequence after the point of deletion. As a result, different codons would be lined up on the messenger RNA that was transcribed from the affected region. These codons, in turn, would result in the incorporation of a different series of amino acids into the polypeptide. The polypeptide product would definitely be abnormal and may not be functional.
3. If spindle fibers failed to form during mitosis, the cell would not be able to separate the chromosomes into two sets. If cytokinesis occurred, the result would be one cell with two sets of chromosomes and one cell with none.

Page 104 *Level 1 Reviewing Facts and Terms*

b 2. c 3. d 4. a 5. c 6. a 7. c 8. a 9. b

10. (1) Cells are the building blocks of all plants and animals. (2) Cells are produced by the division of preexisting cells. (3) Cells are the smallest units that perform all vital physiological functions. (4) Each cell maintains homeostasis at the cellular level. (5) Homeostasis at the tissue, organ, organ system, and organism levels reflect the combined and coordinated actions of many cells.
11. (1) physical isolation, (2) regulation of exchange with the environment, (3) sensitivity, and (4) structural support
12. Membrane proteins function as receptors, channels, carriers, enzymes, anchors, and identifiers.
13. (1) diffusion, (2) carrier-mediated transport, and (3) vesicular transport
14. (1) distance (2) size of the gradient, (3) molecule size, and (4) temperature
15. (1) synthesis of proteins, carbohydrates, and lipids; (2) storage of absorbed or synthesized molecules; (3) transport of materials; and

(4) detoxification of drugs or toxins

Level 2 Reviewing Concepts

16. b 17. d 18. b 19. c 20. c 21. d 22. b 23. c

24. G0: normal cell functions; G1: cell growth, duplication of organelles, and protein synthesis; S: DNA replication and synthesis of histones; G2: protein synthesis

25. Prophase: Chromatin condenses and chromosomes become visible; centrioles migrate to opposite poles of the cell and spindle fibers develop; and the nuclear membrane disintegrates. Metaphase: Chromatids attach to spindle fibers and line up along the metaphase plate. Anaphase: Chromatids separate and migrate toward opposite poles of the cell. Telophase: The nuclear membrane forms; chromosomes disappear as the chromatin relaxes; and nucleoli appear.

26. **(a)** Cytokinesis is the cytoplasmic movement that separates two daughter cells. **(b)** It completes the process of cell division.

Level 3 Critical Thinking and Clinical Applications

27. This process is facilitated diffusion, which requires a carrier molecule but not cellular energy. The energy for this process is provided by the concentration gradient of the substance being transported. When all the carriers are actively involved in transport, the rate of transport reaches a saturation point.

28. Solution A must have initially had more solutes than solution B. As a result, water moved by osmosis across the selectively permeable membrane from side B to side A, increasing the fluid level on side A.

29. c

30. The isolation of the internal contents of membrane bound organelles allows them to manufacture or store secretions, enzymes, or toxins that could adversely affect the cytoplasm in general. Another benefit is the increased efficiency of having specialized enzyme systems concentrated in one place. For example, the concentration of enzymes

necessary for energy production in the mitochondrion increases the efficiency of cellular respiration.

Chapter 4

Page 110

1. Epithelial tissue is characterized by cellularity, polarity, attachment, avascularity, and regeneration.
2. The presence of many microvilli on the free surface of epithelial cells greatly increases the cell's surface area, allowing for increased absorption.
3. Gap junctions allow small molecules and ions to pass from cell to cell. Among epithelial cells, they help coordinate functions such as the beating of cilia. In cardiac and smooth muscle tissues, they are essential to the coordination of muscle cell contractions.

Page 118

1. No. A simple squamous epithelium does not provide enough protection against infection, abrasion, or dehydration and so is not located on the skin surface.
2. All these regions are subject to mechanical trauma and abrasion—by food (pharynx and esophagus), feces (anus), and intercourse or childbirth (vagina).
3. This process is holocrine secretion.
4. The gland is an endocrine gland.

Page 123

1. Collagen fibers add strength to connective tissue. A vitamin C deficiency thus might result in the production of connective tissue that is weak and prone to damage.
2. Antihistamines act against the molecule histamine, which is produced by mast cells and basophils that leave the bloodstream.
3. This tissue is adipose (fat) tissue.

Page 129

1. Cartilage lacks a direct blood supply, which is necessary for proper healing to occur. Instead of having chondrocytes repair the injury site with new cartilage, fibroblasts migrate into the area and replace the damaged cartilage with fibrous scar tissue.
2. Intervertebral discs are composed of fibrocartilage.
3. The two connective tissues that contain a fluid matrix are blood and lymph.

Page 132
1. The pleural, peritoneal, and pericardial cavities are all lined by serous membranes.
2. This is an example of a mucous membrane.
3. This tissue is probably fascia, a type of dense connective tissue that attaches muscles to skin and bones.

Page 134
1. This muscle tissue is smooth muscle tissue; both cardiac and skeletal muscle tissues are striated.
2. The cells are probably neurons.
3. New skeletal muscle is produced by the division and fusion of satellite cells, mesenchymal cells that persist in adult skeletal muscle tissue. *Page* 140 *Level 1 Reviewing Facts and Terms*

10. a 11. b 12. e 13. a 14. b

15. (1) It provides physical protection; (2) it controls permeability; (3) it provides sensations; and (4) it produces specialized secretions.
16. Endocrine glands secrete hormones onto the surface of the gland or directly into the surrounding fluid; exocrine glands secrete via ducts.
17. (1) merocrine secretion; (2) apocrine secretion; (3) holocrine secretion
18. (1) specialized cells; (2) extracellular protein fibers; and (3) a fluid ground substance

19. The four membranes in the body are 1) serous membranes, 2) mucous membranes, 3) cutaneous membrane and 4) synovial membranes.

20. (1) neurons, which transmit electrical impulses in the form of changes in the transmembrane potential; and (2) neuroglia, which comprise several kinds of supporting cells and play a role in providing nutrients to neurons

Level 2 Reviewing Concepts

21. Exocrine secretions are secreted onto a surface or outward through a duct. Endocrine secretions are secreted by ductless glands into surrounding tissues. The secretions are called hormones, which usually diffuse into the bloodstream for distribution to other parts of the body.

22. Tight junctions block the passage of water or solutes between the cells. In the digestive system, these junctions keep enzymes, acids, and waste products from damaging delicate underlying tissues.

23. The fluid connective tissues have a liquid, watery matrix. They differ from supporting connective tissues in that they have many soluble proteins in the matrix and they do not include insoluble fibers.

24. The extensive connections between cells formed by cell junctions, intercellular cement, and physical interlocking hold skin cells together and can deny access to chemicals or pathogens that cover their free surfaces. If the skin is damaged and the connections are broken, infection can easily occur.

25. b 26. b

27. Similarities: actin and myosin interactions produce contractions, calcium ions trigger and sustain contractions. Differences: skeletal muscles are relatively large, multinucleate, striated, and contract only under neural stimulation; cardiac muscles have 1–5 nuclei; they are interconnected in a branching network; they contract in response to pacemaker cell activity. Smooth muscles are small and spindle shaped, nonstriated; each has only 1 nucleus.

Level 3 Critical Thinking and Clinical Applications

28. Because apocrine secretions are released by pinching off a portion of the secreting cell, you could test for the presence of cell membranes, specifically for the phospholipids in cell membranes. Merocrine secretions do not contain a portion of the secreting cell, so they would lack membrane constituents.

29. Skeletal muscle tissue would be made up of densely packed fibers running in the same direction, but since these fibers are composed of cells they would have many nuclei and mitochondria. Skeletal muscle also has an obvious banding pattern or striations due to the arrangement of the actin and myosin filaments within the cell. The student is probably looking at a slide of tendon (dense connective tissue). The small nuclei would be those of fibroblasts.

30. You would expect the skin in the area of the injury to become red and warm. It would also swell and Jim would experience a painful sensation. These changes occur as a result of the inflammation reaction, our body's first response to injury. Injury to the epithelium and underlying connective tissue would trigger the release of chemicals like histamine and heparin from mast cells in the area. These chemicals in turn initiate the changes that we observe.

Chapter 5

Page 157

1. Dandruff consists of cells from the stratum corneum.

2. This splinter is lodged in the stratum granulosum.

3. Fresh water is hypotonic with respect to skin cells, so water will move into the cells by osmosis, causing them to swell.

4. Sanding the tips of the fingers will not permanently remove fingerprints. The ridges of the fingerprints are formed in layers of the skin that are constantly regenerated, so these ridges will eventually reappear. The pattern of the ridges is determined by the arrangement of tissue in the dermis, which is not affected by sanding.

Page 161

1. When exposed to the ultraviolet radiation in sunlight or sunlamps, melanocytes in the epidermis and dermis synthesize the pigment melanin, darkening the color of the skin.

2. When skin is warm, blood is diverted to the superficial dermis for the purpose of eliminating heat. Because blood is red, it imparts a red cast to the skin.

3. The hormone cholecalciferol (vitamin D3) is needed to form strong bones and teeth. The first step in this hormone's production involves the exposure of the skin to specific wavelengths of UV light. When the body surface is covered, UV light cannot penetrate to the blood in the skin to begin vitamin D3 production, resulting in fragile bones.

Page 163

1. The capillaries and sensory neurons that supply the epidermis are located in the papillary layer of the dermis.

2. The presence of elastic fibers and the resilience of skin turgor allow the dermis to undergo repeated cycles of stretching and recoil.

Page 167

1. The contraction of the arrector pili muscle pulls the hair follicle erect, depressing the area at the base of the hair and making the surrounding skin appear higher. The result is known as "goose bumps."

2. Hair is a derivative of the epidermis, but the follicles are in the dermis. Where the epidermis and deep dermis are destroyed, new hair will not grow.

Page 169

1. Sebaceous glands produce a secretion called sebum. Sebum lubricates and protects the keratin of the hair shaft, lubricates and conditions the surrounding skin, and inhibits the growth of bacteria.

2. Apocrine sweat glands produce a secretion that contains several kinds of organic compounds. Some of these compounds have an odor, and others produce an odor when metabolized by skin bacteria. Deodorants are used to mask the odor of such secretions.

3. Apocrine sweat glands enlarge and increase their secretion production in response to the increase in sex hormones that occurs at puberty.

Page 173

1. The combination of fibrin clot, fibroblasts, and the extensive network of capillaries in tissue that is healing is called granulation tissue.

2. Skin can regenerate effectively even after considerable damage has occurred because stem cells persist in both the epithelial and connective tissue components of skin. When injury occurs, cells of the stratum germinativum replace epithelial cells while mesenchymal cells replace cells lost from the dermis.

3. As a person ages, the blood supply to the dermis decreases and merocrine sweat glands become less active. These changes make it more difficult for the elderly to cool themselves in hot weather.

Page 177 *Level 1 Reviewing Facts and Terms*

a 2. c 3. d 4. d 5. c 6. a 7. d 8. b 9. b 10. d 11. d 12. b 13. a

14. Epidermal cell division occurs in the stratum germinativum.

15. This smooth muscle causes hairs to stand erect when stimulated.

16. Epidermal growth factor promotes the divisions of germinal cells in the stratum germinativum and stratum spinosum. It also accelerates the production of keratin in differentiating epidermal cells and stimulates both epidermal development and epidermal repair after injury and synthetic activity and secretion by epithelial cells.

17. (1) papillary layer, which consists of loose connective tissue and contains capillaries and sensory neurons; (2) reticular layer, which consists of dense irregular connective tissue and bundles of collagen fibers. Both layers contain networks of blood vessels, lymphatic vessels, and nerve fibers.

18. (1) bleeding; (2) scab formation; (3) granulation tissue formation; (4) scarring

Level 2 Reviewing Concepts

19. Insensible perspiration is water loss via evaporation through the stratum corneum of the skin. Sensible perspiration is produced by active sweat glands.

20. Substances that are fat soluble pass through the permeability barrier easily, because the barrier is composed primarily of lipids surrounding the epidermal cells. Water-soluble drugs are hydrophobic and thus don’t penetrate the permeability barrier easily.

21. A tan is a result of the synthesis of melanin in the skin. Melanin helps prevent skin damage by absorbing UV radiation before it reaches the deep layers of the epidermis and dermis. Within the epidermal cells, melanin concentrates around the outer wall of the nucleus, so it absorbs the UV light before it can damage nuclear DNA.

22. Lines of cleavage represent the orientation of the collagen and elastin fibers of the dermis, an orientation that resists normal stresses on the skin. Incisions along the lines of cleavage are more likely to remain closed, and thus will heal more quickly, than would incisions not along lines of cleavage.

23. c 24. c 25. d

Level 3 Critical Thinking and Clinical Applications

26. a

27. The puncture wound has a greater chance of becoming infected than the knife cut because the cut from the knife will bleed freely, washing away many of the bacteria from the wound site. In a puncture wound, bacteria can be forced beneath the surface of the skin where oxygen is limited (anaerobic) and past the skin’s protective barriers, thus increasing the possibility of infection.

28. **(a)** Ultraviolet radiation in sunlight converts a cholesterol-related steroid into vitamin D3, or cholecalciferol. This compound is then converted to calcitriol, which is essential for normal calcium and phosphorus absorption by the small intestine. Calcium and phosphorus

are necessary for normal bone maintenance and growth. **(b)** They can drink more milk. Milk is routinely fortified with cholecalciferol, normally identified as “vitamin D,” which is easily absorbed by the intestines.

29. Sweating from merocrine glands is precisely regulated, and one influencing factor is emotional state. Presumably, a person who is lying is nervous and sweats noticeably; this sweating is detected by the lie detector machine.

30. The chemicals in hair dyes break the protective covering of the cortex allowing the dyes themselves to stain the medulla of the shaft. This is not permanent because the cortex remains damaged, allowing shampoo and UV rays from the sun to enter the medulla and affect the color. Also, the viable portion of the hair remains unaffected, so that when the shaft is replaced the color will be lost.

Chapter 6

Page 188

1. If the ratio of collagen to hydroxyapatite in a bone increased, the bone would become less strong (as well as more flexible).

2. The presence of concentric layers of bone around a central canal is indicative of an osteon. Osteons make up compact bone. Because the ends (epiphyses) of long bones are primarily cancellous (spongy) bone, this sample is most likely from the marrow cavity of the shaft (diaphysis) of a long bone.

3. Because osteoclasts break down or demineralize bone, the bone would have a reduced mineral content (less mass); as a result, it would also be weaker.

Page 193

1. During intramembranous ossification, fibrous connective tissue is replaced by bone.

2. In endochondral ossification, cells of the inner layer of the perichondrium differentiate into osteoblasts, and a cartilage model is gradually replaced by bone.

3. Long bones of the body, such as the femur, have an epiphyseal cartilage, a plate of cartilage that separates the epiphysis from the diaphysis so long as the bone is still growing lengthwise. An x-ray would indicate whether the epiphyseal cartilage is still present. If it is, growth is still occurring; if it is not, the bone has reached its adult length.

Page 196

1. The larger arm muscles of the weight lifter would apply more mechanical stress to the bones of the upper limbs. In response to that stress, the bones would grow thicker. For similar reasons, we would expect the jogger to have heavier thigh bones.
2. Growth continues throughout childhood. At puberty, a growth spurt occurs and is followed by the closure of the epiphyseal cartilages. The later puberty begins, the taller the child will be when the growth spurt begins, so the taller the individual will be when growth is completed.
3. Increased levels of growth hormone prior to puberty will result in excessive bone growth, making the individual taller.

Page 198

1. The bones of children who have rickets are poorly mineralized and as a result are quite flexible. Under the weight of the body, the leg bones bend. The instability makes walking difficult and can lead to other problems of the legs and feet.
2. Parathyroid hormone (PTH) stimulates osteoclasts to release calcium ions from bone. Increased PTH secretion would result in an increase in the level of calcium ions in the blood.
3. Calcitonin lowers blood calcium levels by inhibiting osteoclast activity and increasing the rate of calcium excretion at the kidneys.

Page 201

1. An external callus forms early in the healing process, when cells from the endosteum and periosteum migrate to the area of the fracture. These cells form an enlarged collar (external callus) that circles the bone in the area of the fracture.

2. The sex hormones known as estrogens play an important role in moving calcium into bones. After menopause, the level of these hormones decreases dramatically; as a result, older women have difficulty replacing the calcium in bones that is being lost due to normal aging. In males, the level of sex hormones (androgens) does not decrease until much later in life.

Page 203 *Level 1 Reviewing Facts and Terms*

b 2. a 3. a 4. c 5. b 6. b 7. c 8. a 9. a

10. (1) support; (2) storage of minerals and lipids; (3) blood cell production; (4) protection; and (5) leverage

11. (1) osteocytes; (2) osteoblasts; (3) osteoclasts; and (4) osteoprogenitor cells

12. (1) diaphysis (shaft); (2) epiphysis; (3) epiphyseal cartilages/line; (4) articular cartilage; (5) medullary canal;

(6) periosteum; (7) endosteum

13. In intramembranous ossification, bone develops from mesenchyme or fibrous connective tissue. In endochondral ossification, bone develops from a cartilage model.

14. (1) organic = collagen; (2) inorganic = hydroxyapatite crystals

15. **(a)** calcium salts and phosphate salts and vitamins A, C, and D3; **(b)** calcitriol, growth hormone, thyroxine, estrogens (in females) or androgens (in males,) calcitonin, and parathyroid hormone (PTH)

16. (1) the bones; (2) the intestinal tract; and (3) the kidneys

17. Parathyroid hormone stimulates osteoclast activity, increases the rate of intestinal absorption, and decreases the rate of excretion of calcium ions.

Level 2 Reviewing Concepts

18. Nutrients reach the osteocytes by diffusion along canaliculi that open onto the surface of the trabeculae.

19. The osteons are parallel to the long axis of the shaft, which does not bend when forces are applied to either end. Stresses or impacts to the side of the shaft can lead to a fracture.

20. Inactivity in unstressed bones leads to the removal of calcium salts. Up to one-third of the bone mass can be lost in this manner, causing the bones to become thin and brittle.

21. The digestive and urinary systems (kidneys) play important roles in providing the calcium and phosphate minerals needed for bone growth. In return, the skeleton provides protection and acts as a reserve of calcium, phosphate, and other minerals that can compensate for changes in the dietary supplies of these ions.

22. b

23. There are many long bones in the hand, each of which has an epiphyseal cartilage. Measuring the width of these plates will provide clues to the hormonal control of growth in the child.

24. When a bone fracture is repaired, the bone tends to be stronger and thicker than normal at the fracture site.

25. b

26. Bone markings give clues as to the size, age, sex, and general appearance of an individual.

Level 3 Critical Thinking and Clinical Applications

27. The fracture might have damaged the epiphyseal cartilage in Sally's right leg. Even though the bone healed properly, the damaged leg did not produce as much cartilage as did the undamaged leg. The result would be a shorter bone on the side of the injury.

28. d 29. a

30. The matrix of bone will absorb traces of minerals from the diet. These minerals can be identified hundreds of years later. A diet rich in calcium and vitamin B will produce denser bones than will a diet lacking these. Cultural practices such as binding of appendages, or

wrapping of infant heads will manifest in misshapen bones. Heavy muscular activity will result in larger bone markings, indicating an athletic lifestyle.

Chapter 7

Page 220

1. The foramen magnum is located in the base of the occipital bone.
2. Tomás has fractured his right parietal bone.
3. The sphenoid bone contains the sella turcica, which in turn contains the pituitary gland.

Page 226

1. The adult vertebral column has fewer vertebrae because the five sacral vertebrae fuse to form a single sacrum and the four coccygeal vertebrae fuse to form a single coccyx.
2. The secondary curves of the spine allow us to balance our body weight on our lower limbs with minimal muscular effort. Without the secondary curves, we would not be able to stand upright for extended periods.
3. When you run your finger along a person's spine, you can feel the spinous processes of the vertebrae.

Page 231

1. The dens is located on the axis, or second cervical vertebra, which is in the neck.
2. The presence of transverse foramina indicate that this vertebra is a cervical vertebra.
3. The lumbar vertebrae must support a great deal more weight than do vertebrae that are more superior in the spinal column. The large vertebral bodies allow the weight to be distributed over a larger area.

Page 234

1. True ribs are attached directly to the sternum by their own costal cartilage. False ribs either do not attach to the sternum (as in the floating ribs) or attach by means of a common costal cartilage (as in the vertebrochondral ribs).

2. Improper compression of the chest during CPR can—and commonly does—result in a fracture of the sternum or ribs.

3. Vertebrosternal ribs, or true ribs, attach directly to the sternum, whereas vertebrochondral ribs fuse together and merge with the costal cartilages of ribs 8–10 and and then with the cartilages of rib pair 7 before they reach the sternum.

Page 236 *Level 1 Reviewing Facts and Terms*

9. the frontal bone, sphenoid, ethmoid, palatine bones, and maxillary bones

10. (1) lacrimal bone; (2) nasal bone; (3) maxillary bone; (4) zygomatic bone; and (5) mandible

11. (1) sphenoid; (2) frontal bone; (3) ethmoid; (4) lacrimal bone; (5) maxillary bone; (6) palatine bone; (7) zygomatic bone

12. The vomer forms the anterior, inferior portion of the bony nasal septum that separates the right and left nasal cavities.

13. the frontal bone, sphenoid, ethmoid, palatine bones, and maxillary bones

Level 2 Reviewing Concepts

14. The petrous part of the temporal bone encloses the structures of the inner ear. The middle ear is located in the tympanic cavity within the petrous part. The external acoustic canal ends at the tympanic membrane, which leads to the inner ear. Mastoid air cells within the mastoid process are connected to the tympanic cavity.

15. The ethmoid forms the superior surface of the nasal cavity. The olfactory foramina within the cribriform plate of the ethmoid allows neurons associated with the sense of smell to extend into the nasal cavity.

16. The ribs raise and lower to increase and decrease the volume of the chest cavity. They move similar to the handle of a bucket. When they rise, the chest cavity expands and we breathe in. When the ribs are lowered to their original position, the volume of the chest cavity decreases and we breathe out.

17. Keeping your back straight keeps the weight aligned along the axis of your vertebral column, where it can be transferred to your lower limbs. Bending your back would strain the muscles and ligaments of the back, increasing the risk of injury.

18. d

19. Fontanels are fibrous connections between cranial bones. They permit distortion of the skull without damaging the structure during delivery, helping to ease the child through the birth canal.

20. a 21. c 22. e

Level 3 Critical Thinking and Clinical Applications

23. d

24. The large bones of a child's cranium are not yet fused; they are connected by fontanels, areas of fibrous tissue. By examining the bones, the archaeologist could readily see if sutures had formed. By knowing approximately how long it takes for the various fontanels to close and by determining their sizes, she could estimate the ages of the bones.

25. Women in later stages of pregnancy develop lower back pain because of the changes in the lumbar curvature of the spine. The increased mass of the pregnant uterus shifts the center of gravity and to compensate for this the lumbar curvature is exaggerated and more of the body weight is supported by the lumbar region than normal. This results in sore muscles and the lower back pain.

Chapter 8

Page 242

1. The clavicle attaches the scapula to the sternum and thus restricts the scapula's range of movement. When the clavicle is broken, the scapula has a greater range of movement and is less stable.

2. The head of the humerus articulates with the scapula at the glenoid cavity.

Page 245

1. The two rounded projections on either side of the elbow are the lateral and medial epicondyles of the humerus.
2. The radius is lateral when the forearm is pronated, as in the anatomical position.
3. The first distal phalanx is located at the tip of the thumb; Bill’s thumb is broken.

Page 249

1. The three bones that make up the os coxae are the ilium, ischium, and pubis.
2. The pelvis of females is generally smoother and lighter than that of males and has less-prominent markings. The pelvic outlet is enlarged, and there is less curvature on the sacrum and coccyx. The pelvic inlet is wider and more circular. The pelvis as a whole is relatively broad and low. The ilia project farther laterally. The inferior angle between the pubic bones is greater than 100°, as opposed to 90° or less for the pelvis of males. These differences adapt the pelvis of females for supporting the weight of the developing fetus and enable the newborn to pass through the pelvic outlet during delivery.
3. When you are seated, your body weight is borne by the ischial tuberosities of the pelvis.

Page 253

1. Although the fibula is not part of the knee joint and does not bear weight, it is an important point of attachment for many leg muscles. When the fibula is fractured, these muscles cannot function properly to move the leg, and walking is difficult and painful. The fibula also helps stabilize the ankle joint.
2. Joey has most likely fractured the calcaneus (heel bone).
3. The talus transmits the weight of the body from the tibia toward the toes.

Page 256 *Level 1 Reviewing Facts and Terms*

6. extension and flexion

7. ischium, ilium, and pubis

8. (1) talus; (2) calcaneus; (3) cuboid bone; (4) navicular bone; and (5–7) three cuneiform bones

Level 2 Reviewing Concepts

9. d 10. a 11. c 12. d 13. d 14. d 15. c

16. The pelvic girdle consists of the ossa coxae. The pelvis is a composite structure; it consists of the ossa coxae of the appendicular skeleton and the sacrum and coccyx of the axial skeleton.

17. d

18. The clavicles are small and fragile, so they are easy to break. Once this part of the pectoral girdle is broken, the assailant would no longer have efficient use of the arms.

19. e

20. The slender fibula parallels the tibia of the leg and provides an important site for muscle attachment. It does not help in transferring weight to the ankle and foot, however, because it is excluded from the knee joint.

21. e

Level 3 Critical Thinking and Clinical Applications

22. In osteoporosis, a decrease in the calcium content of the bones leads to bones that are weak and brittle. Since the hip joint and leg bones must support the weight of the body, any weakening of these bones may result in not enough strength to support the body mass, and as a result the bone will break under the great weight. The shoulder joint is not a load-bearing joint and is not subject to the same great stresses or strong muscle contractions as the hip joint. As a result, breaks in the bones of this joint should occur less frequently.

23. Fred probably dislocated his shoulder, which is quite a common injury due to the weak nature of the glenohumeral joint.

24. The general appearance of the pelvis, the shape of the pelvic inlet, the depth of the iliac fossa, the characteristics of the ilium, the angle inferior to the pubic symphysis, the position of the acetabulum, the shape of the obturator foramen, and the characteristics of the ischium are all important in determining an individual’s sex from a skeleton. Age can be

determined by the size, degree of mineralization, and various markings on the bone. The individual's general appearance can be reconstructed by looking at the markings where muscles attach to the bones. This can indicate the size and shape of the muscles and thus the general body contours of the individual.

Chapter 9

Page 262

1. All these joints (but not synostoses) consist of bony regions separated by fibrous or cartilaginous connective tissue.

2. Originally, each of these joints is a syndesmosis. As the bones interlock, they form sutural joints.

3. Articular cartilages lack a blood supply; they rely on synovial fluid to supply nutrients and eliminate wastes. Impairing the circulation of synovial fluid would have the same effect as impairing a tissue's blood supply. Nutrients would not be delivered to meet the tissue's needs, and wastes would accumulate. Damage to and ultimately the death of the cells in the tissue would result.

Page 267

1. When you do jumping jacks and move your lower limbs away from the midline of the body, the movement is abduction. When you bring the lower limbs back together, the movement is adduction.

2. Flexion and extension are the movements associated with hinge joints.

Page 270

1. Intervertebral discs are not found between the first and second cervical vertebrae, between sacral vertebrae in the sacrum, or between coccygeal vertebrae in the coccyx. An intervertebral disc between the first and second cervical vertebrae would prohibit rotation. The vertebrae in the sacrum and coccyx are fused.

2. **(a)** flexion; **(b)** lateral flexion; **(c)** rotation

Page 273

1. Ligaments and muscles provide most of the stability for the shoulder joint.
2. Because the subscapular bursa is located in the shoulder joint, the tennis player would be more likely to develop inflammation of this structure (bursitis). The condition is associated with repetitive motion that occurs at the shoulder, such as swinging a tennis racket. The jogger would be more at risk for injuries to the knee joint.
3. A shoulder separation is an injury involving partial or complete dislocation of the acromioclavicular joint.
4. Terry has most likely damaged his annular ligament.

Page 276

1. The iliofemoral, pubofemoral, and ischiofemoral ligaments are at the hip joint.
2. Damage to the menisci of the knee joint would result in a decrease in the joint's stability. The individual would have a hard time locking the knee in place while standing and would have to use muscle contractions to stabilize the joint. If the person had to stand for a long period, the muscles would fatigue and the knee would "give out." We would also expect the individual to feel pain.
3. "Clergyman's knee" is a bursitis that commonly affects members of the clergy, who spend a great deal of time kneeling. The work of carpet layers and roofers necessitates kneeling and sliding along on their knees, causing a similar inflammation of the bursae in the knee joint.

20. b

21. Menisci may subdivide a synovial cavity, channel the flow of synovial fluid, and allow variations in the shape of the articular surfaces.

22. shoulder separation

23. Articular cartilages do not have perichondrium, and their matrix contains more water than do other cartilages.

24. The nucleus pulposus does not extrude in a slipped disc. In a herniated disc, the nucleus pulposus breaks through the annulus fibrosus.

25. Height decreases during adulthood in part as a result of osteoporosis in the vertebrae and in part as a result of the decline in water content of the nucleus pulposus region of the intervertebral discs.

26. ankylosis

27. (1) gliding: clavicle and sternum; (2) hinge: elbow; (3) pivot: atlas and axis; (4) ellipsoid: radius and carpal bones; (5) saddle: thumb;

(6) ball and socket: shoulder

Level 3 Critical Thinking and Clinical Applications

28. The injury was a strain – movement outside of the normal range of motion has stretched the ligaments and probably stressed and irritated the tendons. This leads to inflammation and pain on movement.

29. Cartilage does not have any blood vessels, so the chondrocytes rely on diffusion to gain nutrients and eliminate wastes. The synovial fluid is very important in supplying nutrients to the articular cartilages that it bathes and in removing wastes. If the circulation of the synovial fluid is impaired or stopped, the cells will not get enough nutrients or be able to get rid of their waste products. This combination of factors can lead to the death of the chondrocytes and the breakdown of the cartilage.

30. Shoulder dislocations would occur more frequently than hip dislocations because the shoulder is a more mobile joint. Because of its mobility, the shoulder joint is not bound tightly by ligaments or other elements and is easier to dislocate when excessive forces are applied. The hip joint, although mobile, is stabilized by four heavy ligaments, and the bones fit together snugly in the joint. The synovial capsule of the hip joint is larger than the shoulder, and the range of motion is not as great. These factors contribute to the joint being more stable and less easily dislocated.

Chapter 10

Page 292

1. Because tendons attach muscles to bones, severing the tendon would disconnect the muscle from the bone. If the muscle were to contract, nothing would happen.
2. Skeletal muscle appears striated when viewed through a microscope because the Z lines and thick filaments of the myofibrils within the muscle fibers are aligned.
3. You would expect the greatest concentration of calcium ions to be in the cisternae of the sarcoplasmic reticulum in resting skeletal muscle.

Page 300

1. A muscle’s ability to contract depends on the formation of cross-bridges between the myosin and actin myofilaments in the muscle. A drug that interferes with cross-bridge formation would prevent muscle contraction.
2. Because the amount of cross-bridge formation is proportional to the amount of available calcium ions, increased permeability of the sarcolemma to Ca^{2+} would lead to an increased intracellular concentration of Ca^{2+} and a greater degree of contraction. In addition, because the amount of calcium ions in the sarcoplasm must be reduced for relaxation to occur, an increase in the permeability of the sarcolemma to Ca^{2+} could make the muscle unable to relax completely.

3. Without acetylcholinesterase, the motor end plate would be continuously stimulated by acetylcholine; the muscle would lock in a state of contraction.

Page 308

1. A muscle's ability to contract depends on the formation of cross-bridges between the myosin and actin myofilaments in the muscle. In a muscle that is overstretched, the myofilaments would overlap very little. Very few cross-bridges would form, and the contraction would be weak. If the myofilaments did not overlap at all, then no cross-bridges would form and the muscle could not contract.

2. During treppe, there is not enough time between successive contractions to reabsorb all the calcium ions that were released during the prior contraction event. As a result, calcium ions accumulate in the sarcoplasm at higher than normal levels, allowing more cross-bridges to form and tension to increase.

3. Yes. Contraction occurs as thick and thin filaments interact. The entire muscle can shorten (isotonic, concentric), elongate (isotonic, eccentric), or remain the same length (isometric), depending on the relationship between the resistance and the tension produced by actin and myosin interactions.

Page 316

1. A sprinter requires large amounts of energy for a short burst of activity. To supply this demand for energy, the sprinter's muscles switch to anaerobic metabolism. Anaerobic metabolism is not as efficient in producing energy as aerobic metabolism is, and the process also produces acidic waste products; this combination contributes to fatigue. Conversely, marathon runners derive most of their energy from aerobic metabolism, which is more efficient and does not produce the amount of waste products that anaerobic metabolism does.

2. Activities that require short periods of strenuous activity produce a greater oxygen debt, because this type of activity relies heavily on energy production by anaerobic metabolism. Because lifting weights is more strenuous over the short term than swimming is, weight

lifting would likely produce a greater oxygen debt than would swimming laps, which is an aerobic activity.

3. Individuals who excel at endurance activities have a higher than normal percentage of slow fibers. Those fibers are physiologically better adapted to this type of activity than are fast fibers, which are less vascular and fatigue faster.

Page 320

1. Cardiac muscle cells are joined by gap junctions, which allow ions and small molecules to flow directly from one cell to another. This type of junction allows for action potentials that are generated in one cell to spread rapidly to adjacent cells. Thus all the cells contract simultaneously as if they were a single unit (a syncytium).

2. Cardiac and smooth muscle contractions are more affected by changes in the concentration of Ca^{2+} in the extracellular fluid than are skeletal muscle contractions because in cardiac and smooth muscles, most of the calcium ions that trigger a contraction come from the extracellular fluid. In skeletal muscle, most of the calcium ions come from the sarcoplasmic reticulum.

3. The actin and myosin filaments of smooth muscle are not as rigidly organized as those of skeletal muscle. This loose organization allows smooth muscle to contract over a wider range of resting lengths.

17. d 18. b 19. a 20. e

21. In an initial latent period (after the stimulus arrives and before the tension begins to increase), the action potential in the muscle is generated and triggers the release of calcium ions from the SR. In the contraction phase, the calcium binds to troponin (cross-bridges form) and the tension begins to increase. In the relaxation phase, tension drops because cross-bridges have detached and because calcium levels have fallen; the active sites are once again covered by the troponin–tropomyosin complex.

22. (1) O2 for aerobic respiration is consumed by liver cells, which need to make a great deal of ATP to convert lactic acid to glucose. (2) O2 for aerobic respiration is consumed by skeletal muscle fibers as they restore ATP, creatine phosphate, and glycogen concentrations to their former levels. (3) The normal O2 concentration in blood and peripheral tissues is replenished.

23. Cardiac muscle tissue has the property of automaticity. The contractions are timed by pacemaker cells, specialized cardiac muscle fibers.

24. At the motor end plates of neuromuscular junctions, the blocking of the binding process by atracurium would inhibit the ability of the muscle to contract. Thus the muscle would remain relaxed. Atracurium could be useful if administered before surgery.

25. In rigor mortis, the membranes of the dead cells are no longer selectively permeable; the SR is no longer able to retain calcium ions. As calcium ions enter the sarcoplasm, a sustained contraction develops. The muscles lock in the contracted position, making the

body extremely stiff. Contraction persists because the dead muscle cells can no longer make ATP, which is necessary for cross-bridge detachment from the active sites. Rigor mortis begins a few hours after death and lasts 15–25 hours, until the lysosomal enzymes released by autolysis break down the myofilaments.

26. c

Level 3 Critical Thinking and Clinical Applications

27. Because organophosphates block the action of acetylcholinesterase, the acetylcholine released into the synaptic cleft would not be removed. It would continue to stimulate the motor end plate, causing a state of persistent contraction (spastic paralysis). If the muscles of respiration were affected (which is likely), Ivan would die of suffocation. Prior to death, the most obvious symptoms would be uncontrolled tetanic contractions of the skeletal muscles.

28. The enzyme CPK (creatine phosphokinase) functions in the reaction that transfers phosphate from creatine phosphate to ADP in muscle cells. This reaction occurs primarily during anaerobic activity. The enzyme LDH (lactate dehydrogenase) is responsible for converting pyruvic acid to lactic acid, a reaction that also occurs under anaerobic conditions. Elevations of these two enzymes would indicate that muscle tissue was working hard under anaerobic conditions, and since enzymes from different tissues have slightly different amino acid sequences (isozymes), it would be possible to verify that the CPK and LDH were released from damaged heart muscle. The presence of cardiac troponin, a form found only in cardiac muscle cells, provides direct evidence that cardiac muscle cells have been severely damaged.

29. If a muscle is not stimulated by a motor neuron on a regular basis, the muscle will lose tone and mass and become weak (atrophy). During the time that his leg was immobilized, it did not receive sufficient stimulation to maintain proper tone. It will take a while for the muscle to build back up to support Bill’s weight.

Chapter 11

Page 330

1. A pennate muscle contains more muscle fibers than does a parallel muscle of the same size. A muscle that has more muscle fibers has more myofibrils and sarcomeres. As a result, the contraction of a pennate muscle generates more tension than would the contraction of a parallel muscle of the same size.

2. The opening between the stomach and the small intestine would be guarded by a circular muscle, or sphincter. The concentric circles of muscle fibers found in sphincters are ideally suited for opening and closing passageways and for acting as valves in the body.

3. The joint between the occipital bone and the first cervical vertebra is part of a first-class lever system. The joint between the two bones, the fulcrum, lies between the skull, which provides the resistance, and the neck muscles, which provide the applied force.

Page 333

1. The origin of a muscle is the end that remains stationary during an action. Because the gracilis muscle moves the tibia, the origin of this muscle must be on the pelvis (pubis and ischium).

2. Muscles A and B are antagonists, because they perform opposite actions.

3. The name *flexor carpi radialis longus* tells you that this muscle is a long muscle that lies next to the radius and flexes the wrist. *Page* 343

1. Contraction of the masseter muscle elevates the mandible; relaxation of this muscle depresses the mandible. You would probably be chewing something.

2. You would expect the buccinator muscle, which positions the mouth for blowing, to be well developed in a trumpet player.

3. Swallowing involves contractions of the palatal muscles, which elevate the soft palate as well as portions of the superior pharyngeal wall. Elevation of the superior portion of the pharynx enlarges the opening to the auditory tube, permitting airflow to the middle ear and

the inside of the eardrum. Making this opening larger by swallowing facilitates airflow into or out of the middle ear cavity.

Page 348

1. Damage to the external intercostal muscles would interfere with breathing.
2. A blow to the rectus abdominis muscle would cause that muscle to contract forcefully, resulting in flexion of the vertebral column. In other words, you would “double over.”
3. The sore muscles are most likely the erector spinae muscles, especially the longissimus and the iliocostalis muscles of the lumbar region. These muscles would have to contract harder to counterbalance the increased anterior weight you would bear when carrying heavy boxes.

Page 363

1. When you shrug your shoulders, you are contracting your levator scapulae muscles.
2. The rotator cuff muscles include the supraspinatus, infraspinatus, subscapularis, and teres minor muscles. The tendons of these muscles help enclose and stabilize the shoulder joint.
3. Injury to the flexor carpi ulnaris muscle would impair the ability to perform flexion and adduction at the wrist.

Page 370

1. Injury to the obturator muscle would impair your ability to perform lateral rotation at the hip.
2. “Hamstring” refers to a group of muscles that collectively flex the knee. These muscles are the biceps femoris, semimembranosus, and semitendinosus muscles.
3. The calcaneal tendon attaches the soleus and gastrocnemius muscles to the calcaneus (heel bone). When these muscles contract, they produce extension (plantar flexion) at the ankle. A torn calcaneal tendon would make ankle extension difficult.

Page 375 *Level 1 Reviewing Facts and Terms*

13. An aponeurosis is a collagenous sheet connecting two muscles. The epicranial aponeurosis and the linea alba are examples.

14. (1) muscles of the head and neck, (2) muscles of the vertebral column, (3) oblique and rectus muscles, and (4) muscles of the pelvic floor

15. (1) supporting the organs of the pelvic cavity; (2) flexion at joints of the sacrum and coccyx; and (3) controlling movement of materials through the urethra and anus

16. (1) supraspinatus; (2) infraspinatus; (3) subscapularis; and (4) teres minor muscles

17. (1) muscles thet move the thigh, (2) muscles that move the leg, and (3) muscles that move the foot and toes

Level 2 Reviewing Concepts

18. b 19. a 20. hernia 21. tendon sheaths

22. The vertebral column does not need a massive series of flexors, because many of the large trunk muscles flex the vertebral column when they contract. In addition, most of the body weight lies anterior to the vertebral column and gravity tends to flex the intervertebral joints.

23. In a convergent muscle, the direction of pull can be changed by stimulating only one group of muscle cells at any one time. When all the fibers contract at once, they do not pull as hard on the tendon as would a parallel muscle of the same size. The reason is that the muscle fibers on opposite sides of the tendon are pulling in different directions rather than working together.

24. A pennate muscle contains more muscle fibers than does a parallel muscle of the same size. A muscle that has more muscle fibers also has more myofibrils and sarcomeres, resulting in a contraction that generates more tension.

25. Lifting heavy objects becomes easier as the elbow approaches a 90° angle. As you decrease the angle at or near full flexion, tension production declines, so movement becomes more difficult.

26. flexion at the knee and extension at the hip

Level 3 Critical Thinking and Clinical Applications

27. Contraction of the frontalis muscle would wrinkle Mary's brow; contraction of the procerus muscle would flare her nostrils. Contraction of the levator labii muscle on the right side would raise the right side of her lip, as in sneering. Mary is not happy to see Jill.

28. b

29. Although the pectoralis muscle is located across the chest, it inserts on the greater tubercle of the humerus, the bone of the arm. When the muscle contracts, it contributes to flexion, adduction, and medial rotation of the humerus. All of these arm movements would be impaired if the muscle were damaged.

Chapter 12

Page 389

1. The afferent division of the PNS is composed of nerves that carry sensory information to the brain and spinal cord. Damage to this division would interfere with a person's ability to experience a variety of sensory stimuli.

2. Most sensory neurons of the PNS are unipolar. Thus these neurons are most likely sensory neurons.

3. Microglial cells are small phagocytic cells that occur in increased number in damaged and diseased areas of the CNS.

Page 404

1. The depolarization of the neuron cell membrane involves the opening of gated sodium channels and the rapid influx of sodium ions into the cell. If the sodium channels were blocked, a neuron would not be able to depolarize.

2. If the extracellular concentration of potassium ions were to decrease, more potassium ions would leave the cell; hence the electrical gradient across the membrane (transmembrane potential) would increase. This condition is called hyperpolarization.

3. Action potentials are propagated along myelinated axons by saltatory propagation at speeds much higher than those along unmyelinated axons. The axon with a propagation speed of 50 meters per second must be the myelinated axon.

Page 412

1. When an action potential reaches the presynaptic terminal of a cholinergic synapse, voltage-regulated calcium ion channels open and the

influx of Ca^{2+} triggers the release of ACh into the synapse to stimulate the next neuron. If these calcium channels were blocked, the ACh would not be released and transmission across the synapse would cease.

2. Because of synaptic delay, the pathway with fewer neurons (three) will transmit impulses more rapidly.

Page 416

No 2. Yes 3. Spatial summation

12. (1) satellite cells and (2) Schwann cells

13. (1) sensory neurons: transmit impulses from the PNS to the CNS; (2) motor neurons: transmit impulses from the CNS to peripheral effectors; and (3) interneurons: analyze sensory inputs and coordination of motor outputs

Level 2 Reviewing Concepts

14. b 15. d 16. b 17. a

18. Neurons lack centrioles and therefore cannot divide and replace themselves.

19. Axoplasmic transport is the movement of products that are synthesized in the cell body out to the synaptic knobs. Retrograde flow is the movement of materials toward the cell body.

20. Voltage-regulated channels open or close in response to changes in the transmembrane potential. Chemically regulated channels open or close when they bind specific extracellular chemicals. Mechanically regulated channels open or close in response to physical distortion of the membrane surface.

21. The all-or-none principle of action potentials states that if a depolarization event is sufficient to reach threshold, it will cause an action potential in the cell. This action potential will be of the same strength regardless of the degree of stimulation above threshold.

22. The membrane depolarizes to threshold. Next, voltage-regulated sodium channels are activated, and the membrane rapidly depolarizes. These sodium channels are then inactivated, and potassium channels are activated. Finally, normal permeability returns. The voltage-regu-lated sodium channels become activated once the repolarization is complete; the voltage-regulated potassium channels begin closing as the transmembrane potential reaches the normal resting potential.

23. In saltatory conduction, which occurs in myelinated axons, only the nodes along the axon can respond to a depolarizing stimulus. In continuous conduction, which occurs in unmyelinated axons, an action potential appears to move across the membrane surface in a series of tiny steps.

24. Type A fibers are myelinated and carry action potentials very quickly (140 m > sec). Type B are also myelinated, but carry action potentials more slowly due to their smaller diameter. Type C fibers are extremely slow due to small diameter and lack of myelination.

25. (1) The action potential arrives at the synaptic knob, depolarizing it; (2) extracellular calcium enters the synaptic knob triggering the exocytosis of ACh: (3) ACh binds to the postsynaptic membrane and depolarizes the next neuron in the chain; (4) ACh is removed by AChE.

26. Temporal summation is the addition of stimuli that arrive in rapid succession. It occurs at a single synapse and is active repeatedly. Spatial summation occurs when simultaneous stimuli have a cumulative effect on the transmembrane potential. It involves multiple synapses that are active simultaneously.

Level 3 Critical Thinking and Clinical Applications

27. The kidney condition is causing Harry to retain potassium ions. As a result, the K^+ concentration of the extracellular fluid is higher than normal. Under these conditions, less potassium diffuses from heart muscle cells than normal, resulting in a resting potential that is less negative (more positive). This change in resting potential moves the transmembrane potential closer to threshold, so it is easier to stimulate the muscle. The ease of stimulation accounts for the increased number of contractions that produces the rapid heart rate.

28. To reach threshold, the postsynaptic membrane must receive enough neurotransmitter to produce an EPSP of + 20 mV (+ 10 mV to reach threshold and + 10 mV to cancel the IPSPs produced by the inhibitory neurons). Each neuron releases enough neurotransmitter to produce a change of + 2 mV, so 10 of the 15 excitatory neurons must be stimulated to produce this effect by spatial summation.

29. Action potentials travel faster along fibers that are myelinated than fibers that are nonmyelinated. Destruction of the myelin sheath slows the time it takes for motor neurons to communicate with their effector muscles. This delay in response results in varying degrees of uncoordinated muscle activity. The situation is very similar to a newborn where the infant cannot control its arms and legs very well because the myelin sheaths are still being laid down for the first year. Since not all motor neurons to the same muscle may be demyelinated to the same degree, there would be some fibers that are slow to respond while

others are responding normally producing contractions that are erratic and poorly controlled.

30. The absolute refractory period sets a limit to the number of action potentials that can travel along an axon in a particular unit of time. During the absolute refractory period, the membrane is not able to conduct an action potential. Thus a new depolarization event could not occur until after the absolute refractory period had passed. If the absolute refractory period for a particular axon was 0.001 second, the maximum frequency of action potentials conducted by this axon would be 1000 > sec.

Chapter 13

Page 427

1. The ventral root of a spinal nerve is composed of both visceral and somatic motor fibers. Damage to this root would interfere with motor function.
2. The cerebrospinal fluid that surrounds the spinal cord is located in the subarachnoid space, which lies beneath the epithelium of the arachnoid mater and superficial to the pia mater.

Page 429

1. Because the virus that causes polio would be located in somatic motor neurons, it would be in the anterior gray horns of the spinal cord, where the cell bodies of these neurons are located.
2. A disease that damages myelin sheaths would affect the columns of the spinal cord, because that part of the cord is composed of bundles of myelinated axons.

Page 437

1. The dorsal rami of spinal nerves innervate the skin and muscles of the back. The skin and muscles of the back of the neck and of the shoulders will be affected by such an anesthetic.

2. The phrenic nerves that innervate the diaphragm originate in the cervical plexus. Damage to this plexus, or more specifically to the phrenic nerves, would greatly interfere with the ability to breathe and might result in death.

3. Compression of the sciatic nerve produces the characteristic sensation that you perceive when your leg has "fallen asleep."

Page 443

1. The minimum number of neurons required for a reflex arc is two. One must be a sensory neuron, to bring impulses to the CNS, and the other a motor neuron, to bring about a response to the sensory input.

2. The suckling reflex is an innate reflex.

3. When stretch receptors are stimulated by gamma motor neurons, the muscle spindles become more sensitive. As a result, little if any stretching stimulus would be needed to stimulate the contraction of the quadriceps muscles in the patellar reflex. Thus the reflex response would appear more quickly.

Page 446

1. This response is the tendon reflex.

2. During a withdrawal reflex, the limb on the opposite side is extended. This response is called a crossed extensor reflex.

3. A positive Babinski reflex is abnormal for an adult; it indicates possible damage of descending tracts in the spinal cord.

Level 2 Reviewing Concepts

15. The vertebral column continues to grow, extending beyond the cord. The end of the cord is visible as the conus medularis near L1 and the cauda equina extends the remainder of the column.

16. (1) arrival of stimulus and activation of receptor; (2) activation of sensory neuron; (3) information processing; (4) activation of a motor neuron; and (5) response by an effector (muscle or gland)

17. d

18. The first cervical nerve exits superior to vertebra C1 (between the skull and vertebra); the last cervical nerve exits inferior to vertebra C7 (between the last cervical vertebra and the first thoracic vertebra). There are thus 8 cervical nerves but only 7 cervical vertebrae.

19. The cell bodies of spinal motor neurons are located in the anterior gray horns, so damage to these horns would result in a loss of motor control.

20. Inside the CNS, cerebrospinal fluid fills the central canal and the ventricles. Inside the CNS meninges, cerebrospinal fluid fills the subarachnoid space. The CSF acts as a shock absorber as well as a diffusion medium for dissolved gases, nutrients, chemical messengers, and waste products.

21. (1) involvement of pools of interneurons; (2) intersegmental distribution; (3) involvement of reciprocal innervation; (4) motor response prolonged by reverberating circuits; and (5) cooperation of reflexes to produce a coordinated, controlled response

22. Transection of the spinal cord at C7 would most likely result in paralysis from the neck down. A transection at T10 would paralyze the lower half of the body only. Sensory input and motor control of the body from the waist down would be lost.

23. a 24. b 25. a

26. Stimulation will increase muscle tone.

Level 3 Critical Thinking and Clinical Applications

27. the median nerve

28. the radial nerve

29. The person would still exhibit a defecation (bowel) and micturition (bladder) reflex because the spinal reflex is processed at the level of the spinal cord. Efferent impulses from the organs would stimulate specific interneurons in the sacral region that would synapse with the motor neurons controlling the sphincters, thus brining about emptying when organs began to fill. This is the same situation that exists in a newborn infant who has not yet fully developed the descending traits necessary for conscious control. The individual with the spinal cord transection would lose voluntary control of the bowel and bladder because these functions rely on impulses carried by motor neurons in the brain that must travel down the cord and synapse with the interneurons and motor neurons that are involved in the reflex.

30. The anterior horn cells of the spinal cord are somatic motor neurons that direct the activity of skeletal muscles. The lumbar region of the spinal cord controls the skeletal muscles that are involved with the control of the muscles of the hip, leg, and foot. As a result of the injury, Karen would have poor control of most muscles of the lower limb, a problem with walking if she could walk at all, and if she could stand, problems maintaining balance.

Chapter 14

Page 455

1. The mesencephalon, the pons, and the medulla oblongata make up the brain stem.

2. The three primary brain vesicles are the prosencephalon, the mesencephalon, and the rhombencephalon. The prosencephalon gives rise to the cerebrum and diencephalon; the mesencephalon does not subdivide further; and the rhombencephalon develops into the cerebellum, the pons, and the medulla oblongata.

Page 459

1. If an interventricular foramen became blocked, cerebrospinal fluid could not flow from the lateral ventricles into the third ventricle. Cerebrospinal fluid would continue to form within that ventricle, so the blocked ventricle would swell with fluid—a condition known as hydrocephalus.

2. Diffusion across the arachnoid granulations is the means by which cerebrospinal fluid reenters the bloodstream. If this process decreased, excess fluid would accumulate in the ventricles; the volume of fluid in the ventricles would increase, damaging the brain.

3. The blood–brain barrier restricts and regulates the movement of water-soluble molecules from the blood to the extracellular fluid of the brain.

Page 464

1. The vermis and arbor vitae are part of the cerebellum.

2. Although the medulla oblongata is small, it contains many vital reflex centers, including those that control breathing and regulate the heart rate and blood pressure. Damage to the medulla oblongata can result in a cessation of breathing or in lethal changes in heart rate and blood pressure.

3. Damage to the respiratory centers of the pons could result in loss of ability to modify the rhythmicity center of the medulla oblongata during prolonged inhalation or extensive exhalation.

Page 470

1. Reflexive movements of the eyes, head, and neck are controlled by the superior colliculi of the mesencephalon.

2. The lateral geniculate nuclei are involved with processing visual information. Damage to these nuclei would interfere with the sense of sight.

3. Changes in body temperature would stimulate the preoptic area of the hypothalamus, a division of the diencephalon.

4. The amygdaloid regulates the “fight or flight” response of the sympathetic division of the autonomic nervous system.

Page 474

1. Projection fibers link the cerebral cortex to the spinal cord, passing through the diencephalon, brain stem, and cerebellum.

2. The basal nuclei are involved in the subconscious control of skeletal muscle tone and the coordination of learned movement patterns. Damage to the basal nuclei would result in loss of these functions and decreased muscle tone (see Parkinson’s disease, p. 474).

Page 479

1. The primary motor cortex is located in the precentral gyrus of the frontal lobe of the cerebrum.

2. Damage to the temporal lobes of the cerebrum would interfere with the processing of olfactory (smell) and auditory (sound) impulses.

3. The stroke has damaged Jake’s speech center, located in the frontal lobe.

4. The temporal lobe of Paul’s cerebrum is probably involved, specifically the hippocampus and the amygdaloid body. His problems may also involve other parts of the limbic system that act as a gate for loading and retrieving long-term memories.

Page 493 *Level 1 Reviewing Facts and Terms*

13. (1) portions of the hypothalamus where the capillary endothelium is extremely permeable; (2) capillaries in the pineal gland; and

(3) capillaries at the choroid plexus

14. I: olfactory nerve; II: optic nerve; III: oculomotor nerve; IV: trochlear nerve; V: trigeminal nerve; VI: abducens nerve; VII: facial nerve;
VIII: vestibulocochlear nerve; IX: glossopharyngeal nerve; X: vagus nerve; XI: accessory nerve; and XII: hypoglossal nerve

Level 2 Reviewing Concepts

15. The brain includes many more interneurons, pathways, and connections than the tracts of the spinal cord, allowing for greater integration of impulses and versatility of response.

16. The functions of the cerebellum include adjusting voluntary and involuntary motor activities on the basis of sensory information and stored memories of previous experiences.

17. d

18. the substantia nigra, which releases the neurotransmitter dopamine at the basal nuclei

19. (1) subconscious control of skeletal muscle contractions, (2) control of autonomic functions, (3) coordination of nervous and endocrine systems, (4) secretion of hormones, (5) production of emotions and drives, (6) coordination of autonomic and voluntary functions, (7) regulation of body temperature, (8) control of circadian rhythms

20. Stimulation of the feeding and thirst centers of the hypothalamus would produce these sensations.

21. hippocampus, which is part of the limbic system

22. The left hemisphere contains the general interpretive and speech centers and is responsible for language-based skills. Reading, writing, speaking, performing analytical tasks, and logical decision making are dependent on processing done in the left hemisphere. The right hemisphere analyzes sensory information and relates the body to the sensory environment. Interpretive centers in this hemisphere permit the identification of familiar objects by touch, smell, sight, taste, or feel. It is important in understanding three-dimensional relationships and in analyzing the emotional context of a conversation.

23. d 24. c

25. The general intrepretive area (Wernicke's area, sensory) and the speech center (Broca's area, motor) are involved in speech. Aphasia results in the absence of or defects in speech and the inability to comprehend language. Lesions in the general interpretive area produce defective visual and auditory comprehension of language, repetition of spoken sentences, and defective naming of objects. Lesions in the speech center result in hesitant and distorted speech.

Level 3 Critical Thinking and Clinical Applications

26. The sensory innervation of the nasal mucosa is by way of the maxillary branch of the trigeminal nerve (V). Irritation of the nasal lining increases the frequency of action potentials along the maxillary branch of the trigeminal nerve through the semilunar ganglion to reach centers in the mesencephalon, which in turn excite the neurons of the reticular activating system (RAS). Increased activity by the RAS can raise the cerebrum back to consciousness.

27. The officer is testing the function of Bill's cerebellum. Many drugs, including alcohol, have pronounced effects on the function of the cerebellum. A person who is under the influence of alcohol cannot properly anticipate the range and speed of limb movement, because processing and correction by the cerebellum are slow. As a result, Bill might have a difficult time walking a straight line or touching his finger to his nose.

28. Increasing pressure in the cranium could compress important blood vessels leading to further brain damage in areas not directly affected by the hematoma. Pressure on the brain stem could disrupt vital respiratory, cardiovascular, and vasomotor function and possibly cause death. Pressure on the motor nuclei of the cranial nerves would lead to drooping eyelids and dilated pupils. Pressure on descending motor tracts would impair muscle function and decrease muscle tone in the affected areas of the body.

29. As in any inflamed tissue, there is edema in the area of inflammation. The accumulation of fluid in the subarachnoid space can cause damage by pressing against the neurons. If the

intracranial pressure is excessive, brain damage can occur, and if the pressure involves vital autonomic reflex areas, death could occur.

30. Most of the functional problems are the result of trauma to the cerebral hemispheres due to contact between the brain and the skull. Distortion and damage to the brain stem and medulla oblongata can cause death.

Chapter 15

Page 502

1. The receptor with the smaller receptor field will provide more-precise sensory information—thus, receptor A.

2. Nociceptors are pain receptors. When they are stimulated, you perceive a painful sensation in the affected hand.

3. Proprioceptors relay information about limb position and movement to the CNS, especially to the cerebellum. If this information were blocked, your movements would be uncoordinated and you would probably not be able to walk.

Page 507

1. The fasciculus gracilis in the posterior column of the spinal cord carries information about touch and pressure from the lower limbs to the brain. It is this tract that is being compressed.

2. Nociceptors are stimulated by pain. The action potentials generated by these receptors are carried by the lateral spinothalamic tracts.

3. Impulses carried along the right fasciculus gracilis are destined for the primary sensory cortex of the left cerebral hemisphere.

Page 513

1. The anatomical basis for opposite-side motor control is crossing-over (decussation) of axons, so the motor fibers of the corticospinal pathway innervate lower motor neurons on the opposite side of the body.
2. The superior portion of the motor cortex controls the upper limb and upper portion of the lower limb. An injury to this area would affect the ability to control the muscles in those regions of the body.
3. Motor neurons of the red nucleus help control the muscle tone of skeletal muscles in the upper limbs. Increased stimulation of these neurons would increase stimulation of the skeletal muscles, producing increased muscle tone.

Page 515 *Level 1 Reviewing Facts and Terms*

5. (1) free nerve endings: sensitive to touch and pressure; (2) root hair plexus: monitors distortions and movements across the body surface;

(3) tactile discs: detect fine touch and pressure; (4) tactile corpuscles: detect fine touch and pressure; (5) lamellated corpuscles: sensitive to pulsing or vibrating stimuli (deep pressure); and (6) Ruffini corpuscles: sensitive to pressure and distortion of the skin
6. (1) tactile receptors; (2) baroreceptors; and (3) proprioceptors
7. (1) posterior column pathway: provides conscious sensations of highly localized ("fine") touch, pressure, vibration, and proprioception;

(2) spinothalamic pathway: provides conscious sensations of poorly localized ("crude") touch, pressure, pain, and temperature; and (3) spinocerebellar pathway: carries proprioceptive information about the position of skeletal muscles, tendons, and joints to the cerebellum
8. (1) corticobulbar tracts; (2) lateral corticospinal tracts; and (3) anterior corticospinal tracts

9. (1) vestibulospinal pathway; (2) tectospinal pathway; and (3) reticulospinal pathway

10. (1) It integrates proprioceptive sensations with visual information from the eyes and equilibrium-related sensations from the inner ear; and (2) it adjusts the activities of the voluntary and involuntary motor centers on the basis of sensory information and the stored memories of previous experiences.

11. c

12. (1) An arriving stimulus alters the transmembrane potential of the receptor membrane. (2) The receptor potential directly or indirectly affects a sensory neuron. (3) Action potentials travel to the CNS along an afferent fiber.

13. (1) The number of neurons in the cerebral cortex continues to increase until at least age 1; (2) the brain as a whole grows in size and complexity until at least age 4; and (3) myelination of CNS neurons continues at least until puberty, reducing the delay between stimulus and response and improving motor control.

Level 2 Reviewing Concepts

14. A tonic receptor is always active, while a phasic receptor is normally inactive. Phasic receptors are active only when a change occurs in the condition being monitored.

15. A motor homunculus, a mapped-out area of the primary motor cortex, provides an indication of the degree of fine motor control available. A sensory homunculus indicates the degree of sensitivity of peripheral sensory receptors.

16. The sensory neuron that delivers the sensations to the CNS is a first-order neuron. Within the CNS, the axon of the first-order neuron synapses on a second-order neuron, an interneuron located in the spinal cord or brain stem. The second-order neuron synapses on a third-order neuron in the thalamus. The axons of third-order neurons synapse on neurons of the primary sensory cortex of the cerebral hemispheres.

17. b

18. Injury to the primary motor cortex affects the ability to exert fine control over motor units. Gross movements are still possible, however, because they are controlled by the basal nuclei that use the reticulospinal or rubrospinal tracts. Thus, walking and other voluntary and involuntary movements can be performed with difficulty, and the movements are imprecise and awkward.

19. Muscle tone is controlled by the basal nuclei, cerebellum, and red nuclei through commands distributed by the reticulospinal and rubrospinal tracts.

20. Strong pain sensations arriving at a particular segment of the spinal cord can cause stimulation of the interneurons of the spinothalamic pathway. This stimulation is interpreted by the sensory cortex as originating in the region of the body surface associated with the origin of that same pathway.

Level 3 Critical Thinking and Clinical Applications

21. The tumor is most likely adjacent to the corticobulbar tracts. The axons of those tracts carry action potentials to motor nuclei of the cranial nerves, which control eye muscles and facial expression.

22. Injuries to the motor cortex eliminate the ability to produce fine control of motor units. However, as long as the cerebral nuclei are functional, gross movements would still be possible. Clarence should still be able to walk, maintain his balance, and perform voluntary and involuntary movements using the rubrospinal and reticulospinal tracts in place of the corticospinal tracts. Although these movements may be awkward or difficult, they will still be able to take place.

23. Phil is experiencing phantom pain. Since pain perception occurs in the sensory cortex of the brain, he can still feel pain in his fingers if the brain projects feeling to that area. When he bumps the arm at the elbow, sensory receptors are stimulated that send impulses to the sensory cortex. The brain perceives a sensation from a general area, and projects that feeling to a body part. Since more sensory information reaches the brain from the hands and fingers, it is not unusual for the brain to project to this area.

Chapter 16

Page 520

1. Two neurons are required to conduct an action potential from the spinal cord to smooth muscles in the wall of the intestine. One neuron is required to carry the action potential from the spinal cord to the autonomic ganglion, and a second to carry the action potential from the autonomic ganglion to the smooth muscle.
2. The sympathetic division of the autonomic nervous system is responsible for the physiological changes that occur in response to stress and increased activity.
3. The sympathetic division of the autonomic nervous system includes preganglionic fibers from the lumbar and thoracic portions of the spinal cord, whereas the parasympathetic division includes preganglionic fibers from the cranial and sacral portions.

Page 526

1. The nerves that synapse in collateral ganglia originate in the inferior thoracic and superior lumbar portion of the spinal cord; they pass through the chain ganglia to the collateral ganglia.
2. Acetylcholine is the neurotransmitter released by the preganglionic fibers of the sympathetic nervous system. A drug that stimulates ACh receptors would stimulate the postganglionic fibers of the sympathetic nerves, resulting in increased sympathetic activity.
3. Blocking the beta receptors on cells would decrease or prevent sympathetic stimulation of the tissues that contain those cells. The heart rate, the force of contraction of cardiac muscle, and the contraction of smooth muscle in the walls of blood vessels would decrease. These changes would contribute to a lowering of the blood pressure.

Page 530

1. The vagus nerve (X) carries preganglionic parasympathetic fibers that innervate the lungs, heart, stomach, liver, pancreas, and parts of the small and large intestines (as well as several other visceral organs).

2. Muscarinic receptors are a type of acetylcholine receptor located in postganglionic synapses of the parasympathetic nervous system. The stimulation of these receptors at the heart would cause potassium ion channels to open, resulting in hyperpolarization of the cell membrane and a decreased heart rate.

3. The parasympathetic division is sometimes referred to as the anabolic system because parasympathetic stimulation leads to a general increase in the nutrient content of the blood. Cells throughout the body respond to the increase by absorbing the nutrients and using them to support growth and other anabolic activities.

Page 536

1. Most blood vessels receive sympathetic stimulation, so a decrease in sympathetic tone would lead to a relaxation of the smooth muscles in the walls of these vessels and hence to vasodilation. Blood flow to the tissue would, in turn, increase.

2. A patient who is anxious about an impending root canal would probably exhibit some or all of the following changes: a dry mouth, an increased heart rate, an increase in blood pressure, an increased rate of breathing, cold sweats, an urge to urinate or defecate, a change in the motility of the digestive tract (that is, “butterflies in the stomach”), and dilated pupils. These changes would be the result of anxiety or stress causing an increase in sympathetic stimulation.

3. A brain tumor that interferes with hypothalamic function would interfere with autonomic function as well. Centers in the posterior and lateral hypothalamus coordinate and regulate sympathetic function, whereas centers in the anterior and medial hypothalamus control parasympathetic function.

Page 539

1. Higher order functions require the cerebral cortex, involve both conscious and unconscious information processing, and are subject to modification and adjustment over time.

2. An inability to comprehend the spoken or written word indicates a problem with the general interpretive area of the brain, which in most individuals is located in the left temporal lobe of the cerebrum.

3. You are using short term memory, although your teacher would like it if this information were transferred to long term memory. *Page* 542

1. The reticular activating system is responsible for rousing the cerebrum to a state of consciousness. If your RAS were suddenly stimulated, you would wake up.

2. A drug that increases the amount of serotonin released in the brain would produce a heightened perception of certain sensory stimuli, such as auditory or visual stimuli, and hallucinations.

3. Some possible reasons for slower recall and for loss of memory in the elderly include a loss of neurons (possibly those involved in specific memories), changes in synaptic organization of the brain, changes in the neurons themselves, and decreased blood flow, which would affect the metabolic rate of neurons and perhaps slow the retrieval of information from memory.

Page 547 *Level 1 Reviewing Facts and Terms*

d 2. a 3. b 4. d

5. preganglionic neuron T5 -L2 : collateral ganglia : postganglionic fibers : visceral effector in abdominopelvic cavity

6. (1) ciliary ganglion; (2) pterygopalatine ganglion; (3) submandibular ganglion; and (4) otic ganglion

7. receptor, sensory neuron, interneuron (may or may not be present), and two visceral motor neurons

8. increased neurotransmitter release, facilitation of synapses, and the formation of additional synaptic connections

9. During non-REM sleep, the entire body relaxes and activity at the cerebral cortex is at a minimum. The heart rate, blood pressure, respiratory rate, and energy utilization decline.

During REM sleep, active dreaming occurs, accompanied by alterations in blood pressure and respiratory rates. Muscle tone decreases markedly, and there is less response to outside stimuli.

10. a reduction in brain volume and weight, a reduction in the number of neurons, a decrease in blood flow to the brain, changes in the synaptic organization, and intracellular and extracellular changes in CNS neurons

11. c 12. d

13. Sympathetic preganglionic fibers emerge from the thoracolumbar area (T1 through L2) of the spinal cord. Parasympathetic fibers emerge from the brain stem and the sacral region of the spinal cord (craniosacral).

14. (1) celiac ganglion; (2) superior mesenteric ganglion; and (3) inferior mesenteric ganglion

15. (1) the release of norepinephrine at specific locations and (2) the secretion of epinephrine (and modest amounts of norepinephrine) into the bloodstream

16. III, VII, IX, and X

17. (1) cardiac plexus: heart rate–increase (sympathetic)/ decrease (parasympathetic); heart strength–increase (sympathetic)/decrease (parasympathetic); blood pressure– increase (sympathetic)/decrease (parasympathetic);

(2) pulmonary plexus: respiratory passageways dilate/constrict; (3) esophageal plexus: respiratory rate increase/decrease; (4) celiac plexus: digestion inhibited/stimulated; (5) inferior mesenteric plexus: digestion inhibited/stimulated; and (6) hypogastric plexus: defecation inhibited/stimulated; urination inhibited/stimulated; sexual organs: stimulate secretion/ erection

18. (1) They are performed by neurons of the cerebral cortex and involve complex interactions between areas of the cortex and between the cerebral cortex and other parts of the brain; (2) they involve both conscious and unconscious information processing; and (3) their functions are subject to modification and adjustment over time.

Level 2 Reviewing Concepts

19. a 20. c

21. The preganglionic fibers innervating the cervical ganglia originate in the white rami of thoracic segments, which are undamaged.

22. c 23. b 24. d

25. Due to the stimulation of the sympathetic division, you would experience increased respiratory rate, increased peripheral vasoconstriction and elevation of blood pressure, increased heart rate and force of contraction, and an increased rate of glucose release into the bloodstream.

26. If autonomic motor neurons maintain a background level of activity at all times, they can either increase or decrease their activity, providing a range of control options.

27. Since cholinergic receptors are found in all of the ganglia of the autonomic nervous system, you would expect nicotine to stimulate both sympathetic and parasympathetic responses in the cardiovascular target tissues. In response to increased sympathetic stimulation the heart would beat faster and more forcefully. At the same time, however, increased parasympathetic stimulation would decrease the blood flow to the heart muscle. The increased heart rate and force of contraction would contribute to increased blood pressure as would vasoconstriction of peripheral blood vessels as a result of sympathetic stimulation.

28. The upsetting stimuli would be processed by the higher centers of the central nervous system and relayed to the hypothalamus. The hypothalamus could suppress the vasomotor center of the medulla, resulting in fewer sympathetic impulses to peripheral blood vessels. This would cause a decrease in sympathetic tone in the smooth muscle of the blood vessels resulting in vasodilation. The vasodilation would cause blood to pool in the limbs decreasing the amount of blood returning to the heart and producing shock.

Level 3 Critical Thinking and Clinical Applications

29. epinephrine, because it would reduce inflammation and relax the smooth muscle of the airways, making it easier for Phil to breathe

30. It is probably mimicking NE and binding to alpha-1 receptors.

Chapter 17

Page 554

1. By the end of the lab period, adaptation has occurred. In response to the constant level of stimulation, your receptor neurons have become less active, partially as the result of synaptic fatigue.

2. Your taste receptors (taste buds) are sensitive only to molecules and ions that are in solution. If you dry the surface of your tongue, the salt ions or sugar molecules have no moisture in which to dissolve, so they will not stimulate the taste receptors.

3. The difference in the taste of your grandfather’s food is the result of several age-related factors. The number of taste buds declines dramatically after age 50, and those that remain are not as sensitive as they once were. In addition, the loss of olfactory receptors contributes to the perception of less flavor in foods.

Page 556

1. The first layer of the eye that would be affected by inadequate tear production would be the conjunctiva. Drying of this layer would produce an irritated, scratchy feeling.

2. When the lens is round, you are looking at an object that is close to you.

3. Renee will probably not be able to see at all. The fovea of the eye contains cones but no rods. Rods respond to light of low intensity, but cones need high light intensity to be stimulated. In a dimly lit room, the light would not be strong enough to stimulate these photoreceptors.

If the canal of Schlemm were blocked, the aqueous humor would not be able to drain; glaucoma would develop. As the quantity of fluid increased, the pressure within the eye would increase, distorting soft tissues and interfering with vision. If untreated, the condition would ultimately cause blindness.

Page 573

1. Even with a congenital lack of cones in your eyes, you would still be able to see—as long as you had functioning rods. But because cone cells function in color vision, you would see only black and white.

2. A deficiency of vitamin A in the diet would affect the quantity of retinal the body could produce and thus would interfere with night vision, which is more sensitive to deficiencies since it is working at the threshold of the body's ability to respond to light.

3. A decrease in phosphodiesterase activity would lead to a higher level of intracellular cGMP. This rise would, in turn, keep the gated sodium channels open and decrease the ability of receptor neurons to respond to photons.

Page 586

1. Without the movement of the round window, the perilymph would not be moved by the vibration of the stapes at the oval window. There would be little or no perception of sound.

2. The loss of stereocilia (as a result of constant exposure to loud noises, for instance) would reduce hearing sensitivity and could lead to deafness.

3. The auditory tube allows pressure to equalize on both sides of the tympanic membrane. If this tube were blocked and external pressures then declined, the pressure on the inside of the tympanic membrane would be greater than that on the outside, forcing the membrane outward and producing pain.

Page 588 *Level 1 Reviewing Facts and Terms*

1. d 2. c 3. e 4. c 5. c 6. b 7. d 8. b 9. d
10. d 11. c

12. (1) filiform papillae; (2) fungiform papillae; and (3) circumvallate papillae

13. **(a)** the sclera and the cornea **(b)** It (1) provides mechanical support and some physical protection, (2) serves as an attachment site for the extrinsic eye muscles, and (3) contains structures that assist in the focusing process.

14. iris, ciliary body, and choroid

15. (1) malleus, (2) incus, and (3) stapes, which transmit a mechanical vibration (amplified along the way) from the tympanic membrane to the oval window

Level 2 Reviewing Concepts

16. Axons leaving the olfactory epithelium collect into twenty or more bundles that penetrate the cribriform plate of the ethmoid bone to reach the olfactory bulbs of the cerebrum. Axons leaving the olfactory bulb travel along the olfactory tract to reach the olfactory cortex, the hypothalamus, and portions of the limbic system.

17. Olfactory sensations are long lasting and important to memories because the sensory information they provide goes directly to the cerebral cortex via the hypothalamus and the limbic system. These sensations are not first filtered through the thalamus

18. a sty, a painful swelling

19. a 20. c 21. a

Level 3 Critical Thinking and Clinical Applications

22. Your medial rectus muscles would contract, directing your gaze more medially. In addition, your pupils would constrict and the lenses would become more spherical.

23. b

24. In removing the polyps, some of the olfactory epithelium was probably damaged or destroyed. This would decrease the area available for the solution of odor molecules and thus the intensity of the stimulus. As a result, it would take a larger stimulus to provide the same level of smell after the surgery than before the surgery.

25. The rapid descent in the elevator causes the maculae in the saccule of your vestibule to slide upward, producing the sensation of downward vertical motion. When the elevator abruptly stops, the maculae do not. It takes a few seconds for them to come to rest in the normal position. As long as the maculae are displaced, you will perceive movement.

26. When Juan closes his eyes, the visual cues are gone and his brain must rely solely on proprioceptive information and information from the static equilibrium centers (saccule and

utricle). As a result of his problem with the saccules or utricles, his brain does not receive sufficient information to maintain balance. The movement of the arms toward the side of the impaired receptors is due to the deficit of information arriving from that side of the body.

Chapter 18

Page 600

1. Neural responses occur within fractions of a second and do not last long (short duration). Conversely, endocrine responses may be slow to appear but will last for minutes to days (long duration).

2. Adenylate cyclase is the enzyme that converts ATP to cAMP. A molecule that blocks this enzyme would block the action of any hormone that required cAMP as a second messenger.

3. A cell’s hormonal sensitivities are determined by the presence or absence of the necessary receptor complex for a given hormone.

Page 606

1. Dehydration increases the osmotic pressure of the blood. The increase in blood osmotic pressure would stimulate the posterior pituitary to release more ADH.

2. Somatomedins mediate the action of growth hormone. When the levels of somatomedins are elevated, the level of growth hormone would be elevated as well.

3. Elevated circulating levels of cortisol would inhibit the cells that control the release of ACTH from the pituitary gland; therefore, the level of ACTH would decrease. This is an example of a negative feedback mechanism.

Page 616

1. An individual whose diet lacks iodine would not be able to form the hormone thyroxine. As a result, we would expect to see the symptoms associated with thyroxine deficiency,

such as a decreased rate of metabolism, a decreased body temperature, a poor response to physiological stress, and an increase in the size of the thyroid gland (goiter).

2. Most of the thyroid hormone in the blood is bound to proteins called thyroid-binding globulins. These compounds represent a large reservoir of the thyroid hormone thyroxine that guards against rapid fluctuations in the level of this important hormone. Because such a large amount is stored in this way, it takes several days to deplete the supply of thyroxine, even after the thyroid gland has been removed.

3. The removal of the parathyroid glands would result in a decrease in the blood concentration of calcium ions. This decrease could be counteracted by increasing the amounts of vitamin D and calcium in the diet.

4. One of the functions of cortisol is to decrease the cellular use of glucose while increasing the available glucose by promoting the breakdown of glycogen and the conversion of amino acids to carbohydrates. The net result of elevated cortisol levels would be an elevation in the level of glucose in the blood.

Page 624

1. An individual with type 1 or type 2 diabetes has such elevated levels of glucose in the blood that the kidneys cannot reabsorb all the glucose; some glucose is lost in urine. Because the urine contains high concentrations of glucose, less water can be reclaimed by osmosis; the volume of urine production increases. The water losses reduce blood volume and elevate blood osmotic pressure, promoting thirst and triggering the secretion of ADH.

2. Glucagon stimulates the conversion of glycogen to glucose in the liver. Increased levels of glucagon would lead to decreased amounts of glycogen in the liver.

3. Increased amounts of light would inhibit the production (and release) of melatonin from the pineal gland, which receives neural input from the optic tracts. The secretion of melatonin by the pineal gland is influenced by light–dark cycles.

Page 629

1. The type of hormonal interaction exemplified by the effects of insulin and glucagon is antagonism. In this type of hormonal interaction, two hormones have opposite effects on their target tissues.

2. The hormones GH, thyroid hormone, PTH, and the gonadal hormones all play a role in formation and development of the skeletal system.

3. During the resistance phase of the general adaptation syndrome, there is a high demand for glucose, especially by the nervous system. The hormones GH-RH and CRH increase the levels of GH and ACTH, respectively. Growth hormone mobilizes fat reserves and promotes the catabolism of protein; ACTH increases cortisol, which stimulates the conversion of glycogen to glucose as well as the catabolism of fat and protein.

Page 634 *Level 1 Reviewing Facts and Terms*

b 2. c 3. d 4. a 5. d 6. d 7. d 8. b

9. (1) The hypothalamus produces regulatory hormones that control secretion by endocrine cells in the anterior lobe of the pituitary gland.

(2) The hypothalamus contains autonomic centers that exert direct neural control over the endocrine cells of the adrenal medulla. (3) The hypothalamus releases ADH and oxytocin into the bloodstream at the posterior lobe of the pituitary gland. These mechanisms are adjusted through negative feedback loops involving the hormones released by peripheral endocrine tissues and organs

10. (1) thyroid-stimulating hormone (TSH); (2) adrenocorticotropic hormone (ACTH); (3) follicle-stimulating hormone (FSH); (4) luteinizing hormone (LH); (5) prolactin (PRL); (6) growth hormone (GH); and (7) melanocyte-stimulating hormone (MSH)

11. (1) growth hormone, (2) thyroid hormones, (3) insulin, (4) parathyroid hormone, (5) calcitriol, and (6) the reproductive hormones

12. (1) an increase in the rate of energy consumption and utilization in cells; (2) an acceleration in the production of sodium–potassium ATPase; (3) the activation of genes coding for the synthesis of enzymes involved in glycolysis and energy production; (4) the

acceleration of ATP production by mitochondria; and (5) in growing children, the normal development of the skeletal, muscular, and nervous systems

13. calcitonin: decreases the concentration of calcium ions in body fluids; parathyroid hormone: causes an increase in the concentration of calcium ions in body fluids

14. (1) zona glomerulosa: mineralocorticoids; (2) zona fasciculata: glucocorticoids; and (3) zona reticularis: androgens

15. erythropoietin, which stimulates the production of RBCs by the bone marrow; and calcitriol, responsible for stimulating calcium and phosphate absorption along the digestive tract

16. (1) Natriuretic peptides promote the loss of sodium ions and water at the kidneys; (2) inhibit the secretion of water-conserving hormones, such as ADH and aldosterone; (3) suppress thirst; and (4) block the effects of angiotensin II and norepinephrine on arterioles. Angiotensin II opposes these actions.

17. (1) alpha cells: glucagon; (2) beta cells: insulin; (3) delta cells: somatostatin; and (4) F cells: pancreatic polypeptide

Level 2 Reviewing Concepts

18. In the nervous system, the source and destination of communication are quite specific and the effects are short lived. In endocrine communication, the effects are slow to appear and commonly persist for days. A single hormone can alter the metabolic activities of multiple tissues and organs simultaneously.

19. Hormones direct the synthesis of an enzyme (or other protein) not already present in the cytoplasm. They turn an existing enzyme “on” or “off ” and increase the rate of synthesis of a particular enzyme or other protein.

20. In endocrine reflexes—the functional counterpart of neural reflexes—a stimulus triggers the production of a hormone. Both neural and endocrine reflexes are controlled by negative feedback mechanisms in most cases.

21. Because phosphodiesterase converts cAMP to AMP, the inactivation of this enzyme would prolong the effect of the hormone.

22. The adrenal medulla is controlled by the sympathetic nervous system, whereas the cortex is stimulated by the release of ACTH from the anterior pituitary gland.

23. b 24. a 25. b

Level 3 Critical Thinking and Clinical Applications

26. Extreme thirst and frequent urination are characteristics of both diabetes insipidus and diabetes mellitus. To distinguish between the two, glucose levels in the blood and urine could be measured. A high glucose concentration would indicate diabetes mellitus.

27. Julie’s poor diet would not supply enough Ca^{2+} for her developing fetus, which would remove large amounts of Ca^{2+} from the maternal blood. A lowering of the mother’s blood Ca^{2+} would lead to an increase in parathyroid hormone levels and increased mobilization of stored Ca^{2+} from maternal skeletal reserves.

28. Sherry’s symptoms suggest hyperthyroidism. Blood tests could be performed to assay the levels of TSH, T3 , and T4 . From these tests, the physician could make a positive diagnosis (hormone levels would be elevated in hyperthyroidism) and also determine whether the condition is primary (a problem with the thyroid gland) or secondary (a problem with hypothalamo-pituitary control of the thyroid gland).

29. One benefit of a portal system is that it ensures that the controlling hormones will be delivered directly to the target cells. Secondly, because the hormones go directly to their target cells without first passing through the general circulation, they are not diluted. The hypothalamus can control the cells of the anterior lobe of the pituitary gland with much smaller amounts of releasing and inhibiting hormones than would be necessary if the hormones had to first go through the circulatory pathway before reaching the pituitary.

30. Anabolic steroids are derivatives of testosterone. The natural effects of this are to increase muscle mass, increase endurance, and enhance the “competitive spirit.” Additional side effects in women include hirsutism, enlargement of the laryngeal cartilages, premature closure of the epiphyseal cartilages, and liver dysfunction.

Chapter 19

Page 643

1. Venipuncture is a common sampling technique because (1) superficial veins are easy to locate; (2) the walls of veins are thinner than those of arteries; and (3) blood pressure in veins is relatively low, so the puncture wound seals quickly.

2. A decrease in the amount of plasma proteins in the blood would cause a decrease in (1) plasma osmotic pressure; (2) the ability to fight infection; and (3) the transport and binding of some ions, hormones, and other molecules.

3. During a viral infection, you would expect the level of immunoglobulins (antibodies) in the blood to be elevated.

Page 649

1. The hematocrit measures the amount of formed elements (mostly red blood cells) as a percentage of the total blood. In hemorrhage, the loss of blood, especially of red blood cells, would lower the hematocrit.

2. A decreased blood flow to the kidneys will trigger the release of erythropoietin. The elevated erythropoietin will lead to an increase in erythropoiesis (red blood cell formation). Thus, Dave’s hematocrit will increase.

3. The liver processes bilirubin prior to excretion in the bile. Diseases that cause damage to the liver, such as hepatitis or cirrhosis, would impair the liver’s ability to perform this function. As a result, bilirubin would accumulate in the blood, producing jaundice.

Page 654

1. Surface antigens on RBCs are glycolipids in the cell membrane.

2. A person with Type O blood can accept only Type O blood.

3. If a person with Type A blood receives a transfusion of Type B blood, the red blood cells will clump, or agglutinate, potentially blocking blood flow to various organs and tissues.

Page 660

1. In an infected cut, we would find a large number of neutrophils, phagocytic white blood cells that are generally the first to arrive at the site of an injury. They specialize in dealing with infectious bacteria.
2. The cells that produce circulating antibodies are B lymphocytes; these white blood cells would be found in elevated numbers.
3. During inflammation, basophils release a variety of chemicals, such as histamine and heparin, that exaggerate the inflammation and attract other types of white blood cells.

Page 664
1. Megakaryocytes are the precursors of platelets, which play an important role in hemostasis and the clotting process. A decreased number of megakaryocytes would result in fewer platelets, which in turn would interfere with the blood's ability to clot properly.
2. Fruit juice and water do not contain fats, which are required for vitamin K absorption, leading to a vitamin K deficiency. This would lead to a decrease in the production of several clotting factors—most notably, prothrombin. As a result, clotting time would increase.
3. The activation of Factor XII initiates the intrinsic pathway.

Page 667 *Level 1 Reviewing Facts and Terms*
c 2. c 3. a 4. d 5. d 6. b 7. d 8. b
9. (1) the transportation of dissolved gases, nutrients, hormones, and metabolic wastes; (2) the regulation of pH and electrolyte composition of interstitial fluids throughout the body; (3) the restriction of fluid losses through damaged vessels or at other injury sites; (4) defense against toxins and pathogens; and (5) the stabilization of body temperature
10. albumins, which maintain the osmotic pressure of plasma and are important in the transport of fatty acids; globulins, which bind small ions, hormones, or compounds that might otherwise be filtered out of the blood at the kidneys or have very low solubility in water (transport globulins) or attack foreign proteins and pathogens (immunoglobulins); and fibrinogen, which functions in blood clotting

11. **(a)** anti-B antibodies **(b)** anti-A antibodies **(c)** neither anti-A nor anti-B antibodies **(d)** anti-A and anti-B antibodies

12. (1) ameboid movement, the extension of a cellular process; (2) emigration, squeezing between adjacent endothelial cells in the capillary wall; (3) positive chemotaxis, the attraction to specific chemical stimuli, and (4) neutrophils, eosinophils, and monocytes are capable of phagocytosis

13. neutrophils, eosinophils, basophils, and monocytes

14. (1) T cells, which are responsible for cell-mediated immunity; (2) B cells, which are responsible for humoral immunity; and (3) NK cells, which are responsible for immune surveillance

15. (1) the transport of chemicals important to clotting; (2) the formation of a temporary patch in the walls of damaged blood vessels; and

(3) active contraction after the clot has formed

16. Erythropoeitin is released (1) during anemia, (2) when blood flow to the kidneys declines, (3) when oxygen content of the air in the lungs declines, and (4) when the respiratory surfaces of the lungs are damaged.

17. The common pathway begins when thromboplastin from either the extrinsic or intrinsic pathway appears in the plasma.

Level 2 Reviewing Concepts

18. a 19. d 20. c 21. c

22. Red blood cells are biconcave discs that lack mitochondria, ribosomes, and nuclei, and they contain a large amount of hemoglobin. RBCs transport oxygen, while WBCs are involved in immunity.

23. White blood cells defend against toxins and pathogens. Neutrophils, eosinophils, and monocytes engulf and digest bacteria, protozoa, fungi, viruses, and cellular debris. Lymphocytes specialize to attack and destroy specific foreign cells, proteins, and cancerous cells, directly or through the production of antibodies.

24. Blood stabilizes and maintains body temperature by absorbing and redistributing the heat of the body. Heat is absorbed from active skeletal muscles. Dermal capillaries dilate when body temperature rises, thereby increasing blood flow to the skin and dissipating the excess heat to the air. Dermal capillaries constrict when body temperature falls, thereby decreasing blood flow to the skin and thus conserving heat for organs that are more temperature sensitive.

25. Hemoglobin is a protein that demonstrates quaternary structure. An iron is found in the center of each of the four proteins that make up one molecule of hemoglobin. This central iron atom is what actually picks up and releases the oxygen molecules.

26. Aspirin inactivates platelet enzymes involved in the production of thromboxanes and prostaglandins, and it inhibits endothelial cell production of prostacyclin. Thus, aspirin inhibits clotting.

Level 3 Critical Thinking and Clinical Applications

27. A prolonged prothrombin time and a normal partial thromboplastin time indicate a deficiency in the extrinsic system but not in the intrinsic system or common pathway. Factor VII would be deficient.

28. A major function of the spleen is to destroy old, defective, and worn out red blood cells. As the spleen increases in size, so does its capacity to eliminate red blood cells and this produces anemia. The decreased number of red blood cells decreases the body’s ability to deliver oxygen to the tissues and thus their metabolism is slowed down. This would account for the tired feeling and lack of energy. Because there are fewer red blood cells than normal, the blood circulating through the skin is not as red and so the person has a pale or white skin coloration.

29. Broad spectrum antibiotics act to kill a wide range of bacteria, both pathogenic and nonpathogenic. When an individual takes such an antibiotic, it kills a large number of the normal flora of the intestine. Decreasing the normal flora in this way substantially decreases the amount of vitamin K that is available to the liver for the production of prothrombin, a procoagulant that is vital to the functioning of the common pathway. With

decreased amounts of prothrombin in the blood, normal daily injuries such as breaks in the vessels in the nasal passageways (which are normally sealed off quickly by coagulation) do not seal off as quickly, producing the effect of nosebleeds.

30. Intrinsic factor, an essential part of the transport system for the absorption of vitamin B12 by the intestinal cells, is produced by specialized stomach cells. When most of the stomach was removed, intrinsic factor was no longer available to facilitate the absorption of vitamin B12, so injection directly into the bloodstream was necessary. (If Randy did not take the B12 shots, he would develop pernicious anemia.)

Chapter 20

Page 681

1. The semilunar valves on the right side of the heart guard the opening to the pulmonary artery. Damage to these valves would interfere with the blood flow to this vessel.

2. When the ventricles begin to contract, they force the AV valves to close, tensing the chordae tendineae. The chordae tendineae are attached to the papillary muscles, which begin contracting just before the rest of the ventricular myocardium does. Their contraction prevents the AV valves from opening back into the atria.

3. The left ventricle is more muscular than the right ventricle because the left ventricle must generate enough force to propel blood throughout all the body except the alveoli of the lungs. The right ventricle must generate only enough force to propel blood a few centimeters to the lungs.

Page 690

1. If these cells failed to function, the heart would still continue to beat but at a slower rate; the AV node would act as pacemaker.

2. If the impulses from the atria were not delayed at the AV node, they would be conducted through the ventricles so quickly by the bundle branches and Purkinje cells that the ventricles would begin contracting immediately, before the atria had finished their

contraction. As a result, the ventricles would not be as full of blood as they could be, and the pumping of the heart would not be as efficient, especially during activity.

Page 695

1. No. When pressure in the left ventricle first rises, the heart is contracting but no blood is leaving the heart. During this initial phase of contraction, both the AV valves and the semilunar valves are closed. The increase in pressure is the result of increased tension as the cardiac muscle contracts. When the pressure in the ventricle exceeds the pressure in the aorta, the aortic semilunar valves are forced open and blood is rapidly ejected from the ventricle.
2. An increase in the size of the QRS complex indicates a larger-than-normal amount of electrical activity during ventricular depolarization. One possible cause is an increase in the size of the heart. Because more cardiac muscle is depolarizing, the magnitude of the electrical event would be greater.

Page 699

1. Caffeine acts directly on the conducting system and contractile cells of the heart, increasing the rate at which they depolarize. Drinking large amounts of caffeinated coffee would increase the heart rate.
2. The cardioinhibitory center of the medulla oblongata is part of the parasympathetic division of the autonomic nervous system. Damage to

this center would result in fewer parasympathetic action potentials to the heart and an increase in heart rate due to sympathetic dominance.

A drug that increases the length of time required for the repolarization of pacemaker cells would decrease the heart rate, because the pacemaker cells would generate fewer action potentials per minute.

Page 702

1. If the heart beats too rapidly, it does not have sufficient time to fill completely between beats. The heart pumps in proportion to the amount of blood that enters: The less blood that enters, the less the heart can pump. If it beats too fast, very little blood will enter the bloodstream; tissues will suffer damage from the lack of blood supply.

2. Stimulating the acetylcholine receptors of the heart would cause the heart to slow down. Since the cardiac output is the product of stroke volume and heart rate, if the heart rate decreases, so will the cardiac output (assuming that the stroke volume doesn’t change).

3. The venous return fills the heart with blood, stretching the heart muscle. According to the Frank–Starling principle, the more the heart muscle is stretched, the more forcefully it will contract (to a point). The more forceful the contraction, the more blood the heart will eject with each beat (stroke volume). Therefore, increased venous return would increase the stroke volume (if all other factors are constant).

4. An increase in sympathetic stimulation of the heart would result in an increased heart rate and increased force of contraction. The end-sys-tolic volume (ESV) is the amount of blood that remains in a ventricle after a contraction (systole). The more forcefully the heart contracts, the more blood it ejects and the lower the ESV is. Therefore, increased sympathetic stimulation should result in a lower ESV.

5. SV = EDV -ESV, so SV = 125 ml -40 ml = 85 ml

Page 706 *Level 1 Reviewing Facts and Terms*

c 2. b 3. b 4. b 5. d 6. e 7. b 8. a 9. a

10. During ventricular contraction, tension in the papillary muscles pulls against the chordae tendineae, which keep the cusps of the AV valve from swinging into the atrium. This action prevents the backflow, or regurgitation, of blood into the atrium as the ventricle contracts.

11. (1) The epicardium is the visceral pericardium, which covers the outer surface of the heart. (2) The myocardium is the muscular wall of the heart, which forms both atria and ventricles. It contains cardiac muscle tissue and associated connective tissues, blood

vessels, and nerves. (3) The endocardium is a squamous epithelium that covers the inner surfaces of the heart, including the valves.

12. The atrioventricular (AV) valves prevent the backflow of blood from the ventricles into the atria. The right AV valve is the tricuspid valve; the left AV valve is the bicuspid valve. The pulmonary and aortic semilunar valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles.

13. SA node : AV node : AV bundle : right and left bundle branches : Purkinje fibers (into the mass of ventricular muscle tissue)

14. The cardiac cycle is a complete heartbeat, including a contraction/relaxation period for both atria and ventricles. The cycle begins with atrial systole as the atria contract and push blood into the relaxed ventricles. As the atria relax (atrial diastole), the ventricles contract (ventricular systole), forcing blood through the semilunar valves into the pulmonary trunk and aorta. The ventricles then relax (ventricular diastole). For the rest of the cardiac cycle, both the atria and ventricles are in diastole; passive filling occurs.

15. (1) preload, the stretch on the heart before it contracts; (2) contractility, the forcefulness of contraction of individual ventricular muscle fibers; and (3) afterload, the pressure that must be exceeded before blood can be ejected from the ventricles

Level 2 Reviewing Concepts

16. c 17. a 18. d 19. a

20. The SA node is the pacemaker of the heart, composed of cells that exhibit rapid prepotential. The AV nodal cells are smaller than those of the conduction pathway and the impulse that signals contraction is slowed.

21. The first sound (“lubb”), which marks the start of ventricular contraction, is produced as the AV valves close and the semilunar valves open. The second sound (“dupp”) occurs when the semilunar valves close, marking the start of ventricular diastole. The third heart sound is associated with blood flow into the atria, and the fourth with atrial contraction. Listening to the heart sounds (auscultation) is a simple, effective method of cardiac diagnosis.

22. Stroke volume (SV) is the volume of blood ejected by a ventricle in a single contraction. Cardiac output (CO) is the amount of blood pumped by a ventricle in 1 minute. CO (in ml min) = SV (in ml) * HR (in beats min)

>>

23. stroke volume and heart rate

24. Sympathetic activation causes the release of NE by postganglionic fibers and the secretion of NE and E by the adrenal medullae. These hormones stimulate the metabolism of cardiac muscle cells and increase the force and degree of contraction. They also depolarize nodal cells toward threshold, which in turn increases the heart rate. Parasympathetic stimulation causes the release of ACh at membrane surfaces, where it produces hyperpolarization and inhibition. The result is a decrease in the heart rate and the force of cardiac contractions.

25. All these hormones have positive inotropic effects, which means that they increase the strength of contraction of the heart.

Level 3 Critical Thinking and Clinical Applications

26. During tachycardia, the heart beats at an abnormally fast rate. The faster the heart beats, the less time there is in between contractions for it to fill with blood again. As a result, over a period of time the heart fills with less and less blood and thus pumps less blood out. The stroke volume decreases, as does the cardiac output. When the cardiac output decreases to the point where not enough blood reaches the central nervous system, loss of consciousness occurs.

27. It would appear that Harvey has a regurgitating mitral valve. When an AV valve fails to close properly, the blood flowing back into the atrium produces the abnormal heart sound or murmur. If the sound is heard at the beginning of the systole, this would indicate the AV valve because this is the period when the valve is just closed and the blood in the ventricle is under increasing pressure; thus the likelihood of backflow is the greatest. If the sound

were heard at the end of systole or the beginning of diastole, it would indicate a regurgitating semilunar valve—in this case, the aortic semilunar valve.

28. Person 1 has a cardiac output of 4500 ml (CO = HR * SV). Person 2 has a cardiac output of 8550 ml. According to Starling’s law, in a normal heart the cardiac output is directly proportional to the venous return. Thus, person 2 has the greater venous return. Ventricular filling decreases with increased heart rate; person 1 has the lower heart rate and therefore the longer ventricular filling time.

29. It will decrease the force of cardiac contraction, which directly affects stroke volume. Verpamil should lower Karen’s stroke volume.

Chapter 21

Page 718

1. These blood vessels are veins. Arteries and arterioles have a large amount of smooth muscle tissue in a thick, well-developed tunica media.

2. Blood pressure in the arterial system pushes blood into the capillaries. Blood pressure in the venous system is very low, and other forces help keep the blood moving. Valves in veins prevent blood from flowing backward whenever the venous pressure drops; this is not a problem in arteries.

3. You would find fenestrated capillaries in organs and tissues where small peptides move freely into and out of the blood—for instance, endocrine glands, the choroid plexus of the brain, absorptive areas of the intestine, and filtration areas of the kidneys.

Page 725

1. In a healthy individual, the blood pressure should be greater at the aorta than at the inferior vena cava. Blood, like other fluids, moves along a pressure gradient from areas of high pressure to areas of low pressure. If the pressure were higher in the inferior vena cava, the blood would flow backward.

2. While a person stands for periods of time, blood pools in the lower limbs. This pooling decreases the venous return to the heart. In turn, the cardiac output decreases, sending less

blood to the brain, causing light-headedness and fainting. A hot day adds to this effect, because body water is lost and blood volume is reduced, through sweating.

3. 70 + 125> 3 = approx. 112 mm Hg.

Page 736

During exercise, blood pressure increases despite the increased blood flow to skeletal muscles because (1) cardiac output increases and

(2) resistance in visceral tissues increases.

2. Pressure at this site would decrease blood pressure at the carotid sinus, where the carotid baroreceptors are located. This decrease would cause a decreased frequency of action potentials along the glossopharyngeal nerve (IX) to the medulla oblongata, and more sympathetic impulses would be sent to the heart. The net result would be an increase in the heart rate.

3. Vasoconstriction of the renal artery would decrease both blood flow and blood pressure at the kidney. In response, the kidney would increase the amount of renin it releases, which in turn would lead to an increase in the level of angiotensin II. The angiotensin II would bring about increased blood pressure and increased blood volume.

Page 745

1. The left subclavian artery is the branch of the aorta that delivers blood to the left arm.

2. The common carotid arteries carry blood to the head. A compression of the common carotid arteries would result in decreased blood pressure at the carotid sinus and a rapid fall in blood flow to the brain, resulting in unconsciousness. An immediate reflexive increase in heart rate and blood pressure would follow.

3. Organs served by the celiac trunk include the stomach, spleen, liver, and pancreas.

Page 756

1. The vein that is bulging is the external jugular vein.

2. A blockage of the popliteal vein would interfere with blood flow in the tibial and peroneal veins (which form the popliteal vein) and the small saphenous vein (which joins the popliteal vein).

3. This blood sample must have come from the umbilical vein, which carries oxygenated, nutrient-rich blood from the placenta to the fetus.

Page 761 *Level 1 Reviewing Facts and Terms*

b 2. e 3. c 4. a 5. b 6. d 7. b 8. c 9. b 10. c 11. c 12. c 13. c 14. c

15. **(a)** Capillary hydrostatic pressure forces fluid out of the capillary at the arteriole end. **(b)** The blood colloid osmotic pressure causes the movement of fluid back into the capillary at its venous end.

16. When an infant takes its first breath, the lungs expand and pulmonary vessels dilate. The smooth muscles in the ductus arteriosus contract, due to increased venous return from the lungs, isolating the pulmonary and aortic trunks, and blood begins flowing through the pulmonary circuit. As pressure rises in the left atrium, the valvular flap closes the foramen ovale, completing the circulatory remodeling.

Level 2 Reviewing Concepts

17. b 18. b 19. a

20. Artery walls are generally thicker, and they contain more smooth muscle and elastic fibers, enabling them to resist and adjust to the pressure generated by the heart. Venous walls are thinner; the pressure in veins is less than that in arteries. Arteries constrict more than veins do when not expanded by blood pressure, due to a greater degree of elastic tissue. Finally, the endothelial lining of an artery has a pleated appearance because it cannot contract and so forms folds. The lining of a vein looks like a typical endothelial layer.

21. Capillary walls are thin, so distances for diffusion are small. Continuous capillaries have small gaps between adjacent endothelial cells that permit the diffusion of water and small solutes into the surrounding interstitial fluid but prevent the loss of blood cells and

plasma proteins. Fenestrated capillaries contain pores that permit very rapid exchange of fluids and solutes between interstitial fluid and plasma. The walls of arteries and veins are several cell layers thick and are not specialized for diffusion.

22. Movement in the surrounding skeletal muscles squeezes venous blood toward the heart. This mechanism, the muscular pump, is assisted by the presence of valves in the veins, which prevent backflow of the blood. The respiratory pump results from the increase in internal pressure of the thoracic cavity on exhalation, which pushes venous blood into the right atrium.

23. Cardiac output and peripheral blood flow are directly proportional to blood pressure. Blood pressure is closely regulated by a combination of neural and hormonal mechanisms. The resistance of the circulatory system opposes the movement of blood, so blood flow is inversely proportional to the resistance. Sources of peripheral resistance include vascular resistance, viscosity, and turbulence.

24. The brain receives arterial blood via four arteries that form anastomoses within the cranium. An interruption of any one vessel will not compromise the circulatory supply to the brain.

25. The cardioacceleratory and vasomotor centers are stimulated when a general sympathetic activation occurs. The result is an increase in cardiac output and blood pressure. When the parasympathetic division is activated, the cardioinhibitory center is stimulated, reducing cardiac output.

Level 3 Critical Thinking and Clinical Applications

26. Three factors are contributing to Bob’s elevated blood pressure: (1) The loss of water by sweating increases blood viscosity. The number of red blood cells remains about the same, but because there is less plasma volume, the concentration of red cells is increased, thus increasing the blood viscosity. Increased viscosity increases peripheral resistance and contributes to increased blood pressure. (2) To cool Bob’s body, there is increased blood flow to the skin. This in turn increases venous return, which increases stroke volume and cardiac output (Starling’s law of the heart). The increased cardiac output can also

contribute to increased blood pressure. (3) The heat stress that Bob is experiencing leads to increased sympathetic stimulation (the reason for the sweating). Increased sympathetic stimulation of the heart will increase heart rate and stroke volume, thus increasing cardiac output and blood pressure.

27. In response to the high temperature of the water, Tom’s body shunted more blood to the superficial veins to decrease body temperature. The dilation of the superficial veins caused a shift in blood to the arms and legs and resulted in a decreased venous return. Because of the decreased venous return, the cardiac output decreased and less blood with oxygen was delivered to the brain. This caused Tom to feel light headed and faint nearly causing his demise.

28. When Jolene rapidly moved from a lying position to a standing position, gravity caused her blood volume to move to the lower parts of her body away from the heart, decreasing venous return. The decreased venous return resulted in a decreased EDV, leading to a decreased stroke volume and cardiac output. In turn, blood flow to the brain decreased, so the diminished oxygen supply caused her to be light-headed and feel faint. This reaction doesn’t happen all the time because as soon as the pressure drops due to inferior movement of blood, the baroreceptor reflex should be triggered. Normally, a rapid change in blood pressure is sensed by baroreceptors in the aortic arch and carotid sinus. Action potentials from these areas are carried to the medulla oblongata, where appropriate responses are integrated. In this case, we would expect an increase in peripheral resistance to compensate for the decreased blood pressure. If this doesn’t compensate enough for the drop, then an increase in heart rate and force of contraction would occur. Normally, these responses occur so quickly that changes in pressure following changes in body position go unnoticed.

Chapter 22

Page 775

1. The thoracic duct drains lymph from the area beneath the diaphragm and from the left side of the head and thorax. Most of the lymph enters the venous blood by way of this duct.

A blockage of this duct would impair the circulation of lymph through most of the body and would promote the accumulation of fluid in the limbs (lymphedema).

2. The thymic hormones play a role in the differentiation of lymphoid stem cells into T lymphocytes. A lack of these hormones would result in an absence of T lymphocytes.

3. During an infection, the lymphocytes and phagocytes in the lymph nodes in the affected region undergo cell division to deal with the infectious agent more effectively. This increase in the number of cells in the node causes the node to become enlarged or swollen.

Page 782

1. A decrease in the number of monocyte-forming cells in the bone marrow would result in a decreased number of macrophages in the body, because all types of macrophages are derived from monocytes. These include the Kupffer’s cells of the liver, Langerhans cells in the skin and digestive tract, and alveolar macrophages.

2. A rise in the level of interferon would suggest a viral infection. Interferon is released from cells that are infected with viruses. It does not help an infected cell but “interferes” with the virus’s ability to infect other cells.

3. Pyrogens stimulate the temperature control area of the preoptic nucleus of the hypothalamus. The result is an increase in body temperature, or fever.

Page 793

1. Abnormal peptides in the cytoplasm of a cell can become attached to MHC (major histocompatibility complex) proteins and are then displayed on the surface of the cell’s membrane. Peptides presented in this manner are then recognized by T cells, which can initiate an immune response.

2. Cytotoxic T cells function in cell-mediated immunity. A decrease in the number of cytotoxic T cells would interfere with the ability to kill foreign cells and tissues as well as cells infected by viruses.

3. Helper T cells promote B cell division, the maturation of plasma cells, and the production of antibodies by the plasma cells. Without helper T cells, the antibody-mediated immune response would probably not occur.
4. Plasma cells produce and secrete antibodies. In a sample containing an elevated number of plasma cells, we would expect the amount of antibodies in the blood to increase.

Page 802
1. The secondary response would be more affected by the lack of memory B cells for a particular antigen. The ability to produce a secondary response depends on the presence of memory B cells and T cells that are formed during the primary response to an antigen. These cells are not involved in the primary response but are held in reserve against future contact with the same antigen.
2. The developing fetus is protected primarily by natural passive immunity, the product of IgG antibodies that cross the placenta from the mother's bloodstream.
3. Stress can interfere with the immune response by depressing the inflammatory response, reducing the number and activity of phagocytes, and inhibiting interleukin secretion.

Page 809 *Level 1 Reviewing Facts and Terms*

10. c

11. lymph nodes: filtration of lymph, detection of pathogens, initiation of immune response; tonsils, lymphoid nodules, and aggregated lymphoid nodules: defense of entrance and passageways of digestive tract against pathogens and foreign proteins or toxins; spleen: filtration of blood, recycling of red blood cells, detection of blood-borne pathogens or toxins; thymus: production of mature T cells and hormones that promote immune function; lymphatics: movement of lymph from interstitial spaces to the venous system
12. **(a)** lymphocytes responsible for cell-mediated immunity **(b)** stimulate the activation and function of T cells and B cells **(c)** inhibit the activation and function of both T cells and

B cells **(d)** produce and secrete antibodies **(e)** recognize and destroy abnormal cells **(f)** produce in-terleukin-7, which promotes the differentiation of B cells **(g)** maintain the blood–thymus barrier and secrete the thymic hormones that stimu

late stem cell division and T cell differentiation **(h)** interfere with viral replication inside the cell and stimulate the activities of macrophages and NK cells **(i)** reset the body's thermostat, causing a rise in body temperature (fever) **(j)** provide cell-mediated immunity, which defends against abnormal cells and pathogens inside cells **(k)** provide humoral immunity, which defends against antigens and pathogens in the body (but not inside cells) **(l)** enhance nonspecific defenses and increase T cell sensitivity and stimulate B cell activity **(m)** slow tumor growth and kill sensitive tumor cells **(n)** stimulate the production of blood cells in the bone marrow and lymphocytes in lymphoid tissues and organs

13. (1) T cells, derived from the thymus; (2) B cells, derived from bone marrow; and (3) NK cells, derived from bone marrow

14. (1) physical barriers; (2) phagocytic cells; (3) immunological surveillance; (4) interferons; (5) complement; (6) inflammation; and

(7) fever

Level 2 Reviewing Concepts

15. c 16. c 17. b 18. b

19. Complement may rupture the cell membrane through the release of perforin, kill the target cell by secreting a poisonous lymphotoxin, or activate genes within the nucleus of the cell that tell the cell to die. Interferon interferes with viral replication inside infected cells by triggering the production of antiviral proteins.

20. by rupturing the antigenic cell membrane, by killing the target cell through lymphotoxin secretions, or by activating genes in the nucleus that program cell death

21. by neutralization, agglutination and precipitation, the activation of complement, the attraction of phagocytes, opsonization, the stimulation of inflammation, or the prevention of bacterial and viral adhesion

22. innate immunity = genetically programmed immunity; naturally acquired immunity = immunity that develops after birth, due to contact with pathogens. Exposure to chicken pox in grade school is an example of naturally acquired immunity; induced active immunity is immunity that develops after purposeful contact with a pathogen, such as vaccinations; induced passive immunity is temporary immunity provided by injection with antibodies produced in another organism; natural passive immunity is immunity gained through acquiring antibodies from either mother's milk or placental exchange.

23. The injections are timed to trigger the primary and secondary responses of the immune system. When the technician is first exposed to the hepatitis antigens, B cells produce daughter cells that differentiate into plasma cells and memory B cells. The plasma cells begin producing antibodies, which represent the primary response to exposure. However, the primary response does not maintain elevated antibody levels for long periods, so the second and third injections are necessary to trigger the secondary (anamnestic) response, when memory B cells differentiate into plasma cells and produce antibody concentrations that remain high much longer.

Level 3 Critical Thinking and Clinical Applications

24. IgA antibodies are found in body secretions such as tears, saliva, semen, and vaginal secretions, but not in blood plasma. Plasma contains IgM, IgG, IgD, and IgE antibodies. By testing for the presence or absence of IgA and IgG, the lab could determine whether the sample is blood plasma or semen.

25. On initial contact with a virus, the immune system first produces IgM antibodies. The response is fairly rapid but short-lived. About the time that IgM peaks, IgG levels are beginning to rise. IgG plays the more important role in eventually controlling the disease. The fact that Ted's blood sample has an elevated level of IgM antibodies indicates that he is in the early stages of a primary response to the measles virus. He has been exposed; he will not develop the disease unless his immune response proves unable to control and then eliminate the virus.

26. In a radical mastectomy, the neighboring lymph glands in the axilla and surrounding region are removed along with the cancerous breast. (The lymph nodes are removed as a precautionary measure to try to prevent the spread of cancer cells spread by way of the lymphatic system.) The lymphatic vessels from the limb on the affected side are tied off, because there is no place for the lymph to drain to. Over time, lymphedema occurs, causing swelling of the limb.

27. A key characteristic of cancer cells is their ability to break free from a tumor and migrate to other tissues of the body forming new tumors. This process is called metastasis. The primary route for the spread of cancer cells is the lymphatic system, and cancer cells may remain in a lymph node for a period of time before moving on to other tissues. Examination of regional lymph nodes for the presence of cancer cells can help the physician determine if the cancer was caught in an early stage or whether it has started to spread to other tissues. It can also give the physician an idea of what other tissues may be affected by the cancer, which would help him to decide on the proper treatment.

28. Allergies occur when antigens called allergens bind to specific IgE antibodies that are bound to the surface of mast cells and basophils. A person becomes allergic when they develop IgE antibodies for a specific allergen. Theoretically, at least, a molecule that would bind to the specific IgE for ragweed allergen and prevent the allergen from binding should help to relieve the allergy.

Chapter 23

Page 821

1. The rich blood supply to the nose delivers body heat to the nasal cavity, so the inhaled air is warmed before it leaves the nasal cavity. The heat also evaporates moisture from the epithelium to humidify the incoming air. The moisture is derived from the blood supply as well. The blood supply also brings nutrients and water to the secretory cells of the nasal mucosa.

2. The nasopharynx receives only air from the nasal cavity. The oropharynx and laryngopharynx receive both air from the nasal cavity and food from the oral cavity. Ingested solids and liquids can damage delicate cells; thus, the areas that are in contact with food have a highly protective stratified squamous epithelium, like that of the exterior skin. The lining of the nasopharynx is the same as that of the nasal cavity, a pseudostratified ciliated columnar epithelium.

3. Increased tension in the vocal folds will raise the pitch of your voice.

Page 829

1. The tracheal cartilages are C-shaped to allow room for esophageal expansion when large pieces of food or volumes of liquid are swallowed.

2. Without surfactant, the alveoli would collapse as a result of surface tension in the thin layer of water that moistens the alveolar surfaces.

3. Air that passes through the glottis flows into the larynx and through the trachea. From there, the air flows into a primary bronchus, which supplies the lungs. In the lungs, the air passes to bronchi, bronchioles, a terminal bronchiole, a respiratory bronchiole, an alveolar duct, an alveolar sac, an alveolus, and ultimately to the respiratory membrane.

Page 829

The pulmonary arteries supply the exchange surfaces; the external carotid arteries, the thyrocervical trunks, and the bronchial arteries supply the conducting portions of the respiratory system.

The pleura is a serous membrane. Pleural surfaces secrete pleural fluid, which lubricates the opposing parietal and visceral surfaces to prevent friction during breathing.

Page 839

1. Because the rib penetrates Mark’s chest wall, atmospheric air will enter his thoracic cavity. This condition is pneumothorax. Pressure within the pleural cavity is normally lower than atmospheric pressure, but when air enters the pleural cavity, the natural

elasticity of the lung may cause the lung to collapse. The resulting condition is atelectasis, or a collapsed lung.

2. Because the fluid produced in pneumonia takes up space that would normally be occupied by air, the vital capacity would decrease.

Page 847

1. As skeletal muscles become more active, they generate more heat and more acidic waste products, which lower the pH of the surrounding fluid. The combination of increased temperature and reduced pH causes the hemoglobin to release more oxygen than it would otherwise.

2. Blockage of the trachea would interfere with the body’s ability to gain oxygen and to eliminate carbon dioxide. Because most carbon dioxide is carried in blood as bicarbonate ion that is formed from the dissociation of carbonic acid, an inability to eliminate carbon dioxide would result in an excess of hydrogen ions, thus lowering the body’s pH.

Page 854

1. The pneumotaxic centers inhibit the inspiratory center and the apneustic center. Exciting the pneumotaxic centers would result in shorter breaths and a more rapid rate of breathing.

2. Peripheral chemoreceptors are more sensitive to carbon dioxide levels than to oxygen levels. When carbon dioxide dissolves, it produces hydrogen ions, thereby lowering pH and altering cell or tissue activity.

3. Johnny’s mother shouldn’t worry. When Johnny holds his breath, the level of carbon dioxide in his blood will increase. This increase will in turn lead to increased stimulation of the inspiratory center, forcing Johnny to breathe again.

Page 860 *Level 1 Reviewing Facts and Terms*

d 2. c 3. a 4. c 5. c

6. Since the air that Brad is breathing is not humidified (thus dry), large amounts of moisture are leaving the mucus to humidify the air that is being respired. This makes the

mucus tacky and difficult for the cilia to move. As more mucus is produced, it builds up forming the nasal congestion in the morning. As Brad showers and drinks fluid, the moisture is replaced and the mucus loosens up and is moved along the proper route as usual. The reason this happens mostly at night is because Brad is probably not getting up frequently to drink water to replace what is being lost to humidify the air.

7. The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. The lower respiratory system consists of the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs.

8. (1) nasopharynx, the superior portion, where the nasal cavity opens into the pharynx; (2) oropharynx, the middle portion, posterior to the oral cavity; and (3) laryngopharynx, the inferior portion that is posterior to the hyoid bone and glottis

9. Thyroid cartilage forms the anterior walls of the larynx; the cricoid cartilage protects the glottis and the entrance to the trachea; the epiglottis forms a lid over the glottis; the arytenoid cartilages and the corniculate cartilages are involved in the formation of sound; the cuneiform cartilages are found in the folds of the larynx.

10. (1) pulmonary ventilation (breathing); (2) gas diffusion across the respiratory membrane; (3) the storage and transport of oxygen and carbon dioxide; and (4) the exchange of dissolved gases between blood and interstitial fluids

11. Fetal hemoglobin has a higher affinity for oxygen, enabling it to “steal” oxygen from the maternal hemoglobin. Fetal hemoglobin also binds more oxygen than adult hemoglobin.

12. (1) conversion to carbonic acid; (2) binding to the hemoglobin of red blood cells; and (3) dissolution in plasma

Level 2 Reviewing Concepts

13. c 14. d 15. c 16. b

17. The nasal cavity is designed to cleanse, moisten, and warm inhaled air, whereas the mouth is not. Air that has entered through the mouth is drier than air that has entered through the nose and as a result can irritate the trachea, causing soreness of the throat.

18. The walls of bronchioles, like the walls of arterioles, are dominated by smooth muscle tissue. Varying the diameter of the bronchioles (bronchodilation or bronchoconstriction) provides control over the amount of resistance to airflow and the distribution of air within the lungs, just as vasodilation and vasoconstriction of the arterioles regulate blood flow and blood distribution.

19. Septal cells produce surfactant, which reduces surface tension in the fluid coating the alveolar surface. The alveolar walls are so delicate that without surfactant, the surface tension would be so high that the alveoli would collapse.

20. Pulmonary ventilation is the physical movement of air into and out of the respiratory tract. Its primary function is to maintain adequate alveolar ventilation. Alveolar ventilation is air movement into and out of the alveoli. This process prevents the buildup of carbon dioxide in the alveoli and ensures a continuous supply of oxygen that keeps pace with absorption by the bloodstream.

21. **(a)** Boyle’s law describes the inverse relationship between pressure and volume: If volume decreases, pressure rises; if volume increases, pressure falls. **(b)** Dalton’s law states that each of the gases that make up a mixture of gases contributes to the total pressure in proportion to its relative abundance; that is, all the partial pressures added together equal the total pressure exerted by the gas mixture. **(c)** Henry’s law states that, at a given temperature, the amount of a particular gas that dissolves in a liquid is directly proportional to the partial pressure of that gas.

22. Both sneezing and coughing involve a temporary cessation of respiration (apnea).

23. Pulmonary volumes include resting tidal volume (averaging 500 ml), expiratory reserve volume (approximately 1200 ml), residual volume (averaging 1200 ml), minimal volume (30–120 ml), and inspiratory reserve volume (approximately 3600 ml). These values are determined experimentally. Respiratory capacities include inspiratory capacity, functional residual capacity, vital capacity, and total lung capacity. Respiratory capacities are determined by adding the values of various volumes.

24. The DRG is the inspiratory center that contains neurons that control lower motor neurons innervating the external intercostal muscles and the diaphragm. The DRG

functions in every respiratory cycle, whether quiet or forced. The VRG functions only during forced respira

tion—active exhalation and maximal inhalation. The neurons involved with active exhalation are sometimes said to form an expiratory center.

Level 3 Critical Thinking and Clinical Applications

25. AVR = respiratory rate * (tidal volume -dead space). In this case, the dead air space is 200 ml (the anatomical dead air space plus the volume of the snorkel); therefore, AVR = respiratory rate * (500 -200). To maintain an AVR of 6 l > min, or 6000 ml > minute, the respiratory rate must be 6,000 (500-200), or 20 breaths per minute.

>

26. A person with chronic emphysema has constantly elevated levels of PCO_2 in the blood, due to an inability to eliminate CO2 efficiently as a result of the physical damage to the lungs. Over time, the brain ignores the stimulatory signals produced by the increased CO2 and begins to rely on information from the peripheral chemoreceptors to set the pace of breathing (in other words, accommodation has occurred). The peripheral chemoreceptors also accommodate to the elevated CO2 and respond primarily to the level of O2 in the blood, increasing breathing when O2 levels are low and decreasing breathing when O2 levels are high. When pure O2 was administered, chemoreceptors responded with fewer action potentials to the medulla oblongata, so Mr. B. stopped breathing.

27. Hyperventilation causes a decrease in the alveolar PCO_2 and more carbon dioxide is eliminated from the body. The elimination of large amounts of carbon dioxide upsets the body’s acid-base balance by shifting the pH to be more alkaline (carbon dioxide in solution forms hydrogen ions and contributes to the body’s acid reserves). The increase in pH causes dilation of peripheral blood vessels and a decreased venous return to the heart. This results in a decreased cardiac output and insufficient amounts of oxygen reaching the brain, causing Cary to lose consciousness.

28. In anemia, the decreased ability of blood to carry oxygen is due to the lack of functional hemoglobin, red blood cells, or both. The disease does not interfere with the exchange of

carbon dioxide within the alveoli nor with the amount of oxygen that will dissolve in the plasma. Because the chemoreceptors respond to dissolved gases and pH, as long as the concentrations of dissolved carbon dioxide, oxygen, and pH are normal, ventilation patterns should not change significantly.

29. The obstruction in Doris's right lung would not allow for gas exchange. Thus, the blood moving through the right lung would not oxygenate and would retain carbon dioxide. The retention of carbon dioxide in the blood would lead to a lower pH than the blood leaving the left lung. The lower pH would shift the oxygen–hemoglobin saturation curve to the left (the Bohr effect) for the right lung, compared with that for the left lung.

Chapter 24

Page 870

1. The mesenteries are double layers of serous membrane that support and stabilize the positions of organs in the abdominopelvic cavity and provide a route for the associated blood vessels, nerves, and lymphatic vessels.

2. Peristalsis is more efficient in propelling intestinal contents. Segmentation is essentially a churning action that mixes intestinal contents with digestive fluids. Peristalsis consists of waves of contractions that not only mix the contents but also propel them along the digestive tract.

3. Parasympathetic stimulation increases muscle tone and activity in the digestive tract. A drug that blocks this activity would decrease the rate of peristalsis.

Page 875

1. The oral cavity is lined by a stratified squamous epithelium. This type of lining is very protective and so is located in areas of the body that receive a great deal of friction or abrasion.

2. Because the parotid salivary glands secrete salivary amylase, an enzyme that digests complex carbohydrates, damage to these glands would interfere with the digestion of carbohydrates.

3. The incisors are the type of tooth best suited for chopping (or cutting or shearing) pieces of relatively rigid food, such as raw vegetables.

Page 877

1. The muscularis externa of the esophagus is unusual because (1) it contains skeletal muscle cells along most of the length of the esophagus and (2) it is surrounded by an adventitia rather than a serosa.

2. The fauces is the opening between the oral cavity and the pharynx.

3. Swallowing (deglutition) is occurring.

Page 884

1. The larger the meal (especially in terms of protein), the more stomach acid is secreted. The hydrogen ions for the acid come from the blood that enters the stomach; therefore, the blood leaving the stomach will have fewer than normal hydrogen ions and will be decidedly al-kaline—that is, have a higher pH. This phenomenon is referred to as the alkaline tide.

2. The vagus nerve contains parasympathetic motor fibers that can stimulate gastric secretions. This stimulation can occur even if food is not present in the stomach (the cephalic phase of gastric digestion). Cutting the branches of the vagus that supply the stomach would prevent this type of secretion from occurring and thereby decrease the likelihood of ulcer formation.

Page 896

1. The small intestine has several adaptations that increase surface area to increase its absorptive capacity. The walls of the small intestine are thrown into folds, the plicae circulares. The tissue that covers the plicae forms fingerlike projections, the villi. The cells

that cover the villi have an exposed surface covered by small fingerlike projections, the microvilli. In addition, the small intestine has a very rich supply of blood vessels and lymphatic vessels, which transport the nutrients that are absorbed.

2. The cholecystokinin level in the blood would increase.

3. The hormone secretin, among other things, stimulates the pancreas to release fluid high in buffers to neutralize the chyme that enters the duodenum from the stomach. If the small intestine did not secrete secretin, the pH of the intestinal contents would be lower than normal.

4. Damage to the exocrine pancreas would most affect the digestion of fats (lipids). Enzymes for carbohydrate digestion are produced by salivary glands and the small intestine, as well as by the pancreas. Enzymes for protein digestion are produced by the stomach and the small intestine, as well as by the pancreas. Even though the digestion of carbohydrates and proteins would not be as complete as it is when the pancreas is functioning, some digestion would still take place. Because the pancreas is the primary source of lipases, lipid digestion would be most impaired.

Page 908

1. Chylomicrons are formed from the fats digested in a meal. A meal that is high in fat would increase the number of chylomicrons in the lacteals.

2. The removal of the stomach would interfere with the absorption of vitamin B12 . This vitamin requires intrinsic factor, which is produced by the parietal cells of the stomach.

3. A person can lose fluid and electrolytes faster than these substances can be replaced. This loss would result in dehydration and possibly death. Although it can be quite uncomfortable, constipation is not potentially life-threatening, because it does not interfere with any major body process that supports life. The few toxic waste products that are normally eliminated by way of the digestive system can move into the blood and can ultimately be eliminated by the kidneys.

Page 913 *Level 1 Reviewing Facts and Terms*

11. (1) ingestion; (2) mechanical processing; (3) secretion; (4) digestion; (5) absorption; and (6) excretion

12. mucosa: the epithelial layer that performs chemical digestion and absorption of nutrients; submucosa: the connective tissue layer containing lymphatic and blood vessels and the submucosal nerve plexus; muscularis externa: the smooth muscle layer containing the myenteric nerve plexus; and serosa: the outermost layer, epithelium and connective tissue that forms the visceral peritoneum (or connective tissue that forms the adventitia)

13. (1) neural mechanisms; (2) hormonal mechanisms; and (3) local mechanisms

14. (1) buccal phase; (2) pharyngeal phase; and (3) esophageal phase. Swallowing is controlled by the swallowing center of the medulla oblongata via the trigeminal and glossopharyngeal nerves. The motor commands originating at the swallowing center are distributed by cranial nerves V, IX, X, and XII. Along the esophagus, primary peristaltic contractions are coordinated by afferent and efferent fibers within the glossopharyngeal and vagus nerves, but secondary peristaltic contractions occur in the absence of CNS instructions.

15. The pancreas provides digestive enzymes as well as buffers that assist in the neutralization of chyme. The liver and gallbladder provide bile, which contains additional buffers and bile salts that facilitate the digestion and absorption of lipids. The liver is responsible for metabolic regulation, hematological regulation, and bile production. It is the primary organ involved with regulating the composition of circulating blood.

16. enterocrinin, which stimulates the submucosal glands of the duodenum; secretin, which stimulates the pancreas and liver to increase the secretion of water and buffers; cholecystokinin (CCK), which causes an increase in the release of pancreatic secretions and bile into the duodenum, inhibits gastric activity, and appears to have CNS effects that reduce the sensation of hunger; gastric inhibitory peptide (GIP), which stimulates insulin release at pancreatic islets and the activity of the duodenal submucosal glands; vasoactive intestinal peptide (VIP), which stimulates the secretion of intestinal glands, dilates regional capillaries, and inhibits acid production in the stomach; gastrin, which is secreted by G

cells in the duodenum when they are exposed to large quantities of incompletely digested proteins; and, in small quantities, motilin, which stimulates intestinal contractions, villikinin, which promotes the movement of villi and associated lymph flow, and somatostatin, which inhibits gastric secretion

17. (1) resorption of water and compaction of the intestinal contents into feces; (2) absorption of important vitamins liberated by bacterial action; and (3) storage of fecal material prior to defecation

18. (1) Stretch receptors in the rectal walls promote a series of peristaltic contractions in the colon and rectum, moving feces toward the anus; and (2) the sacral parasympathetic system, also activated by the stretch receptors, stimulates peristalsis via motor commands distributed by the pelvic nerves.

Level 2 Reviewing Concepts

19. d 20. e 21. a

22. through the enamel and the dentin

23. The stomach is protected by mucous secretions of its epithelial lining and by neural and hormonal control over the times and rates of acid secretion.

24. (1) The cephalic phase begins with the sight or thought of food. Directed by the CNS, this phase prepares the stomach to receive food.

(2) The gastric phase begins with the arrival of food in the stomach; this phase is initiated by distension of the stomach, an increase in the pH of the gastric contents, and the presence of undigested materials in the stomach. (3) The intestinal phase begins when chyme starts to enter the small intestine. This phase controls the rate of gastric emptying and ensures that the secretory, digestive, and absorptive functions of the small intestine can proceed at reasonable efficiency.

25. After a heavy meal, bicarbonate ions pass from the parietal cells of the stomach into the extracellular fluid, causing the pH of the extracellular fluid to rise. As the extracellular fluid exchanges ions with the blood, the blood pH also increases.

Level 3 Critical Thinking and Clinical Applications

26. If a gallstone is small enough, it can pass through the common bile duct and block the pancreatic duct. Enzymes from the pancreas then cannot reach the small intestine. As they accumulate, the enzymes irritate the duct and ultimately the exocrine pancreas, producing pancreatitis.

27. The darker color of his urine is probably due to increased amounts of the pigment urobilin which gives the normal yellow color to urine. Urobilin is derived from urobilinogen, which is formed in the large intestine by the action of intestinal bacteria on bile pigments. In an intestinal obstruction, the bile pigments cannot be eliminated by their normal route, so a larger than normal amount diffuses into the blood where it is eliminated by the kidneys.

28. If an individual cannot digest lactose, then the sugar will pass through to the large intestine in an undigested form. The presence of the extra sugar in the chyme increases the osmolarity of the chyme, resulting in less water being reabsorbed by the intestinal mucosa. The bacteria that inhabit the large intestine can metabolize the lactose and in the process they produce large amounts of carbon dioxide. The gas overstretches the intestine, which stimulates local reflexes that increase peristalsis. The combination of more fluid contents and increased peristalsis produces the symptom of diarrhea. The overexpansion of the intestine by gas causes the severe pain and abdominal cramping, and of course, the increase in intestinal gas release is directly related to increased gas production by the bacteria.

29. The primary impact would be a reduction in the volume consumed because the person feels full after eating a small amount. This can result in significant weight loss.

Chapter 25

Page 926

1. The primary role of the TCA cycle in ATP production is to transfer electrons from substrates to coenzymes. These electrons carry energy that can then be used as an energy source for the production of ATP by the electron transport system.

2. The NADH produced by glycolysis cannot enter the mitochondria, where the enzymes of the electron transport chain are located. An intermediary in the mitochondrial membrane can, however, transfer the electrons from the NADH to a coenzyme within the mitochondria. In skeletal muscle cells, the intermediary transfers the electrons to FAD, whereas in cardiac muscle cells, a different intermediary is used that transfers the electrons to another NAD. In mitochondria, each NADH yields 3 molecules of ATP, whereas each FADH2 yields just 2 molecules
of ATP. The different intermediaries account for the difference in ATP yield.

3. A decrease in the level of cytoplasmic NAD would lead to a decrease in the amount of ATP production in mitochondria. The mitochondria depend on a supply of pyruvic acid from glycolysis. Glycolysis, in turn, requires NAD. A decrease in NAD would decrease the available pyruvic acid for the TCA cycle and thus would decrease overall ATP production.

Page 933

1. Pyridoxine (vitamin B6) is an important coenzyme in deamination and transamination, the first steps in processing amino acids in the cell. A diet deficient in this vitamin would interfere with the ability to metabolize proteins.

2. Uric acid is the product of purine degradation in the body. The macromolecules that contain purines are the nucleic acids. Elevated levels of uric acid can indicate increased breakdown of nucleic acids.

3. High-density lipoproteins are considered to be beneficial because they reduce the amount of fat (including cholesterol) in the bloodstream by transporting fat back to the liver for storage or excretion in the bile.

Page 935

1. After you have eaten a high-carbohydrate meal, you would expect increased glycogenesis (the formation of glycogen) to occur in the liver.

2. Urea is formed from by-products of protein metabolism. During the postabsorptive state, many amino acids are being metabolized and the ammonia produced by deamination is converted to urea in the liver. Thus, the amount of urea in the blood increases.

3. Excess acetyl-CoA is likely converted into ketone bodies.

Page 940

1. An athlete in extensive training—adding muscle mass—would try to maintain a positive nitrogen balance.

2. Bile salts are necessary for the digestion and absorption of fats and fat-soluble vitamins. Vitamin A is a fat-soluble vitamin. A decrease in the amount of bile salts in the bile would result in a decreased ability to absorb vitamin A from food and over time could result in symptoms of a vitamin A deficiency.

Page 946

1. The BMR of a pregnant woman would be higher than her own BMR when she is not pregnant, due to the increased metabolism associated with support of the fetus as well as the added effect of fetal metabolism.

2. The vasoconstriction of peripheral vessels would decrease both blood flow to the skin and the amount of heat that the body can lose. As a result, the body temperature would increase.

3. Infants have higher surface-to-volume ratios than do adults, and the temperature-regulating mechanisms of the body are not fully functional at birth. As a result, infants must expend more energy to maintain body temperature, and they get cold more easily than do healthy adults.

Page 949 *Level 1 Reviewing Facts and Terms*

1. d 2. a 3. d 4. a 5. b 6. c 7. d 8. b 9. c

10. a

11. Metabolism is all of the chemical reactions occurring in the cells of the body. Anabolism is those chemical reactions that result in the synthesis of complex molecules from simpler reactants; products of anabolism are used for maintenance/repair, growth, and secretion. Catabolism is the breakdown of complex molecules into their building block molecules, resulting in the release of energy for the synthesis of ATP and related molecules.

12. $C_6H_{12}O_6 + 6 O_2$ ¡ $6 CO_2 + 6 H_2O$

13. Lipoproteins are lipid–protein complexes that contain large insoluble glycerides and cholesterol, with a superficial coating of phospholipids and proteins. The major groups are chylomicrons, which consist of 95 percent triglyceride, are the largest lipoproteins, and carry absorbed lipids from the intestinal tract to the bloodstream; very low-density lipoproteins (VLDLs), which consist of triglyceride, phospholipid, and cholesterol and transport triglycerides to peripheral tissues; intermediate-density lipoproteins (IDLs), which are intermediate in size and composition between VLDLs and LDLs; low-density lipoproteins (LDLs, or "bad cholesterols"), which are mostly cholesterol and deliver cholesterol to peripheral tissues; and high-density lipoproteins (HDLs, or "good cholesterols"), which are equal parts protein and lipid (cholesterol and phospholipids) and transport excess cholesterol back to the liver for storage or excretion in bile.

Level 2 Reviewing Concepts

14. b

15. Oxidative phosphorylation is the generation of ATP within mitochondria, through a reaction sequence that requires coenzymes and consumes oxygen. The electron transport system consists of a sequence of metalloproteins called cytochromes, which pass electrons (from H atoms) along in small steps, gradually releasing energy for the formation of ATP and producing water as a by-product.

16. A triglyceride is hydrolyzed, yielding glycerol and fatty acids. Glycerol is converted to pyruvic acid and enters the TCA cycle. Fatty acids are broken into two-carbon fragments

by beta-oxidation inside mitochondria. The two-carbon compounds then enter the TCA cycle.

17. The primary hormone of the absorptive state is insulin, which prevents a large surge in blood glucose after a meal. Insulin causes the liver to remove glucose from the hepatic portal circulation. During the postabsorptive state, blood glucose begins to decline, triggering the liver to release glucose via glycogenolysis and gluconeogenesis.

18. Liver cells can break down or synthesize most carbohydrates, lipids, and amino acids. The liver has an extensive blood supply and thus can easily monitor blood composition of these nutrients and regulate accordingly. The liver also stores energy in the form of glycogen.

19. The food pyramid indicates how much of each food group an individual should consume per day to ensure adequate intake of nutrients and calories. The placement of fats, oils, and sugars at the top of the food pyramid indicates that such foods are to be consumed very sparingly, whereas carbohydrates, placed at the bottom of the pyramid, are to be consumed in largest relative quantities.

20. The body cannot synthesize most of its required vitamins and minerals.

21. These terms refer to the high-density lipoproteins (HDL) and low-density lipoproteins (LDL), lipoproteins in the blood that transport cholesterol. HDL (“good cholesterol”) transports excess cholesterol to the liver for storage or breakdown, whereas LDL (“bad cholesterol”) transports cholesterol to peripheral tissues, which unfortunately may include the arteries. The buildup of cholesterol in the arteries is linked to cardiovascular disease.

Level 3 Critical Thinking and Clinical Applications

22. c

23. Based just on the information given, Charlie would appear to be in good health, at least relative to his diet and probably exercise. Problems are associated with elevated levels of LDLs, which carry cholesterol to peripheral tissues and make it available for the formation of atherosclerotic plaques in blood vessels. High levels of HDLs indicate that a considerable amount of cholesterol is being removed from the peripheral tissues and carried

to the liver for disposal. You would encourage Charlie not to change, and keep up the good work.

24. It appears that Jill is suffering from ketoacidosis as a consequence of her anorexia. Because she is literally starving herself, her body is metabolizing large amounts of fatty acids and amino acids to provide energy and in the process is producing large quantities of ketone bodies (normal metabolites from these catabolic processes). One of the ketones that is formed is acetone, which can be eliminated through the lungs. This accounts for the smell of aromatic hydrocarbons on Jill’s breath. The ketones are also converted into keto acids such as acetic acid. In large amounts this lowers the body’s pH and begins to exhaust the alkaline reserves of the buffer system. This is probably the cause of her arrhythmias.

Chapter 26

Page 961

1. The renal corpuscle, proximal convoluted tubule, distal convoluted tubule, and the proximal portions of the loop of Henle and collecting duct are all in the renal cortex. (In cortical nephrons most of the loops of Henle are in the cortex; in juxtamedullary nephrons, most of the loops of Henle are in the medulla.)
2. The pores of the glomerular capillaries will not allow substances the size of plasma proteins to pass into the capsular space, but the filtration slits of the podocyte will allow only the smallest plasma proteins to pass.
3. Damage to the juxtaglomerular apparatus of the nephron would interfere with the hormonal control of blood pressure.

Page 970

1. The primary components involved in filtration are the glomerular capillaries, the lamina densa, and the filtration slits of the podocytes.
2. When the plasma concentration of a substance exceeds its tubular maximum, the excess is not reabsorbed but is excreted in urine.

3. A decrease in blood pressure would reduce the blood hydrostatic pressure within the glomerulus and hence decrease the GFR.

Page 982

1. Aldosterone promotes Na^+ retention and K^+ secretion at the kidneys. In response to increased amounts of aldosterone, the K^+ concentration of urine would increase.

2. The secretion of H^+ by the nephron involves a countertransport mechanism with Na^+. If the concentration of Na^+ in the filtrate decreased, fewer hydrogen ions could be secreted. The result would be a tubular fluid with a higher pH.

3. With no juxtamedullary nephrons, there would not be a large osmotic gradient in the medulla. The kidneys would not be able to form concentrated urine.

4. When the amount of Na^+ in the tubular fluid passing through the distal convoluted tubule decreases, the cells of the macula densa are stimulated to release renin. Renin activates angiotensin, and this activation brings about an increase in blood pressure.

Page 987

1. Urea, a nitrogenous waste, is formed during the metabolism of amino acids, which are obtained by the breakdown of proteins. Thus, a high-protein diet would lead to increased urea production and an increased amount of urea in the urine. Fluid volume might also increase as a result of the need to flush the excess urea.

2. An obstruction of a ureter would interfere with the passage of urine between the renal pelvis and the urinary bladder.

3. To control the micturition reflex, you must be able to control the external urinary sphincter, a ring of skeletal muscle formed by the urogenital diaphragm, that acts as a valve.

Page 992 *Level 1 Reviewing Facts and Terms*

a 2. e 3. c 4. d 5. d

6. The urinary system performs vital excretory functions and eliminates the organic waste products generated by cells throughout the body. It also regulates the volume and solute concentration of body fluids.

7. the kidneys, ureters, urinary bladder, and urethra

8. renal corpuscle (glomerulus/Bowman’s capsule) : proximal convoluted tubule : loop of Henle : distal convoluted tubule : collecting duct : papillary duct : renal pelvis

9. proximal convoluted tubule: reabsorbs all the useful organic substrates from the filtrate; loop of Henle: reabsorbs over 90 percent of the water in the filtrate; and distal convoluted tubule: secretes into the filtrate waste products that were missed by filtration

10. The juxtaglomerular apparatus secretes the enzyme renin and the hormone erythropoietin.

11. renal artery : segmental arteries : interlobar arteries : arcuate arteries : interlobular arteries : afferent arterioles : nephrons : interlobular veins : arcuate veins : interlobar veins : renal vein

12. (1) filtration: the selective removal of large solutes and suspended materials from a solution on the basis of size; requires a filtration membrane and hydrostatic pressure, as provided by gravity or by blood pressure; (2) reabsorption: the removal of water and solute molecules from the filtrate after it enters the renal tubules; and (3) secretion: the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid

13. In peripheral capillary beds, angiotensin II causes powerful vasoconstriction of precapillary sphinchters, elevating pressures in the renal arteries and their tributaries. At the nephron, angiotensin II causes the efferent arteriole to constrict, elevating glomerular pressures and filtration rates. At the PCT, it stimulates the reabsorption of sodium ions and water. In the CNS, angiotensin II triggers the release of ADH, stimulating the reabsorption of water in the distal portion of the DCT and the collecting system, and it causes the sensation of thirst. At the adrenal gland, angiotensin II stimulates the secretion of aldosterone by the cortex and epinephrine by the medulla oblongata. The aldosterone accelerates sodium reabsorption in the DCT and the cortical portion of the collection

system. Epinephrine causes the heart rate and force of contraction to increase, elevating renal blood pressure.

14. ureters, urinary bladder, and urethra

Level 2 Reviewing Concepts

15. d 16. d 17. c 18. a 19. a

20. Proteins are too large to fit through the slit pores. Maintaining proteins in the plasma ensures the blood colloid osmotic pressure will oppose filtration and return water to the plasma.

21. autoregulation at the local level; hormonal regulation initiated by the kidneys; and autonomic regulation (sympathetic division of the ANS)

22. As a result of facilitated diffusion and cotransport mechanisms, 99 percent of the glucose, amino acids, and other nutrients are reabsorbed before the filtrate leaves the PCT. A reduction of the solute concentration of the tubular fluid occurs due to active ion reabsorption of sodium, potassium, calcium, magnesium bicarbonate, phosphate, and sulfate ions. The passive diffusion of urea, chloride ions, and lipid-soluble materials further reduces the solute concentration of the tubular fluid and promotes additional water reabsorption.

23. (1) It is an efficient way to reabsorb solutes and water before the tubular fluid reaches the DCT and collecting system; and (2) it establishes a concentration gradient that will permit the passive reabsorption of water from urine in the collecting system.

24. The urge to urinate usually appears when the urinary bladder contains about 200 ml of urine. The micturition reflex begins to function when the stretch receptors have provided adequate stimulation to the parasympathetic motor neurons. The activity in the motor neurons generates action potentials that reach the smooth muscle in the wall of the urinary bladder. These efferent impulses travel over the pelvic nerves, producing a sustained contraction of the urinary bladder.

Level 3 Critical Thinking and Clinical Applications

25. d 26. c

27. Increasing the volume of urine produced would decrease the total blood volume of the body. This in turn would lead to a decreased blood hydrostatic pressure. Edema is frequently the result of hydrostatic pressure of the blood exceeding the opposing forces at the capillaries in the affected area. Depending on the actual cause of the edema, decreasing the blood hydrostatic pressure would decrease edema formation and possibly cause some of the fluid to move from the interstitial spaces back to the blood.

28. Renal hypertension restricts blood flow to the kidneys and produces renal ischemia. Decreased blood flow and ischemia triggers the juxtaglomerular apparatus to produce more rennin, which leads to elevated levels of angiotensin II and aldosterone. Angiotensin II causes vasoconstriction, increased peripheral resistance and thus increased blood pressure. The aldosterone promotes sodium retention. This leads to more water retained by the body and an increase in blood volume. This too contributes to a higher blood pressure. Another factor to consider is the release of more erythropoietin in response to tissue hypoxia. The erythropoietin stimulates the formation of red blood cells, which leads to increased blood viscosity and again contributes to the hypertenion.

29. Because mannitol is filtered but not reabsorbed, drinking a mannitol solution would lead to an increase in the osmolarity of the filtrate. Less water would be reabsorbed, and an increased volume of urine would be produced.

30. Carbonic anhydrase catalyzes the reaction that forms carbonic acid, a source of hydrogen ions that are excreted by the kidneys. Hydrogen ion excretion is accomplished by an antiport system in which sodium ions are exchanged for hydrogen ions. Fewer hydrogen ions would be available, so less sodium would be reabsorbed, contributing to an increased osmolarity of the filtrate. In turn, an increased volume of urine and more-frequent urination would result.

Chapter 27

Page 1002

1. Drinking a pitcher of distilled water would temporarily lower your blood osmolarity (osmotic concentration). Because ADH release is triggered by increases in osmolarity, a decrease in osmolarity would lead to a decrease in the level of ADH in your blood.

2. Being in the desert without water, you would lose fluid through perspiration, urine formation, and respiration. As a result, the osmotic concentration of your plasma (and other body fluids) would increase.

Page 1007

1. Sweat is a hypotonic solution with lower sodium concentration than the ECF. Sweating causes a greater loss of water than sodium, increasing plasma sodium ion levels.

2. Disturbances in sodium balance are followed by dehydration or edema of tissues. Potassium ion imbalances, on the other hand, can lead to extensive muscle weakness or even paralysis when plasma concentrations are too low, and cardiac arrhythmias when the levels are too high. Potassium ion imblances are therefore more dangerous than sodium ion imbalances.

Page 1019

A decrease in the pH of body fluids would stimulate the respiratory centers of the medulla oblongata. The result would be an increase in the respiratory rate.

-

2. The kidney tubules modify the pH of the filtrate by secreting H^+ or reabsorbing HCO3 . The pH of the tubular fluid must be kept above

about 4.5, because H^+ secretion cannot continue against a large concentration gradient. The buffers allow the filtrate to take more without decreasing the pH below the critical level.

3. In a prolonged fast, fatty acids are mobilized and large numbers of ketone bodies are formed. These molecules are acids that lower the body’s pH. (The lowered pH would eventually lead to ketoacidosis.)

4. In vomiting, large amounts of stomach acid are lost from the body. This acid is formed by the parietal cells of the stomach by taking H^+

from blood. Prolonged vomiting would lead to the excessive removal of H^+ from the blood to produce the acid, thus raising the body's pH and leading to metabolic alkalosis.

Page 1024 *Level 1 Reviewing Facts and Terms*

9. (1) antidiuretic hormone (ADH): stimulates water conservation at the kidneys and stimulates the thirst center; (2) aldosterone: determines the rate of sodium reabsorption and potassium secretion along the DCT and collecting system of the kidney; and (3) and (4) thenatriuretic peptides, ANP and BNP; reduce thirst and blocks the release of ADH and aldosterone

Level 2 Reviewing Concepts

10. d 11. a 12. d 13. c

14. Fluid balance is a state in which the amount of water gained each day is equal to the amount lost to the environment. It is vital that the water content of the body remain stable, because water is an essential ingredient of cytoplasm and accounts for about 99 percent of the volume of extracellular fluid. Electrolyte balance exists when there is neither a net gain nor a net loss of any ion in body fluids. It is important that the ionic concentrations in body water remain within normal limits; if levels of calcium or potassium become too high, for instance, cardiac arrhythmias can develop. Acid–base balance exists when the production of hydrogen ions precisely offsets their loss. The pH of body fluids must remain within a relatively narrow range; variations outside this range can be life threatening.

15. Fluid shifts are rapid water movements between the ECF and the ICF, reaching equilibrium in a matter of minutes. They occur in response to osmotic changes in the ECF. They are caused by increasing or decreasing osmotic concentration of the ECF.

16. The temperature rise accompanying a fever can increase water losses. For each degree the temperature rises above normal, the daily water loss increases by 200 ml.

17. **(a)** A volatile acid is an acid that can leave solution and enter the atmosphere, such as carbonic acid. **(b)** Sulfuric acid is an example of a fixed acid. These are acids that do not leave solution. **(c)** Aerobic metabolism produces organic acids, such as lactic acid.

18. (1) protein buffer systems: These depend on the ability of amino acids to respond to changes in pH by accepting or releasing hydrogen

ions. If the pH rises, the carboxyl group of the amino acid dissociates to release a hydrogen ion. If the pH drops, the amino group accepts an additional hydrogen ion to form an NH4$^+$ group. The plasma proteins contribute to the buffering capabilities of the blood; inside cells, protein buffer systems stabilize the pH of the ECF by absorbing extracellular hydrogen ions or exchanging intracellular hydrogen ions for extracellular potassium. (2) carbonic acid–bicarbonate system: Most carbon dioxide generated in tissues is converted to carbonic acid, which dissociates into a hydrogen ion and a bicarbonate ion. Hydrogen ions released by dissociation of organic or fixed acids combine with bicarbonate ions, elevating the PCO_2 ; additional CO2 is lost at the lungs. (3) phosphate buffer systems: This buffer system consists of H2PO4 , a weak acid

2

that, in solution, reversibly dissociates into a hydrogen ion and HPO4 . The phosphate buffer system plays a relatively small role in regulating the pH of the ECF, because the ECF contains far higher concentrations of bicarbonate ions than phosphate ions; however, it is important in buffering the pH of the ICF.

19. Respiratory and renal mechanisms support buffer systems by secreting or absorbing hydrogen ions, controlling the excretion of acids and bases, and generating additional buffers.

20. Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Increasing or decreasing the rate of respiration alters pH by lowering or raising the PCO_2 .

When the PCO_2 goes down, the pH rises; when the PCO_2 increases, the pH decreases. Renal compensation is a change in the rates of hydrogen and bicarbonate ion secretion or reabsorption in response to changes in plasma pH. Tubular hydrogen ion secretion results in the diffusion of bicarbonate ions into the ECF.

21. Respiratory disorders result from abnormal carbon dioxide levels in the ECF. An imbalance exists between the rate of CO2 removal at the lungs and its generation in other tissues. Metabolic disorders are caused by the generation of organic or fixed acids or by conditions affecting the concentration of bicarbonate ions in the ECF.

22. Acidosis is a decline in the pH of body fluids. Respiratory acidosis (hypercapnia) results from an abnormally high level of carbon dioxide,

usually caused by hypoventilation. Metabolic acidosis occurs when bicarbonate ion levels fall, reducing the effectiveness of this buffer system. It can result from over-production of fixed or organic acids, impaired ability to secrete H^+ ions at the kidney, or during severe bicarbonate loss.

23. **(a)** Excessive salt and water intake causes an increase in total blood volume and blood pressure. Increased blood pressure results in decreased ADH secretion and reduced renin secretion from the kidneys. Decreased renin results in a decreased production of angiotensin II, which reduces the rate at which aldosterone is secreted. Increased sodium ions and increased blood pressure cause the secretion of natriuretic peptides, inhibiting ADH secretion and sodium ion reabsorption in the DCT. These changes cause increased loss of sodium in the urine and an increase in the volume of urine produced. **(b)** If the amount of salt ingested is excessive, the urine volume will rise and the concentration of salt in the urine will be high. If the amount of water is excessive, the urine volume will increase and the concentration of sodium ions in the urine will decrease. **(c)** If the amount of salt and water ingested in food exceeds the amount needed to maintain a constant ECF composition, the total blood volume and the blood pressure will increase.

24. Since sweat is usually hypotonic, the loss of a large volume of sweat causes hypertonicity in body fluids. The loss of fluid volume is primarily from the interstitial space, which leads to a reduction in plasma volume and an increase in the hematocrit. Severe dehydration can cause the blood viscosity to increase substantially, resulting in an increased work load on the heart, ultimately increasing the probability of heart failure.

Level 3 Critical Thinking and Clinical Applications

25. The young boy has metabolic and respiratory acidosis. Sustained hypoventilation during drowning leads to decreased arterial and oxy-gen-starved tissues generate large quantities of lactic acid. Prompt emergency treatment is essential; the usual procedure involves some form of artificial or mechanical respiratory assistance coupled with the intravenous infusion of an isotonic solution containing sodium lactate, sodium gluconate, or sodium bicarbonate.

26. a

27. When tissues are burned, cells are destroyed and the contents of their cytoplasm leak into the interstitial fluid and then move into the plasma. Since potassium ions are normally found within the cell, damage to a large number of cells would release relatively large amounts of potassium ions into the blood. The elevated potassium level would stimulate the cells of the adrenal cortex to produce aldosterone and the cells of the juxtaglomerular apparatus to produce rennin. The rennin would activate the angiotensin mechanism. Ultimately angiotensin II would stimulate more aldosterone secretion. The elevated levels of aldosterone would promote sodium retention and potassium secretion by the kidneys, thus accounting for the elevated levels of potassium in the patient’s urine.

28. Digestive secretions contain high levels of bicarbonate, so persons with diarrhea can lose significant amounts of this important ion, leading to acidosis. We would expect Milly’s blood pH to be lower than 7.4 and the pH of her urine to be low (due to increased renal excretion of hydrogen ion). We would also expect an increase in the rate and depth of breathing as the respiratory system tries to compensate by eliminating carbon dioxide.

29. The hypertonic solution will cause fluid to move from the ICF to the ECF, further aggravating Yuka’s dehydration. The slight increase in pressure and osmolarity of the blood should lead to an increase in ADH, although ADH levels are probably quite high already. Urine volume would probably increase, because much of the glucose would not be reabsorbed. The osmolarity of the tubular filtrate would increase, decreasing water reabsorption and increasing urine volume.

30. Patient 1 has compensated respiratory alkalosis. Patient 2 has acute metabolic acidosis due to generation or retention of organic or fixed acids. Patient 3 has acute respiratory acidosis. Patient 4 has metabolic alkalosis.

Chapter 28

Page 1046

1. On a warm day, the cremaster muscle (as well as the dartos muscle) would be relaxed so that the scrotal sac could descend away from the warmth of the body and cool the testes.
2. The dilation of the arteries within the penis allows blood flow to increase and the vascular chambers to become engorged with blood, resulting in erection.
3. FSH is required for the production of ABP, a protein that binds testosterone and keeps a high level of that hormone available to support spermatogenesis. Low levels of FSH would lead to low levels of testosterone in the seminiferous tubules and thus a lower rate of sperm production and a low sperm count.

Page 1061

1. The blockage of both uterine tubes would cause sterility.
2. The acidic pH of the vagina helps prevent bacterial, fungal, and parasitic infections in this area.
3. The functional layer of the endometrium sloughs off during menstruation.
4. The blockage of a single lactiferous sinus would not interfere with the delivery of milk to the nipple, because each breast generally has 15–20 lactiferous sinuses.

Page 1065

1. If the LH surge did not occur during an ovarian cycle, ovulation and corpus luteum formation would not occur.

2. Progesterone is responsible for the functional maturation and secretion of the endometrium. A blockage of progesterone receptors would inhibit the development of the endometrium (and would make the uterus unprepared for pregnancy).

3. A decline in the levels of estrogens and progesterone signals the beginning of the menses, the end of the uterine cycle.

Page 1067

1. An inability to contract the ischiocavernosus and bulbospongiosus muscles would interfere with a male's ability to ejaculate and to experience orgasm.

2. As the result of parasympathetic stimulation in females during sexual arousal, the erectile tissues of the clitoris engorge with blood, the secretion of cervical and vaginal glands increases, blood flow to the walls of the vagina increases, and the blood vessels in the nipples engorge.

3. At menopause, circulating estrogen levels begin to drop. Estrogen has an inhibitory effect on FSH (and on GnRH). As the level of estrogen declines, the levels of FSH rise and remain high.

Page 1072 *Level 1 Reviewing Facts and Terms*

c 2. d 3. c 4. b 5. a

6. seminiferous tubules : rete testis : efferent ducts : epididymis : ductus deferens : ejaculatory duct : urethra

7. The accessory organs/glands include the seminal vesicles, prostate gland, and the bulbourethral glands. The major functions of these glands are activating the spermatozoa, providing the nutrients sperm need for motility, propelling sperm and fluids along the reproductive tract, and producing buffers that counteract the acidity of the urethral and vaginal contents.

8. interstitial cells (cells of Leydig): produce male sex hormones (androgens), the most important one being testosterone; sustentacular cells: maintain the blood–testis barrier,

support spermatogenesis and spermiogenesis, and secrete inhibin, androgen-binding protein, and Müller-ian-inhibiting factor

9. (1) prostatic urethra; (2) membranous urethra; and (3) spongy urethra

10. stimulating spermatogenesis and promoting the functional maturation of spermatozoa; maintaining the male accessory reproductive organs; determining male secondary sex characteristics; stimulating metabolic operations, especially those concerned with protein synthesis and muscle growth; and influencing brain development by stimulating sexual behaviors and sexual drive

11. (1) the formation of primary follicles; (2) the formation of secondary follicles; (3) the formation of a tertiary follicle; (4) ovulation; and

(5) the formation and degeneration of the corpus luteum

12. The myometrium is the outer muscular layer; the endometrium is the inner glandular layer; and the perimetrium is an incomplete serosal layer.

13. The clitoris is a structural component of the external genitalia of the female. It is the female equivalent of the penis; they are derived from the same embryonic structures. Internally, the clitoris contains erectile tissue comparable to the corpus spongiosum of the penis. The clitoris becomes engorged with blood during sexual arousal and provides pleasurable sensations.

14. secretory lobules of glandular tissue (lobes) : ducts : lactiferous duct : lactiferous sinus : open onto the surface of each nipple

Level 2 Reviewing Concepts

15. c 16. e

17. Males produce gametes from puberty until death; females produce gametes only from menarche to menopause. Males produce many gametes at a time, females produce one to two per 28-day cycle. Males release mature gametes that have completed meiosis; females release secondary oocytes held in metaphase of meiosis II.

18. The corpora cavernosa extend along the length of the penis as far as the neck of the penis, and the erectile tissue within each corpus cavernosum surrounds a central artery. The slender corpus spongiosum surrounds the urethra. This erectile body extends from the superficial fascia of the urogenital diaphragm to the tip of the penis, where it expands to form the glans. The sheath surrounding the corpus spongiosum contains more elastic fibers than do the corpora cavernosa, and the erectile tissue contains a pair of arteries. Erection occurs when the parasympathetic neurons of the penile arteries release nitric oxide, causing the smooth muscles in the arterial walls to relax. The vessels dilate, blood flow increases, the vascular channels become engorged with blood, and erection of the penis occurs.

19. (1) menses: the interval marked by the degeneration and loss of the functional zone of the endometrium; lasts from 1–7 days, and 35–50 ml of blood is lost; (2) proliferative phase: growth and vascularization result in the complete restoration of the functional zone; lasts from the end of menses until the beginning of ovulation, around day 14; (3) secretory phase: the endometrial glands enlarge, accelerating their rates of secretion and the arteries elongate and spiral through the tissues of the functional zone; occurs under the combined stimulatory effects of progestins and estrogens from the corpus luteum; begins at ovulation and persists as long as the corpus luteum remains intact

20. As follicular development proceeds, the concentration of circulating estrogen rises. Secondary follicles contain increased numbers of granulosa cells, and the level of circulating inhibin rises. The rising estrogen and inhibin levels inhibit hypothalamic secretion of GnRH and pituitary production and release of FSH. As the follicles develop and estrogen levels rise, the pituitary output of LH gradually increases. Estrogens, FSH, and LH continue to support follicular development and maturation despite a gradual decline in FSH levels. In the second week of the ovarian cycle, estrogen levels sharply increase—and the tertiary follicle enlarges in preparation for ovulation. By day 14, estrogen levels peak, triggering a massive outpouring of LH from the anterior pituitary. The rupture of the follicular wall results in ovulation. Next, LH stimulates the formation of the corpus luteum, which secretes moderate amounts of estrogens but large amounts of progesterone, the principal hormone of the postovulatory period. About 12 days after ovulation, declining

progesterone and estrogen levels stimulate hypothalamic receptors and GnRH production increases, leading to increased FSH and LH production in the anterior pituitary; the cycle begins again.

21. The corpus luteum degenerates and progesterone and estrogen levels drop, resulting in the endometrial breakdown of menses. Next, rising levels of FSH, LH, and estrogen stimulate the repair and regeneration of the functional zone of the endometrium. During the postovulatory phase, the combination of estrogen and progesterone cause the enlargement of the endometrial glands and an increase in their secretory activity.

22. During sexual arousal, erotic thoughts or physical stimulation of sensory nerves in the genital region increases the parasympathetic outflow over the pelvic nerve, leading to erection of the clitoris or penis. Orgasm is the intensely pleasurable sensation associated with perineal muscle contraction and ejaculation in males, and with uterine and vaginal contractions and perineal muscle contraction in females. These processes are comparable in males and females.

23. Women age 45–55 undergo menopause, the time that ovulation and menstruation cease, accompanied by a sharp and sustained rise in the production of GnRH, FSH, and LH and a drop in the concentrations of circulating estrogen and progesterone. The decline in estrogen levels leads to reductions in the size of the uterus and breasts, accompanied by a thinning of the urethral and vaginal walls. In addition to neural and cardiovascular effects, reduced estrogen concentrations have been linked to the development of osteoporosis, presumably because bone deposition proceeds at a slower rate. Men age 50 -60+ undergo the male climacteric, a time when circulating testosterone levels begin to decline and circulating levels of FSH and LH rise. Although sperm production continues, there is a gradual reduction in sexual activity in older men.

Level 3 Critical Thinking and Clinical Applications

24. There is no direct entry into the abdominopelvic cavity in males as there is in females. In females, the urethral opening is in close proximity to the vaginal orifice, so infectious organisms can exit from the urethral orifice and enter the vagina. They can then proceed

through the vagina to the uterus, into the uterine tubes, and finally into the peritoneal cavity.

25. The endometrial cells have receptors for the hormones estrogen and progesterone and respond to these hormones the same as they would if they were in the body of the uterus. Under the influence of estrogen, they proliferate at the beginning of the menstrual cycle and begin to develop glands and blood vessels, which then further develop under the control of progesterone. This dramatic change in tissue size and characteristics interferes with neighboring tissues by pressing on them or interrupting function in other ways. It is this interference that causes the periodic painful sensations.

26. Slightly elevated levels of estradiol and progesterone inhibit both GnRH at the hypothalamus and the release of FSH and LH from the pituitary. Without FSH primordial follicles do not initiate development and the endogenous levels of estrogen remain low. An LH surge is necessary for ovulation to occur and the LH surge is triggered by the peaking of estradiol. If the level of estradiol is not allowed to rise above the critical level, the LH surge will not occur and ovulation will no occur, even if a follicle managed to develop to a stage that it could ovulate. Any mature follicles would ultimately degenerate and no new follicles would mature to take their place. Although the ovarian cycle is interrupted, the level of hormones is still adequate to regulate a normal menstrual cycle.

27. It suggests that a certain amount of body fat is necessary for menstrual cycles to occur. The nervous system appears to respond to circulating levels of the hormone leptin; when leptin levels fall below a certain set point, menstruation ceases. Without proper fat reserves, a woman might not be able to have a successful pregnancy. To avoid harm to the mother and the death of a fetus, the body prevents pregnancy by shutting down the ovarian cycle and, thus, the menstrual cycle. When appropriate energy reserves are available, the cycles begin again.

Chapter 29

Page 1088

1. The inner cell mass of the blastocyst eventually develops into the embryo.

2. Cells of the mesoderm migrate to form the yolk sac, in which blood vessels appear. The yolk sac becomes an important site of blood cell formation. Improper development of this extraembryonic membrane would thus affect the development and function of the cardiovascular system.

3. After fertilization, the developing trophoblasts and, later, the placenta produce and release the hormone hCG. Sue is pregnant.

4. Placental functions include (1) supplying the developing fetus with a route for gas exchange, nutrient transfer, and waste product elimination; and (2) producing hormones that affect maternal systems.

Page 1098

1. During pregnancy, blood flow through the placenta reduces the volume of blood in the mother's systemic circuit. This reduction stimulates an increase in maternal blood volume to compensate.

2. Progesterone reduces uterine contractions. A decrease in progesterone at any time during the pregnancy could lead to uterine contractions and, in late pregnancy, labor.

3. An increase in the levels of GnRH, FSH, LH, and sex hormones in blood mark the onset of puberty.

Page 1104

1. A person who is heterozygous for curly hair would have one dominant allele and one recessive allele for that trait. The person's phenotype would be "curly hair."

2. One reason that children are not identical copies of their parents is that during meiosis, parental chromosomes are randomly distributed such that each gamete has a unique set of chromosomes. Also, mutations and the crossing-over that occurs during meiosis introduce new variations.

Page 1108 *Level 1 Reviewing Facts and Terms*

d 2. c 3. b 4. b 5. a 6. b 7. b

8. When a sperm contacts the secondary oocyte, their cell membranes fuse. The oocyte is then activated: Its metabolic rate rises; it completes meiosis II; and a cortical reaction occurs that prevents additional sperm from entering. (Vesicles beneath the oocyte surface fuse with the cell membrane and discharge their contents.) The male and female pronuclei fuse (amphimixis), and the zygote begins preparing for the first cleavage division.

9. **(a)** (1) yolk sac; (2) amnion; (3) allantois; and (4) chorion **(b)** The yolk sac forms from endoderm and mesoderm; it is an important site of blood cell formation. The amnion forms from ectoderm and mesoderm; it encloses the fluid that surrounds and cushions the developing embryo and fetus. The allantois forms from endoderm and mesoderm; its base gives rise to the urinary bladder. The chorion forms from mesoderm and trophoblast; circulation through chorionic vessels provides a “rapid transit system” for blood and nutrients.

10. (1) dilation stage: It begins with the onset of true labor, as the cervix dilates and the fetus begins to move toward the cervical canal; late in this stage, the amniochorionic membrane ruptures. (2) expulsion stage: It begins as the cervix dilates completely and continues until the fetus has completely emerged from the vagina (delivery). (3) placental stage: The uterus gradually contracts, tearing the connections between the endometrium and the placenta and ejecting the placenta.

11. Relaxin produced by the placenta softens the pubic symphysis, and the weight of the fetus then deforms the cervical os. Deformation of the cervix and the rising estrogen levels promote the release of oxytocin, and the already stretched muscles become even more excitable.

12. (1) neonatal period (birth to 1 month): The newborn becomes relatively self-sufficient and begins performing respiration, digestion, and excretion on its own. Heart rates and fluid requirements are higher than those of adults. Neonates have little ability to thermoregulate. (2) infancy (1 month to 2 years): Major organ systems (other than those related to reproduction) become fully operational. (3) Childhood (2 years to puberty): Growth continues; body proportions change significantly.

13. Three events interact to promote increased hormone production and sexual maturation at puberty: (1) The hypothalamus increases its production of GnRH; (2) the anterior pituitary becomes more sensitive to the presence of GnRH and the circulating levels of FSH and LH rise rapidly; and (3) ovarian or testicular cells become more sensitive to FSH and LH. Puberty initiates adolescence, which includes gametogenesis and the production of male or female sex hormones that stimulate the appearance of secondary sexual characteristics and behaviors.

Level 2 Reviewing Concepts

14. b 15. b 16. c

17. The post-implantation embryo obtains nutrients through the chorionic villi and later the placenta. The placenta develops during placentation.

18. The placenta produces human chorionic gonadotropin, which maintains the integrity of the corpus luteum and promotes the continued secretion of progesterone (keeping the endometrial lining functional); human placental lactogen and placental prolactin, which help prepare the mammary glands for milk production; and relaxin, which increases the flexibility of the pubic symphysis, causes dilation of the cervix, and suppresses the release of oxytocin by the hypothalamus, delaying the onset of labor contractions.

19. The respiratory rate and tidal volume increase, allowing the lungs to obtain the extra oxygen and remove the excess carbon dioxide generated by the fetus. Maternal blood volume increases, compensating for blood that will be lost during delivery. Requirements for nutrients and vitamins climb 10–30 percent, reflecting the fact that some of the mother’s nutrients go to nourish the fetus. The glomerular filtration rate increases by about 50 percent, which corresponds to the increased blood volume and accelerates the excretion of metabolic wastes generated by the fetus.

20. Positive feedback mechanisms ensure that labor contractions continue until delivery has been completed.

21. The neonate must fill its lungs (which are collapsed and filled with fluid at birth) with air, changing the pattern of cardiovascular circulation due to changes in blood pressure and

flow rates. It must excrete the mixture of debris that has collected in the fetal digestive system. The neonate must obtain nourishment from a new source—the mother's mammary glands. Neonatal fluid requirements are high, because the infant cannot concentrate its urine significantly. The infant also has little ability to thermoregulate, although as it grows its insulating adipose tissue increases and its metabolic rate also rises.

22. **(a)** Genotype refers to all the chromosomes and their genes of the individual. Phenotype refers to the physical and physiological characteristics of the individual. The genotype is a primary determinant of the phenotype, although other factors (injury, disease, environment) can also play a role. **(b)** If both chromosomes of a homologous pair carry the same allele of a particular gene, the individual is homozygous for that trait. If the two chromosomes carry different alleles for that gene, the individual is heterozygous for that trait. **(c)** In simple inheritance, phenotypes are determined by interactions between a single pair of alleles. In polygenic inheritance, interactions occur among multiple genes.

23. **(a)** dominant **(b)** recessive **(c)** X-linked **(d)** autosomal

24. The Human Genome Project has transcribed the entire human genome. The project has already helped to identify the genes that are responsible for inherited disorders and will localize the specific chromosomes involved.

Level 3 Critical Thinking and Clinical Applications

25. The probability that this couple's daughters will have hemophilia is 0, because each daughter will receive a normal allele from her father. There is a 50 percent chance that a son will have hemophilia, because each son has a 50 percent chance of receiving the mother's normal allele and a 50 percent chance of receiving the father's recessive allele.

26. Excess calcium could cause tetanic contractions of the smooth muscle of the uterus. These contractions would cut off the blood supply to the placenta and deprive the fetus of oxygen.

27. Although technically what Joe says is true, it only takes one sperm to fertilize an egg, the probability of this occurring if not enough sperm are deposited are very slim. Of the millions of sperm that enter the female reproductive tract, most are killed or disabled before they reach the uterus. Many of the sperm reaching the uterus are incapable of reaching the secondary oocyte, which is in a uterine tube. Once at the oocyte, the sperm must penetrate the coronar radiata, and this requires the combined acrosomal enzymes of one hundred or more sperm. If too few sperm arrive in the vagina, the number reaching the uterine tube is too small to disrupt the corona radiata and fertilize the oocyte.

28. The most obvious possibility is that there is a problem with the cardiovascular supply to the lungs. A good guess would be a patent ductus arteriosus (the ductus arteriosus has failed to complete close off). When the baby is not being stressed (bathing creates heat loss and thermal stress) or eating (less air is entering the lungs), the infant appears normal. Because some of the blood flow to the lungs is being shunted over to the aorta during stress and eating, there is not enough blood being oxygenated and the infant becomes cyanotic.

29. It is very unlikely that the baby's condition is the result of a viral infection contracted during the third trimester. The development of organ systems occurs during the first trimester. By the end of the second trimester, most organ systems are fully formed. During the third trimester, the fetus undergoes tremendous growth but very little new organ formation.

Appendix II

Weights and Measures

Accurate descriptions of physical objects would be impossible without a precise method of reporting the pertinent data. Dimensions such as length and width are reported in standardized units of measurement, such as inches or centimeters. These values can be used to calculate the **volume** of an object, a measurement of the amount of space the object fills. Mass is another important physical property. The **mass** of an object is determined by the amount of matter the object contains; on Earth the mass of an object determines the object's weight.

In the United States, length and width are typically described in inches, feet, or yards; volumes in pints, quarts, or gallons; and weights in ounces, pounds, or tons. These are units of the **U.S. system** of measurement. Table 1 summarizes the terms used in the U.S. system. For reference purposes, this table also includes a definition of the "household units" popular in recipes. The U.S. system can be very difficult to work with, because there is no logical relationship among the various units. For example, there are 12 inches in a foot, 3 feet in a yard, and 1760 yards in a mile. Without a clear pattern of organization, the conversion of feet to inches or miles to feet can be confusing and time-consuming. The relationships among ounces, pints, quarts, and gallons are no more logical than those among ounces, pounds, and tons.

In contrast, the **metric system** has a logical organization based on powers of 10, as indicated in Table 2. For example, a **meter (m)** is the basic unit for the measurement of size. For measurements of larger objects, data can be reported in **dekameters** (*deka*, ten), **hectometers** (*hekaton*, hundred), or **kilometers** (**km**; *chilioi*, thousand); for smaller objects, data can be reported in **decimeters** (0.1 m; *decem*, ten), **centimeters** (**cm** = 0.01 m; *centum*, hundred), **millimeters** (**mm** = 0.001 m; *mille*, thousand), and so forth. In the metric system, the same prefixes are used to report weights, based on the **gram (g)**, and volumes, based on the **liter (L)**. This text reports data in metric units, in most cases with

U.S. system equivalents. Use this opportunity to become familiar with the metric system, because most technical sources report data only in metric units; most of the world outside the United States uses the metric system exclusively. Conversion factors are included in Table 2.

The U.S. and metric systems also differ in their methods of reporting temperatures. In the United States, temperatures are usually reported in degrees Fahrenheit (°F), whereas scientific literature and individuals in most other countries report temperatures in degrees centigrade or Celsius (°C). The relationship between temperatures in degrees Fahrenheit and those in degrees centigrade is indicated in Table 2.

The following illustration spans the entire range of measurements that we will consider in this book. Gross anatomy traditionally deals with structural organization as seen with the naked eye or with a simple hand lens. A microscope can provide higher levels of magnification and can reveal finer details. Before the 1950s, most information was provided by *light microscopy*. A photograph taken through a *light microscope* is called a **light micrograph (LM)**. Light microscopy can magnify cellular structures up to about 1000 times and can show details as fine as 0.25 mm. The symbol M**m** stands for **micrometer**; 1 mm = 0.001 mm, or 0.00004 inches. With a light microscope, we can identify cell types, such as muscle fibers or neurons, and can see large structures within a cell. Because individual cells are relatively transparent, thin sections cut through a cell are treated with dyes that stain specific structures to make them easier to see.

Although special staining techniques can show the general distribution of proteins, lipids, carbohydrates, and nucleic acids in the cell, many fine details of intracellular structure remained a mystery until investigators began using *electron microscopy*. This technique uses a focused beam of electrons, rather than a beam of light, to examine cell structure. In *transmission electron microscopy*, electrons pass through an ultrathin section to strike a photographic plate. The result is a **transmission electron micrograph (TEM)**. Transmission electron microscopy shows the fine structure of cell membranes and intracellular structures. In *scanning electron microscopy*, electrons bouncing off exposed surfaces create a **scanning electron micrograph (SEM)**. Although it cannot achieve as much magnification as transmission microscopy, scanning microscopy provides a three-dimensional perspective of cell structure.

Appendix III

Periodic Table

The **periodic table** presents the known elements in order of their atomic weights. Each horizontal row represents a single electron shell. The number of elements in that row is determined by the maximum number of electrons that can be stored at that energy level. The element at the left end of each row contains a single electron in its outermost electron shell; the element at the right end of the row has a filled outer electron shell. Organizing the elements in this fashion highlights similarities that reflect the composition of the outer electron shell. These similarities are evident when you examine the vertical columns. All the gases of the right-most column—helium, neon, argon, krypton, xenon, and radon—have full electron shells; each is a gas at normal atmospheric temperature and pressure, and none reacts readily with other elements. These elements, highlighted in blue, are known as the *noble*, or *inert*, *gases*. In contrast, the elements of the leftmost column below hydrogen—lithium, sodium, potassium, rubidium, cesium, and francium—are silvery, soft metals that are so highly reactive that pure forms cannot be found in nature. The fourth and fifth electron levels can hold up to 18 electrons. Table inserts are used for the so-called *lanthanide* and *actinide series* to save space, as higher levels can store up to 32 electrons. Elements of particular importance to our discussion of human anatomy and physiology are highlighted in pink.

Appendix IV

Normal Physiological Values

Tables 3 and 4 present normal averages or ranges for the chemical composition of body fluids. These values are approximations rather than absolute values, because test results vary from laboratory to laboratory owing to differences in procedures, equipment, normal solutions, and so forth. Blanks in the tabular data appear where data are not available; sources used in the preparation of these tables follow. The following locations in the text contain additional information about body fluid analysis:

Table 19-3 (p. 658) presents data on the cellular composition of whole blood.

Table 26-2 (p. 962) compares the average compositions of urine and plasma.

Tables 26-5 (p. 978) and 26-6 (p. 979) give the general characteristics of normal urine.

[†] S = serum, P = plasma, WB = whole blood.

[†] Because urinary output averages just over 1 liter per day, these electrolyte values are comparable to mEq > L.

[‡] Because urinary metabolite and protein data approximate mg > L or g > L, these data must be divided by 10 for comparison with CSF or blood concentrations. [§] Venous blood sample.

Appendix V

100 Keys

1. All physiological functions are performed by anatomical structures. These functions follow the same physical and mechanical principles that can be seen in the world at large.

2. The body can be divided into 11 organ systems, but all work together and the boundaries between them aren't absolute.

3. Physiological systems work together to maintain a stable internal environment—the condition of homeostasis. In doing so, they monitor and adjust the volume and composition of body fluids and keep body temperature within normal limits.

4. A state of equilibrium exists when opposing processes or forces are in balance. When homeostasis is threatened, physiological systems attempt to restore a state of equilibrium within normal homeostatic limits. If they cannot do so, internal conditions become increasingly abnormal and survival becomes uncertain.

5. Anatomical descriptions refer to an individual in the anatomical position: standing, with the hands at the sides, palms facing forward, and feet together.

6. All matter is composed of atoms in various combinations. The chemical rules governing the interactions among atoms, both alone and in combination, establish the foundations of physiology at the cellular level.

7. When energy is exchanged, heat is produced. Heat raises local temperatures, but cells cannot capture it or use it to perform work.

8. Things tend to even out, unless something prevents this from happening. Most reversible reactions quickly reach equilibrium, in which opposing reaction rates are balanced. If reactants are added or removed, reaction rates change until a new equilibrium is established.

9. Most of the chemical reactions that sustain life cannot occur unless appropriate enzymes are present.

10. Water accounts for most of your body weight; proteins, the key structural and functional components of cells, and nucleic acids, which control cell structure and function, work only in solution.

11. The pH of body fluids is an indication of how many free hydrogen ions are in solution. Hydrogen ions in excess (a low pH) can damage cell and tissues, change the shapes and functions of proteins, and interfere with normal physiological systems. A high pH also has adverse effects, but problems due to low pH are much more common.

12. Carbohydrates are important as a quick source of energy and as integral components of membranes. Lipids form membranes within and between cells that prevent the diffusion of solutes. Fats are large lipids important as energy reserves.

13. Proteins are the most abundant organic components of the body, and they are the key to both anatomical structure and physiological function. Proteins determine cell shape and tissue properties, and almost all cell functions are performed by proteins and by interactions between proteins and their immediate environment.

14. The DNA in the nucleus contains the information needed to construct all of the proteins in the body.

15. Everything falls apart eventually, but some things last longer than others. Your survival depends on preventive maintenance; your body must recycle and renew all of its chemical components at intervals ranging from minutes to years. Although it has a relatively high energy cost, metabolic turnover lets your body grow and change, adapting to new conditions and activities.

16. A cell is the basic structural and functional unit of life. Cells respond directly to their environment and help maintain homeostasis at the cellular level. They can also change their internal structure and physiological functions over time.

17. Mitochondria provide most of the energy needed to keep your cells (and you) alive. They require oxygen and organic substrates and they generate carbon dioxide and ATP.

18. The nucleus contains the genetic instructions needed to synthesize the proteins that determine cell structure and function. This information is stored in chromosomes, which consist of DNA and various proteins involved in controlling and accessing the genetic information.

19. Genes are the functional units of DNA that contain the instructions for making one or more proteins. The creation of specific proteins involves multiple enzymes and three types of RNA.

20. A mutation is a change in the nucleotide sequence of a gene. Mutations can occur at any time, due to chemical or radiation exposure, but they can also occur during DNA replication. Mistakes in copying are usually detected and corrected, but any that persist may alter or disrupt gene function.

21. Things tend to even out, unless something—such as a cell membrane—prevents this from happening. In the absence of a cell membrane, or across a freely permeable membrane, diffusion will quickly eliminate concentration gradients. Osmosis acts to eliminate concentration gradients across membranes permeable to water but not permeable to the solutes involved.

22. Mitosis is the duplication of the chromosomes in the nucleus in preparation for cell division.

23. Cancer results from mutations that disrupt the control mechanism that regulates cell growth and division. Cancers most often begin where stem cells are dividing rapidly, because the more chromosomes are copied, the greater the chance of error.

24. All cells in your body except sex cells (which form sperm or oocytes) contain the same 46 chromosomes. What makes one cell different from another is which genes are active, and which are inactive.

25. Tissues are collections of cells and extracellular material that perform a specific but limited range of functions. There are four tissue types that in varying combinations form all of the structures of the human body: epithelial, connective, muscle, and neural tissues.

26. The epidermis is a multilayered, flexible, self-repairing barrier that prevents fluid loss, provides protection from UV radiation, produces vitamin D3 , and resists damage from abrasion, chemicals, and pathogens.

27. The dermis provides mechanical strength, flexibility, and protection for underlying tissues. It is highly vascular and contains a variety of sensory receptors that provide information about the external environment.

28. The skin plays a major role in controlling body temperature. It acts as a radiator, with the heat being delivered by the dermal circulation and removed primarily by the evaporation of sensible perspiration.

29. Bone is continually remodeled, recycled, and replaced. That rate of turnover varies from bone to bone and from moment to moment. When deposition exceeds removal, bones get stronger, when removal exceeds deposition, bones get weaker.

30. What you don't use, you lose. The stresses applied to bones during physical activity are essential to maintaining bone strength and bone mass.

31. Each day calcium and phosphate ions circulating in the blood are lost in the urine. To keep body fluid concentrations stable, those ions must be replaced; if they aren't obtained from the diet, they will be released from the skeleton, and the bones will become weaker as a result. If you want to keep your bones strong, you must exercise and make sure your diet contains plenty of calcium—at least enough to compensate for daily excretion.

32. The axial skeleton protects the brain, spinal cord, and visceral organs of the chest. The vertebrae conduct the body weight to the lower limbs; the inferior vertebrae are larger and stronger because they bear the most weight.

33. The pectoral girdle is highly mobile and stabilized primarily by muscles; the pelvic girdle is more massive, stronger, and far less mobile.

34. A joint cannot be both-highly mobile and very strong; the greater the mobility, the weaker the joint, because mobile joints rely on muscular and ligamentous support rather than solid bone-to-bone connections.

35. Skeletal muscle fibers shorten as thin filaments interact with thick filaments and sliding occurs. The trigger for contraction is the appearance of free calcium ions in the sarcoplasm; the calcium ions are released by the sarcoplasmic reticulum when the muscle fiber is stimulated by the associated motor neuron. Contraction is an active process; relaxation and the return to resting length is entirely passive.

36. All voluntary muscle contractions and intentional movements involve the sustained, tetanic contractions of skeletal muscle fibers. The force exerted can be increased by increasing the frequency of motor neuron action potentials or the number of stimulated motor units (recruitment).

37. Skeletal muscles at rest metabolize fatty acids and store glycogen. During light activity, muscles can generate APT through the aerobic breakdown of carbohydrates, lipids, or amino acids. At peak levels of activity, most of the energy is provided by anaerobic reactions that generate lactic acid as a by-product.

38. What you don’t use, you lose. Muscle tone is an indication of the chronic background level of activity in the motor units in skeletal muscles. When inactive for days or weeks, muscles become flaccid, and the muscle fibers break down their contractile proteins and grow smaller and weaker. If inactive for long periods, muscle fibers may be replaced by fibrous tissue.

39. Most skeletal muscles can shorten to roughly 70 percent of their “ideal” resting length. The versatility in terms of power, speed, and range of body movements results from differences in the position of muscle attachments relative to the joints involved.

40. Neurons perform all of the communication, information processing, and control functions of the nervous system. Neuroglia outnumber neurons and have functions that are essential to the preservation of the physical and biochemical structure of neural tissue and the survival and functionality of neurons.

41. A transmembrane potential exists across the cell membrane. It is there because (1) the cytosol differs from extracellular fluid in its chemical and ionic composition and (2) the cell membrane is selectively permeable. The transmembrane potential can change from moment to moment, as the cell membrane changes its permeability in response to chemical or physical stimuli.

42. “Information” travels within the nervous system primarily in the form of propagated electrical signals known as action potentials. The most important information, including vision and balance sensations and the motor commands to skeletal muscles, is carried by large-diame-ter myelinated axons.

43. At a chemical synapse a synaptic terminal releases a neurotransmitter that binds to the postsynaptic cell membrane. The result is a temporary, localized change in the permeability or function of the postsynaptic cell. This change may have broader effects on the postsynaptic cell, depending on the nature and number of the stimulated receptors. Many drugs affect the nervous system by stimulating receptors that otherwise respond only to neurotransmitters. These drugs can have complex effects on perception, motor control, and emotional states.

44. In the nervous system, the changes in transmembrane potential that determine whether action potentials are generated represent the simplest form of information processing.

45. The spinal cord has a narrow central canal surrounded by gray matter containing sensory and motor nuclei. Sensory nuclei are dorsal; motor nuclei are ventral. The gray matter is covered by a thick layer of white matter consisting of ascending and descending axons. These axons are organized in columns that contain axon bundles with specific functions. Because the spinal cord is so highly organized, it is often possible to predict the results of injuries to localized areas.

46. Each peripheral nerve provides sensory and/or motor innervation to specific structures.

47. Reflexes are rapid, automatic responses to stimuli that “buy time” for the planning and execution of more complex responses that are often consciously directed. The fastest reflexes are somatic motor reflexes that (1) involve myelinated axons, (2) involve only one segment of the spinal cord or one nucleus of the brain, and (3) are monosynaptic.

48. The brain is a large, delicate mass of neural tissue that contains internal passageways and chambers filled with cerebrospinal fluid. Each of the five major regions of the brain has specific functions. As you ascend from the medulla oblongata, which connects to the spinal cord, to the cerebrum, those functions become more complex and variable. Conscious thought and intelligence are provided by the neural cortex of the cerebral hemispheres.

49. The meninges stabilize the position of the brain within the cranial cavity, and cerebrospinal fluid provides protection against sudden jolts and shocks. CSF also provides nutrients and removes wastes generated by active neural tissues. The blood-brain barrier and the blood–CSF barrier selectively isolate the neurons of the CNS from chemicals in blood that might disrupt neural function.

50. There are 12 pairs of cranial nerves. They are responsible for the special senses of smell, sight, and hearing/balance, and for control over the muscles of the eye, jaw, face, and tongue and the superficial muscles of the neck, back, and shoulders. The cranial nerves also provide sensory information from the face, neck, and upper chest and autonomic innervation (parasympathetic) to organs in the thoracic and abdominopelvic cavities.

51. Stimulation of a receptor produces action potentials along the axon of a sensory neuron. The frequency or pattern of action potentials contains information about the strength, duration, and variation of the stimulus. Your perception of the nature of that stimulus depends on the path it takes inside the CNS and the region of the cerebral cortex it stimulates.

52. Most somatic sensory information is relayed to the thalamus for processing. A small fraction of the arriving information is projected to the cerebral cortex and reaches our conscious awareness.

53. The neurons of the primary motor cortex innervate motor neurons in the brain and spinal cord responsible for stimulating skeletal muscles. Higher centers in the brain can suppress or facilitate reflex responses; reflexes can complement or increase the complexity of voluntary movements.

54. The automatic nervous system operates largely outside our awareness. It includes a sympathetic division concerned with increasing alertness, metabolic rate, and muscular abilities, and a parasympathetic division concerned with reducing metabolic rate and promoting visceral activities such as digestion.

55. The preganglionic neurons of the autonomic nervous system release acetylcholine (ACh) as a neurotransmitter. The ganglionic neurons of the sympathetic division primarily release norepinephrine as a neurotransmitter (and both NE and E as hormones at the adrenal medulla). The ganglionic neurons of the parasympathetic division release ACh as a neurotransmitter.

56. Memory storage involves anatomical as well as physiological changes in neurons. The hippocampus is involved in the conversion of temporary, short-term memories into durable long-term memories.

57. The state of consciousness is variable and complex, ranging from energized and “hyper” to unconscious and comatose. During deep sleep, all metabolic functions are significantly reduced; during REM sleep, muscular activities are inhibited while cerebral activity is similar to that seen in awake individuals. Sleep disorders result in abnormal reaction times and behaviors, as well as mood swings. Awakening occurs when the reticular activating system becomes active; the greater the level of activity, the more alert the individual.

58. Olfactory information is routed directly to the cerebrum, and olfactory stimuli have powerful effects on mood and behavior. Gustatory sensations are strongest and clearest when integrated with olfactory sensations.

59. Light passes through the conjunctiva and cornea, crosses the anterior cavity to reach the lens, transits the lens, crosses the posterior chamber, and then penetrates the neural tissue of the retina before reaching and stimulating the photoreceptors. Cones are most abundant at the fovea and macula lutea, and they provide high-resolution color vision in brightly lit environments. Rods dominate the peripheral areas of the retina, and they provide relatively low-resolution black-and-white vision in dimly lit environments.

60. Balance and hearing rely on the same basic types of sensory receptors (hair cells). The anatomical structure of the associated sense organ determines what stimuli affect the hair cells. In the semicircular ducts, the stimulus is fluid movement caused by head rotation in the horizontal, sagittal, or frontal planes. In the utricle and saccule, the stimulus is gravity-induced shifts in the position of attached otoliths. In the cochlea, the stimulus is movement of the tectorial membrane as pressure waves distort the basilar membrane.

61. Hormones coordinate cell, tissue, and organ activities on a sustained basis. They circulate in the extracellular fluid and bind to specific receptors on or in target cells. They then modify cellular activities by altering membrane permeability, activating or inactivating key enzymes, or changing genetic activity.

62. The hypothalamus produces regulatory factors that adjust the activities of the anterior lobe of the pituitary gland, which produces seven hormones. Most of these hormones control other endocrine organs, including the thyroid gland, adrenal gland, and gonads. The anterior lobe also produces growth hormone, which stimulates cell growth and protein synthesis. The posterior lobe of the pituitary gland releases two hormones produced in the hypothalamus; ADH restricts water loss and promotes thirst, and oxytocin stimulates smooth muscle contractions in the mammary glands and uterus (in females) and the prostate gland (in males).

63. The thyroid gland produces (1) hormones that adjust tissue metabolic rates and (2) a hormone that usually plays a minor role in calcium ion homeostasis by opposing the action of parathyroid hormone.

64. The adrenal glands produce hormones that adjust metabolic activities at specific sites, affecting either the pattern of nutrient utilization, mineral ion balance, or the rate of energy consumption by active tissues.

65. The pancreatic islets release insulin and glucagon. Insulin is released when blood glucose levels rise, and it stimulates glucose transport into, and utilization by, peripheral tissues. Glucagon is released when blood glucose levels decline, and it stimulates glycogen breakdown, glucose synthesis, and fatty acid release.

66. Your total blood volume, in liters, is roughly equal to seven percent of your body weight in kilograms. Approximately half of the volume of whole blood consists of cells and cell products. Plasma resembles interstitial fluid, but it contains a unique mixture of proteins not found in other extracellular fluids.

67. Red blood cells (RBCs) are the most numerous cells in the body. They remain in circulation for approximately four months before being recycled; several million are produced each second. The hemoglobin inside RBCs transports oxygen from the lungs to peripheral tissues; it also carries carbon dioxide from those tissues to the lungs.

68. White blood cells (WBCs) are usually outnumbered by RBCs by a ratio 1000:1. WBCs are responsible for defending the body against infection, foreign cells, or toxins, and for assisting in the cleanup and repair of damaged tissues. The most numerous are neutrophils, which engulf bacteria, and lymphocytes, which are responsible for the specific defenses of the immune response.

69. Platelets are involved in the coordination of homeostasis (blood clotting). When platelets are activated by abnormal changes in their local environment, they release clotting factors and other chemicals. Hemostasis is a complex cascade that establishes a fibrous patch that can subsequently be remodeled and then removed as the damaged area is repaired.

70. The heart has four chambers, two associated with the pulmonary circuit (right atrium and right ventricle) and two with the systemic circuit (left atrium and left ventricle). The left ventricle has a greater workload and is much more massive than the right ventricle, but the two chambers pump equal amounts of blood. AV valves prevent backflow from the ventricles into the atria, and semilunar valves prevent back-flow from the aortic and pulmonary trunks into the ventricles.

71. The heart rate is normally established by the cells of the SA node, but that rate can be modified by autonomic activity, hormones, and other factors. From the SA node the stimulus is conducted to the AV node, the AV bundle, the bundle branches, and Purkinje fibers before reaching the ventricular muscle cells. The electrical events associated with the heart beat can be monitored in an electrocardiogram (ECG).

72. Cardiac output is the amount of blood pumped by the left ventricle each minute. It is adjusted on a moment-to-moment basis by the ANS, and in response to circulating hormones, changes in blood volume, and alterations in venous return. Most healthy people can increase cardiac output by 300–500 percent.

73. It is blood flow that’s the goal, and total peripheral blood flow is equal to cardiac output. Blood pressure is needed to overcome friction

and elastic forces and sustain blood flow. If blood pressure is too low, vessels collapse, blood flow stops, and tissues die; if blood pressure is too high, vessel walls stiffen and capillary beds may rupture.

74. Cardiac output cannot increase indefinitely, and blood flow to active versus inactive tissues must be differentially controlled. This is accomplished by a combination of autoregulation, neural regulation, and hormone release.

75. Cell-mediated immunity involves close physical contact between activated TC cells and foreign, abnormal, or infected cells. T cell activation usually involves (1) antigen presentation by a phagocytic cell and (2) costimulation by cytokines released by active phagocytes. TC cells may destroy target cells through the local release of cytokines, lymphotoxins, or perform.

76. Antibody-mediated immunity involves the production of specific antibodies by plasma cells derived from activated B cells. B cell activation usually involves (1) antigen recognition, through binding to surface antibodies, and (2) costimulation by a TH cell. The antibodies produced by active plasma cells bind to the target antigen and either inhibit its activity, destroy it, remove it from solution, or promote its phagocytosis by other defense cells.

77. Immunization produces a primary response to a specific antigen under controlled conditions. If the same antigen is encountered at a later date, it triggers a powerful secondary response that is usually sufficient to prevent infection and disease.

78. Viruses replicate inside cells, whereas bacteria may live independently. Antibodies (and administered antibiotics) work outside cells, so they are primarily effective against bacteria rather than viruses. (That’s why antibiotics can’t fight the common cold or flu.) T dells, NK cells, and interferons are the primary defenses against viral infection.

79. Hemoglobin within RCBs carries most of the oxygen in the bloodstream, and it releases it in response to changes in the oxygen partial pressure in the surrounding plasma. If the PO_2 increases, hemoglobin binds oxygen; if the PO_2 decreases, hemoglobin releases oxygen. At a

given PO_2 hemoglobin will release additional oxygen if the pH decreases or the temperature increases.

80. Carbon dioxide travels in the bloodstream primarily as bicarbonate ions, which form through dissociation of the carbonic acid produced by carbonic anydrase inside RBCs. Lesser amounts of CO2 are bound to hemoglobin or dissolved in plasma.

81. A basic pace of respiration is established by the interplay between respiratory centers in the pons and medulla oblongata. That pace is modified in response to input from chemoreceptors, baroreceptors, and stretch receptors. In general, carbon dioxide levels, rather than oxygen levels, are the primary drivers of respiratory activity. Respiratory activity can also be interrupted by protective reflexes and adjusted by the conscious control of respiratory muscles.

82. The stomach is a storage site that provides time for the physical breakdown of food that must precede chemical digestion. Protein digestion begins in the acid environment of the stomach through the action of pepsin. Carbohydrate digestion, which began with the release of salivary amylase by the salivary glands before swallowing, continues for a variable period after food arrives in the stomach.

83. The small intestine receives and raises the pH of materials from the stomach. It then absorbs water, ions, vitamins, and the chemical products released by the action of digestive enzymes produced by intestinal glands and the exocrine glands of the pancreas.

84. The exocrine pancreas produces a mixture of buffers and enzymes essential for normal digestion. Pancreatic secretion occurs in response to the release of regulatory hormones (CCK and secretin) by the duodenum.

85. The liver is the center for metabolic regulation in the body. It also produces bile that is stored in the gallbladder and ejected into the duodenum under the stimulation of CCK. Bile is essential for the efficient digestion of lipids; it breaks down large lipid droplets so that individual lipid molecules can be attacked by digestive enzymes.

86. The large intestine stores digestive wastes ans reabsorbs water. Bacterial residents of the large intestine are an important source of vitamins, especially vitamin K, biotin, and vitamin B5 .

87. There is an energy cost to staying alive, even at rest. All cells must expend ATP to perform routine maintenance, removing and replacing intracellular and extracellular structures and components. In addition, cells must spend additional energy performing other vital functions, such as growth, secretion, and contraction.

88. In the absorption state that follows a meal, cells absorb nutrients that are used to support growth and maintenance, and stored as energy reserves. Hours later, in the postabsorptive state, blood glucose levels are maintained by gluconeogenesis within the liver, but most cells begin conserving energy and shifting from glucose to lipid metabolism and, if necessary, ketone bodies become the preferred energy source. This metabolic shift reserves the circulating glucose for use by neurons.

89. A balanced diet contains all the ingredients needed to maintain homeostasis, including adequate substrates for energy generation, essential amino acids and fatty acids, minerals, vitamins, and water.

90. The kidneys remove waste products from the blood; they also assist in the regulation of blood volume and blood pressure, ion levels, and blood pH. Nephrons are the primary functional units of the kidneys.

91. Roughly 180 L of filtrate is produced at the glomeruli each day, and that represents 70 times the total plasma volume. Almost all of that fluid volume must be reabsorbed to avoid fatal dehydration.

92. Reabsorption involves a combination of diffusion, osmosis, channel-mediated diffusion, and active transport. Many of these processes are independently regulated by local or hormonal mechanisms. The primary mechanism governing water reabsorption can be described as “water follows salt.” Secretion is a selective, carrier-mediated process.

93. Fluid balance and electrolyte balance are interrelated. Small water gains or losses affect electrolyte concentrations only temporarily. The impacts are reduced by fluid shifts between the ECF and ICF and by hormonal responses that adjust the rates of water intake and excretion. Similarly, electrolyte gains or losses produce only temporary changes in solute concentration. These changes are opposed by fluid shifts, adjustments in the rates of ion absorption and secretion, and adjustments to the rates of water gain and loss.

94. The most common and acute acid–base disorder is respiratory acidosis, which develops when respiratory activity cannot keep pace with the rate of carbon dioxide generation in peripheral tissues.

95. Meiosis produces gametes that contain half of the number of chromosomes found in somatic cells. For each cell entering meiosis, the testes produce four spermatozoa, whereas the ovaries produce a single ovum.

96. Spermatogenesis begins at puberty and continues until relatively late in life (past age 70). It is a continuous process, and all stages of meiosis can be observed within the seminiferous tubules.

97. Oogenesis begins during embryonic development, and primary oocyte production is completed before birth. Each month after puberty, the ovarian cycle produces one or more secondary oocytes from the existing population of primary oocytes. The number of viable and responsive primary oocytes declines markedly over time, until ovarian cycles end at age 45–55.

98. Cyclic changes in FSH and LH levels are responsible for the maintenance of the ovarian cycle; the hormones produced by the ovaries in turn regulate the uterine cycle. Inadequate hormone levels, inappropriate or inadequate responses to circulating hormones, and poor coordination and timing of hormone production or secondary oocyte release will reduce or eliminate the chances of pregnancy.

99. Sexual hormones have widespread effects on the body. They affect brain development and behavioral drives, muscle mass, bone mass and density, body proportions, and the patterns of hair and body fat distribution. As aging occurs, reduction in sexual hormone levels affect appearance, strength, and a variety of physiological functions.

100. The basic body plan, the foundations of all of the organ systems, and the four extraembryonic membranes appear during the first trimester. These are complex and delicate processes; not every zygote starts cleavage, and fewer than half of the zygotes that do being cleavage survive until the end of the first trimester. The second trimester is a period of rapid growth, accompanied by the development of fetal organs that will then become fully functional by the end of the third trimester.
