Five Supplements Are Included with Your New Textbook!

These media and print supplements are referenced throughout the chapters of your textbook. The references are called out with distinctive designs and colors for easy integration with your studies.

***InterActive Physiology*® CD-ROM** This award-winning tutorial software program for physiology uses detailed animations and engaging quizzes to help you learn the most difficult concepts in your A&P course.

Anatomy 360º™ CD-ROM

Featuring highly realistic, rotatable images with a wide variety of interactive exercises and self-review questions, this engaging anatomy media program will guide you through hundreds of anatomy terms, locations, and concepts.

Student Access Kit for MyA&P™ online resource center and The Anatomy & Physiology Place companion website

The access code in this kit opens the door to the one-stop location for all of the great media available with this program. If your instructor does not have a Course ID for MyA&P, you may use the same access code to register instead for The Anatomy & Physiology Place companion website.

Martini's Atlas of the Human Body

Spiral bound for ease of use and in full color, the atlas contains vivid anatomical photographs, radiological images, and embryology summaries.

A&P Applications Manual

This guide includes clinical topics — such as disorders, diagnostics, and case studies — related to the chapter content.

1

Levels of Organization

Chapter 1, An Introduction to Anatomy and Physiology, explores the structural and functional characteristics of living things. It includes both the levels of organization that anatomical structures and physiological processes display, and homeostasis, the goal of physiological regulation and the key to survival in a changing environment.

Chapter 2, The Chemical Level of Organization, considers the structure of atoms the basic chemical building blocks; this chapter shows how atoms can be combined to form increasingly complex structures.

Chapter 3, The Cellular Level of Organization, relates how combinations of chemicals form *cells*, the smallest living units in the human body; it also describes the chemical events that sustain life, most of which occur inside cells.

Chapter 4, The Tissue Level of Organization, discusses how a variety of cell types arranged in various combinations form *tissues*, structures with discrete structural and functional properties. Tissues in combination form organs, such as the heart or liver, and in turn organs can be grouped into 11 *organ systems*. The *Systems Overview* at the end of this unit provides a broad summary of these organ systems, and the major organs associated with them.

The End of Chapter questions within this unit include critical thinking questions about both normal and abnormal functions.

An Introduction to Studying the Human Body

Objective

- Define anatomy and physiology, and describe various specialties of each discipline.

This textbook will serve as an introduction to the inner workings of your body, providing information about both its structure and its function. Many of the students who use this book are preparing for careers in health-related fields—but regardless of your career choice, you will find the information within these pages relevant to your future. You do, after all, live in a human body! Being human, you most likely have a seemingly insatiable curiosity—and few subjects arouse so much curiosity as our own bodies. The study of anatomy and physiology, which you are now beginning, will provide answers to many questions regarding the functioning of your body in both health and disease.

Although we will be focusing on the human body, the principles we will learn apply to other living things as well. Our world contains an enormous diversity of living organisms that vary widely in appearance and lifestyle. One aim of biology—the science of life—is to discover the unity and the patterns that underlie this diversity, and so shed light on what we have in common with other living things.

Animals can be classified according to their shared characteristics, and birds, fish, and humans are members of a group called the *vertebrates*, characterized by a segmented vertebral column. The shared characteristics and organizational patterns provide useful clues about how these animals have evolved over time. Many of the complex structures and functions of the human body discussed in this text have distant evolutionary origins.

People have always been interested in the inner workings of the human body. The word *anatomy* has Greek origins, as do many other anatomical terms and phrases that originated more than 1500 years ago. **Anatomy**, which means “a cutting open,” is the study of internal and external structures of the body and the physical relationships among body parts. In contrast, **physiology**, another Greek term, is the study of how living organisms perform their vital functions. Thus, someone studying anatomy might, for example, examine how a particular muscle attaches to the skeleton, whereas someone studying physiology might consider how a muscle contracts or what forces a contracting muscle exerts on the skeleton. Because you will be studying anatomy and physiology for the next 29 chapters, it is appropriate that we spend some time at the outset taking a closer look at the relationships between these sciences.

The Relationship between Anatomy and Physiology

Anatomy and physiology are closely integrated both theoretically and practically. Anatomical information provides clues about functions, and physiological mechanisms can be explained only in terms of the underlying anatomy. This is a very important concept: *All specific functions are performed by specific structures*. The link between structure and function is always present, but not always understood. For example, although the anatomy of the heart was clearly described in the 15th century, almost 200 years passed before the heart’s pumping action was demonstrated.

Anatomists and physiologists approach the relationship between structure and function from different perspectives. To understand the difference, consider a simple nonbiological analogy. Suppose that an anatomist and a physiologist were asked to examine a pickup truck and report their findings. The anatomist might begin by measuring and photographing the various parts of the truck and, if possible, taking it apart and putting it back together. The anatomist could then explain its key *structural* relationships—for example, how the pistons are seated in the engine cylinders, how the drive shaft is connected to the pistons, how the transmission links the drive shaft to the axles, and thus to the wheels. The physiologist also would note the relationships among the truck’s components, but his or her primary focus would be on *functional* characteristics, such as how the combustion of gasoline in the cylinders moves the pistons up and down and causes the drive shaft to rotate, and how the transmission conveys this motion to the axles and wheels so that the car moves. Additionally, he or she might also study the amount of power that the engine could generate, the amount of force transmitted to the wheels in different gears, and so on.

This text will introduce anatomical structures and the physiological processes that make human life possible. The basic approach will be to start with the descriptive anatomy (appearance, size, shape, location, weight, and color) before considering the related functions. Sometimes the organs within an organ system perform very diverse functions, and in those cases the functions of each individual organ will be considered separately. A good example is the discussion of the digestive system, where you will learn about the functions of the salivary glands in one section, and the functions of the tongue in another. In other systems, the organs work together so extensively that the physiological discussion is presented in a block, after the system’s anatomy has been described. The lymphatic system and the cardiovascular system are examples of this approach.

Knowledge of the anatomy and physiology of the healthy human body will enable you to understand important mechanisms of disease and will help you make intelligent decisions about personal health.

100 Keys | All physiological functions are performed by specific anatomical structures. These functions follow the same physical and mechanical principles that can be seen in the world at large.

Anatomy

How you look at things often determines what you see; you get a very different view of your neighborhood from a satellite photo than when standing in your front yard. Your method of observation has an equally dramatic effect on your understanding of the structure of the human body. Based on the degree of structural detail under consideration, anatomy can be divided into *gross (macroscopic) anatomy* and *microscopic anatomy*. Other anatomical specialties focus on specific processes, such as respiration, or medical applications, such as *surgical anatomy*, which deals with landmarks on the body that are useful during surgical procedures.

Anatomy is a dynamic field. Despite centuries of observation and dissection, new information and interpretations occur frequently. As recently as 1996, researchers working on the Visible Human database described a facial muscle that had previously been overlooked. The Clinical Note on the Visible Human Project describes the origins and uses of one of the most powerful tools in modern anatomy.

Gross Anatomy

Gross anatomy, or *macroscopic anatomy*, involves the examination of relatively large structures and features usually visible with the unaided eye. There are many different forms of gross anatomy:

- *Surface anatomy* is the study of general form and superficial markings.
- *Regional anatomy* focuses on the anatomical organization of specific areas of the body, such as the head, neck, or trunk. Many advanced courses in anatomy stress a regional

approach, because it emphasizes the spatial relationships among structures already familiar to students.

- *Systemic anatomy* is the study of the structure of **organ systems**, which are groups of organs that function together in a coordinated manner. Examples include the *skeletal system*, composed of bones; the *muscular system*, made up of muscles; and the *cardiovascular system*, consisting of the heart, blood, and vessels which distribute oxygen and nutrients throughout the body. Introductory texts such as this take a systemic anatomy approach because that approach clarifies functional relationships among the component organs. The text will introduce the 11 organ systems in the human body later in the chapter.
- *Developmental anatomy* describes the changes in form that occur between conception and physical maturity. Because developmental anatomy considers anatomical structures over such a broad range of sizes (from a single cell to an adult human), the techniques of developmental anatomists are similar to those used in gross anatomy and in microscopic anatomy. The most extensive structural changes occur during the first two months of development. The study of these early developmental processes

(anatomical landmarks important in surgery).

surgical anatomy

), and

[AM]

‾e

Applications Manual

discussed in the

‾e

is called **embryology** (em-br -OL-o-j).

- *Clinical anatomy* includes a number of subspecialties important in clinical practice. Examples include *medical anatomy* (anatomical features that change during illness), *radiographic anatomy* (anatomical structures seen using specialized imaging techniques,

Microscopic Anatomy

Microscopic anatomy deals with structures that cannot be seen without magnification, and thus the boundaries of microscopic anatomy are established by the limits of the equipment used. With a dissecting microscope you can see tissue structure; with a light microscope, you can see basic details of cell structure; with an electron microscope, you can see individual molecules that are only a few nanometers (billionths of a meter) across.

¯e

–

ı

Microscopic anatomy includes two major subdivisions: cytology and histology. **Cytology** (s -TOL-o-j) is the analysis of the internal structure of individual **cells**, the simplest units of life. Cells are composed of chemical substances in various combinations, and our lives depend on the chemical processes occurring in the trillions of cells in the body. For this reason, we consider
basic chemistry (Chapter 2) before we examine cell structure (Chapter 3). **Histology** (his-TOL-o-j
¯e
) is the examination of
tissues—groups of specialized cells and cell products that work together to perform specific functions (Chapter 4). Tissues combine to form **organs**, such as the heart, kidney, liver, or brain. Many organs are easily examined without a microscope, so at the organ level we cross the boundary from microscopic anatomy to gross anatomy. As we proceed through the text, we will consider details at all levels, from macroscopic to microscopic. (Readers unfamiliar with the terms used to describe measurements and weights should consult the reference tables in Appendix II.)

Physiology

As noted earlier, physiology is the study of the function of anatomical structures; **human physiology** is the study of the functions of the human body. These functions are complex and much more difficult to examine than most anatomical structures. As a result, there are even more specialties in physiology than in anatomy, including the following:

- *Cell physiology*, the study of the functions of cells, is the cornerstone of human physiology. Cell physiology considers events at the chemical and molecular levels—both chemical processes within cells and chemical interactions between cells.
- *Special physiology* is the study of the physiology of specific organs. An example is *cardiac physiology*, the study of heart function.
- *Systemic physiology* includes all aspects of the functioning of specific organ systems. Cardiovascular physiology, respiratory physiology, and reproductive physiology are examples of systemic physiology.
- *Pathological physiology* is the study of the effects of diseases on organ or system functions. (*Pathos* is the Greek word for "disease.") Modern medicine depends on an understanding of both normal physiology and pathological physiology. You will find extensive information on clinically important topics in subsequent chapters and in the *Applications Manual* that accompanies this text. AM: Disease, Pathology, and Diagnosis

Physicians normally use a combination of anatomical, physiological, and psychological information when they evaluate patients. When a patient presents symptoms to a physician, the physician will look at the structures affected (gross anatomy), perhaps collect a fluid or tissue sample (microscopic anatomy) for analysis, and ask questions to determine what alterations from normal functioning the patient is experiencing. Think back to your last trip to a doctor's office. Not only did the attending physician examine your body, noting any anatomical abnormalities, but he or she also evaluated your physiological processes by asking questions, observing your movements, listening to your body sounds, taking your temperature, and perhaps requesting chemical analyses of fluids such as blood or urine. In evaluating all these observations to reach a diagnosis, physicians rely on a logical framework based on the *scientific method*. The scientific method is at the core of all scientific thought, including medical diagnosis.

AM: The Scientific Method

Levels of Organization

Objectives

- Identify the major levels of organization in organisms, from the simplest to the most complex.
- Identify the organ systems of the human body and the major components of each system.

Over the next three chapters, we will consider events and structures at several interdependent levels of organization. These levels of organization are illustrated in Figure 1–1•.

- **The Chemical (or Molecular) Level.** Atoms, the smallest stable units of matter, can combine to form molecules with complex shapes. Even at this simplest level, form determines function: The functional properties of a particular molecule are determined by its unique three-dimensional shape. We explore this level of organization in Chapter 2.
- **The Cellular Level.** Molecules can interact to form various types of organelles, each type of which has specific functions. Organelles are structural and functional components of cells, the smallest living units in the body. Interactions among protein filaments, for example, produce the contractions of muscle cells in the heart. We examine the cellular level of organization in Chapter 3.
- **The Tissue Level.** A *tissue* is a group of cells working together to perform one or more specific functions. Heart muscle cells, or cardiac muscle cells (*cardium*, heart), interact with other types of cells and with extracellular materials to form *cardiac muscle tissue*. We consider the tissue level of organization in Chapter 4.
- **The Organ Level.** *Organs* consist of two or more tissues working in combination to perform several functions. Layers of cardiac muscle tissue, in combination with *connective tissue*, another type of tissue, form the bulk of the wall of the *heart*, a hollow, three-dimensional organ.
- **The Organ System Level.** Organs interact in **organ systems**. Each time it contracts, the heart pushes blood into a network of blood vessels. Together, the heart,

blood, and blood vessels form the cardiovascular system, one of 11 organ systems in the body.

- **The Organism Level.** An organism—in this case, a human—is the highest level of organization. All organ systems of the body must work together to maintain the life and health of the organism.

The organization at each level determines not only the structural characteristics, but also the functions, of higher levels. For example, the arrangement of atoms and molecules at the chemical level creates the protein filaments that, at the cellular level, give cardiac muscle cells the ability to contract powerfully. At the tissue level, these cells are linked, forming cardiac muscle tissue. The structure of the tissue ensures that the contractions are coordinated, producing a heartbeat. When that beat occurs, the internal anatomy of the heart, an organ, enables it to function as a pump. The heart is filled with blood and connected to the blood vessels, and the pumping action circulates blood through the vessels of the cardiovascular system. Through interactions with the respiratory, digestive, urinary, and other systems, the cardiovascular system performs a variety of functions essential to the survival of the organism.

Something that affects a system will ultimately affect each of the system’s components. For example, the heart cannot pump blood effectively after massive blood loss. If the heart cannot pump and blood cannot flow, oxygen and nutrients cannot be distributed. Very soon, the cardiac muscle tissue begins to break down as individual muscle cells die from oxygen and nutrient starvation. These changes will not be restricted to the cardiovascular system; all cells, tissues, and organs in the body will be damaged. Figure 1–2• introduces the 11 interdependent, interconnected organ systems in the human body.

The cells, tissues, organs, and organ systems of the body coexist in a relatively small shared environment, much like the inhabitants of a large city. Just as city dwellers breathe the same air and drink the water provided by the local water company, cells in the human body absorb oxygen and nutrients from the fluids that surround them. If a city is blanketed in smog or its water supply is contaminated, the inhabitants will become ill. Similarly, if the body fluid composition becomes abnormal, cells will be injured or destroyed. Suppose the temperature or salt content of the blood changes. The effect on the heart could range from the need for a minor adjustment (heart muscle tissue contracts more often, raising the heart rate) to a total disaster (the heart stops beating, so the individual dies).

Various physiological mechanisms act to prevent damaging changes in the composition of body fluids and the environment inside our cells. **Homeostasis** (*homeo*, unchanging + *stasis*, standing) refers to the existence of a stable internal environment. To survive, every organism must maintain homeostasis.

100 Keys | The body can be divided into 11 organ systems, but all work together and the boundaries between them aren't absolute.

Concept Check

At which level of organization does a histologist investigate structures?

What field of study is the specialty of a researcher who studies the factors that cause heart failure?

Answers begin on p. A-1

Homeostasis

Objectives

- Explain the concept of homeostasis and its significance for organisms.
- Describe how negative feedback and positive feedback are involved in homeostatic regulation.

Homeostasis is absolutely vital to an organism; failure to maintain homeostasis soon leads to illness or even death. The principle of homeostasis is the central theme of this text and the foundation of all modern physiology. *Homeostatic regulation* is the adjustment of physiological systems to preserve homeostasis. Physiological systems have evolved to maintain homeostasis in an environment that is often inconsistent, unpredictable, and potentially dangerous. An understanding of homeostatic regulation is crucial to making accurate predictions about the body's responses to both normal and abnormal conditions.

Two general mechanisms are involved in homeostatic regulation: autoregulation and extrinsic regulation.

1. Autoregulation, or *intrinsic regulation*, occurs when a cell, a tissue, an organ, or an organ system adjusts its activities automatically in response to some environmental change. For example, when oxygen levels decline in a tissue, the cells release chemicals that dilate local blood vessels. This dilation increases the rate of blood flow and provides more oxygen to the region.

2. Extrinsic regulation results from the activities of the nervous system or endocrine system, two organ systems that control or adjust the activities of many other systems simultaneously. For example, when you exercise, your nervous system issues commands that increase your heart rate so that blood will circulate faster. Your nervous system also reduces blood flow to less active organs, such as the digestive tract. The oxygen in circulating blood is thus available to the active muscles, where it is needed most.

In general, the nervous system directs rapid, short-term, and very specific responses. When you accidentally set your hand on a hot stove, the heat produces a painful, localized disturbance of homeostasis. Your nervous system responds by ordering the immediate contraction of specific muscles that will pull your hand away from the stove. These contractions last only as long as the neural activity continues, usually a matter of seconds.

In contrast, the endocrine system releases chemical messengers called *hormones*, which affect tissues and organs throughout the body. Even though the responses may not be immediately apparent, they may persist for days or weeks. Examples of homeostatic regulation dependent on endocrine function include the long-term regulation of blood volume and composition, and the adjustment of organ system function during starvation. The endocrine system also plays a major role in growth and development: It is responsible for the changes that take place in your body as you mature and age.

Regardless of the system involved, the function of homeostatic regulation is always to keep the characteristics of the internal environment within certain limits. A homeostatic regulatory mechanism consists of three parts: (1) a **receptor**, a sensor that is sensitive to a particular environmental change, or *stimulus*; (2) a **control center**, or *integration center*, which receives and processes the information supplied by the receptor, and which sends out commands; and (3) an **effector**, a cell or organ that responds to the commands of the control center and whose activity either opposes or enhances the stimulus. You are probably already familiar with comparable regulatory mechanisms, such as the thermostat in your house or apartment (Figure 1–3•).

The thermostat is the control center; it receives information about room temperature from an internal or remote thermometer (a receptor). The dial on the thermostat establishes the *set point*, or desired value, which in this case is the temperature you select. (In our example, the set point is 22°C, or about 72°F.) The function of the thermostat is to keep room temperature within acceptable limits, usually within a degree or so of the set point. In summer, the thermostat accomplishes this function by controlling an air conditioner (an effector). When the temperature at the thermometer rises above the acceptable range, the thermostat turns on the air conditioner, which then cools the room (Figure 1–3b•); when the temperature at the thermometer returns to the set point, the thermostat turns off the air conditioner. The control is not precise; the room is large, and the thermostat is located on just one wall. Over time, the temperature in the center of the room oscillates around the set point. The essential feature of temperature control by thermostat can be summarized very simply: A variation outside the desired range triggers an automatic response that corrects the situation. This method of homeostatic regulation is called *negative feedback,* because an effector activated by the control center opposes, or *negates,* the original stimulus. Negative feedback thus tends to minimize change, keeping variation in key body systems within limits that are compatible with our long-term survival.

100 Keys | Physiological systems work together to maintain a stable internal environment, the condition of homeostasis.

In doing so they monitor and adjust the volume and composition of body fluids, and keep body temperature within normal limits.

The Role of Negative Feedback in Homeostasis

Most homeostatic regulatory mechanisms involve **negative feedback.** An important example is the control of body temperature, a process called *thermoregulation.* In thermoregulation, the relationship between heat loss, which occurs primarily at the body surface, and heat production, which occurs in all active tissues, is altered.

In the homeostatic control of body temperature (Figure 1–4•), the control center is in the *hypothalamus,* a region of the brain. This control center receives information from two sets of temperature receptors, one in the skin and the other within the hypothalamus. At the normal set point, body temperature (as measured with an oral thermometer) will be approximately 37°C (98.6°F). If body temperature rises above 37.2°C, activity in the control center targets two effectors: (1) muscle tissue in the walls of blood vessels supplying the skin and (2) sweat glands. The muscle tissue relaxes and the blood vessels dilate, increasing blood flow through vessels near the body surface; the sweat glands accelerate their secretion. The skin then acts like a radiator by losing heat to the environment, and the evaporation of sweat speeds the process. As body temperature returns to normal, temperature at the hypothalamus declines, and the thermoregulatory control center becomes less active. Superficial blood flow and sweat gland activity then decrease to previous levels, although body temperature declines past the set point as the secreted sweat evaporates.

Negative feedback is the primary mechanism of homeostatic regulation, and it provides long-term control over the body’s internal conditions and systems. Homeostatic mechanisms using negative feedback normally ignore minor variations, and they maintain a normal *range* rather than a fixed value. In the previous example, body temperature oscillated around the set-point temperature (see Figure 1–4b•). The regulatory process itself is dynamic, because the set point may vary with changing environments or differing activity levels. For example, when you are asleep, your thermoregulatory set point is lower, whereas when you work outside on a hot day (or when you have a fever), it is higher. Thus, body temperature can vary from moment to moment or from day to day for any individual, due to either (1) small oscillations around the set point or (2) changes in the set point. Comparable variations occur in all other aspects of physiology.

The variability among individuals is even greater than that within an individual. Each of us has homeostatic set points determined by genetic factors, age, gender, general health, and environmental conditions. It is therefore impractical to define “normal” homeostatic conditions very precisely. By convention, physiological values are reported either as average values obtained by sampling a large number of individuals, or as a range that includes 95 percent or more of the sample population. For example, for 95 percent of healthy adults, body temperature ranges between 36.7 and 37.2°C. However, 5 percent of healthy adults have resting body temperatures that are below 36.7°C or above 37.2°C. These temperatures are perfectly normal for them, and the variations have no clinical significance. Physicians must keep this variability in mind when they review lab reports or clinical discussions, because unusual values—even those outside the “normal” range—may represent individual variation rather than disease.

The Role of Positive Feedback

In **positive feedback**, an initial stimulus produces a response that exaggerates or enhances the change in the original conditions, rather than opposing it. You seldom encounter positive feedback in your daily life, simply because it tends to produce extreme responses. For example, suppose that the thermostat in Figure 1–3a• was accidentally connected to a heater rather than to an air conditioner. Now, when room temperature exceeds the set point, the thermostat turns on the heater, causing a further rise in room temperature. Room temperature will continue to increase until someone switches off the thermostat, turns off the heater, or intervenes in some other way. This kind of escalating cycle is often called a *positive feedback loop*.

In the body, positive feedback loops are typically found when a potentially dangerous or stressful process must be completed quickly before homeostasis can be restored. For example, the immediate danger from a severe cut is loss of blood, which can lower blood pressure and reduce the efficiency of the heart. The body's response to blood loss is diagrammed in Figure 1–5•. Damage to cells in the blood vessel wall releases chemicals that begin the process of blood clotting. As clotting gets under way, each step releases chemicals that accelerate the process. This escalating process is a positive feedback loop that ends with the formation of a blood clot, which patches the vessel wall and stops the bleeding. Blood clotting will be examined more closely in Chapter 19. Labor and delivery, another example of positive feedback in action, will be discussed in Chapter 29.

The human body is amazingly effective in maintaining homeostasis. Nevertheless, an infection, an injury, or a genetic abnormality can sometimes have effects so severe that homeostatic mechanisms can't fully compensate for them. One or more characteristics of the internal environment may then be pushed outside normal limits. When this happens, organ systems begin to malfunction, producing a state known as illness, or **disease**. Chapters 2–29 devote considerable attention to the mechanisms responsible for a variety of human diseases. AM: Homeostasis and Disease

Systems Integration, Equilibrium, and Homeostasis

Homeostatic regulation controls characteristics of the internal environment that affect every cell in the body. No one organ system has total control over any of these characteristics; such control requires the coordinated efforts of multiple organ systems. In later chapters we will explore the functions of each organ system and see how the systems interact to preserve homeostasis. Table 1–1 lists the roles of various organ systems in regulating several important physiological characteristics that are subject to homeostatic control. Note that in each case such regulation involves several organ systems.

A **state of equilibrium** exists when opposing processes or forces are in balance. In the case of body temperature, a state of equilibrium exists when heat gain and loss occur at the same rates. Each physiological system functions to maintain a state of equilibrium that keeps vital conditions within normal limits. This is often called a state of *dynamic equilibrium* because physiological systems are continually adapting and adjusting to changing conditions. For example, when muscles become more active, more heat is produced. More heat must then be lost at the skin surface to re-establish a state of equilibrium before body temperature rises outside normal limits. Yet the adjustments made to control body temperature have other consequences: The sweating that increases heat loss at the skin surface increases losses of both water and salts. Other systems must then compensate for these losses and re-establish an equilibrium state for water and salts. This is a general pattern: Any adjustments made by one physiological system have direct and indirect effects on a variety of other systems. The maintenance of homeostasis is like a juggling act that keeps lots of balls in the air.

Although each organ system interacts with and is, in turn, dependent on other organ systems, it is much easier for introductory students to learn the basics of anatomy and physiology one system at a time. Although Chapters 5–29 are organized around individual systems, remember that these systems all work together. The 11 Systems in Perspective figures in later chapters will help reinforce this message; each provides an overview of one system's functions and summarizes its functional relationships with other systems.

100 Keys | A state of equilibrium exists when opposing processes or forces are in balance. When homeostasis is threatened, physiological systems attempt to restore a state of equilibrium within normal homeostatic limits. If they cannot do so, internal conditions become increasingly abnormal, and survival becomes uncertain.

Concept Check

Why is homeostatic regulation important to humans?

What happens to the body when homeostasis breaks down?

Why is positive feedback helpful in blood clotting, but unsuitable for the regulation of body temperature?

Answers begin on p. A-1

Frames of Reference for Anatomical Studies

Objectives

- Use anatomical terms to describe body sections, body regions, and relative positions.
- Identify the major body cavities and their subdivisions.

Early anatomists faced serious problems in communication. Stating that a bump is “on the back,” for example, does not give very precise information about its location. So anatomists created maps of the human body. Prominent anatomical structures serve as landmarks, distances are measured in centimeters or inches, and specialized directional terms are used. In effect, anatomy uses a special language that must be learned almost at the start of your study.

A familiarity with Latin and Greek word roots and patterns makes anatomical terms more understandable. As new terms are introduced, notes on pronunciation and relevant word roots will be provided. Additional information on roots, prefixes, suffixes, and combining forms can be found inside the front cover.

Latin and Greek terms are not the only ones that have been imported into the anatomical vocabulary over the centuries, and the vocabulary continues to expand. Many anatomical structures and clinical conditions were initially named after either the discoverer or, in the case of diseases, the most famous victim. Over the last 100 years, most of these commemorative names, or *eponyms*, have been replaced by more precise terms. The Glossary includes a table listing the most important eponyms and related historical details.

In the following sections we will introduce the terms used in superficial and sectional anatomy.

Superficial Anatomy

A familiarity with anatomical landmarks, anatomical regions, and terms for anatomical directions will make subsequent chapters more understandable. As you encounter new terms, create your own mental maps from the information provided in the accompanying anatomical illustrations.

Anatomical Landmarks

Important anatomical landmarks are presented in Figure 1–6•. Understanding the terms and their etymology (origins) will help you remember both the location of a particular structure and its name. For example, *brachium* refers to the arm; later we will consider the *brachialis muscle* and the *brachial artery*, which are (as their names suggest) in the arm.

Standard anatomical illustrations show the human form in the **anatomical position**. When the body is in this position, the hands are at the sides with the palms facing forward, and the feet are together. Figure 1–6a• shows an individual in the anatomical position as seen from the front (an *anterior view*), Figure 1–6b• from the back (a *posterior view*). Unless otherwise noted, all descriptions in this text refer to the body in the anatomical position. A person lying down in the anatomical position is said to be

supine (soo-P N) when face up, and **prone** when face down.

I¯

100 Keys | Anatomical descriptions refer to an individual in the anatomical position: standing, with the hands at the sides,

palms facing forward, and feet together.

Anatomical Regions

Major anatomical regions of the body are listed in Table 1–2. But to describe a general area of interest or injury, anatomists and clinicians often need broader terms in addition to specific landmarks. Two methods are used to map the surface of the abdomen and pelvis.

Clinicians refer to four **abdominopelvic quadrants** (Figure 1–7a•) formed by a pair of imaginary perpendicular lines that intersect at the umbilicus (navel). This simple method provides useful references for the description of aches, pains, and injuries. The location can help the physician determine the possible cause; for example, tenderness in the right lower quadrant (RLQ) is a symptom of appendicitis, whereas tenderness in the right upper quadrant (RUQ) may indicate gallbladder or liver problems.

Anatomists prefer more precise terms to describe the location and orientation of internal organs. They recognize nine **abdominopelvic regions** (Figure 1–7b•). Figure 1–7c• shows the relationships among quadrants, regions, and internal organs.

Anatomy 360 | Review surface anatomy on the **Anatomy 360 CD-ROM: Anatomy Introduction/Surface Anatomy.**

Anatomical Directions

Figure 1–8• and Table 1–3 introduce the principal directional terms and some examples of their use. There are many different terms, and some can be used interchangeably. For example, *anterior* refers to the front of the body when viewed in the anatomical position; in humans, this term is equivalent to *ventral*, which refers to the belly. Before you read further, analyze the table in detail, and practice using these terms. If you are familiar with the basic vocabulary, the descriptions in subsequent chapters will be easier to follow. When reading anatomical descriptions, you will find it useful to remember that the terms *left* and *right* always refer to the *left* and *right* sides of the *subject*, not of the observer.

Sectional Anatomy

Sometimes the only way to understand the relationships among the parts of a three-dimensional object is to slice through it and look at the internal organization. An understanding of sectional views is particularly important now that electronic imaging techniques enable us to see inside the living body. Although these views are sometimes difficult to interpret, it is worth spending the time required to understand what they show. Once you are able to interpret sectional views, you will have a good mental model for studying the anatomy and physiology of a particular region or system. Radiologists and other medical professionals responsible for interpreting medical scans spend much of their time analyzing sectional views of the body.

Planes and Sections

Any slice through a three-dimensional object can be described in reference to three **sectional planes**, as indicated in Figure 1–9• and Table 1–4. A *plane* is an axis; three planes are needed to describe any three-dimensional object. A *section* is a single view or slice along one of these planes. The **transverse plane** lies at right angles to the long axis of the body, dividing it into *superior* and *inferior* portions. A cut in this plane is called a **transverse section**, or *cross section*. The **frontal plane** (or *coronal plane*) and the **sagittal plane** are parallel to the long axis of the body. The frontal plane extends from side to side, dividing the body into *anterior* and *posterior* portions. The sagittal plane extends from front to back, dividing the body into left and right portions. A cut that passes along the midline and divides the body into left and right halves is a *midsagittal section*, or *median section*; a cut parallel to the midsagittal line is a *parasagittal section* (see Table 1–4). The atlas that accompanies this text contains images of sections taken through the body in various planes. You will be referred to these images later in the text, for comparison with specific illustrations in figures.

Body Cavities

Many vital organs are suspended in internal chambers called *body cavities*. These cavities have two essential functions: (1) They protect delicate organs, such as the brain and spinal cord, from accidental shocks and cushion them from the thumps and bumps that occur when we walk, jump, or run; and (2) they permit significant changes in the size and shape of internal organs. For example, because they are inside body cavities, the lungs, heart, stomach, intestines, urinary bladder, and many other organs can expand and contract without distorting surrounding tissues or disrupting the activities of nearby organs.

The *ventral body cavity*, or *coelom* (S

¯E

-l

¯o

m; *koila*, cavity), appears early in embryological development. It contains organs of the respiratory, cardiovascular, digestive, urinary, and reproductive systems. As these internal organs develop, their relative positions change, and the ventral body cavity is gradually subdivided. The **diaphragm** (D -uh-fram), a flat muscular sheet, divides

I¯the ventral body cavity into a superior **thoracic cavity**, bounded by the chest wall, and an inferior **abdominopelvic cavity**, enclosed by the abdominal wall and by the bones and muscles of the pelvis. The boundaries between the divisions of the ventral body cavity are depicted in Figure 1–10•.

Many of the organs in the thoracic and abdominopelvic cavities change size and shape as they perform their functions. For example, the lungs inflate and deflate as you breathe, and your stomach swells at each meal and shrinks between meals. These organs are surrounded by moist internal spaces that permit expansion and limited movement while preventing friction. The internal organs that are partially or completely enclosed by these cavities are called **viscera** (VIS-e-ruh). A delicate layer called a *serous membrane* lines the walls of these internal cavities and covers the surfaces of the enclosed viscera. Serous membranes are moistened by a watery fluid that coats the opposing surfaces and reduces friction. The portion of a serous membrane that covers a visceral organ is called the *visceral* layer; the opposing layer that lines the inner surface of the body wall or chamber is called the *parietal* layer.

We will now take a closer look at the anatomy of the thoracic and abdominopelvic cavities.

The Thoracic Cavity

The thoracic cavity contains the lungs and heart; associated organs of the respiratory, cardiovascular, and lymphatic systems; the inferior portions of the esophagus; and the thymus. The boundaries of the thoracic cavity are established by the muscles and bones of the chest wall and the diaphragm (see Figure 1–10a•). The thoracic cavity is subdivided into the left and right **pleural cavities**,

separated by the **mediastinum** (m

¯e

-d
¯e
-as-T I¯
-num or m
¯e
-d
¯e
-AS-ti-num) (see Figure 1–10c•). Each pleural cavity, which contains a lung, is lined by a shiny, slippery serous membrane that reduces friction as the lung expands and recoils during respiration. The serous membrane lining a pleural cavity is called a *pleura* (PLOOR-ah). The *visceral pleura* covers the outer surfaces of a lung, whereas the *parietal pleura* covers the mediastinal surface and the inner body wall.

The mediastinum consists of a mass of connective tissue that surrounds, stabilizes, and supports the esophagus, trachea, and thymus, as well as the major blood vessels that originate or end at the heart. The mediastinum also contains the **pericardial cavity**, a small chamber that surrounds the heart. The relationship between the heart and the pericardial cavity resembles that of a fist pushing into a balloon (see Figure 1–10b•). The wrist corresponds to the *base* (attached portion) of the heart, and the balloon corresponds to the serous membrane that lines the pericardial cavity. The serous membrane covering the heart is called the *pericardium* (*peri-*, around + *cardium*, heart). The layer covering the heart is the *visceral pericardium*, and the opposing surface is the *parietal pericardium*. During each beat, the heart changes in size and shape. The pericardial cavity permits these changes, and the slippery pericardial lining prevents friction between the heart and adjacent structures in the thoracic cavity.

The Abdominopelvic Cavity

The abdominopelvic cavity extends from the diaphragm to the pelvis. It is subdivided into a superior **abdominal cavity** and an

inferior **pelvic cavity** (see Figure 1–10a•). The abdominopelvic cavity contains the *peritoneal* (per-i-t
¯o
-N

E¯
-al) *cavity*, a chamber
lined by a serous membrane known as the *peritoneum* (per-i-t
¯o
-N

E¯
-um). The *parietal peritoneum* lines the inner surface of the
body wall. A narrow space containing a small amount of fluid separates the parietal peritoneum from the *visceral peritoneum*, which covers the enclosed organs. You are probably already aware of the movements of the organs in this cavity. Who has not had at least one embarrassing moment when the contraction of a digestive organ produced a movement of liquid or gas and a gurgling or rumbling sound? The peritoneum allows the organs of the digestive system to slide across one another without damage to themselves or the walls of the cavity.

The abdominal cavity extends from the inferior surface of the diaphragm to the level of the superior margins of the pelvis. This cavity contains the liver, stomach, spleen, small intestine, and most of the large intestine. (The positions of most of these organs are shown in Figure 1–7c•, p. 17.) The organs are partially or completely enclosed by the peritoneal cavity, much as the heart and lungs are enclosed by the pericardial and pleural cavities, respectively. A few organs, such as the kidneys and pancreas, lie between the peritoneal lining and the muscular wall of the abdominal cavity. Those organs are said to be *retroperitoneal* (*retro*, behind).

The pelvic cavity is the portion of the ventral body cavity inferior to the abdominal cavity. The bones of the pelvis form the walls of the pelvic cavity, and a layer of muscle forms its floor. The pelvic cavity contains the distal portion of the large intestine, the urinary bladder, and various reproductive organs. The pelvic cavity of females, for example, contains the ovaries, uterine tubes, and uterus; in males, it contains the prostate gland and seminal vesicles. The pelvic cavity also contains the inferior portion of the peritoneal cavity. The peritoneum covers the ovaries and the uterus in females, as well as the superior portion of the urinary bladder in both sexes.

Anatomy 360 | Review the use of anatomical terminology on the **Anatomy 360 CD-ROM: Anatomy Introduction/ Orienta-tion/Topography.**

Concept Check

Which type of section would separate the two eyes?

If a surgeon makes an incision just inferior to the diaphragm, which body cavity will be opened?

Answers begin on p. A-1

This chapter provided an overview of the locations and functions of the major components of each organ system. It also introduced the vocabulary you need to follow more detailed anatomical descriptions in later chapters. Many of the figures in those chapters contain images produced by modern clinical imaging procedures. You will find numerous examples in the *Atlas* and the related discussions in the *Applications Manual*. AM: Sectional Anatomy and Clinical Technology

Chapter Review

Selected Clinical Terminology

abdominopelvic quadrant: One of four divisions of the anterior abdominal surface. (p. 17)

abdominopelvic region: One of nine divisions of the anterior abdominal surface. (p. 17)

CT, CAT (computerized [axial] tomography)**:** An imaging technique that uses X rays to reconstruct the body's three-dimensional struc

ture. [AM] **disease:** A malfunction of organs or organ systems resulting from a failure of homeostatic regulation. (p. 14) **DSA** (digital subtraction angiography)**:** A technique used to monitor blood flow through specific organs, such as the brain, heart, lungs,

or kidneys. X rays are taken before and after a radiopaque dye is administered, and a computer "subtracts" details common to both

images. The result is a high-contrast image showing the distribution of the dye. [AM] **embryology:** The study of structural changes during the first two months of development. (p. 5) **histology:** The study of tissues. (p. 5) **MRI** (magnetic resonance imaging)**:** An imaging technique that employs a magnetic field and radio waves to portray subtle structural

differences. [AM] **PET** (positron emission tomography) **scan:** An imaging technique that shows the chemical functioning, as well as the structure, of an

organ. [AM] **radiologist:** A physician who specializes in performing and analyzing radiological procedures. [AM] **spiral-CT:** A method of processing computerized tomography data to provide rapid, three-dimensional images of internal organs. [AM] **ultrasound:** An imaging technique that uses brief bursts of high-frequency sound waves reflected by internal structures. [AM] **X rays:** High-energy radiation that can penetrate living tissues. [AM]

Study Outline

An Introduction to Studying the Human Body p. 4

1. Biology is the study of life. One of its goals is to discover the unity and the patterns that underlie the diversity of organisms.

The Relationship between Anatomy and Physiology p. 4

2. **Anatomy** is the study of internal and external structures of the body and the physical relationships among body parts. **Physiology** is the study of how living organisms perform thair vital functions. All physiological functions are performed by specific structures.

100 Keys | p. 5

Anatomy p. 5

3. In **gross** *(macroscopic)* **anatomy**, we consider features that are visible without a microscope. This field includes *surface anatomy* (general form and superficial markings); *regional anatomy* (anatomical organization of specific areas of the body); and *systemic anatomy* (structure of organ systems). In *developmental anatomy*, we examine the changes in form that occur between conception and physical maturity. In *embryology*, we study developmental processes that occur during the first two months of development. *Clinical anatomy* includes anatomical subspecialties important to the practice of medicine.

4. The boundaries of *microscopic anatomy* are established by the equipment used. In **cytology**, we analyze the internal structure of individual **cells**. In **histology**, we examine **tissues**, groups of cells that perform specific functions. Tissues combine to form **organs**, anatomical units with multiple functions.

Physiology p. 5

5. **Human physiology** is the study of the functions of the human body. It is based on *cell physiology*, the study of the functions of cells. In *special physiology*, we study the physiology of specific organs. In *systemic physiology*, we consider all aspects of the functioning of specific organ systems. In *pathological physiology*, we study the effects of diseases on organ or system functions.

Levels of Organization p. 6

1. Anatomical structures and physiological mechanisms occur in a series of interacting levels of organization. *(Figure 1–1)*

2. The 11 **organ systems** of the body are the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, respiratory, digestive, urinary, and reproductive systems. *(Figure 1–2)*

100 Keys | p. 8

Homeostasis p. 11

1. **Homeostasis** is the existence of a stable environment within the body.

2. Physiological systems preserve homeostasis through *homeostatic regulation*.

100 Keys | p. 11

3. **Autoregulation** occurs when a cell, a tissue, an organ, or an organ system adjusts its activities automatically in response to some environmental change. **Extrinsic regulation** results from the activities of the nervous system or endocrine system.

4. Homeostatic regulation mechanisms usually involve a **receptor** that is sensitive to a particular stimulus; a **control center**, which receives and processes the information supplied by the receptor, and then sends out commands; and an **effector** that responds to the commands of the control center and whose activity either opposes or enhances the stimulus.

The Role of Negative Feedback in Homeostasis p. 12

5. **Negative feedback** is a corrective mechanism involving an action that directly opposes a variation from normal limits. *(Figures 1–3, 1–4)*

6. In **positive feedback**, an initial stimulus produces a response that exaggerates or enhances the change in the original conditions, creating a *positive feedback loop*. *(Figure 1–5)*

7. No one organ system has total control over the internal environmental characteristics; all organ systems work in concert. *(Table 1–1)*

Systems Integration, Equilibrium, and Homeostasis p. 14

100 Keys | p. 14

Frames of Reference for Anatomical Studies p. 15 Superficial Anatomy p. 15

1. Standard anatomical illustrations show the human form in the **anatomical position**. If the figure is shown lying down, it can be either **supine** (face up) or **prone** (face down). *(Figure 1–6)*

100 Keys | p. 17

2. **Abdominopelvic quadrants** and **abdominopelvic regions** represent two approaches to describing anatomical regions of that portion of the body. *(Figure 1–7; Table 1–2)*

3. The use of special directional terms provides clarity for the description of anatomical structures. *(Figure 1–8; Table 1–3)*

Anatomy 360 | Anatomy Introduction/Surface Anatomy

Sectional Anatomy p. 18

4. The three **sectional planes** (**transverse plane**; **frontal**, or *coronal*, **plane**; and **sagittal plane**) describe relationships among the parts of the three-dimensional human body. *(Figure 1–9; Table 1–4)*

Body Cavities p. 19

5. *Body cavities* protect delicate organs and permit significant changes in the size and shape of internal organs. The **ventral body cavity**, or *coelom*, surrounds developing respiratory, cardiovascular, digestive, urinary, and reproductive organs. *(Figure 1–10)*

6. The **diaphragm** divides the ventral body cavity into the (superior) **thoracic** and (inferior) **abdominopelvic cavities**. The thoracic cavity consists of two **pleural cavities** (each containing a lung), separated by the **mediastinum**. Within the mediastinum is the

pericardial cavity, which contains the heart. The abdominopelvic cavity consists of the **abdominal cavity** and the **pelvic cavity** and contains the *peritoneal cavity*, a chamber lined by the *peritoneum*, a *serous membrane*. *(Figure 1–10)*

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A-1.

LEVEL 1 Reviewing Facts and Terms

Match each numbered item with the most closely related lettered item. Use letters for answers in the spaces provided.

___ **1.** cytology ___ **2.** physiology ___ **3.** histology ___ **4.** metabolism ___ **5.** homeostasis ___ **6.** muscle ___ **7.** heart ___ **8.** endocrine ___ **9.** temperature regulation ___**10.** labor and delivery ___**11.** supine ___**12.** prone ___**13.** ventral body cavity ___**14.** abdominopelvic cavity ___**15.** pericardium

(a) study of tissues

(b) constant internal
environment

(c) face up

(d) study of functions

(e) positive feedback

(f) organ system

(g) study of cells

(h) negative feedback

(i) brain and spinal cord

(j) all chemical activity in body

(k) thoracic and abdominopelvic

(l) tissue

(m) peritoneal cavity

(n) organ

(o) face down

16. The following is a list of six levels of organization that make up the human body:

1. tissue **2.** cell

3. organ **4.** molecule

5. organism **6.** organ system

The correct order, from the smallest to the largest level, is

(a) 2, 4, 1, 3, 6, 5 **(b)** 4, 2, 1, 3, 6, 5

(c) 4, 2, 1, 6, 3, 5 **(d)** 4, 2, 3, 1, 6, 5

(e) 2, 1, 4, 3, 5, 6

17. The study of the structure of tissue is called

(a) gross anatomy **(b)** cytology

(c) histology **(d)** organology

18. The increasingly forceful labor contractions during childbirth are an example of

(a) receptor activation **(b)** effector shutdown

(c) negative feedback **(d)** positive feedback

19. Failure of homeostatic regulation in the body results in

(a) autoregulation **(b)** extrinsic regulation

(c) disease **(d)** positive feedback

20. A plane through the body that passes perpendicular to the long axis of the body and divides the body into a superior and an inferior section is a

(a) sagittal section **(b)** transverse section

(c) coronal section **(d)** frontal section

21. In which body cavity would you find each of the following organs?

(a) heart

(b) small intestine, large intestine

(c) lung

(d) kidneys

22. The mediastinum is the region between the

(a) lungs and heart **(b)** two pleural cavities

(c) chest and abdomen **(d)** heart and pericardium

LEVEL 2 Reviewing Concepts

23. **(a)** Define *anatomy*. **(b)** Define *physiology*.

24. The two primary subdivisions of the ventral body cavity are the:

(a) pleural cavity and pericardial cavity

(b) coelom and peritoneal cavity

(c) pleural cavity and peritoneal cavity

(d) thoracic cavity and abdominopelvic cavity

25. What distinguishes autoregulation from extrinsic regulation?

26. Describe the position of the body when it is in the anatomical position.

27. Which sectional plane could divide the body so that the face remains intact?

(a) sagittal plane **(b)** coronal plane

(c) equatorial plane **(d)** midsagittal plane

(e) parasagittal plane

28. Which the following is *not* an example of negative feedback?

(a) Increased pressure in the aorta triggers mechanisms to lower blood pressure.

(b) A rise in blood calcium levels triggers the release of a hormone that lowers blood calcium levels.

(c) A rise in estrogen during the menstrual cycle increases the number of progesterone receptors in the uterus.

(d) Increased blood sugar stimulates the reloease of a hormane from the pancreas that stimulates the liver to store blood sugar.

LEVEL 3 Critical Thinking and Clinical Applications

29. The hormone *calcitonin* is released from the thyroid gland in response to increased levels of calcium ions in the blood. If this hormone is controlled by negative feedback, what effect would calcitonin have on blood calcium levels?

30. It is a warm day and you feel a little chilled. On checking your temperature, you find that your body temperature is 1.5 degrees below normal. Suggest some possible reason for this situation.

TABLE 1–1

Internal Characteristic	**Primary Organ Systems Involved**	**Functions of the Organ Systems**
Body temperature	Integumentary system	Heat loss
	Muscular system	Heat production
	Cardiovascular system	Heat distribution
	Nervous system	Coordination of blood flow, heat production, and heat loss
Body fluid composition		
Nutrient concentration	Digestive system	Nutrient absorption, storage, and release
	Cardiovascular system	Nutrient distribution
	Urinary system	Control of nutrient loss in the urine
Oxygen, carbon dioxide levels	Respiratory system	Absorption of oxygen, elimination of carbon dioxide

	Cardiovascular system	Internal transport of oxygen and carbon dioxide
Body fluid volume	Urinary system	Elimination or conservation of water from the blood
	Digestive system	Absorption of water; loss of water in feces
	Integumentary system	Loss of water through perspiration
	Cardiovascular system	Distribution of water
Waste product concentration	Urinary system	Elimination of waste products from the blood
	Cardiovascular system	Transport of waste products to sites of excretion
Blood pressure	Cardiovascular system	Pressure generated by the heart moves blood through blood vessels
	Nervous system and endocrine system	Adjustments in heart rate and blood vessel diameter can raise or lower blood pressure

TABLE 1–2 Regions of the Human Body (see Figure 1–6)

Structure	**Region**
Cephalon (head)	Cephalic region
Cervicis (neck)	Cervical region
Thoracis (thorax or chest)	Thoracic region
Brachium (arm)	Brachial region
Antebrachium (forearm)	Antebrachial region
Carpus (wrist)	Carpal region
Manus (hand)	Manual region
Abdomen	Abdominal region
Lumbus (loin)	Lumbar region
Gluteus (buttock)	Gluteal region

Pelvis Pelvic region

Pubis (anterior pelvis) Pubic region

Inguen (groin) Inguinal region

Femur (thigh) Femoral region

Crus (anterior leg) Crural region

Sura (calf) Sural region

Tarsus (ankle) Tarsal region

Pes (foot) Pedal region

Planta (sole) Plantar region

TABLE 1–3 Directional Terms (see Figure 1–8)

Term Region or Reference **Example**

Anterior The front; before The navel is on the *anterior* surface of the trunk. **Ventral** The belly side (equivalent to anterior The navel is on the *ventral* surface of the trunk.

when referring to human body)

Posterior or **dorsal** The back; behind The shoulder blade is located *posterior* to the rib cage.

Cranial or **cephalic** The head The *cranial*, or *cephalic*, border of the pelvis is on the side toward the head

rather than toward the thigh. **Superior** Above; at a higher level (in human In humans, the cranial border of the pelvis is *superior* to the thigh.

body, toward the head)

Caudal The tail (coccyx in humans) The hips are *caudal* to the waist.

Inferior Below; at a lower level The knees are *inferior* to the hips.

Medial Toward the body's longitudinal The *medial* surfaces of the thighs may be in contact; moving medially from

axis; toward the midsagittal plane the arm across the chest surface brings you to the sternum. **Lateral** Away from the body's longitudinal The thigh articulates with the *lateral* surface of the pelvis; moving laterally axis; away from the midsagittal plane from the nose brings you to the cheeks. **Proximal** Toward an attached base The thigh is *proximal* to the foot; moving proximally from the wrist brings you to the elbow. **Distal** Away from an attached base The fingers are *distal* to the wrist; moving distally from the elbow brings you to the wrist.

Superficial At, near, or relatively close to the body surface The skin is *superficial* to underlying structures.

Deep Farther from the body surface The bone of the thigh is *deep* to the surrounding skeletal muscles.

TABLE 1–4 Terms That Indicate Sectional Planes (see Figure 1–9)

Orientation of Plane	Plane	Directional Reference
Perpendicular to long axis	Transverse or horizontal	
		and inferior portions of

the body.

Parallel to long axis Sagittal Sagittally A *sagittal section* separates right and left portions. You

examine a sagittal section, but you section sagittally.

Midsagittal In a *midsagittal section*, the plane passes through the midline, dividing the body in half and separating the right and left sides.

Parasagittal A *parasagittal section* misses the midline, separating right and left portions of unequal size.

Frontal or coronal Frontally or coronally A *frontal*, or *coronal*, section separates anterior and posterior portions of the body; *coronal* usually refers to sections passing through the skull.

• **FIGURE 1–1** Levels of Organization. Interacting atoms form molecules that combine in the protein fibers of a heart muscle cell. Such cells interlock, creating heart muscle tissue, which constitutes most of the walls of the heart, a three-dimensional organ. The heart is but one component of the cardiovascular system, which also includes the blood and blood vessels. The various organ systems must work together to maintain life at the organism level.

- **FIGURE 1–2** An Introduction to Organ Systems

- **FIGURE 1–2** An Introduction to Organ Systems (*continued*)

- **FIGURE 1–3** The Control of Room Temperature. **(a)** In response to input from a receptor (a thermometer), a thermostat (the control center) triggers an effector response (either an air conditioner or a heater) that restores normal temperature. In this case, when room temperature rises above the set point, the thermostat turns on the air conditioner, and the temperature returns to normal. **(b)** With this regulatory system, room temperature oscillates around the set point.

- **FIGURE 1–4** Negative Feedback in the Control of Body Temperature. In negative feedback, a stimulus produces a response that opposes or negates the original stimulus. **(a)** Events in the regulation of body temperature, which are comparable to those shown in *Figure 1–3*. A control center in the brain (the hypothalamus) functions as a thermostat with a set point of 37°C. If body temperature exceeds 37.2°C, heat loss is increased through enhanced blood flow to the skin and increased sweating. **(b)** The thermoregulatory center keeps body temperature oscillating within an acceptable range, usually between 36.7 and 37.2°C.

- **FIGURE 1–5** Positive Feedback: Blood Clotting. Positive feedback loops are important in accelerating processes that must proceed to completion rapidly. In this example, positive feedback accelerates the clotting process until a blood clot forms and stops the bleeding.

- **FIGURE 1–6** Anatomical Landmarks. Anatomical terms are shown in boldface type, common names in plain type, and anatomical adjectives in parentheses.

- **FIGURE 1–7** Abdominopelvic Quadrants and Regions. **(a)** The four abdominopelvic quadrants, formed by two perpendicular lines that intersect at the umbilicus. The terms for these quadrants, or their abbreviations, are most often used in clinical discussions. **(b)** The nine abdominopelvic regions, which provide more precise regional descriptions. **(c)** The relationship between the abdominopelvic quadrants and regions.

- **FIGURE 1–8** Directional References. **(a)** A lateral view. **(b)** An anterior view. Important directional terms used in this text are indicated by arrows; definitions and descriptions are given in Table 1–3.
- **FIGURE 1–9** Sectional Planes. The three primary sectional planes, which are defined and described in Table 1–4. The photos of sectional images were derived from the Visible Human data set.
- **FIGURE 1–10** The Ventral Body Cavity and Its Subdivisions. **(a)** A lateral view showing the ventral body cavity, which is divided by the muscular diaphragm into a superior thoracic (chest) cavity and an inferior abdominopelvic cavity. **(b)** The heart is suspended within the pericardial cavity like a fist pushed into a balloon. The attachment site, corresponding to the wrist of the hand, lies at the connection between the heart and major blood vessels. **(c)** A transverse section through the ventral body cavity, showing the central location of the pericardial cavity within the thoracic cavity. Notice how the mediastinum divides the thoracic cavity into two pleural cavities.

Atoms, Molecules, and Bonds

Objectives

- Describe an atom and how atomic structure affects interactions between atoms.
- Compare the ways in which atoms combine to form molecules and compounds.

Our study of the human body begins at the chemical level of organization. *Chemistry* is the science that deals with the structure of *matter*, defined as anything that takes up space and has mass. *Mass* is a physical property that determines the weight of an object in Earth's gravitational field. For our purposes, the mass of an object is the same as its weight. However, the two are not always equivalent: In orbit you would be weightless, but your mass would remain unchanged.

The smallest stable units of matter are called **atoms**. Air, elephants, oranges, oceans, rocks, and people are all composed of atoms in varying combinations. The unique characteristics of each object, living or nonliving, result from the types of atoms involved and the ways those atoms combine and interact.

Atoms are composed of **subatomic particles**. Although many different subatomic particles exist, only three are important for understanding the chemical properties of matter: *protons*, *neutrons*, and *electrons*. Protons and neutrons are similar in size and mass,

0

but **protons** (p^+) bear a positive electrical charge, whereas **neutrons** (n or n) are electrically *neutral*, or uncharged. **Electrons**

>

(e^-) are much lighter than protons—only 1 1836 as massive—and bear a negative electrical charge. The mass of an atom is therefore determined primarily by the number of protons and neutrons in the nucleus, the central region of an atom. The mass of a large object, such as your body, is the sum of the masses of all the component atoms.

100 Keys | All matter is composed of atoms in various combinations. The chemical rules governing the interactions among
atoms, both alone and in combination, establish the foundations of physiology at the cellular level.

Atomic Structure

Atoms normally contain equal numbers of protons and electrons. The number of protons in an atom is known as its **atomic number**. *Hydrogen* (H) is the simplest atom, with an atomic number of 1. Thus, an atom of hydrogen contains one proton, and one electron as well. The proton is located in the center of the atom and forms the nucleus. Hydrogen atoms seldom contain neutrons, but when neutrons are present, they are also located in the nucleus. All atoms other than hydrogen have both neutrons and protons in their nuclei.

Electrons orbit the nucleus at high speed, forming a spherical **electron cloud**. We often illustrate atomic structure in the simplified form shown in Figure 2–1a•. In this two-dimensional representation, the electrons occupy a circular **electron shell**. One reason an electron tends to remain in its electron shell is that the negatively charged electron is attracted to the positively charged proton. The attraction between opposite electrical charges is an example of an *electrical force*. As you will see in later chapters, electrical forces are involved in many physiological processes.

The dimensions of the electron cloud determine the overall size of the atom. To get an idea of the scale involved, consider that if the nucleus were the size of a tennis ball, the electron cloud of a hydrogen atom would have a radius of 10 km (roughly 6 miles!).

In reality, atoms are so small that atomic measurements are most conveniently reported in *nanometers* (NAN-ōm-ē-ter) (nm). One nanometer is 10^{-9} meter (0.000000001 m). The very largest atoms approach 0.5 nm in diameter (0.0000000005 m, or 0.00000002 in.).

Elements and Isotopes

Based on their atomic number, atoms can be classified into groups called **elements**. Each element includes all the atoms that have the same number of protons, and thus the same atomic number. Only 92 elements exist in nature, although about two dozen additional elements have been created through nuclear reactions in research laboratories. Every element has a chemical symbol, an abbreviation recognized by scientists everywhere. Most of the symbols are easily connected with the English names of the elements (O for oxygen, N for nitrogen, C for carbon, and so on), but a few are abbreviations of their Latin names. For example, the symbol for sodium, Na, comes from the Latin word *natrium*. (Appendix III, the *periodic table*, gives the chemical symbol and atomic number of each element.)

Because atomic nuclei are unaltered by ordinary chemical processes, elements cannot be changed or broken down into simpler substances in chemical reactions. Thus, an atom of carbon always remains an atom of carbon, regardless of the chemical events in which it may take part.

The relative contributions of the 13 most abundant elements in the human body to total body weight are shown in Table 2–1. The human body also contains atoms of another 13 elements—called *trace elements*—that are present in very small amounts.

The atoms of a single element can differ in the number of neutrons in the nucleus. For example, although most hydrogen nuclei consist of a single proton, 0.015 percent also contain one neutron, and a very small percentage contain two neutrons (see Figure 2–1•). Atoms of the same element whose nuclei contain the same number of protons, but different numbers of neutrons, are called **isotopes**. Different isotopes of an element have essentially identical chemical properties, and so are indistinguishable except on the basis of mass. The **mass number**—the total number of protons plus neutrons in the nucleus—is used to designate isotopes. Thus, the three isotopes of hydrogen are hydrogen-1, or ^{1}H, with one proton and one electron (see Figure 2–1a•); hy-drogen-2, or ^{2}H, also known as *deuterium*, with one proton, one electron, and one neutron (see Figure 2–1b•); and hydrogen-3, or ^{3}H, also known as *tritium*, with one proton, one electron, and two neutrons (see Figure 2–1c•).

The nuclei of some isotopes spontaneously emit subatomic particles or radiation in measurable amounts. Such isotopes are called **radioisotopes**, and the emission process is called *radioactive decay*. Strongly radioactive isotopes are dangerous, because the emissions can break molecules apart, destroy cells, and otherwise damage living tissues. Weakly radioactive isotopes are sometimes used in diagnostic procedures to monitor the structural or functional characteristics of internal organs.

Radioisotopes differ in how rapidly they decay. The decay rate of a radioisotope is commonly expressed in terms of its **half-life**: the time required for half of a given amount of the isotope to decay. The half-lives of radioisotopes range from fractions of a second to billions of years. AM: Medical Use of Radioisotopes

Atomic Weights

A typical *oxygen* atom, which has an atomic number of 8, contains eight protons and eight neutrons. The mass number of this isotope is therefore 16. The mass numbers of other isotopes of oxygen depend on the number of neutrons present. Mass numbers are useful because they tell us the number of subatomic particles in the nuclei of different atoms. However, they do not tell us the *actual* mass of the atoms. For example, they do not take into account the masses of the electrons or the slight difference between the mass of a proton and that of a neutron. The actual mass of an atom is known as its **atomic weight**.

The unit used to express atomic weight is the **dalton** (also known as the *atomic mass unit*, or *amu*). One dalton is very close to the weight of a single proton. Thus, the atomic weight of the most common isotope of hydrogen is very close to 1, and that of the most common isotope of oxygen is very close to 16.

The atomic weight of an element is an average mass number that reflects the proportions of different isotopes. That is, the atomic weight of an element is usually very close to the mass number of the most common isotope of that element. For example, the atomic number of hydrogen is 1, but the atomic weight of hydrogen is 1.0079, primarily because some hydrogen atoms (0.015 percent) have a mass number of 2, and even fewer have a mass number of 3. The atomic weights of the elements are included in Appendix III.

Atoms participate in chemical reactions in fixed numerical ratios. To form water, for example, exactly two atoms of hydrogen combine with one atom of oxygen. But individual atoms are far too small and too numerous to be counted, so chemists use a unit called the *mole*. For any element, a **mole** (abbreviated *mol*) is a quantity with a weight in grams equal to that element's atomic weight. The mole is useful because one mole of a given element always contains the same number of atoms as one mole of any other element. That number (called *Avogadro's number*) is $6.023 * 10^{23}$, or about 600 billion trillion. Expressing relationships in moles rather than in grams makes it much easier to keep track of the relative numbers of atoms in chemical samples and processes. For example, if a report stated that a sample contains 0.5 mol of hydrogen atoms and 0.5 mol of oxygen atoms, you would know immediately that they were present in equal numbers. That would not be so evident if the report stated that there were 0.505 g of hydrogen atoms and 8.00 g of oxygen atoms. Most chemical analyses and clinical laboratory tests report data in moles (mol), millimoles (mmol—1> 1000 mol, or 10^{-3} mol), or micromoles (mmol—1> 1,000,000 mol, or 10^{-6} mol). (Additional information on metric weights and measures can be found in Appendix II.)

Electrons and Energy Levels

Atoms are electrically neutral; every positively charged proton is balanced by a negatively charged electron. Thus, each increase in the atomic number is accompanied by a comparable increase in the number of electrons orbiting the nucleus. Within the electron cloud, electrons occupy an orderly series of **energy levels**. Although the electrons in an energy level may travel in complex orbits around the nucleus, for our purposes the orbits can be diagrammed as a series of concentric electron shells. The first electron shell (the one closest to the nucleus) corresponds to the lowest energy level.

Each energy level is limited in the number of electrons it can hold. The first energy level can hold at most two electrons, while the next two levels can each hold up to eight electrons. The electrons in an atom occupy successive shells in an orderly manner: The first energy level is filled before any electrons enter the second, and the second energy level is filled before any electrons enter the third.

The outermost energy level forms the “surface” of the atom. The number of electrons in this level determines the chemical properties of the element. Atoms with unfilled energy levels are unstable—that is, they will react with other atoms, usually in ways that give them full outer electron shells. In contrast, atoms with a filled outermost energy level are stable and therefore do not readily react with other atoms.

As indicated in Figure 2–2a•, a hydrogen atom has one electron in the first energy level, and that level is thus unfilled. A hydrogen atom readily reacts with other atoms. A *helium* atom has two electrons in its first energy level (Figure 2–2b•). Because its outer energy level is filled, a helium atom is very stable; it will not ordinarily react with other atoms. A *lithium* atom has three electrons (Figure 2–2c•). Its first energy level can hold only two of them, so lithium has a single electron in a second, unfilled energy level. As you would expect, lithium is extremely reactive. The second energy level is filled in a *neon* atom, which has an atomic number of 10 (Figure 2–2d•). Neon atoms, like helium atoms, are thus very stable. The atoms that are most important to biological systems are *un*stable, because those atoms interact to form larger structures (see Table 2–1). (Further information on these and other elements is given in Appendix III.)

Chemical Bonds

Elements that do not readily participate in chemical processes are said to be *inert*. Helium, neon, and argon have filled outermost energy levels. These elements are called *inert gases*, because their atoms neither react with one another nor combine with atoms of other elements. Elements with unfilled outermost energy levels, such as hydrogen and lithium, are called *reactive*, because they readily interact or combine with other atoms. In doing so, these atoms achieve stability by gaining, losing, or sharing electrons to fill their outermost energy level. The interactions often involve the formation of **chemical bonds**, which hold the participating atoms together once the reaction has ended. In the sections that follow, we will consider three basic types of chemical bonds: *ionic bonds*, *covalent bonds*, and *hydrogen bonds*.

When chemical bonding occurs, the result is the creation of new chemical entities called *molecules* and *compounds*. The term **molecule** refers to any chemical structure consisting of atoms held together by covalent bonds. A **compound** is any chemical substance made up of atoms of two or more elements, regardless of the type of bond joining them. The two categories overlap, but they aren't the same. Not all molecules are compounds, because some molecules consist of atoms of only one element. (Two oxygen atoms, for example, can be joined by a covalent bond to form a molecule of oxygen.) And not all compounds consist of molecules, because some compounds, such as ordinary salt (sodium chloride) are held together by ionic rather than covalent bonds. Many substances, however, belong to both categories. Water is a compound because it contains two different elements—hydrogen and oxygen—and it consists of molecules, because the hydrogen and oxygen atoms are held together by covalent bonds. As we will see in subsequent sections, most biologically important compounds, from water to DNA, are molecular.

Regardless of the type of bonding involved, a chemical compound has properties that can be quite different from those of its components. For example, a mixture of hydrogen gas and oxygen gas can explode, but the explosion is a chemical reaction that produces liquid water, a compound used to put out fires.

The human body consists of countless molecules and compounds, so it is a challenge to describe these substances and their varied interactions. Fortunately, chemists rely on a standardized system of *chemical notation*. The very useful rules of this system are listed in “FOCUS: Chemical Notation,” p. 34.

Ionic Bonds

As the name implies, ionic bonds form between ions. **Ions** are atoms or molecules that carry an electric charge, either positive or negative. Ions with a positive charge (+) are called **cations** (KAT-¯ı -onz); ions with a negative charge (-) are called **anions** (AN-¯-onz). **Ionic bonds** are chemical bonds created by the electrical attraction between anions and cations.

ı

Ions have an unequal number of protons and electrons. Atoms become ions by losing or gaining electrons. We assign a value of + 1 to the charge on a proton; the charge on an electron is -1. When the number of protons is equal to the number of electrons, an atom is electrically neutral. An atom that loses an electron becomes a cation with a charge of + 1, because it then has one proton that lacks a corresponding electron. Losing a second electron would give the cation a charge of +2. Adding an extra electron to a neutral atom produces an anion with a charge of -1; adding a second electron gives the anion a charge of -2.

In the formation of an ionic bond,

- one atom—the *electron donor*—loses one or more electrons and becomes a cation, with a positive (+) charge.
- another atom—the *electron acceptor*—gains those same electrons and becomes an anion, with a negative (-) charge.
- attraction between the opposite charges then draws the two ions together.

The formation of an ionic bond is illustrated in Figure 2–3a•. The sodium atom diagrammed in STEP 1 has an atomic number of 11, so this atom normally contains 11 protons and 11 electrons. (Because neutrons are electrically neutral, their presence has no effect on the formation of ions or ionic bonds.) Electrons fill the first and second energy levels, and a single electron occupies the outermost level. Losing that one electron would give the sodium atom a full outermost energy level—the second level—

and would produce a **sodium ion**, with a charge of + 1. (The chemical shorthand for a sodium ion is Na^+.) But a sodium atom cannot simply throw away the electron: The electron must be donated to an electron acceptor. A chlorine atom has seven electrons in its outermost energy level, so it needs only one electron to achieve stability. A sodium atom can provide the extra electron. In the process (STEP 1), the chlorine atom becomes a **chloride ion** (Cl^-) with a charge of -1.

Both atoms have now become stable ions with filled outermost energy levels. But the two ions do not move apart after the electron transfer, because the positively charged sodium ion is attracted to the negatively charged chloride ion (STEP 2). The combination of oppositely charged ions forms an *ionic compound*—in this case, **sodium chloride**, otherwise known as table salt (STEP 3). Large numbers of sodium and chloride ions interact to form highly structured crystals, held together only by the electrical attraction of oppositely charged ions (Figure 2–3b•). Although sodium chloride and other ionic compounds are common in body fluids, they are not present as intact crystals. When placed in water, ionic compounds dissolve, and the component anions and cations separate.

Covalent Bonds

Some atoms can complete their outer electron shells not by gaining or losing electrons, but by sharing electrons with other atoms. Such sharing creates **covalent** (ko¯-VAL-ent) **bonds** between the atoms involved.

Individual hydrogen atoms, as diagrammed in Figure 2–2a•, do not exist in nature. Instead, we find hydrogen molecules. Molecular hydrogen consists of a pair of hydrogen atoms (Figure 2–4•). In chemical shorthand, molecular hydrogen is indicated by H2, where H is the chemical symbol for hydrogen, and the subscript 2 indicates the number of atoms. Molecular hydrogen is a gas that is present in the atmosphere in very small quantities. The two hydrogen atoms share their electrons, and each electron whirls around both nuclei. The sharing of one pair of electrons creates a **single covalent bond** (¬).

Oxygen, with an atomic number of 8, has two electrons in its first energy level and six in its second. The oxygen atoms diagrammed in Figure 2–4• attain a stable electron configuration by sharing two pairs of electrons, thereby forming a **double covalent bond**. In a structural formula, a double covalent bond is represented by two lines ( ). Molecular oxygen (O2) is an atmospheric gas that is very important to most organisms. Our cells would die without a relatively constant supply of oxygen.

In our bodies, chemical processes that consume oxygen generally also produce **carbon dioxide** (CO2) as a waste product. Each of the oxygen atoms in a carbon dioxide molecule forms double covalent bonds with the carbon atom.

A triple covalent bond, such as the one joining two nitrogen molecules (N2), is indicated by three lines (,). Molecular nitrogen accounts for roughly 79 percent of our planet's atmosphere, but our cells ignore it completely. In fact, deep-sea divers live for long periods while breathing artificial air that does not contain nitrogen. (We will discuss the reasons for eliminating nitrogen under these conditions in Chapter 23.) Covalent bonds usually form molecules that complete the outer energy levels of the atoms involved. An ion or molecule that contains unpaired electrons in its outermost energy level is called a *free radical*. Free radicals are highly reactive. Almost as fast as it forms, a free radical enters additional reactions that are typically destructive. For example, free radicals can damage or destroy vital compounds, such as proteins. Free radicals sometimes form in the course of normal metabolism, but cells have several methods of removing or inactivating them. However, *nitric oxide* (NO) is a free radical that has important functions in the body. It is involved in chemical communication in the nervous system, in the control of blood vessel diameter, in blood clotting, and in the defense against bacteria and other pathogens. Evidence suggests that the cumulative damage produced by free radicals inside and outside our cells is a major factor in the aging process.

Nonpolar Covalent Bonds Covalent bonds are very strong, because the shared electrons hold the atoms together. In typical covalent bonds the atoms remain electrically neutral, because each shared electron spends just as much time "at home" as away. (If you and a friend were tossing a pair of baseballs back and forth as fast as you could, on average, each of you would have just one baseball.) Many covalent bonds involve an equal sharing of electrons. Such bonds—which occur, for instance, between two atoms of the same type—

are called **nonpolar covalent bonds**. Nonpolar covalent bonds are very common; those involving carbon atoms form most of the structural components of the human body.

Polar Covalent Bonds Covalent bonds involving different types of atoms may instead involve an unequal sharing of electrons, because the elements differ in how strongly they attract electrons. An unequal sharing of electrons creates a **polar covalent bond**. For example, in a molecule of water (Figure 2–5•), an oxygen atom forms covalent bonds with two hydrogen atoms. The oxygen nucleus has a much stronger attraction for the shared electrons than the hydrogen atoms do. As a result, the electrons spend more time orbiting the oxygen nucleus than orbiting the hydrogen nuclei. Because the oxygen atom has two extra electrons most of the time, it develops a slight (partial) negative charge, indicated by d^{-}. At the same time, each hydrogen atom develops a slight (partial) positive charge, d^{+}, because its electron is away much of the time. (Suppose you and a friend were tossing a pair of baseballs back and forth, but one of you returned them back as fast as possible while the other held onto them for a while before throwing them back. One of you would now, on average, have more than one baseball, and the other would have less than one.) The unequal sharing of electrons makes polar covalent bonds somewhat weaker than nonpolar covalent bonds. Polar covalent bonds often create *polar molecules*—molecules that have positive and negative ends. Polar molecules have very interesting properties; we will consider the characteristics of the most important polar molecule in the body, water, in a later section.

Hydrogen Bonds

Covalent and ionic bonds tie atoms together to form molecules and compounds. Other, comparatively weak forces also act between adjacent molecules, and even between atoms within a large molecule. The most important of these weak attractive forces is

-

the **hydrogen bond**. A hydrogen bond is the attraction between a d^{+} on the hydrogen atom of a polar covalent bond and a don an oxygen or nitrogen atom of another polar covalent bond. The polar covalent bond containing the oxygen or nitrogen atom can be in a different molecule from, or in the same molecule as, the hydrogen atom.

Hydrogen bonds are too weak to create molecules, but they can change molecular shapes or pull molecules together. For example, hydrogen bonding occurs between water molecules (Figure 2–6•). At the water surface, the attraction between molecules slows the rate of evaporation and creates the phenomenon known as surface tension. **Surface tension** acts as a barrier that keeps small objects from entering the water. For example, it allows insects to walk across the surface of a pond or puddle. Similarly, small objects such as dust particles are prevented from touching the surface of the eye by the surface tension in a layer of tears. At the cellular level, hydrogen bonds affect the shapes and properties of complex molecules, such as proteins and nucleic acids (including DNA), and they may also determine the three-dimensional relationships between molecules.

States of Matter

Matter in our environment exists in one of three states: solid, liquid, or gaseous. *Solids* maintain their volume and their shape at ordinary temperatures and pressures. A lump of granite, a brick, and a textbook are solid objects. *Liquids* have a constant volume, but no fixed shape. The shape of a liquid is determined by the shape of its container. Water, coffee, and soda are liquids. A *gas* has neither a constant volume nor a fixed shape. Gases can be compressed or expanded; unlike liquids they will fill a container of any size. The air of our atmosphere is the gas with which we are most familiar.

Whether a particular substance is a solid, a liquid, or a gas depends on the degree of interaction among its atoms or molecules. Water is the only substance that occurs as a solid (ice), a liquid (water), and a gas (water vapor) at temperatures compatible with life. Water exists in the liquid state over a broad range of temperatures primarily because of hydrogen bonding among the water molecules. We will talk more about the unusual properties of water in a later section.

Molecular Weights

The **molecular weight** of a molecule is the sum of the atomic weights of its component atoms. It follows from the definition of the mole given previously that the molecular weight of a molecule in grams is equal to the weight of one mole of molecules. Molecular weights are important because you can neither handle individual molecules nor easily count the billions of molecules involved in chemical reactions in the body. Using molecular weights, you can calculate the quantities of reactants needed to perform a specific reaction and determine the amount of product generated. For example, suppose you want to create water from hydrogen and oxygen according to the equation

$2H_2 + O_2$ ¡ $2H_2O$.

The first step would be to calculate the molecular weights involved. The atomic weight of hydrogen is close to 1.0, so one hydrogen molecule (H_2) has a molecular weight near 2.0. Oxygen has an atomic weight of about 16, so the molecular weight of an oxygen molecule (O_2) is roughly 32. Thus you would combine 4 g of hydrogen with 32 g of oxygen to produce 36 g of water. You could also work with ounces, pounds, or tons, as long as the proportions remained the same.

Concept Check

 Both oxygen and neon are gases at room temperature. Oxygen combines readily with other elements, but neon does not. Why?

 How is it possible for two samples of hydrogen to contain the same number of atoms, yet have different weights?

 Which kind of bond holds atoms in a water molecule together? What attracts water molecules to one another?

Answers begin on p. A-1

Chemical Reactions

Objectives

- Use chemical notation to symbolize chemical reactions.
- Distinguish among the major types of chemical reactions that are important for studying physiology.
- Describe the crucial role of enzymes in metabolism.

Cells remain alive and functional by controlling chemical reactions. In a **chemical reaction**, new chemical bonds form between atoms, or existing bonds between atoms are broken. These changes occur as atoms in the reacting substances, or **reactants**, are rearranged to form different substances, or **products**. (See “FOCUS: Chemical Notation,” p. 34.)

In effect, each cell is a chemical factory. Growth, maintenance and repair, secretion, and contraction all involve complex chemical reactions. Cells use chemical reactions to provide the energy needed to maintain homeostasis and to perform essential functions. All of the reactions under way in the cells and tissues of the body at any given moment constitute its **metabolism** (me-TAB-o¯-lizm).

Basic Energy Concepts

An understanding of some basic relationships between matter and energy is essential for any discussion of chemical reactions. **Work** is the movement of an object or a change in the physical structure of matter. In your body, work includes movements like walking or running, and also the synthesis of organic (carbon containing) molecules and the conversion of liquid water to water vapor (evaporation). **Energy** is the capacity to perform work; movement or physical change cannot occur unless energy is provided. The two major types of energy are kinetic energy and potential energy:

1. Kinetic energy is the energy of motion—energy that is doing work. When you fall off a ladder, it is kinetic energy that does the damage.

2. Potential energy is stored energy—energy that has the potential to do work. It may derive from an object's position (you standing on a ladder) or from its physical or chemical structure (a stretched spring or a charged battery).

Kinetic energy must be used in climbing the ladder, in stretching the spring, or in charging the battery. The resulting potential energy is converted back into kinetic energy when you descend, the spring recoils, or the battery discharges. The kinetic energy can then be used to perform work. For example, in an MP3 player, the chemical potential energy stored in small batteries is converted to kinetic energy that vibrates the sound-producing membranes in headphones or external speakers.

Energy cannot be destroyed; it can only be converted from one form to another. A conversion between potential energy and kinetic energy is never 100 percent efficient. Each time an energy exchange occurs, some of the energy is released in the form of heat. *Heat* is an increase in random molecular motion; the temperature of an object is proportional to the average kinetic energy of its molecules. Heat can never be completely converted to work or any other form of energy, and cells cannot capture it or use it to perform work.

Cells perform work as they synthesize complex molecules and move materials into, out of, and within the cell. The cells of a skeletal muscle at rest, for example, contain potential energy in the form of the positions of protein filaments and the covalent bonds between molecules inside the cells. When a muscle contracts, it performs work; potential energy is converted into kinetic energy, and heat is released. The amount of heat is proportional to the amount of work done. As a result, when you exercise, your body temperature rises.

100 Keys | When energy is exchanged, heat is produced. Heat raises local temperatures, but cells cannot capture it or use
it to perform work.

Types of Chemical Reactions

Three types of chemical reactions are important to the study of physiology: decomposition reactions, synthesis reactions, and exchange reactions.

Decomposition Reactions

Decomposition is a reaction that breaks a molecule into smaller fragments. You could diagram a simple *decomposition reaction* as

AB ¡ A + B.

Decomposition reactions occur outside cells as well as inside them. For example, a typical meal contains molecules of fats, sugars, and proteins that are too large and too complex to be absorbed and used by your body. Decomposition reactions in the digestive tract break these molecules down into smaller fragments before absorption begins.

Decomposition reactions involving water are important in the breakdown of complex molecules in the body. In **hydrolysis** (h -DROL-i-sis; *hydro-*, water + *lysis*, dissolution), one of the bonds in a complex molecule is broken, and the components of a

–

ı water molecule (H and OH) are added to the resulting fragments:

A – B – C – D–E + H_2O ¡ A –B –C – H + HO – D –E

Collectively, the decomposition reactions of complex molecules within the body's cells and tissues are referred to as **catabolism** (ka-TAB-o¯-lizm; *katabole*, a throwing down). When a covalent bond—a form of potential energy—is broken, it releases kinetic energy that can perform work. By harnessing the energy released in this way, cells perform vital functions such as growth, movement, and reproduction.

Synthesis Reactions

Synthesis (SIN-the-sis) is the opposite of decomposition. A *synthesis reaction* assembles smaller molecules into larger molecules. A simple synthetic reaction could be diagrammed as

A + B ¡ AB.

Synthesis reactions may involve individual atoms or the combination of molecules to form even larger products. The formation of water from hydrogen and oxygen molecules is a synthesis reaction. Synthesis always involves the formation of new chemical bonds, whether the reactants are atoms or molecules. **Dehydration synthesis**, or *condensation*, is the formation of a complex molecule by the removal of water:

A –B – C – H + HO – D – E ¡ A –B – C –D – E + H_2O

Dehydration synthesis is therefore the opposite of hydrolysis. We will encounter examples of both reactions in later sections.

Collectively, the synthesis of new molecules within the body's cells and tissues is known as **anabolism** (a-NAB-o¯-lizm; *anabole*, a throwing upward). Because it takes energy to create a chemical bond, anabolism is usually considered an "uphill" process. Cells must balance their energy budgets, with catabolism providing the energy to support anabolism and other vital functions.

Exchange Reactions

In an **exchange reaction**, parts of the reacting molecules are shuffled around to produce new products:

AB + CD ¡ AD + CB

Although the reactants and products contain the same components (A, B, C, and D), those components are present in different combinations. In an exchange reaction, the reactant molecules AB and CD must break apart (a decomposition) before they can interact with each other to form AD and CB (a synthesis).

Reversible Reactions

Chemical reactions are (at least theoretically) reversible, so if A + B ¡ AB, then AB ¡ A + B. Many important biological reactions are freely reversible. Such reactions can be represented as an equation:

A + B Δ AB

This equation indicates that, in a sense, two reactions are occurring simultaneously, one a synthesis (A + B ¡ AB) and the other a decomposition (AB ¡ A + B). At equilibrium, the rates at which the two reactions proceed are in balance. As fast as one molecule of AB forms, another degrades into A + B.

The result of a disturbance in the equilibrium condition can be predicted. In our example, the rate at which the synthesis reaction proceeds is directly proportional to the frequency of encounters between A and B. In turn, the frequency of encounters depends on the degree of crowding: You are much more likely to run into another person in a crowded room than in a room that is almost empty. The addition of more AB molecules will increase the rate of conversion of AB to A and B. The amounts of A and B will then increase, leading to an increase in the rate of the reverse reaction—the formation of AB from A and B. Eventually, an equilibrium is again established.

100 Keys | Things tend to even out, unless something prevents this from happening. Reversible reactions quickly reach
equilibrium, in which opposing reaction rates are balanced. If reactants are added or removed, reaction rates change until
a new equilibrium is established.

Enzymes, Energy, and Chemical Reactions

Most chemical reactions do not occur spontaneously, or they occur so slowly that they would be of little value to cells. Before a reaction can proceed, enough energy must be provided to activate the reactants. The amount of energy required to start a reaction is called the **activation energy**. Although many reactions can be activated by changes in temperature or acidity, such changes are deadly to cells. For example, every day your cells break down complex sugars as part of your normal metabolism. Yet to break down a complex sugar in a laboratory, you must boil it in an acidic solution. Your cells don’t have that option; temperatures that high and solutions that corrosive would immediately destroy living tissues. Instead, your cells use special proteins called *enzymes* to perform most of the complex synthesis and decomposition reactions in your body.

Enzymes promote chemical reactions by lowering the activation energy requirements (Figure 2–7•). In doing so, they make it possible for chemical reactions, such as the breakdown of sugars, to proceed under conditions compatible with life. Enzymes belong to a class of substances called **catalysts** (KAT-uh-lists; *katalysis*, dissolution), compounds that accelerate chemical reactions without themselves being permanently changed or consumed. A cell makes an enzyme molecule to promote a specific reaction. Enzymatic reactions, which are reversible, can be written as

enzyme

A + B ERRF AB

Although the presence of an appropriate enzyme can accelerate a reaction, an enzyme affects only the rate of the reaction, not its direction or the products that are formed. An enzyme cannot bring about a reaction that would otherwise be impossible. Enzymatic reactions are generally reversible, and they proceed until an equilibrium becomes established.

The complex reactions that support life proceed in a series of interlocking steps, each controlled by a specific enzyme. Such a reaction sequence is called a *pathway*. A synthetic pathway can be diagrammed as

enzyme 1 enzyme 2 enzyme 3

A ERRF B ERRF C ERRF and so on.

Step 1 Step 2 Step 3

In many cases, the steps in the synthetic pathway differ from those in the decomposition pathway, and separate enzymes are often
involved.

It takes activation energy to start a chemical reaction, but once it has begun, the reaction as a whole may absorb or release energy, generally in the form of heat, as it proceeds to completion. If the amount of energy released is greater than the activation energy needed to start the reaction, there will be a net release of energy. Reactions that release energy are said to be **exergonic** (*exo*, outside). If more energy is required to begin the reaction than is released as it proceeds, the reaction as a whole will absorb energy. Such reactions are called **endergonic** (*endo*-, inside). Exergonic reactions are relatively common in the body; they are responsible for generating the heat that maintains your body temperature.

100 Keys | Most of the chemical reactions that sustain life cannot occur unless appropriate enzymes are present.

Concept Check

☐ In cells, glucose, a six-carbon molecule, is converted into two three-carbon molecules by a reaction that releases energy. How would you classify this reaction?

☐ Why are enzymes needed in our cells?

Answers begin on p. A-1

Inorganic Compounds

Objectives

- Distinguish between organic and inorganic compounds.
- Explain how the chemical properties of water make life possible.
- Discuss the importance of pH and the role of buffers in body fluids.
- Describe the physiological roles of inorganic compounds.

Although the human body is very complex, it contains relatively few elements (see Table 2–1). But knowing the identity and quantity of each element in the body will not help you understand the body any more than studying the alphabet will help you understand this textbook. Just as only 26 letters can be combined to form thousands of different words in this book, only about 26 elements combine to form thousands of different chemical compounds in our bodies. As we saw in Chapter 1, these compounds make up the living cells that constitute the framework of the body and carry on all its life processes. So it is impossible to understand the structure and functioning of the human body without learning about the major classes of chemical compounds.

We will next turn our attention to nutrients and metabolites. **Nutrients** are the essential elements and molecules normally obtained from the diet. **Metabolites** (me-TAB-o¯-l ts; *metabole*, change), a much larger group, include all the molecules (nutrients

–

ı included) that can be synthesized or broken down by chemical reactions inside our bodies. Nutrients and metabolites can be broadly categorized as either inorganic or organic. **Inorganic compounds** generally do not contain carbon and hydrogen atoms as their primary structural ingredients, whereas carbon and hydrogen *always* form the basis for **organic compounds**.

The most important inorganic compounds in the body are (1) *carbon dioxide*, a by-product of cell metabolism; (2) *oxygen*, an atmospheric gas required in important metabolic reactions; (3) *water*, which accounts for most of our body weight; and

(4) *inorganic acids, bases*, and *salts*— compounds held together partially or completely by ionic bonds. In this section, we will be concerned primarily with water, its properties, and how those properties establish the conditions necessary for life. Most of the other inorganic molecules and compounds in the body exist in association with water, the primary component of our body fluids. Both carbon dioxide and oxygen, for example, are gas molecules that are transported in body fluids, and all the inorganic acids, bases, and salts we will discuss are dissolved in body fluids.

Water and Its Properties

Water, H2O, is the most important constituent of the body, accounting for up to two-thirds of total body weight. A change in the body's water content can have fatal consequences because virtually all physiological systems will be affected.

Although water is familiar to everyone, it has some highly unusual properties. These properties are a direct result of the hydrogen bonding that occurs between adjacent water molecules:

1. *Solubility*. A remarkable number of inorganic and organic molecules are soluble, meaning they will *dissolve* or break up in water. The individual molecules become distributed within the water, and the result is a **solution**—a uniform mixture of two or more substances. The medium in which other atoms, ions, or molecules are dispersed is called the **solvent**; the dispersed substances are the **solutes**. In *aqueous solutions*, water is the solvent. The solvent properties of water are so important that we will consider them further in the next section.

2. *Reactivity*. In our bodies, chemical reactions occur in water, and water molecules are also participants in some reactions. Hydrolysis and dehydration synthesis are two examples noted earlier in the chapter.

3. *High Heat Capacity. Heat capacity* is the ability to absorb and retain heat. Water has an unusually high heat capacity, because water molecules in the liquid state are attracted to one another through hydrogen bonding. Important consequences of this at

traction include the following:

- The temperature of water must be quite high before individual molecules have enough energy to break free and become water vapor, a gas. Consequently, water stays in the liquid state over a broad range of environmental temperatures, and the freezing and boiling points of water are far apart.
- Water carries a great deal of heat away with it when it finally does change from a liquid to a gas. This feature accounts for the cooling effect of perspiration on the skin.
- An unusually large amount of heat energy is required to change the temperature of 1 g of water by 1°C. As a result, a large mass of water changes temperature only slowly. This property is called *thermal inertia*. Because water accounts for up to two-thirds of the weight of the human body, thermal inertia helps stabilize body temperature.

4. *Lubrication.* Water is an effective lubricant because there is little friction between water molecules. Thus, if two opposing surfaces are separated by even a thin layer of water, friction between those surfaces will be greatly reduced. (That is why driving on wet roads can be tricky; your tires may start sliding on a layer of water rather than maintaining contact with the road.) Within joints such as the knee, an aqueous solution prevents friction between the opposing surfaces. Similarly, a small amount of fluid
in the ventral body cavities prevents friction between internal organs, such as the heart or lungs, and the body wall. l**p. 22**

100 Keys | Water accounts for most of your body weight; proteins, the key structural and functional components of cells,

and nucleic acids, which control cell structure and function, work only in solution.

The Properties of Aqueous Solutions

Water's chemical structure makes it an unusually effective solvent (Figure 2–8•). The bonds in a water molecule are oriented such that the hydrogen atoms are relatively close together. As a result, the water molecule has positive and negative poles (Figure 2–8a•). A water molecule is therefore called a *polar molecule*, or a *dipole*.

Many inorganic compounds are held together partially or completely by ionic bonds. In water, these compounds undergo *ioni-*

¯A

¯A

zation (-on-i-Z

ı act with the positive or negative ends of polar water molecules (Figure 2–8b•). The result is a mixture of cations and anions surrounded by water molecules. The water molecules around each ion form a *hydration sphere*.

An aqueous solution containing anions and cations will conduct an electrical current. Cations (+) move toward the negative side, or negative *terminal*, and anions (-) move toward the positive terminal. Electrical forces across cell membranes affect the functioning of all cells, and small electrical currents carried by ions are essential to muscle contraction and nerve function. Chapters 10 and 12 will discuss these processes in more detail.

Electrolytes and Body Fluids Soluble inorganic molecules whose ions will conduct an electrical current in solution are called

–

-shun), or *dissociation* (di-s

-shun). In this process, ionic bonds are broken as the individual ions inter-

¯o¯e

-s -

electrolytes (e-LEK-tr

-l ts). Sodium chloride is an electrolyte. The dissociation of electrolytes in blood and other body fluids

ı releases a variety of ions. Table 2–3 lists important electrolytes and the ions released by their dissociation.

–

Changes in the concentrations of electrolytes in body fluids will disturb almost every vital function. For example, declining potassium levels will lead to a general muscular paralysis, and rising concentrations will cause weak and irregular heartbeats. The concentrations of ions in body fluids are carefully regulated, primarily by the coordination of activities at the kidneys (ion excretion), the digestive tract (ion absorption), and the skeletal system (ion storage or release).

Hydrophilic and Hydrophobic Compounds Some organic molecules contain polar covalent bonds, which also attract water molecules. The hydration spheres that form may then carry these molecules into solution (Figure 2–8c•). Molecules such as *glucose*,

¯o

–

an important soluble sugar, that interact readily with water molecules in this way are called **hydrophilic** (h -dr

ı water + *philos*, loving). Many other organic molecules either lack polar covalent bonds or have very few. Such molecules do not have positive and negative terminals, and are said to be *nonpolar*. When nonpolar molecules are exposed to water, hydration spheres do not form and

¯o

-FIL-ik; *hydro*-,

–

the molecules do not dissolve. Molecules that do not readily interact with water are called **hydrophobic** (h -dr ı , water + *phobos* fear). Among the most familiar hydrophobic molecules are fats and oils of all kinds. Body fat deposits, for example, consist of large, hydrophobic droplets trapped in the watery interior of cells. Gasoline and heating oil are hydrophobic molecules not found in the body; when accidentally discharged into lakes or oceans, they form tenacious oil slicks instead of dissolving.

Colloids and Suspensions

Body fluids may contain large and complex organic molecules, such as proteins and protein complexes, that are held in solution by their association with water molecules (Figure 2–8c•). A solution containing dispersed proteins or other large molecules is called a **colloid**. Liquid Jell-O is a familiar viscous (thick) colloid.

The particles or molecules in a colloid will remain in solution indefinitely. A **suspension** contains even larger particles that will, if undisturbed, settle out of solution due to the force of gravity. Stirring beach sand into a bucket of water creates a temporary suspension that will last only until the sand settles to the bottom. Whole blood is another temporary suspension, because the blood cells are suspended in the blood plasma. If clotting is prevented, the cells in a blood sample will gradually settle to the bottom of the container. Measuring that settling rate, or “sedimentation rate,” is a common laboratory test.

pH: The Concentration of Hydrogen Ions in Body Fluids

A hydrogen atom involved in a chemical bond or participating in a chemical reaction can easily lose its electron, to become a hy-

-F

b-ik; *hydro-*

¯o¯o

drogen ion, H^+. Hydrogen ions are extremely reactive in solution. In excessive numbers, they will break chemical bonds, change the shapes of complex molecules, and generally disrupt cell and tissue functions. As a result, the concentration of hydrogen ions in body fluids must be regulated precisely.

A few hydrogen ions are normally present even in a sample of pure water, because some of the water molecules dissociate spontaneously, releasing cations and anions. The dissociation of water is a reversible reaction that can be represented as

$H_2O \Delta H^+ + OH^-$.

The dissociation of one water molecule yields a hydrogen ion and a *hydroxide* (h -DROK-s d) *ion*, OH^-.

—1

1

Very few water molecules ionize in pure water, and the number of hydrogen and hydroxide ions is small. The quantities are usually reported in moles, making it easy to keep track of the relative numbers of hydrogen and hydroxide ions. One liter of pure water contains about 0.0000001 mol of hydrogen ions and an equal number of hydroxide ions. In other words, the concentration of hydrogen ions in a solution of pure water is 0.0000001 mol per liter. This can be written as

$[H^+] = 1 * 10^{-7}$ mol> L.

The brackets around the H^+ signify “the concentration of,” another example of chemical notation.

The hydrogen ion concentration in body fluids is so important to physiological processes that a special shorthand is used to express it. The **pH** of a solution is defined as the negative logarithm of the hydrogen ion concentration in moles per liter. Thus, instead of using the equation $[H^+] = 1 * 10^{-7}$ mol> L, we say that the pH of pure water is -(-7), or 7. Using pH values saves space, but always remember that the pH number is an *exponent* and that the pH scale is logarithmic. For instance, a pH of 6 ($[H^+] = 1 * 10^{-6}$, or 0.000001) means that the concentration of hydrogen ions is *10 times as great* as it is at a pH of 7 ($[H^+] = 1 * 10^{-7}$, or 0.0000001). For common liquids, the pH scale, included in Figure 2–9•, ranges from 0 to 14.

Although pure water has a pH of 7, solutions display a wide range of pH values, depending on the nature of the solutes involved:

- A solution with a pH of 7 is said to be **neutral**, because it contains equal numbers of hydrogen and hydroxide ions.
- A solution with a pH below 7 is **acidic** (a-SI-dik), meaning that it contains more hydrogen ions than hydroxide ions.
- A pH above 7 is **basic**, or *alkaline* (AL-kuh-lin), meaning that it has more hydroxide ions than hydrogen ions.

The pH of blood normally ranges from 7.35 to 7.45. Abnormal fluctuations in pH can damage cells and tissues by breaking chemical bonds, changing the shapes of proteins, and altering cellular functions. *Acidosis* is an abnormal physiological state caused by low blood pH (below 7.35); a pH below 7 can produce coma. *Alkalosis* results from an abnormally high pH (above 7.45); a blood pH above 7.8 generally causes uncontrollable and sustained skeletal muscle contractions.

100 Keys | The pH of body fluids is an indication of how many free hydrogen ions are in solution. Hydrogen ions in excess (a low pH) can damage cells and tissues, change the shapes and functions of proteins, and interfere with normal physiological systems. A high pH also has adverse effects, but problems due to low pH are much more common.

Inorganic Acids and Bases

The body contains both inorganic and organic *acids* and *bases* that may cause acidosis or alkalosis, respectively. An **acid** is any solute that dissociates in solution and releases hydrogen ions, thereby lowering the pH. Because a hydrogen atom that loses its electron consists solely of a proton, hydrogen ions are often referred to simply as protons, and acids as *proton donors*.

A *strong acid* dissociates completely in solution, and the reaction occurs essentially in one direction only. *Hydrochloric acid* (HCl) is a representative strong acid; in water, it ionizes as follows:

$HCl \text{ ¡ } H^{+} + Cl^{-}$

The stomach produces this powerful acid to assist in the breakdown of food. Hardware stores sell HCl under the name muriatic acid, for cleaning concrete and swimming pools.

A **base** is a solute that removes hydrogen ions from a solution and thereby acts as a *proton acceptor*. In solution, many bases release a hydroxide ion (OH^{-}). Hydroxide ions have a strong affinity for hydrogen ions and react quickly with them to form water molecules. A *strong base* dissociates completely in solution. *Sodium hydroxide*, NaOH, is a strong base; in solution, it releases sodium ions and hydroxide ions:

$NaOH \text{ ¡ } Na^{+} + OH^{-}$

Strong bases have a variety of industrial and household uses. Drain openers (Drano) and lye are two familiar examples.

Weak acids and *weak bases* fail to dissociate completely. At equilibrium, a significant number of molecules remain intact in the solution. For the same number of molecules in solution, weak acids and weak bases therefore have less of an impact on pH than do strong acids and strong bases. *Carbonic acid* (H2CO3) is a weak acid found in body fluids. In solution, carbonic acid reversibly

-

dissociates into a hydrogen ion and a *bicarbonate ion*, HCO3 :

$H_2CO_3 \, \Delta \, H^{+} + HCO_3$

Salts

A **salt** is an ionic compound consisting of any cation except a hydrogen ion, and any anion except a hydroxide ion. Because they are held together by ionic bonds, many salts dissociate completely in water, releasing cations and anions. For example, sodium

-

chloride (table salt) dissociates immediately in water, releasing Na^+ and Cl. Sodium and chloride are the most abundant ions in body fluids. However, many other ions are present in lesser amounts as a result of the dissociation of other inorganic compounds. Ionic concentrations in the body are regulated by mechanisms we will describe in Chapters 26 and 27.

The ionization of sodium chloride does not affect the local concentrations of hydrogen ions or hydroxide ions, so NaCl, like many salts, is a "neutral" solute. Through their interactions with water molecules, however, other salts may indirectly affect the concentrations of H^+ and OH^-ions. Thus, the dissociation of some salts makes a solution slightly acidic or slightly basic.

Buffers and pH Control

Buffers are compounds that stabilize the pH of a solution by removing or replacing hydrogen ions. *Buffer systems* typically involve a weak acid and its related salt, which functions as a weak base. For example, the carbonic acid–bicarbonate buffer system (which will be detailed in Chapter 27) consists of carbonic acid and sodium bicarbonate, $NaHCO_3$, otherwise known as baking soda. Buffers and buffer systems in body fluids help maintain the pH within normal limits. The pH of several body fluids is included in Figure 2–9•. Antacids such as Alka-Seltzer use sodium bicarbonate to neutralize excess hydrochloric acid in the stomach. The effects of neutralization are most evident when you add a strong acid to a strong base. For example, by adding hydrochloric acid to sodium hydroxide, you neutralize both the strong acid and the strong base:

$HCl + NaOH \rightarrow H_2O + NaCl$ This reaction produces water and a salt—in this case, the neutral salt sodium chloride.

Concept Check

☐ Why does a solution of table salt conduct electricity, but a sugar solution does not?

☐ How does an antacid help decrease stomach discomfort?

Answers begin on p. A-1

Organic Compounds

Objective

- Discuss the structures and functions of carbohydrates, lipids, proteins, nucleic acids, and high-energy compounds.

Organic compounds always contain the elements carbon and hydrogen, and generally oxygen as well. Many organic molecules are made up of long chains of carbon atoms linked by covalent bonds. The carbon atoms typically form additional covalent bonds with hydrogen or oxygen atoms and, less commonly, with nitrogen, phosphorus, sulfur, iron, or other elements.

Many organic molecules are soluble in water. Although the previous discussion focused on inorganic acids and bases, there are also important organic acids and bases. For example, *lactic acid* is an organic acid, generated by active muscle tissues, that must be neutralized by the carbonic acid–bicarbonate buffer system to prevent a potentially dangerous pH decline in body fluids.

In this discussion, we consider four major classes of organic compounds: *carbohydrates, lipids, proteins*, and *nucleic acids*. We also introduce *high-energy compounds*, which are vital to the survival and operation of our cells. In addition, the human body contains small quantities of many other organic compounds whose structures and functions we will consider in later chapters.

Although organic compounds are diverse, certain groupings of atoms occur again and again, even in very different types of molecules. These *functional groups* greatly influence the properties of any molecule they are part of. Table 2–4 details the functional groups you will encounter in this chapter.

Carbohydrates

A **carbohydrate** is an organic molecule that contains carbon, hydrogen, and oxygen in a ratio near 1 : 2 : 1. Familiar carbohydrates include the *sugars* and *starches* that make up roughly half of the typical U.S. diet. Carbohydrates typically account for less than 1 percent of total body weight. Although they may have other functions, carbohydrates are most important as energy sources that are catabolized rather than stored. We will focus on *monosaccharides*, *disaccharides*, and *polysaccharides*.

Monosaccharides

A *simple sugar*, or **monosaccharide** (mon-o¯-SAK-uh-r d; *mono-*, single + *sakcharon*, sugar), is a carbohydrate containing from

–

ı three to seven carbon atoms. A monosaccharide can be called a *triose* (three-carbon), *tetrose* (four-carbon), *pentose* (five-carbon),

hexose (six-carbon), or *heptose* (seven-carbon). The hexose **glucose** (GLOO-k

¯o

s), $C_6H_{12}O_6$, is the most important metabolic "fuel"

in the body. The atoms in a glucose molecule may form either a straight chain (Figure 2–10a•) or a ring (Figure 2–10b•). In the body, the ring form is more common. A three-dimensional model shows the arrangement of atoms in the ring most clearly (Figure 2–10c•).

The three-dimensional structure of an organic molecule is an important characteristic, because it usually determines the mol-ecule's fate or function. Some molecules have the same molecular formula—in other words, the same types and numbers of atoms— but different structures. Such molecules are called **isomers**. The body usually treats different isomers as distinct molecules. For example, the monosaccharides glucose and fructose are isomers. *Fructose* is a hexose found in many fruits and in secretions of the male reproductive tract. Although its chemical formula, $C_6H_{12}O_6$, is the same as that of glucose, the arrangement of its atoms differs from that of glucose. As a result, separate enzymes and reaction sequences control its breakdown and synthesis. Monosaccharides such as glucose and fructose dissolve readily in water and are rapidly distributed throughout the body by blood and other body fluids. AM: The Pharmaceutical Use of Isomers

Disaccharides and Polysaccharides

Carbohydrates other than simple sugars are complex molecules composed of monosaccharide building blocks. Two monosaccharides joined together form a **disaccharide**

(d -SAK-uh-r d; *di*-, two). Disaccharides such as *sucrose* (table sugar) have a sweet taste and, like monosaccharides, are quite sol-

ıı uble in water. The formation of sucrose (Figure 2–11a•) involves dehydration synthesis, a process introduced earlier in the chapter. Dehydration synthesis, or condensation, links molecules together by the removal of a water molecule. The breakdown of sucrose into simple sugars is an example of hydrolysis, the functional opposite of dehydration synthesis (Figure 2–11b•).

Many foods contain disaccharides, but all carbohydrates except monosaccharides must be disassembled through hydrolysis before they can provide useful energy. Most popular junk foods, such as candies and sodas, abound in monosaccharides (commonly fructose) and disaccharides (generally sucrose). Some people cannot tolerate sugar for medical reasons; others avoid it in an effort to control their weight. (Excess sugars are converted to fat for long-term storage.) Many such people use *artificial sweeteners* in their foods and beverages. These compounds have a very sweet taste, but they either cannot be broken down in the body or are used in insignificant amounts. AM: Artificial Sweeteners

More-complex carbohydrates result when repeated dehydration synthesis reactions add additional monosaccharides or disac

–

–

charides. These large molecules are called **polysaccharides** (pol

–

ı straight or highly branched. *Cellulose*, a structural component of many plants, is a polysaccharide that our bodies cannot digest. Foods such as celery, which contains cellulose, water, and little else, contribute bulk to digestive wastes but are useless as a source of energy. (In fact, you obtain fewer calories from a stalk of celery than you gain by digesting it.)

Starches are large polysaccharides formed from glucose molecules. Most starches are manufactured by plants. Your digestive tract can break these molecules into monosaccharides. Starches such as those in potatoes and grains are a major dietary energy source.

¯e

-SAK-uh-r

dz; *poly*-, many). Polysaccharide chains can be

¯I

The polysaccharide **glycogen** (GL -k cules (Figure 2–12•). Like most other starches, glycogen does not dissolve in water or other body fluids. Muscle cells make and store glycogen. When muscle cells have a high demand for glucose, glycogen molecules are broken down; when the demand is low, they absorb glucose from the bloodstream and rebuild glycogen reserves.

Despite their metabolic importance, carbohydrates account for less than 3 percent of total body weight. Table 2–5 summarizes information about the carbohydrates.

Lipids

Like carbohydrates, **lipids** (*lipos*, fat) contain carbon, hydrogen, and oxygen, but the carbon-to-hydrogen ratio is typically near

1 : 2. Thus, lipids contain much less oxygen than do carbohydrates with the same number of carbon atoms. The hydrogen-to-oxy-gen ratio is therefore very large; a representative lipid, such as lauric acid, has a formula of C12H24O2. Lipids may also contain small quantities of phosphorus, nitrogen, or sulfur. Familiar lipids include *fats*, *oils*, and *waxes*. Most lipids are insoluble in water, but special transport mechanisms carry them in the circulating blood.

Lipids form essential structural components of all cells. In addition, lipid deposits are important as energy reserves. On average, lipids provide roughly twice as much energy as carbohydrates do, gram for gram, when broken down in the body. When the supply of lipids exceeds the demand for energy, the excess is stored in fat deposits. For this reason, there has been great interest in developing *fat substitutes* that provide less energy, but have the same taste and texture as lipids. AM: Fat Substitutes

Lipids normally account for 12–18 percent of the total body weight of adult men, and 18–24 percent of that of adult women. Many kinds of lipids exist in the body. We will consider five classes of lipids: *fatty acids*, *eicosanoids*, *glycerides*, *steroids*, and *phospholipids and glycolipids*.

100 Keys | Carbohydrates are important as a quick source of energy and as integral components of membranes. Lipids form membranes within and between cells that prevent the diffusion of solutes. Fats are large lipids important as energy reserves.

¯o

-jen), or *animal starch*, has many side branches consisting of chains of glucose mole

Fatty Acids

Fatty acids are long carbon chains with hydrogen atoms attached. One end of the carbon chain always bears a *carboxylic* (kar-bok-SIL-ik) *acid group*, ¬ COOH (see Table 2–4). The name *carboxyl* should help you remember that a carbon and a hydroxyl (¬ OH) group are the important structural features of fatty acids. The carbon chain attached to the carboxylic acid group is known as the hydrocarbon *tail* of the fatty acid. Figure 2–13a• shows a representative fatty acid, *lauric acid,* found in coconut oil and oils of the laurel evergreen.

When a fatty acid is in solution, only the carboxyl end associates with water molecules, because that is the only hydrophilic portion of the molecule. The hydrocarbon tail is hydrophobic, so fatty acids have a very limited solubility in water. In general, the longer the hydrocarbon tail, the lower the solubility of the molecule.

Fatty acids may be either saturated or unsaturated (Figure 2–13b•). These terms refer to the number of hydrogen atoms bound to the carbon atoms in the hydrocarbon tail. In a *saturated* fatty acid, each carbon atom in the tail has four single covalent bonds (see Figure 2–13a•). Within the tail, two of those bonds are to adjacent carbon atoms, and the other two bind hydrogen atoms; the carbon atom at the distal end of the tail binds three hydrogen atoms. In an *unsaturated* fatty acid, one or more of the single covalent bonds between the carbon atoms has been replaced by a double covalent bond. As a result, the carbon atoms involved will each bind only one hydrogen atom rather than two. This changes both the shape of the hydrocarbon tail and the way the fatty acid is metabolized. A *monounsaturated* fatty acid has a single double bond in the hydrocarbon tail. A *polyunsaturated* fatty acid contains multiple double bonds. AM: Fatty Acids and Health

Eicosanoids

Eicosanoids (-KO-sa-noydz) are lipids derived from *arachidonic* (ah-rak-i-DON-ik) *acid*, a fatty acid that must be absorbed inı ¯ ¯the diet because it cannot be synthesized by the body. The two major classes of eicosanoids are *leukotrienes* and *prostaglandins*. Leukotrienes are produced primarily by cells involved with coordinating the responses to injury or disease. We will consider leukotrienes in Chapters 18 and 22. We consider only prostaglandins here, because virtually all tissues synthesize and respond to them.

Prostaglandins (pros-tuh-GLAN-dinz) are short-chain fatty acids in which five of the carbon atoms are joined in a ring (Figure 2–14•). These compounds are released by cells to coordinate or direct local cellular activities, and they are extremely powerful even in minute quantities. The effects of prostaglandins vary with their structure and the site of their release. Prostaglandins released by damaged tissues, for example, stimulate nerve endings and produce the sensation of pain (Chapter 15). Those released in the uterus help trigger the start of labor contractions (Chapter 29).

The body uses several types of chemical messengers. Those that are produced in one part of the body but have effects on distant parts are called *hormones*. Hormones are distributed throughout the body in the bloodstream, whereas most prostaglandins affect only the area in which they are produced. As a result, prostaglandins are often called *local hormones*. The distinction is not a rigid one, however, as some prostaglandins also enter the bloodstream and affect other areas to some degree. We will discuss hormones and prostaglandins in Chapter 18.

Glycerides

Unlike monosaccharides, individual fatty acids cannot be strung together in a chain by dehydration synthesis. But they can be attached to another compound, **glycerol** (GLIS-er-ol), through a similar reaction. The result is a lipid known as a **glyceride** (GLIS-er-¯ı d). Dehydration synthesis can produce a **monoglyceride** (mon-o¯-GLI-ser-¯ı d), consisting of glycerol plus one fatty acid. Subsequent reactions can yield a **diglyceride** (glycerol + two fatty acids) and then a **triglyceride** (glycerol + three fatty acids), as in Figure 2–15•. Hydrolysis breaks the glycerides into fatty acids and glycerol. Comparing Figure 2–15• with Figure 2–11• shows that dehydration synthesis and hydrolysis operate the same way, whether the molecules involved are carbohydrates or lipids.

Triglycerides, also known as *triacylglycerols* or *neutral fats*, have three important functions:

1. *Energy Source.* Fatty deposits in specialized sites of the body represent a significant energy reserve. In times of need, the triglycerides are disassembled by hydrolysis, yielding fatty acids that can be broken down to provide energy.

2. *Insulation.* Fat deposits under the skin serve as insulation, slowing heat loss to the environment. Heat loss across a layer of lipids is only about one-third that through other tissues.

3. *Protection.* A fat deposit around a delicate organ such as a kidney provides a cushion that protects against shocks or blows.

Triglycerides are stored in the body as lipid droplets within cells. The droplets absorb and accumulate lipid-soluble vitamins, drugs, or toxins that appear in body fluids. This accumulation has both positive and negative effects. For example, the body's lipid reserves retain both valuable lipid-soluble vitamins (A, D, E, K) and potentially dangerous lipid-soluble pesticides, such as DDT.

Steroids

Steroids are large lipid molecules that share a distinctive carbon framework (Figure 2–16•). They differ in the carbon chains that are attached to the basic structure. The steroid **cholesterol** (ko-LES-ter-ol; *chole-*, bile + *stereos*, solid) and related steroids are important for the following reasons:

- All animal cell membranes contain cholesterol (Figure 2–16a•). Cells need cholesterol to maintain their cell membranes, as well as for cell growth and division.
- Steroid hormones are involved in the regulation of sexual function. Examples include the sex hormones, such as the *estrogens* and *testosterone* (Figure 2–16b,c•).
- Steroid hormones are important in the regulation of tissue metabolism and mineral balance. Examples include the hormones of the adrenal cortex, called *corticosteroids*, and *calcitriol*, a hormone important in the regulation of calcium ion concentrations in the body.
- Steroid derivatives called *bile salts* are required for the normal processing of dietary fats. Bile salts are produced in the liver and secreted in bile. They interact with lipids in the intestinal tract and facilitate the digestion and absorption of lipids.

Cholesterol is obtained in two ways: (1) by absorption from animal products in the diet and (2) by synthesis within the body. Liver, fatty meat, cream, and egg yolks are especially rich dietary sources of cholesterol. A diet high in cholesterol can be harmful, because a strong link exists between high blood cholesterol levels and heart disease. Current nutritional advice suggests limiting cholesterol intake to less than 300 mg per day. This amount represents a 40 percent reduction for the average adult in the United States. Unfortunately, because the body can synthesize cholesterol as well, blood cholesterol levels can be difficult to control by dietary restriction alone. We will examine the connection between blood cholesterol levels and heart disease more closely in later chapters.

Phospholipids and Glycolipids

Phospholipids (FOS-fo¯-lip-idz) and **glycolipids** (GL -ko¯-lip-idz) are structurally related, and our cells can synthesize both types I¯

3-)

of lipids, primarily from fatty acids. In a *phospho*lipid, a *phosphate group* (PO4 links a diglyceride to a nonlipid group (Figure 2–17a•). In a *glyco*lipid, a carbohydrate is attached to a diglyceride (Figure 2–17b•). Note that placing *-lipid* last in these names indicates that the molecule consists primarily of lipid.

The long hydrocarbon tails of phospholipids and glycolipids are hydrophobic, but the opposite ends, the nonlipid *heads*, are hydrophilic. In water, large numbers of these molecules tend to form droplets, or *micelles* (m -SELZ), with the hydrophilic por

–

ı tions on the outside (Figure 2–17c•). Most meals contain a mixture of lipids and other organic molecules, and micelles form as the food breaks down in your digestive tract. In addition to phospholipids and glycolipids, micelles may contain other insoluble lipids, such as steroids, glycerides, and long-chain fatty acids.

Cholesterol, phospholipids, and glycolipids are called *structural lipids*, because they help form and maintain intracellular structures called membranes. At the cellular level, *membranes* are sheets or layers composed primarily of hydrophobic lipids. A membrane surrounds each cell and separates the aqueous solution inside the cell from the aqueous solution in the extracellular environment. A variety of internal membranes subdivide the interior of the cell into specialized compartments, each with a distinctive chemical nature and, as a result, a different function.

The types of lipids and their characteristics are summarized in Table 2–6.

Concept Check

☐ A food contains organic molecules with the elements C, H, and O in a ratio of 1 : 2 : 1. What class of compounds do these molecules belong to, and what are their major functions in the body? ☐ When two monosaccharides undergo a dehydration synthesis reaction, which types of molecules are formed? ☐ Which kind of lipid would be found in a sample of fatty tissue taken from beneath the skin? ☐ Which lipids would you find in human cell membranes?

Answers begin on p. A-1

Proteins

Proteins are the most abundant organic components of the human body and in many ways the most important. The human body may contain as many as 2 million different proteins, and they account for about 20 percent of total body weight. All proteins contain carbon, hydrogen, oxygen, and nitrogen; smaller quantities of sulfur may also be present.

Proteins perform a variety of essential functions, which can be classified into seven major categories:

1. *Support. Structural proteins* create a three-dimensional framework for the body, providing strength, organization, and support for cells, tissues, and organs.

2. *Movement. Contractile proteins* are responsible for muscular contraction; related proteins are responsible for the movement of individual cells.

3. *Transport.* Insoluble lipids, respiratory gases, special minerals such as iron, and several hormones cannot be transported in the blood, unless they are first bound to special *transport proteins*. Other specialized proteins transport materials from one part of a cell to another.

4. *Buffering.* Proteins provide a considerable *buffering* action and thereby help prevent dangerous changes in pH in cells and tissues.

5. *Metabolic Regulation. Enzymes* accelerate chemical reactions in cells. The sensitivity of enzymes to environmental factors is extremely important in controlling the pace and direction of metabolic operations.

6. *Coordination and Control.* Protein *hormones* can influence the metabolic activities of every cell in the body or affect the function of specific organs or organ systems.

7. *Defense.* The tough, waterproof proteins of the skin, hair, and nails protect the body from environmental hazards. Proteins called *antibodies*, components of the *immune response*, help protect us from disease. Special *clotting proteins* restrict bleeding after an injury to the cardiovascular system.

100 Keys | Proteins are the most abundant organic components of the body, and they are the key to both anatomical structure and physiological function. Proteins determine cell shape and tissue properties, and almost all cell functions are performed by proteins and by interactions between proteins and their immediate environment.

Protein Structure

Proteins consist of long chains of organic molecules called **amino acids**. Twenty different amino acids occur in significant quantities in the body. A typical protein contains 1000 amino acids; the largest protein complexes have 100,000 or more. Each amino acid consists of five components (Figure 2–18•):

- a central carbon atom
- a hydrogen atom
- an *amino group* (¬ NH2)
- a *carboxylic acid group* (¬ COOH)
- a variable group, known as an *R group* or *side chain*

The name *amino acid* refers to the presence of the *amino* group and the carboxylic *acid* group, which all amino acids have in common. The different R groups distinguish one amino acid from another, giving each its own chemical properties. All amino acids are relatively small water-soluble molecules. In the normal pH range of body fluids, the carboxylic acid groups

-

on many amino acids release hydrogen ions. When this occurs, the carboxylic acid group changes from ¬ COOH to ¬ COO, and the amino acids become negatively charged.

Figure 2–19• shows how dehydration synthesis can link two representative amino acids: *glycine* and *alanine*. This reaction creates a covalent bond between the carboxylic acid group of one amino acid and the amino group of another. Such a bond is known as a **peptide bond**. Molecules consisting of amino acids held together by peptide bonds are called **peptides**. The molecule created in this example is called a *dipeptide*, because it contains two amino acids.

The chain can be lengthened by the addition of more amino acids. Attaching a third amino acid produces a *tripeptide*. Tripeptides and larger peptide chains are called **polypeptides**. Polypeptides containing more than 100 amino acids are usually called proteins. Familiar proteins include *hemoglobin* in red blood cells and *keratin* in fingernails and hair. Because most proteins contain side groups that are negatively charged, the entire protein acts as an anion. For that reason, they are often indicated by the abbreviation Pr^-.

Protein Shape

The characteristics of a particular protein are determined in part by the R groups on its component amino acids. But the properties of a protein are more than just the sum of the properties of its parts, for polypeptides can have highly complex shapes. Proteins can have four levels of structural complexity (Figure 2–20•):

1. Primary structure is the sequence of amino acids along the length of a single polypeptide (Figure 2–20a•).

2. Secondary structure results from bonds between atoms at different parts of the polypeptide chain. Hydrogen bonding, for example, may create either a simple spiral, known as an *alpha-helix*, or a flat *pleated sheet* (Figure 2–20b•). Which forms depends on the sequence of amino acids in the peptide chain and where hydrogen bonding occurs along the peptide. The alpha-helix is the most common form, but a given polypeptide chain may have both helical and pleated sections.

3. Tertiary structure is the complex coiling and folding that gives a protein its final three-dimensional shape (Figure 2–20c•). Tertiary structure results primarily from interactions between the polypeptide chain and the surrounding water molecules, and to a lesser extent from interactions between the R groups of amino acids in different parts of the molecule. Most such interactions are relatively weak. One, however, is very strong: the *disulfide bond*, a covalent bond that may form between two molecules of the amino acid *cysteine* located at different sites along the chain. Disulfide bonds create permanent loops or coils in a polypeptide chain.

4. Quaternary structure is the interaction between individual polypeptide chains to form a protein complex (Figure 2–20d•). Each of the polypeptide subunits has its own secondary and tertiary structures. The protein *hemoglobin* contains four globular subunits. Hemoglobin is found within red blood cells, where it binds and transports oxygen. In *keratin* and *collagen*, three alpha-helical polypeptides are wound together like the strands of a rope. Keratin is the tough, water-resistant protein at the surface of the skin and in nails and hair. Collagen is the most abundant structural protein and is found in skin, bones, cartilages, and tendons; collagen fibers form the framework that supports cells in most tissues.

Fibrous and Globular Proteins Proteins fall into two general structural classes on the basis of their overall shape and properties:

- **Fibrous proteins** form extended sheets or strands. These shapes are usually the product of secondary structure (for proteins that exhibit the pleated-sheet configuration) or quaternary structure (for keratin and collagen). Fibrous proteins are tough, durable, and generally insoluble in water; in the body, they usually play structural roles.
- **Globular proteins** are compact, generally rounded, and readily enter an aqueous solution. The unique shape of each globular protein is the product of its tertiary structure. *Myoglobin*, a protein in muscle cells, is a globular protein, as is hemoglobin, the oxygen-

carrying pigment in red blood cells. Many enzymes, hormones, and other molecules that circulate in the bloodstream are globular proteins, as are the enzymes that control chemical reactions inside cells. These proteins can function only so long as they remain in solution.

Protein Shape and Function Proteins are extremely versatile and have a variety of functions. The shape of a protein determines its functional properties, and the ultimate determinant of shape is the sequence of amino acids. The 20 common amino acids can be linked in an astonishing number of combinations, creating proteins of enormously varied shape and function. Changing the identity of only one of the 10,000 or more amino acids in a protein can significantly alter the protein's functional properties. For example, several cancers and *sickle cell anemia*, a blood disorder, result from single changes in the amino acid sequences of complex proteins.

The tertiary and quaternary shapes of complex proteins depend not only on their amino acid sequence, but also on the local environmental conditions. Small changes in the ionic composition, temperature, or pH of their surroundings can thus affect the function of proteins. Protein shape can also be affected by hydrogen bonding to other molecules in solution. The significance of these factors is most striking when we consider the function of enzymes, for these proteins are essential to the metabolic operations occurring in every one of our cells.

Enzyme Function

Among the most important of all the body's proteins are the enzymes, first introduced earlier in this chapter. These molecules catalyze the reactions that sustain life: Almost everything that happens inside the human body does so because a specific enzyme makes it possible. AM: Metabolic Anomalies

The reactants in enzymatic reactions are called **substrates**. As in other types of chemical reactions, the interactions among substrates yield specific products. Before an enzyme can function as a catalyst—to accelerate a chemical reaction without itself being permanently changed or consumed—the substrates must bind to a special region of the enzyme. This region, called the **active site**, is typically a groove or pocket into which one or more substrates nestle, like a key fitting into a lock. The physical fit is reinforced by weak electrical attractive forces, such as hydrogen bonding. The tertiary or quaternary structure of the enzyme molecule determines the shape of the active site. Although enzymes are proteins, any organic or inorganic compound that will bind to the active site can be a substrate.

Figure 2–21• presents one example of enzyme structure and function. Substrates bind to the enzyme at its active site (STEP 1). Substrate binding typically results in a temporary, reversible change in the shape of the protein; this change may further the reaction by placing physical stresses on the substrate molecules. The enzyme then promotes product formation (STEP 2). The completed product then detaches from the active site (STEP 3), and the enzyme is free to repeat the process. Enzymes work quickly, cycling rapidly between substrates and products. For example, an enzyme providing energy during a muscular contraction performs its reaction sequence 100 times per second; hydrolytic enzymes can work even faster, breaking down almost 20,000 molecules a second.

Figure 2–21• shows an enzyme that catalyzes a synthesis reaction. Other enzymes may catalyze decomposition reactions or exchange reactions. Regardless of the reaction they catalyze, all enzymes share three basic characteristics:

1. *Specificity.* Each enzyme catalyzes only one type of reaction, a characteristic called **specificity**. An enzyme's specificity is determined by the ability of its active sites to bind only to substrates with particular shapes and charges. Thus, differences in enzyme structure that neither affect the active site nor change the response of the enzyme to substrate binding do not affect enzyme function. In fact, different tissues typically contain enzymes that differ slightly in structure, but catalyze the same reaction. Such enzyme variants are called **isozymes**.

2. *Saturation Limits.* The rate of an enzymatic reaction is directly related to the concentrations of substrate molecules and enzymes. An enzyme molecule must encounter appropriate substrates before it can catalyze a reaction; the higher the substrate concentration, the more frequent encounters will be. When substrate concentrations are high enough that every enzyme molecule is cycling through its reaction sequence at top speed, further increases in substrate concentration will not affect the rate of reaction unless additional enzyme molecules are provided. The substrate concentration required to have the maximum rate of reaction is called the *saturation limit*. An enzyme that has reached its saturation limit is said to be **saturated**. To increase the reaction rate further, the cell must increase the number of enzyme molecules available. This is one important way that cells promote specific reactions.

3. *Regulation.* Each cell contains an assortment of enzymes, and any particular enzyme may be active under one set of conditions and inactive under another. Virtually anything that changes the tertiary or quaternary shape of an enzyme can turn it "on" or "off" and thereby control reaction rates inside the cell. Because the change is immediate, enzyme activation or inactivation is an important method of short-term control over reaction rates and pathways. Here we will consider only one example of enzyme regulation: the presence or absence of *cofactors*.

Cofactors and Enzyme Function A **cofactor** is an ion or a molecule that must bind to the enzyme before substrates can also

bind. Without a cofactor, the enzyme is intact but nonfunctional; with the cofactor, the enzyme can catalyze a specific reaction. Examples of cofactors include ions such as calcium (Ca^{2+}) and magnesium (Mg^{2+}), which bind at the enzyme's active site. Cofactors may also bind at other sites, as long as they produce a change in the shape of the active site that makes substrate binding possible.

Coenzymes are nonprotein organic molecules that function as cofactors. Our bodies convert many vitamins into essential coenzymes. *Vitamins*, detailed in Chapter 25, are structurally related to lipids or carbohydrates, but have unique functional roles. Because the human body cannot synthesize most of the vitamins it needs, you must obtain them from your diet.

Effects of Temperature and pH Each enzyme works best at specific temperatures and pH values. As temperatures rise, protein shape changes and enzyme function deteriorates.

Eventually the protein undergoes **denaturation**, a change in tertiary or quaternary structure that makes it nonfunctional. You see permanent denaturation when you fry an egg. As the temperature rises, the proteins in the clear white denature. Eventually, the proteins become completely and irreversibly denatured, forming an insoluble white mass. Death occurs at very high body temperatures (above 43°C, or 110°F) because the denaturation of structural proteins and enzymes soon causes irreparable damage to organs and organ systems. However, this denaturation can be reversed if the temperature is reduced before the individual dies.

Enzymes are equally sensitive to changes in pH. *Pepsin*, an enzyme that breaks down proteins in stomach contents, works best at a pH of 2.0 (strongly acidic). Your small intestine contains *trypsin*, another enzyme that attacks proteins. Trypsin works only in an alkaline environment, with an optimum pH of 7.7 (weakly basic).

Glycoproteins and Proteoglycans

¯I

Glycoproteins (GL -k -GL -kanz) are combinations of protein and carbohydrate molecules. Glyco*proteins* are large proteins with small carbohydrate groups attached. These molecules may function as enzymes, antibodies, hormones, or protein components of cell membranes. Glycoproteins in cell membranes play a major role in the identification of normal versus abnormal cells, as well as in the initiation and coordination of the immune response (Chapter 22). Glycoprotein secretions called *mucins* absorb water to form **mucus**. Mucus coats the surfaces of the respiratory and digestive tracts, providing lubrication. Proteo*glycans* are large polysaccharide molecules linked by polypeptide chains. The proteoglycans in tissue fluids give them a syrupy consistency.

Concept Check

☐ Proteins are chains of which small organic molecules?

☐ Which level of protein structure would be affected by an agent that breaks hydrogen bonds?

☐ Why does boiling a protein affect its structural and functional properties?

☐ How might a change in an enzyme’s active site affect its function?

ı -ik) **acid**, or **DNA**, and **ribonucleic** (r -b

ı these two classes of nucleic acids differ in composition, structure, and function.

The DNA in our cells determines our inherited characteristics, including eye color, hair color, and blood type. DNA affects all aspects of body structure and function, because DNA molecules encode the information needed to build proteins. By directing the synthesis of structural proteins, DNA controls the shape and physical characteristics of our bodies. By controlling the manufacture of enzymes, DNA regulates not only protein synthesis, but all aspects of cellular metabolism, including the creation and destruction of lipids, carbohydrates, and other vital molecules.

Several forms of RNA cooperate to manufacture specific proteins by using the information provided by DNA. We will detail the functional relationships between DNA and RNA in Chapter 3.

100 Keys | The DNA in the nucleus contains the information needed to construct all of the proteins in the body.

Structure of Nucleic Acids

A nucleic acid consists of one or two long chains that are formed by dehydration synthesis. The individual subunits are called **nucleotides** (Figure 2–22•). Each nucleotide has three components: (1) a *pentose* (five-carbon sugar) attached to both (2) a phosphate group and (3) a **nitrogenous** (nitrogen-containing) **base**. The pentose is either *ribose* (in RNA) or *deoxyribose* (in DNA). Five nitrogenous bases occur in nucleic acids: **adenine** (**A**), **guanine** (**G**), **cytosine** (**C**), **thymine** (**T**), and **uracil** (**U**) (Figure 2–22b,c•). Adenine and guanine are double-ringed molecules called *purines*; the other three bases are single-ringed molecules called *pyrimidines*. Both RNA and DNA contain adenine, guanine, and cytosine. Uracil occurs only in RNA and thymine only in DNA.

A nucleotide forms when a phosphate group binds to a pentose already attached to a nitrogenous base. In the formation of a

-oks-

-b

-noo-KL

-ik) **acid**, or **RNA**. As we will see,

$\bar{}e\bar{}e\bar{}o\bar{}o$

-r

nucleic acid, dehydration synthesis then attaches the phosphate group of one nucleotide to the sugar of another. The "backbone" of a nucleic acid molecule is thus a linear sugar-to-phosphate-to-sugar sequence, with the nitrogenous bases projecting to one side (Figure 2–23•). The primary role of nucleic acids is the storage and transfer of information—specifically, information essential to the synthesis of proteins within our cells. Regardless of whether we are speaking of DNA or RNA, it is the sequence of nitrogenous bases that carries the information.

RNA and DNA

Important structural differences distinguish RNA from DNA. A molecule of RNA consists of a single chain of nucleotides (see Figure 2–23a•). Its shape depends on the order of the nucleotides and the interactions among them. Our cells have three types of RNA: (1) *messenger RNA* (*mRNA*), (2) *transfer RNA* (*tRNA*), and (3) *ribosomal RNA* (*rRNA*). These types have different shapes and functions, but all three are required for the synthesis of proteins, as you will see in Chapter 3.

A DNA molecule consists of a *pair* of nucleotide chains (Figure 2–23b•). Hydrogen bonding between opposing nitrogenous bases holds the two strands together. The shapes of the nitrogenous bases allow adenine to bond only to thymine and cytosine to bond only to guanine. As a result, the combinations adenine–thymine (A-T) and cytosine–guanine (C-T) are known as **complementary base pairs**, and the two nucleotide chains of the DNA molecule are known as **complementary strands**. Through a sequence of events described in Chapter 3, the cell uses one of the two complementary DNA strands to provide the information needed to synthesize a specific protein. The two strands of DNA twist around one another in a double helix that resembles a spiral staircase. Each step of the staircase corresponds to one complementary base pair (see Figure 2–23b•). Table 2–7 compares RNA with DNA.

High-Energy Compounds

To perform their vital functions, cells must use energy, obtained by breaking down organic substrates (catabolism). To be useful, that energy must be transferred from molecule to molecule or from one part of the cell to another.

The usual method of energy transfer involves the creation of *high-energy bonds* by enzymes within cells. A high-energy bond is a covalent bond whose breakdown releases energy the cell can harness. In your cells, a high-energy bond generally connects a phosphate group ($PO4^{3-}$) to an organic molecule. The resulting complex is called a **high-energy compound**. Most high-energy compounds are derived from nucleotides, the building blocks of nucleic acids.

The attachment of a phosphate group to another molecule is called **phosphorylation** (fos-for-i-LA¯-shun). This process does not necessarily produce high-energy bonds. The creation of a high-energy compound requires (1) a phosphate group, (2) enzymes capable of catalyzing the reactions involved, and (3) suitable organic substrates to which the phosphate can be added.

The most important such substrate is the nucleotide *adenosine monophosphate* (*AMP*). Attaching a second phosphate group produces **adenosine diphosphate** (**ADP**). A significant energy input is required to convert AMP to ADP, and the second phosphate is attached by a high-energy bond. Even more energy is required to add a third phosphate and thereby create the high-en-ergy compound **adenosine triphosphate**, or **ATP** (Figure 2–24•).

The conversion of ADP to ATP is the most important method of energy storage in our cells; the reversion of ATP to ADP is the most important method of energy release. The relationships involved can be diagrammed as:

ADP + phosphate group + energy Δ ATP + H2O

The conversion of ATP to ADP requires an enzyme known as **adenosine triphosphatase**, or **ATPase**. Throughout life, cells continuously generate ATP from ADP and use the energy provided by the ATP to perform vital functions, such as the synthesis of proteins or the contraction of muscles.

Although ATP is the most abundant high-energy compound, there are others—typically, other nucleotides that have undergone phosphorylation. For example, *guanosine triphosphate* (*GTP*) and *uridine triphosphate* (*UTP*) are nucleotide-based high-en-ergy compounds that transfer energy in specific enzymatic reactions.

Table 2–8 summarizes the inorganic and organic compounds covered in this chapter.

Concept Check

- A large organic molecule composed of the sugar ribose, nitrogenous bases, and phosphate groups is which kind of nucleic acid?
- What molecule is produced by the phosphorylation of ADP?

Answers begin on p. A-1

Chemicals and Cells

The human body is more than a collection of chemicals. Biochemical building blocks form functional units called *cells*. l**p. 5** Each cell behaves like a miniature organism, responding to internal and external stimuli. This is possible only because cells are dynamic structures that adapt to changes in their environment. Such adaptation may involve changes in the chemical organization of the cell—changes that are easily made because organic molecules other than DNA are temporary rather than permanent components of the cell. Their continuous removal and replacement are part of the process of **metabolic turnover**.

Most of the organic molecules in the cell are replaced at intervals ranging from hours to months. The average time between synthesis and recycling is known as the *turnover rate*. Table 2–9 lists the turnover rates of the organic components of representative cells.

In the next chapter we will learn more about the functions of these organic components as we explore the cellular level of organization.

100 Keys | Everything falls apart eventually, some things faster than others. Your survival depends on preventative maintenance; your body must recycle and renew most of its chemical components at intervals ranging from minutes to years. Although it has a relatively high energy cost, metabolic turnover lets your body grow and change, adapting to new conditions and activities.

Chapter Review

Selected Clinical Terminology

cholesterol: A steroid, important in the structure of cellular membranes, that, in high concentrations, increases the risk of heart disease.

(p. 47) **mole (mol), millimole (mmol):** A quantity of an element or compound that has a weight in grams equal to its atomic or molecular weight, respectively; 1 mmol = 0.001 mol.

(p. 29) **omega-3 fatty acids:** Fatty acids, abundant in fish flesh and fish oils, that have a double bond three carbons away from the end of the

hydrocarbon chain. Their presence in the diet has been linked to reduced risks of heart disease and other conditions. [AM] **radioisotopes:** Isotopes with unstable nuclei that spontaneously emit subatomic particles or radiation in measurable amounts. (p. 28)

Study Outline

Atoms, Molecules, and Bonds p. 27

1. Atoms are the smallest units of matter. They consist of **protons**, **neutrons**, and **electrons**. *(Figure 2–1)*

100 Keys | p. 27

Atomic Structure p. 27

2. The number of protons in an atom is its **atomic number**. Each **element** includes all the atoms that have the same number of protons and thus the same atomic number.

3. Within an atom, an **electron cloud** surrounds the nucleus. *(Figure 2–1; Table 2–1)*

4. The **mass number** of an atom is the total number of protons and neutrons in its nucleus. **Isotopes** are atoms of the same element whose nuclei contain different numbers of neutrons.

5. Electrons occupy an orderly series of **energy levels**, commonly illustrated as **electron shells**. The electrons in the outermost energy level determine an element's chemical properties. *(Figure 2–2)*

Chemical Bonds p. 30

6. Atoms can combine through chemical reactions that create **chemical bonds**. A **molecule** is any chemical structure consisting of atoms held together by covalent bonds. A **compound** is a chemical substance made up of atoms of two or more elements.

7. An **ionic bond** results from the attraction between **ions**, atoms that have gained or lost electrons. **Cations** are positively charged; **anions** are negatively charged. *(Figure 2–3)*

8. Atoms that share electrons to form a molecule are held together by **covalent bonds**. A sharing of one pair of electrons is a **single covalent bond**; a sharing of two pairs is a **double covalent bond**. A bond with equal sharing of electrons is a **nonpolar covalent bond**; a bond with unequal sharing of electrons is a **polar covalent bond**. *(Figures 2–4, 2–5)*

9. A **hydrogen bond** is a weak, but important, force that can affect the shapes and properties of molecules. *(Figure 2–6)*

10. Matter can exist as a *solid*, a *liquid*, or a *gas*, depending on the nature of the interactions among the component atoms or molecules.

11. The **molecular weight** of a molecule is the sum of the atomic weights of its component atoms.

12. Chemical notation is the shorthand that enables us to describe chemical compounds and reactions effectively. *(Table 2–2)*

FOCUS: Chemical Notation p. 34

Chemical Reactions p. 35

1. A chemical reaction occurs when **reactants** are rearranged to form one or more **products**. Collectively, all the **chemical reactions** in the body constitute its **metabolism**. Through metabolism, cells capture, store, and use energy to maintain homeostasis and to perform essential functions.

2. **Work** is the movement of an object or a change in the physical structure of matter. **Energy** is the capacity to perform work.

3. **Kinetic energy** is the energy of motion. **Potential energy** is stored energy that results from the position or structure of an object. Conversions from potential to kinetic energy (or vice versa) are not 100 percent efficient; every such energy conversion releases *heat*.

Basic Energy Concepts p. 35

100 Keys | p. 35

Types of Chemical Reactions p. 35

4. A chemical reaction is classified as a **decomposition**, a **synthesis**, or an **exchange reaction**.

5. Cells gain energy to power their functions by **catabolism**, the breakdown of complex molecules. Much of this energy supports **anabolism**, the synthesis of new molecules.

Reversible Reactions p. 36

6. All chemical reactions are theoretically reversible. At **equilibrium**, the rates of two opposing reactions are in balance.

100 Keys | p. 36

Enzymes, Energy, and Chemical Reactions p. 36

7. **Activation energy** is the amount of energy required to start a reaction. **Enzymes** are **catalysts**—compounds that accelerate chemical reactions without themselves being permanently changed or consumed. Enzymes promote chemical reactions by lowering the activation energy requirements. *(Figure 2–7)*

8. **Exergonic** reactions release energy; **endergonic** reactions absorb energy.

100 Keys | p. 37

Inorganic Compounds p. 37

1. **Nutrients** are the essential elements and molecules normally obtained from the diet; **metabolites** are molecules that can be synthesized or broken down by chemical reactions inside our bodies. Nutrients and metabolites can be broadly categorized as either inorganic or organic. Unlike **organic compounds**, **inorganic compounds** generally do not contain carbon and hydrogen atoms as their primary structural components.

Water and Its Properties p. 37

2. Water is the most important constituent of the body.

3. A **solution** is a uniform mixture of two or more substances. It consists of a medium, or **solvent**, in which atoms, ions, or molecules of another substance, or **solute**, are individually dispersed. In *aqueous solutions*, water is the solvent. *(Figure 2–8)*

100 Keys | p. 38

4. Many inorganic compounds, called **electrolytes**, undergo *ionization*, or *dissociation*, in water to form ions. *(Figure 2–8; Table 2–3)* Molecules that interact readily with water molecules are called **hydrophilic**; those that do not are called **hydrophobic**.

5. The **pH** of a solution indicates the concentration of hydrogen ions it contains. Solutions are classified as **neutral**, **acidic**, or **basic** (*alkaline*) on the basis of pH. *(Figure 2–9)*

100 Keys | p. 41

Inorganic Acids and Bases p. 41

6. An **acid** releases hydrogen ions; a **base** removes hydrogen ions from a solution. *Strong acids* and *strong bases* ionize completely, whereas *weak acids* and *weak bases* do not.

Salts p. 41

-

7. A **salt** is an electrolyte whose cation is not hydrogen (H^+) and whose anion is not hydroxide (OH).

Buffers and pH Control p. 41

8. **Buffers** remove or replace hydrogen ions in solution. Buffers and *buffer systems* in body fluids maintain the pH within normal limits.

Organic Compounds p. 42

1. Carbon and hydrogen are the main constituents of **organic compounds**, which generally contain oxygen as well. Four major classes of organic compounds are *carbohydrates*, *lipids*, *proteins*, and *nucleic acids*. *High-energy compounds* are not abundant, but are vital to the survival of our cells. *(Table 2–4)*

Carbohydrates p. 42

2. **Carbohydrates** are most important as an energy source for metabolic processes. The three major types of carbohydrates are **monosaccharides** (*simple sugars*), **disaccharides**, and **polysaccharides**. Disaccharides and polysaccharides form from monosaccharides

by **dehydration synthesis**. *(Figures 2–10 to 2–12; Table 2–5)*

Lipids p. 44

100 Keys | p. 45

3. **Lipids** include *fats*, *oils*, and *waxes*; most are water-insoluble molecules. The five important classes of lipids are **fatty acids**, **eicosanoids**, **glycerides**, **steroids**, and **phospholipids and glycolipids**. *(Figures 2–13 to 2–17; Table 2–6)*

4. **Triglycerides** (*neutral fats*) consist of three fatty acid molecules attached by dehydration synthesis to a molecule of **glycerol**. **Diglycerides** consist of two fatty acids and glycerol. **Monoglycerides** consist of one fatty acid plus glycerol. *(Figure 2–15)*

5. Steroids (1) are involved in the structure of cell membranes, (2) include sex hormones and hormones regulating metabolic activities, and (3) are important in lipid digestion. *(Figure 2–16)*

Proteins p. 49

6. **Proteins** perform a variety of essential functions in the body. Seven important types of proteins are *structural proteins*, *contractile proteins*, *transport proteins*, *buffering proteins*, *enzymes*, *hormones*, and *antibodies*.

100 Keys | p. 49

7. Proteins are chains of **amino acids**. Each amino acid consists of an *amino group*, a *carboxylic acid group*, a hydrogen atom, and an *R group* (*side chain*) attached to a central carbon atom. A **polypeptide** is a linear sequence of amino acids held together by **peptide bonds**; **proteins** are polypeptides containing over 100 amino acids. *(Figures 2–18, 2–19)*

8. The four levels of protein structure are **primary structure** (amino acid sequence), **secondary structure** (amino acid interactions, such as hydrogen bonds), **tertiary structure** (complex folding, *disulfide bonds*, and interaction with water molecules), and **quaternary structure** (formation of protein complexes from individual subunits). **Fibrous proteins**, such as *keratin* and *collagen*, are elongated, tough, durable, and generally insoluble. **Globular proteins**, such as *myoglobin*, are generally rounded and water-soluble. *(Figure 2–20)*

9. The reactants in an enzymatic reaction, called **substrates**, interact to yield a product by binding to the enzyme’s **active site**. **Cofactors** are ions or molecules that must bind to the enzyme before substrate binding can occur. **Coenzymes** are organic cofactors commonly derived from *vitamins*. *(Figure 2–21)*

10. The shape of a protein determines its functional characteristics. Each protein works best at an optimal combination of temperature and pH and will undergo temporary or permanent **denaturation** at temperatures or pH values outside the normal range.

Nucleic Acids p. 54

11. Nucleic acids store and process information at the molecular level. The two kinds of nucleic acids are **deoxyribonucleic acid (DNA)** and **ribonucleic acid (RNA)**. *(Figures 2–22, 2–23; Table 2–7)*

100 Keys | p. 54

12. Nucleic acids are chains of **nucleotides**. Each nucleotide contains a sugar, a phosphate group, and a **nitrogenous base**. The sugar is *ribose* in RNA and *deoxyribose* in DNA. DNA is a two-stranded double helix containing the nitrogenous bases **adenine**, **guanine**, **cytosine**, and **thymine**. RNA consists of a single strand; it contains **uracil** instead of thymine.

High-Energy Compounds p. 56

13. Cells store energy in the *high-energy bonds* of **high-energy compounds**. The most important high-energy compound is **ATP (adenosine triphosphate)**. Cells make ATP by adding a phosphate group to **ADP (adenosine diphosphate)** through **phosphorylation**. When ATP is broken down to ADP and phosphate, energy is released. The cell can use this energy to power essential activities. *(Figure 2–24; Summary Table 2–8)*

Chemicals and Cells p. 57

1. Biochemical building blocks form functional units called *cells*.

2. The continuous removal and replacement of cellular organic molecules (other than DNA), a process called **metabolic turnover**, allows cells to change and to adapt to changes in their environment. *(Table 2–9)*

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A-1.

LEVEL 1 Reviewing Facts and Terms

1. The lightest of an atom's main constituents

(a) carries a negative charge

(b) carries a positive charge

(c) plays no part in the atom's chemical reactions

(d) is found only in the nucleus

2. Isotopes of an element differ from each other in the number of

(a) protons in the nucleus

(b) neutrons in the nucleus

(c) electrons in the outer shells

(d) a, b, and c are all correct

3. The number and arrangement of electrons in an atom's outer energy level determines the atom's

(a) atomic weight **(b)** atomic number

(c) molecular weight **(d)** chemical properties

4. All organic compounds in the human body contain all of the following elements *except*
(a) hydrogen **(b)** oxygen
(c) carbon **(d)** calcium
(e) both a and d

5. A substance containing atoms of different elements that are bonded together is called a(n)
(a) molecule **(b)** compound
(c) mixture **(d)** isotope
(e) solution

6. All the chemical reactions that occur in the human body are collectively referred to as
(a) anabolism **(b)** catabolism
(c) metabolism **(d)** homeostasis

7. Which of the following equations illustrates a typical decomposition reaction?
(a) A + B ¡ AB
(b) AB + CD ¡ AD + CB
(c) 2A2 + B2 ¡ 2A2B

(d) AB ¡ A + B
8. The speed, or rate, of a chemical reaction is influenced by
(a) the presence of catalysts
(b) the temperature
(c) the concentration of the reactants
(d) a, b, and c are all correct

9. A pH of 7.8 in the human body typifies a condition referred to as

(a) acidosis **(b)** alkalosis

(c) dehydration **(d)** homeostasis

10. A(n) _____ is a solute that dissociates to release hydrogen ions, and a(n) _____ is a solute that removes hydrogen ions from solution.

(a) base, acid **(b)** salt, base

(c) acid, salt **(d)** acid, base

11. Chemical reactions in the human body are controlled by special catalytic molecules called

(a) enzymes

(b) cytozymes

(c) cofactors

(d) activators

(e) cytochromes

12. Which the following is *not* a function protein?

(a) support

(b) transport

(c) metabolic regulation

(d) storage of genetic information

(e) movement

13. Complementary base pairing in DNA includes the pairs

(a) adenine–uracil and cytosine–guanine

(b) adenine–thymine and cytosine–guanine

(c) adenine–guanine and cytosine–thymine

(d) guanine–uracil and cytosine–thymine

14. What are the three stable fundamental particles in atoms?

15. What four major classes of organic compounds are found in the body?

16. List three important functions of triglycerides (neutral fats) in the body.

17. List seven major functions performed by proteins.

18. (a) What three basic components make up a nucleotide of DNA?

(b) What three basic components make up a nucleotide of RNA?

19. What three components are required to create the high-energy compound ATP?

LEVEL 2 Reviewing Concepts

20. If a polypeptide contains 10 peptide bonds, how many amino acids does it contain?

(a) 0 **(b)** 5

(c) 10 **(d)** 11

(e) 12

21. A dehydration synthesis reaction beetween glycerol and a single fatty acids would yield a(n)?

(a) micelle **(b)** omega-3 fatty acid

(c) monoglyceride **(d)** diglyceride

(e) triglyceride

22. Explain how enzymes function in chemical reactions.

23. What is a salt? How does a salt differ from an acid or a base?

24. Explain the differences among nonpolar covalent bonds, polar covalent bonds, and ionic bonds.

25. In an exergonic reaction

(a) large molecules are broken down into smaller ones

(b) small molecules are assembled into larger ones

(c) molecules are rearranged to form new molecules

(d) molecules move from reactans to products and back

(e) energy is released during the reaction

26. The hydrogen bonding that occurs in water is responsible for all of the following, *except*

(a) the high boiling point of water

(b) the low freezing point of water

(c) the ability of water to dissolve nonpolar substances

(d) the ability of water to dissolve inorganic salts

(e) the surface tension of water

27. A sample that contains an organic molecule has the following constituents: carbon, hydrogen, oxygen, nitrogen, and phosphorus. Is the molecule more likely to be a carbohydrate, a lipid, a protein, or a nucleic acid?

LEVEL 3 Critical Thinking and Clinical Applications

28. An atom of the element calcium has 20 protons and 20 neutrons. Determine the following information about calcium:

(a) number of electrons

(b) atomic number

(c) atomic weight

(d) number of electrons in each energy level

29. A certain reaction pathway consists of 4 steps. How would decreasing the amount of enzyme that catalyzes the second step affect the amount of product produced at the end of the pathway?

30. An important buffer system in the human body involves carbon dioxide (CO2) and bicarbonate ion ($HCO3^-$) in the reaction

$CO2 + H2O \ \Delta \ H2CO3 \ \Delta \ H^{+} + HCO3$ If a person becomes excited and exhales large amounts of CO2, how will the pH of the person’s body be affected?

TABLE 2–1 Principal Elements in the Human Body

Element (% of total body weight)	**Significance**
Oxygen, O (65)	A component of water and other compounds; gaseous form is essential for respiration
Carbon, C (18.6)	Found in all organic molecules
Hydrogen, H (9.7)	A component of water and most other compounds in the body
Nitrogen, N (3.2)	Found in proteins, nucleic acids, and other organic compounds
Calcium, Ca (1.8)	Found in bones and teeth; important for membrane function, nerve impulses, muscle contraction, and blood clotting
Phosphorus, P (1.0)	Found in bones and teeth, nucleic acids, and high-energy compounds
Potassium, K (0.4)	Important for proper membrane function, nerve impulses, and muscle contraction
Sodium, Na (0.2)	Important for blood volume, membrane

function, nerve impulses, and muscle
contraction

Chlorine, Cl (0.2) Important for blood volume, membrane
function and water absorption

Magnesium, Mg (0.06) A cofactor for many enzymes
Sulfur, S (0.04) Found in many proteins
Iron, Fe (0.007) Essential for oxygen transport
and energy capture

Iodine, I (0.0002) A component of hormones
of the thyroid gland

Trace elements: Some function as cofactors;
silicon (Si), fluorine (F), the functions of many trace elements
copper (Cu), are poorly understood
manganese (Mn),
zinc (Zn), selenium (Se),
cobalt (Co),
molybdenum (Mo),
cadmium (Cd),
chromium (Cr), tin (Sn),
aluminum (Al),
and boron (B)

Chemical Notation

Before we can consider the specific compounds that occur in the human body, we must be able to describe chemical compounds and reactions effectively. The use of sentences to describe chemical structures and events often leads to confusion. A simple form of "chemical shorthand" makes communication much more efficient. The chemical shorthand we will use is known as **chemical notation**. Chemical notation enables us to describe complex events briefly and precisely; its rules are summarized in Table 2–2.

TABLE 2–2 Rules of Chemical Notation

1. The symbol of an element indicates one atom of that element:

H = one atom of hydrogen
O = one atom of oxigen

2. A number preceding the symbol of an element indicates more than one atom of that element:

2H = two atoms of hydrogen
2O = two atoms of oxygen

3. A subscript following the symbol of an element indicates a molecule with that number of atoms of that element:

H2 = hydrogen molecule, composed of two hydrogen atoms
O2 = oxygen molecule, composed of two oxygen atoms
H2O = water molecule, composed of two hydrogen atoms and one oxygen atom

4. In a description of a chemical reaction, the participants at the start of the reaction are called reactants, and the reaction generates one or more products. An arrow indicates the direction of the reaction, from reactants (usually on the left) to products (usually on the right). In the following reaction, two atoms of hydrogen combine with one atom of oxygen to produce a single molecule of water:

5. A superscript plus or minus sign following the symbol of an element indicates an ion. A single plus sign indicates a cation with a charge of + 1. (The original atom has lost one electron.) A single minus sign indicates an anion with a charge of -1. (The original atom has gained one electron.) If more than one electron has been lost or gained, the charge on the ion is indicated by a number preceding the plus or minus sign:

2H + O ¡ H2O

Na^{+}=sodium ion (the sodium atom has lost one electron)

Cl^{-}=chloride ion (the chlorine atom has gained one electron) Ca^{2+}=calcium ion (the calcium atom has lost two electron)

6. Chemical reactions neither create nor destroy atoms; they merely rearrange atoms into new combinations. Therefore, the numbers of atoms of each ele

ment must always be the same on both sides of the equation for a chemical reaction. When this is the case, the equation is balanced:

Unbalanced: H2 + O2 ¡ H2O Balanced: 2H2 +O2 ¡ 2H2O

26

TABLE 2–3 Important Electrolytes That Dissociate
in Body Fluids

Electrolyte **Ions Released**

NaCl (sodium chloride) ¡ Na^{+} + Cl^{-}

KCl (potassium chloride) ¡ K^{+} + Cl2

CaPO4 (calcium phosphate) ¡ Ca^{2+} +PO4

-

NaHCO3 (sodium bicarbonate) ¡ Na^{+} + HCO3

MgCl2 (magnesium chloride) ¡ Mg^{2+} + 2Cl2

Na2HPO4 (disodium phosphate) ¡ $2Na^{+}$+HPO4

2

Na2SO4 (sodium sulfate) ¡ $2Na^{+}$+SO4

Clinical Note

Solute Concentrations

The concentration of a substance is the amount of that substance in a specified volume of solvent. Physiologists and clinicians often monitor inorganic and organic solute concentrations in body fluids such as blood or urine. Each solute has a normal range of values (see Appendix IV), and variations outside this range may indicate disease. Many solutes are participants in biochemical reactions, and as noted earlier, the concentrations of reactants and products in a chemical reaction directly affect reaction rates.

Solute concentrations can be expressed in several ways. In one method, we express the number of solute atoms, molecules, or ions in a specific volume of solution. Values are reported in moles per liter (mol > L, or M) or millimoles per liter (mmol > L, or mM). A concentration expressed in these units is referred to as the *molarity* of the solution. (Recall that a mole is a quantity of any substance having a weight in grams equal to the atomic or molecular weight of that substance.) Physiological concentrations in clinical lab reports are most often reported in millimoles per liter.

You can report concentrations in terms of molarity only when you know the molecular weight of the ion or molecule in question. When the chemical structure is unknown or when you are dealing with a complex mixture of materials, concentration is expressed in terms of the weight of material dissolved in a unit volume of solution. Values are then reported in milligrams (mg) or grams (g) per deciliter (dl, or 100 ml). This is the method used, for example, in reporting the concentration of plasma proteins in a blood sample. AM: Solutions and Concentrations

TABLE 2–4 Important Functional Groups of Organic Compounds

Functional Group Structural Formula* Importance Examples

Carboxyl group, ¬COOH $^{O\ \ H}_{\ \ f}$ Acts as an acid, releasing H^+ to become Fatty acids, amino acids

-

R Á¬C “O$^{R\ \neg COO}$

Amino group, ¬NH2 $^{H}_{\surd}$ Can accept or release H^+, depending on pH; Amino acids

R ¬N can form bonds with other molecules

≈

H

Hydroxyl group, ¬OH R ¬O ¬H Strong bases dissociate to release hydroxide ions Carbohydrates, fatty acids,

(OH^-); may link molecules through amino acids

dehydration synthesis (condensation)

Phosphate group, ¬PO4 May link other molecules to form Phospholipids, nucleic acids, larger structures; may store high-energy compounds

energy in high-energy bonds

* The term *R group* is used to denote the rest of the molecule, whatever that might be. The R group is also known as a *side chain*.

TABLE 2–5 Carbohydrates in the Body

Structural Class	**Examples**	**Primary Function**	
Monosaccharides (simple sugars)	Glucose, fructose	Energy source	Manufactured in the body and obtained from food; distributed in body fluids

Disaccharides Sucrose, lactose, maltose Energy source Sucrose is table sugar, lactose is in milk, and maltose is malt sugar; all must be broken down to monosaccharides before absorption

Polysaccharides Glycogen Storage of glucose Glycogen is in animal cells; other starches and cellulose is within or around plant cells

TABLE 2–6 Representative Lipids and Their Functions in the Body

Lipid Type Example(s) Primary Function(s) Remarks

Fatty acids Lauric acid Energy source Absorbed from food or synthesized in cells; transported in the blood

Eicosanoids Prostaglandins, leukotrienes Chemical messengers coordinating Prostaglandins are produced local cellular activities in most body tissues

Glycerides Monoglycerides, Energy source, energy storage, Stored in fat deposits; must be broken down to diglycerides, triglycerides insulation, and physical protection fatty acids and glycerol before they can be used as an energy source

Steroids Cholesterol Structural component of cell All have the same carbon ring framework membranes, hormones, digestive secretions in bile

Phospholipids, Lecithin (a phospholipid) Structural components of Derived from fatty acids and **glycolipids** cell membranes nonlipid components

TABLE 2–7 A Comparison of RNA with DNA **Characteristic RNA DNA**

Sugar Ribose Deoxyribose

Nitrogenous bases Adenine (A) Adenine Guanine (G) Guanine Cytosine (C) Cytosine Uracil (U) Thymine

Number of nucleotides in Varies from fewer than 100 to about 50,000 Always more than 45 million **typical molecule**

Shape of molecule Varies with hydrogen bonding along the length of the Paired strands coiled in a double helix strand; three main types (mRNA, rRNA, tRNA)

Function Performs protein synthesis as directed by DNA Stores genetic information that controls protein synthesis

| SUMMARY TABLE 2–8 | CLASSES OF INORGANIC AND ORGANIC COMPOUNDS

Class Building Blocks Sources Functions

INORGANIC Water (pp. 37–41) Hydrogen and oxygen atoms Absorbed as liquid water or Solvent; transport medium for dissolved materials and heat; generated by metabolism cooling through evaporation; medium for chemical reactions; reactant in hydrolysis

Acids, bases, salts H$^+$, OH$^-$ various anions Obtained from the diet or Structural components; buffers; sources of ions

(p. 41) and cations generated by metabolism

Dissolved gases O, C, N, and other atoms Atmosphere O2: required for cellular metabolism

(p. 41) CO2: generated by cells as a waste product

NO: chemical messenger in cardiovascular, nervous, and lymphatic systems

ORGANIC

Carbohydrates C, H, O, in some cases N; Obtained from the diet or Energy source; some structural role when attached

(pp. 42–44) CHO in a 1 : 2 : 1 ratio manufactured in the body to lipids or proteins; energy storage

Lipids (pp. 44–48) C, H, O, in some cases N or P; Obtained from the diet or Energy source; energy storage; insulation; structural

CHO not in 1 : 2 : 1 ratio manufactured in the body components; chemical messengers; protection

Proteins C, H, O, N, commonly S 20 common amino acids; Catalysts for metabolic reactions; structural

(pp. 49–53) roughly half can be components; movement; transport; buffers;

manufactured in the body, defense; control and coordination of activities

others must be obtained

from the diet

Nucleic acids C, H, O, N, and P; nucleotides Obtained from the diet or Storage and processing of genetic information
(pp. 54–55) composed of phosphates, manufactured in the body
sugars, and nitrogenous bases

High-energy Nucleotides joined to phosphates Synthesized by all cells Storage or transfer of energy
compounds by high-energy bonds

(p. 56)

TABLE 2–9 Turnover Rates

Cell Type **Component Average Recycling Time***

Liver Total protein

Enzymes

Glycogen

Cholesterol

5–6 days

1 hour to several days,

depending on the enzyme

1–2 days

5–7 days

Muscle cell Total protein 30 days

Glycogen 12–24 hours

Neuron Phospholipids 200 days

Cholesterol 100 + days

Fat cell Triglycerides 15–20 days

* Most values were obtained from studies on mammals other than humans.

- **FIGURE 2–1** The Structure of Hydrogen Atoms. Three forms of hydrogen atoms are depicted using the two-dimensional electron-shell model, which indicates the location of the electron cloud surrounding the nucleus. **(a)** A typical hydrogen nucleus contains a proton and no neutrons.

(b) A deuterium (^{2}H) nucleus contains a proton and a neutron. **(c)** A tritium (^{3}H) nucleus contains a pair of neutrons in addition to the proton.

- **FIGURE 2–2** The Arrangement of Electrons into Energy Levels. **(a)** A typical hydrogen atom has one proton and one electron. The electron orbiting the nucleus occupies the first energy level, diagrammed as an electron shell. **(b)** An atom of helium has two protons, two neutrons, and two electrons. The two electrons orbit in the same energy level. **(c)** A lithium atom has three protons, four neutrons, and three electrons. The first energy level can hold only two electrons, so the third electron occupies a second energy level. **(d)** A neon atom has 10 protons, 10 neutrons, and 10 electrons. The second level can hold up to eight electrons; thus, both the first and second energy levels are filled.
- **FIGURE 2–3** The Formation of Ionic Bonds. **(a) STEP 1:**

-

A sodium (Na) atom loses an electron, which is accepted by a chlorine (Cl) atom. **STEP 2:** Because the sodium 1Na^{+} 2 and chloride 1Cl 2 ions have opposite charges, they are attracted to one another. **STEP 3:** The association of sodium and chloride ions forms the ionic compound sodium chloride. **(b)** Large numbers of sodium and chloride ions form a crystal of sodium chloride (table salt).

- **FIGURE 2–4** Covalent Bonds in Four Common Molecules. In a hydrogen molecule, two hydrogen atoms share electrons such that each atom has a filled outermost electron shell. This sharing creates a single covalent bond. In an oxygen molecule, two oxygen atoms share two pairs of electrons. The result is a double covalent bond. In a carbon dioxide molecule, a central carbon atom forms double covalent bonds with two oxygen atoms. A nitric oxide molecule is held together by a double covalent bond, but the outer electron shell of the nitrogen atom requires an additional electron to be complete. Thus, nitric oxide is a free radical, which reacts readily with another atom or molecule.
- **FIGURE 2–5** Polar Covalent Bonds and the Structure of Water. **(a)** In forming a water molecule, an oxygen atom completes its outermost energy level by sharing electrons with a pair of hydrogen atoms. The sharing is unequal, because the oxygen atom holds the electrons more tightly than do the hydrogen atoms. **(b)** Because the oxygen atom has two extra electrons much of the time, it develops a slight negative charge, and the hydrogen atoms become weakly positive. The bonds in a water molecule are polar covalent bonds.
- **FIGURE 2–6** Hydrogen Bonds between Water Molecules. The hydrogen atoms of a water molecule have a slight positive charge, and the oxygen atom has a slight negative charge. (*See Figure 2–5b*.) The distances between these molecules have been exaggerated for clarity.
- **FIGURE 2–7** The Effect of Enzymes on Activation Energy. Enzymes lower the activation energy required for a reaction to proceed readily (in order, from 1–4) under conditions in the body.
- **FIGURE 2–8** The Activities of Water Molecules in Aqueous Solutions. **(a)** In a water molecule, oxygen forms polar covalent bonds with two hydrogen atoms. Because both hydrogen atoms are at one end of the molecule, it has an uneven distribution of charges, creating positive and negative poles. **(b)** Ionic compounds, such as sodium chloride, dissociate in water as the polar water molecules break the ionic bonds. Each ion in solution is surrounded by water molecules, creating hydration spheres. **(c)** Hydration spheres also form around an organic molecule containing polar covalent bonds. If the molecule binds

water strongly, as does glucose, it will be carried into solution—in other words, it will dissolve.

- **FIGURE 2–9** pH and Hydrogen Ion Concentration. The pH scale is logarithmic; an increase or decrease of one unit corresponds to a tenfold change in H^+ concentration.
- **FIGURE 2–10** The Structure of Glucose. **(a)** The structural formula of the straight-chain form. **(b)** The structure of the ring form, the most common form in nature. **(c)** A three-dimensional model that shows the organization of the atoms in the ring.
- **FIGURE 2–11** The Formation and Breakdown of Complex Sugars. **(a)** Formation of the disaccharide sucrose through dehydration synthesis. During this reaction, two monosaccharides are joined by the removal of a water molecule. **(b)** Breakdown of sucrose into simple sugars by hydrolysis. During this reaction, which reverses the steps of dehydration synthesis, a complex sugar is broken down by the addition of a water molecule. Both these reactions are performed by enzymes inside cells.
- **FIGURE 2–12** The Structure of the Polysaccharide Glycogen. Liver and muscle cells store glucose as the polysaccharide glycogen, a long, branching chain of glucose molecules. This figure uses a different method of representing a carbon ring structure: At each corner of the hexagon is a carbon atom. The position of an oxygen atom in each glucose ring is shown.
- **FIGURE 2–13** Fatty Acids. **(a)** Lauric acid demonstrates two structural characteristics common to all fatty acids: a long chain of carbon atoms and a carboxylic acid group (¬ COOH) at one end. **(b)** A fatty acid is either saturated (has single covalent bonds only) or unsaturated (has one or more double covalent bonds). The presence of a double bond causes a sharp bend in the molecule.
- **FIGURE 2–14** Prostaglandins. Prostaglandins are unusual short-chain fatty acids.
- **FIGURE 2–15** Triglyceride Formation. The formation of a triglyceride involves the attachment of fatty acids to a glycerol molecule through dehydration synthesis. In this example, a triglyceride is formed by the attachment of one unsaturated and two saturated fatty acids to a glycerol

diglyceride. **(b)** In a glycolipid, a carbohydrate is attached to a diglyceride. **(c)** In large numbers, phospholipids and glycolipids form micelles, with the hydrophilic heads facing the water molecules, and the hydrophobic tails on the inside of each droplet.

molecule.

• **FIGURE 2–16**

rings.

• **FIGURE 2–17** Phospholipids and Glycolipids. **(a)** The phospholipid *lecithin*. In a phospholipid, a phosphate group links a nonlipid molecule to a

• **FIGURE 2–18** Amino Acids. Each amino acid consists of a central carbon atom to which four different groups are attached: a hydrogen atom, an amino group (¬ NH2), a carboxylic acid group (¬ COOH), and a variable group designated R.

• **FIGURE 2–19** The Formation of Peptide Bonds. In this example, a peptide bond links the amino acids glycine and alanine to form a dipeptide. Peptides form as dehydration synthesis creates a peptide bond between the carboxylic acid group of one amino acid and the amino group of another.

• **FIGURE 2–20** Protein Structure. **(a)** The primary structure of a polypeptide is the sequence of amino acids (A1, A2, A3, and so on) along its length. **(b)** Secondary structure is primarily the result of hydrogen bonding along the length of the polypeptide chain. Such bonding often produces a simple spiral (an alpha-helix) or a flattened arrangement known as a pleated sheet. **(c)** Tertiary structure is the coiling and folding of a polypeptide. Within the cylindrical segments of this globular protein, the polypeptide chain is arranged in an alpha-helix. **(d)** Quaternary structure develops when separate polypeptide subunits interact to form a larger molecule. A single hemoglobin molecule contains four globular subunits. Hemoglobin transports oxygen in the blood; the oxygen binds reversibly to the heme units. In keratin and collagen, three fibrous subunits intertwine. Keratin is a tough, water-resistant protein in skin, hair, and nails. Collagen is the principal extracellular protein in most organs.

- **FIGURE 2–21** A Simplified View of Enzyme Structure and Function. Each enzyme contains a specific active site somewhere on its exposed surface.
- **FIGURE 2–22** Nucleotides and Nitrogenous Bases. **(a)** General structure of a nucleotide. The nitrogenous base involved may be a purine or a pyrimidine. **(b)** Purines. **(c)** Pyrimidines.
- **FIGURE 2–23** The Structure of Nucleic Acids. Nucleic acids are long chains of nucleotides. Each molecule starts at the sugar of the first nucleotide and ends at the phosphate group of the last member of the chain. **(a)** An RNA molecule has a single nucleotide chain. Its shape is determined by the sequence of nucleotides and by the interactions among them. **(b)** A DNA molecule has a pair of nucleotide chains linked by hydrogen bonding between complementary base pairs.
- **FIGURE 2–24** The Structure of ATP. A molecule of ATP is formed by attaching two phosphate groups to the nucleotide adenosine monophosphate. These two phosphate groups are connected by high-energy bonds. Cells most often obtain quick energy to power cellular operations by removing one phosphate group from ATP, forming ADP (adenosine diphosphate). ADP can later be reconverted to ATP, and the cycle repeated.

An Introduction to Cells

Objective

- List the main points of the cell theory.

Cells are very small indeed—a typical cell is only about 0.1 mm in diameter. As a result, no one could actually examine the structure of a cell until relatively effective microscopes were invented in the 17th century. In 1665, Robert Hooke inspected thin slices of cork and found that they consisted of millions of small, irregular units. In describing his observations, Hooke used the term *cell* because the many small, bare spaces he saw reminded him of the rooms, or cells, in a monastery or prison. Although Hooke saw only the outlines of the cells, and not the cells themselves, he stimulated considerable interest in the microscopic world and in the nature of cellular life. The research that he began more than 335 years ago has, over time, produced the *cell theory* in its current form. The basic concepts of this theory can be summarized as follows:

- Cells are the building blocks of all plants and animals.
- All cells come from the division of preexisting cells.
- Cells are the smallest units that perform all vital physiological functions.
- Each cell maintains homeostasis at the cellular level.

Homeostasis at the level of the tissue, organ, organ system, and organism reflects the combined and coordinated actions of many cells.

The human body contains trillions of cells, and all our activities—from running to thinking—result from the combined and coordinated responses of millions or even billions of cells. Many insights into human physiology arose from studies of the functioning of individual cells. What we have learned over the last 50 years has given us a new understanding of cellular physiology and the mechanisms of homeostatic control. Today, the study of cellular structure and function, or **cytology**, is part of the broader discipline of **cell biology**, which incorporates aspects of biology, chemistry, and physics. AM: Methods of Microanatomy

The human body contains two general classes of cells: sex cells and somatic cells. **Sex cells** (also called *germ cells* or *reproductive cells*) are either the *sperm* of males or the *oocytes* of females. The fusion of a sperm and an oocyte at fertilization is the first step in the creation of a new individual. **Somatic cells** (*soma*, body) include all the other cells in the human body. In this chapter, we focus on somatic cells; we will discuss sex cells in Chapters 28 and 29, which describe the reproductive system and development, respectively.

In the rest of this chapter, we describe the structure of a typical somatic cell, consider some of the ways in which cells interact with their environment, and discuss how somatic cells reproduce. It is important to keep in mind that the “typical” somatic cell is like the “average” person: Any description masks enormous individual variations. Our model cell, shown in Figure 3–1•, shares features with most cells of the body, without being identical to any one. Table 3–1 summarizes the structures and functions of the cell’s parts. AM: The Nature of Pathogens

Our model cell is surrounded by a watery medium known as the **extracellular fluid**. The extracellular fluid in most tissues is called **interstitial** (in-ter-STISH-ul) **fluid** (*interstitium*, something standing between). A *cell membrane* separates the cell contents, or *cytoplasm*, from the extracellular fluid. The cytoplasm can itself be subdivided into (1) the *cytosol*, a liquid, and (2) intracellular structures collectively known as *organelles* (or-ga-NELZ; “little organs”).

The Cell Membrane

Objective

- Describe the chief structural features of the cell membrane.

We begin our look at the anatomy of cells by discussing the first structure you encounter when viewing cells through a microscope. The outer boundary of the cell is the **cell membrane**, also called the **plasma membrane** or *plasmalemma* (*lemma*, husk). Its general functions include the following:

- **Physical Isolation.** The cell membrane is a physical barrier that separates the inside of the cell from the surrounding extracellular fluid. Conditions inside and outside the cell are very different, and those differences must be maintained to preserve homeostasis. For example, the cell membrane keeps enzymes and structural proteins inside the cell.
- **Regulation of Exchange with the Environment.** The cell membrane controls the entry of ions and nutrients, such as glucose; the elimination of wastes; and the release of secretions.
- **Sensitivity to the Environment.** The cell membrane is the first part of the cell affected by changes in the composition, concentration, or pH of the extracellular fluid. It also contains a variety of receptors that allow the cell to recognize and respond to specific molecules in its environment. For instance, the cell membrane may receive chemical

signals from other cells. The binding of just one molecule may trigger the activation or deactivation of enzymes that affect many cellular activities.

- **Structural Support.** Specialized connections between cell membranes, or between membranes and extracellular materials, give tissues stability. For example, the cells at the surface of the skin are bound together, while those in the deepest layers are attached to extracellular protein fibers in underlying tissues.

The cell membrane is extremely thin and delicate, ranging from 6 to 10 nm in thickness (Figure 3–2•). This membrane contains lipids, proteins, and carbohydrates.

Membrane Lipids

Although lipids form most of the surface area of the cell membrane, they account for only about 42 percent of its weight. The cell

membrane is called a **phospholipid bilayer**, because the phospholipid molecules in it form two layers. Recall from Chapter 2 that a phospholipid has both a hydrophilic end (the phosphate portion) and a hydrophobic end (the lipid portion). l**p. 47** In each half of the bilayer, the phospholipids lie with their hydrophilic heads at the membrane surface and their hydrophobic tails on the inside. Thus, the hydrophilic heads of the two layers are in contact with the aqueous environments on either side of the mem-brane—the interstitial fluid on the outside and the cytosol on the inside—and the hydrophobic tails form the interior of the membrane. The lipid bilayer also contains cholesterol and small quantities of other lipids, but these have relatively little effect on the general properties of the cell membrane.

Notice the similarities in lipid organization between the cell membrane and a micelle (see Figure 2–17c•, p. 48). Ions and water-soluble compounds cannot enter the interior of a micelle, because the lipid tails of the phospholipid molecules are hydrophobic and will not associate with water molecules. For the same reason, water and solutes cannot cross the lipid portion of the cell membrane. Thus, the hydrophobic compounds in the center of the membrane isolate the cytoplasm from the surrounding fluid environment. Such isolation is important because the composition of cytoplasm is very different from that of extracellular fluid, and the cell cannot survive if the differences are eliminated.

Membrane Proteins

Proteins, which are much denser than lipids, account for roughly 55 percent of the weight of a cell membrane. There are two general structural classes of membrane proteins (see Figure 3–2•). **Integral proteins** are part of the membrane structure and cannot be removed without damaging or destroying the membrane. Most integral proteins span the width of the membrane one or more times, and are therefore known as *transmembrane proteins*. **Peripheral proteins** are bound to the inner or outer surface of the membrane and (like Post-it notes) are easily separated from it. Integral proteins greatly outnumber peripheral proteins.

Membrane proteins may have a variety of specialized functions. Examples of important types of functional proteins include the following:

1. *Anchoring Proteins.* **Anchoring proteins** attach the cell membrane to other structures and stabilize its position. Inside the cell, membrane proteins are bound to the *cytoskeleton,* a network of supporting filaments in the cytoplasm. Outside the cell, other membrane proteins may attach the cell to extracellular protein fibers or to another cell.

2. *Recognition Proteins (Identifiers).* The cells of the immune system recognize other cells as normal or abnormal based on the pres

ence or absence of characteristic **recognition proteins**. Many important recognition proteins are glycoproteins. l**p. 53** (We will discuss one group, the *MHC proteins* involved in the immune response, in Chapter 22.)

3. *Enzymes.* Enzymes in cell membranes may be integral or peripheral proteins. They catalyze reactions in the extracellular fluid or in the cytosol, depending on the location of the protein and its active site. For example, dipeptides are broken down into amino acids by enzymes on the exposed membranes of cells that line the intestinal tract.

4. *Receptor Proteins.* **Receptor proteins** in the cell membrane are sensitive to the presence of specific extracellular molecules called

ligands (L -gandz). A ligand can be anything from a small ion, like calcium A receptor protein exposed to an appropriate ligand will bind to it, and that binding may trigger changes in the activity of the cell. For example, the binding of the hormone *insulin* to a specific membrane receptor protein is the key step that leads to an increase in the rate of glucose absorption by the cell. Cell membranes differ in the type and number of receptor proteins they contain, and these differences account for their differing sensitivities to hormones and other potential ligands.

5. *Carrier Proteins.* **Carrier proteins** bind solutes and transport them across the cell membrane. The transport process involves a

change in the shape of the carrier protein when solute binding occurs. The protein returns to its original shape when the solute is released. Carrier proteins may require ATP as an energy source. l**p. 56** For example, virtually all cells have carrier proteins that can bring glucose into the cytoplasm without expending ATP, but these cells must expend ATP to transport ions such as sodium and calcium across the cell membrane and out of the cytoplasm.

6. *Channels.* Some integral proteins contain a central pore, or **channel**, that forms a passageway completely across the cell membrane. The channel permits the movement of water and small solutes across the cell membrane. Ions do not dissolve in lipids, so they cannot cross the phospholipid bilayer. Thus, ions and other small water-soluble materials can cross the membrane only by passing through channels. Many channels are highly specific—that is, they permit the passage of only one particular ion. The movement of ions through channels is involved in a variety of physiological mechanisms. Although channels account for about 0.2 percent of the total surface area of the membrane, they are extremely important in such physiological processes as nerve impulse transmission and muscle contraction, described in Chapters 10 and 12.

Membranes are neither rigid nor uniform. At each location, the inner and outer surfaces of the cell membrane may differ in important respects. For example, some cytoplasmic enzymes are found only on the inner surface of the membrane, and some receptors are found exclusively on its outer surface. Some embedded proteins are always confined to specific areas of the cell membrane. These areas, called *rafts*, mark the location of anchoring proteins and some kinds of receptor proteins. Yet because membrane phospholipids are fluid at body temperature, many other integral proteins drift across the surface of the membrane like ice cubes in a bowl of punch. In addition, the composition of the entire cell membrane can change over time, because large areas of

the membrane surface are continually being removed and recycled in the process of metabolic turnover. l**p. 57**

Membrane Carbohydrates

Carbohydrates account for roughly 3 percent of the weight of a cell membrane. The carbohydrates in the cell membrane are components of complex molecules such as *proteoglycans, glycoproteins*, and *glycolipids*. l**pp. 47, 53** The carbohydrate portions of

¯I

(Ca^{2+}),

to a relatively large and complex hormone.

¯A

–

these large molecules extend beyond the outer surface of the membrane, forming a layer known as the **glycocalyx** (gl -k

ı liks; *calyx*, cup). The glycocalyx has a variety of important functions, including the following:

- **Lubrication and Protection.** The glycoproteins and glycolipids form a viscous layer that lubricates and protects the cell membrane.
- **Anchoring and Locomotion.** Because the components are sticky, the glycocalyx can help anchor the cell in place. It also participates in the locomotion of specialized cells.
- **Specificity in Binding.** Glycoproteins and glycolipids can function as receptors, binding specific extracellular compounds. Such binding can alter the properties of the cell surface and indirectly affect the cell's behavior.

- **Recognition.** Glycoproteins and glycolipids are recognized as normal or abnormal by cells involved with the immune response. The characteristics of the glycocalyx are genetically determined. The body’s immune system recognizes its own membrane glycoproteins and glycolipids as “self” rather than as “foreign.” This recognition system keeps your immune system from attacking your cells, while still enabling it to recognize and destroy invading pathogens.

The cell membrane serves as a barrier between the cytosol and the extracellular fluid. If the cell is to survive, dissolved substances and larger compounds must be permitted to move across this barrier. Metabolic wastes must be able to leave the cytosol, and nutrients must be able to enter the cell. The structure of the cell membrane is ideally suited to this need for selective transport. We will discuss selective transport and other membrane functions further, after we have completed our overview of cellular anatomy.

Concept Check

Which component of the cell membrane is primarily responsible for the membrane’s ability to form a physical barrier between the cell’s internal and external environments?

‾o

-K

-

Which type of integral protein allows water and small ions to pass through the cell membrane?

Answers begin on p. A–1

The Cytoplasm

Objective

- Describe the organelles of a typical cell, and indicate the specific functions of each.

Cytoplasm is a general term for the material located between the cell membrane and the membrane surrounding the nucleus. A
colloid with a consistency that varies between that of thin maple syrup and almost-set gelatin, cytoplasm contains many more proteins than does extracellular fluid. l**p. 40** As an indication of the importance of proteins to the cell, roughly 30 percent of a typical cell's weight can be attributed to proteins. The cytoplasm contains cytosol and organelles. **Cytosol**, or *intracellular fluid*, contains dissolved nutrients, ions, soluble and insoluble proteins, and waste products. **Organelles** are structures suspended within the cytosol that perform specific functions within the cell.

The Cytosol

The most important differences between cytosol and extracellular fluid are as follows:

1. The concentration of potassium ions is much higher in the cytosol than in the extracellular fluid. Conversely, the concentration of sodium ions is much lower in the cytosol than in the extracellular fluid.

2. The cytosol contains a much higher concentration of suspended proteins than does extracellular fluid. Many of the proteins are enzymes that regulate metabolic operations; others are associated with the various organelles. The consistency of the cytosol is determined in large part by the enzymes and cytoskeletal proteins.

3. The cytosol usually contains small quantities of carbohydrates, and small reserves of amino acids and lipids. The extracellular fluid is a transport medium only, and no reserves are stored there. The carbohydrates in the cytosol are broken down to provide energy, and the amino acids are used to manufacture proteins. Lipids, in particular triglycerides, are used primarily as a source of energy when carbohydrates are unavailable.

Both the cytosol and the extracellular fluid within tissues (*interstitial fluid*) may contain masses of insoluble materials. In the cytosol, these masses are known as **inclusions**. Among the most common inclusions are stored nutrients, such as glycogen granules in liver or in skeletal muscle cells, and lipid droplets in fat cells. Other common inclusions are pigment granules, such as the brown pigment *melanin* and the orange pigment *carotene*. Examples of insoluble materials in interstitial fluids include melanin in the skin and mineral deposits in bone.

The Organelles

Organelles are the internal structures that perform most of the tasks that keep a cell alive and functioning normally. Each organelle has specific functions related to cell structure, growth, maintenance, and metabolism. Cellular organelles can be divided into two broad categories, nonmembranous and membranous. **Nonmembranous organelles** are not completely enclosed by membranes, and all of their components are in direct contact with the cytosol. **Membranous organelles** are isolated from the cytosol by phospholipid membranes, just as the cell membrane isolates the cytosol from the extracellular fluid.

The cell's nonmembranous organelles include the *cytoskeleton*, *microvilli*, *centrioles*, *cilia*, *ribosomes*, and *proteasomes*. Membranous organelles include the *endoplasmic reticulum*, the *Golgi apparatus*, *lysosomes*, *peroxisomes*, and *mitochondria*. The *nucleus*, also surrounded by a membranous envelope—and therefore, strictly speaking, a membranous organelle—has so many vital functions that we will consider it in a separate section.

The Cytoskeleton

The **cytoskeleton** functions as the cell's skeleton. It provides an internal protein framework that gives the cytoplasm strength and flexibility. The cytoskeleton of all cells includes *microfilaments*, *intermediate filaments*, and *microtubules*. Muscle cells contain these cytoskeletal elements plus *thick filaments.* The filaments of the cytoskeleton form a dynamic network. The organizational details remain poorly understood, because the network is extremely delicate and thus hard to study intact. Figure 3–3a• is based on our current knowledge of cytoskeletal structure.

We will consider only a few of the many functions of the cytoskeleton in this section. In addition to the functions described here, the cytoskeleton plays a role in the metabolic organization of the cell by determining where in the cytoplasm key enzymatic reactions occur and where specific proteins are synthesized. For example, many intracellular enzymes—especially those involved with metabolism and energy production, and the ribosomes and RNA molecules responsible for the synthesis of proteins—are attached to the microfilaments and microtubules of the cytoskeleton. The varied metabolic functions of the cytoskeleton are now a subject of intensive research.

Microfilaments The smallest of the cytoskeletal elements are the **microfilaments**. These protein strands are generally less than 6 nm in diameter. Typical microfilaments are composed of the protein **actin**. In most cells, actin filaments are common in the periphery of the cell, but relatively rare in the region immediately surrounding the nucleus. In cells that form a layer or lining, such as the lining of the intestinal tract, actin filaments also form a layer, the *terminal web*, just inside the membrane at the exposed surface of the cell (see Figure 3–3a•).

Microfilaments have three major functions:

1. Microfilaments anchor the cytoskeleton to integral proteins of the cell membrane. They provide the cell additional mechanical strength and attach the cell membrane to the enclosed cytoplasm.

2. Microfilaments, interacting with other proteins, determine the consistency of the cytoplasm. Where microfilaments form a dense, flexible network, the cytoplasm has a gelatinous consistency; where they are widely dispersed, the cytoplasm is more fluid.

3. Actin can interact with the protein *myosin* to produce active movement of a portion of a cell or to change the shape of the entire cell.

Intermediate Filaments The protein composition of **intermediate filaments** varies among cell types. These filaments, which range from 7 to 11 nm in diameter, are intermediate in size between microfilaments and thick filaments. Intermediate filaments

(1) strengthen the cell and help maintain its shape, (2) stabilize the positions of organelles, and (3) stabilize the position of the cell with respect to surrounding cells through specialized attachment to the cell membrane. Intermediate filaments, which are insoluble, are the most durable of the cytoskeletal elements. Many cells contain specialized

intermediate filaments with unique functions. For example, the keratin fibers in superficial layers of the skin are intermediate filaments that make these layers strong and able to resist stretching. l**pp. 50–51**

Microtubules All our cells contain **microtubules**, hollow tubes built from the globular protein **tubulin**. Microtubules are the largest components of the cytoskeleton, with diameters of about 25 nm. Microtubules extend outward into the periphery of the cell from a region near the nucleus called the *centrosome* (see Figure 3–1•, p. 64). The number and distribution of microtubules in the cell can change over time. Each microtubule forms by the aggregation of tubulin molecules, growing out from its origin at the centrosome. The entire structure persists for a time and then disassembles into individual tubulin molecules again. At any given moment, roughly half of the tubulin molecules in the cell are tied up in microtubules, and the rest are awaiting recycling.

Microtubules have the following functions:

1. Microtubules form the primary components of the cytoskeleton, giving the cell strength and rigidity and anchoring the position of major organelles.

2. The disassembly of microtubules provides a mechanism for changing the shape of the cell, perhaps assisting in cell movement.

3. Microtubules can serve as a kind of monorail system to move vesicles or other organelles within the cell. The movement is effected by proteins called *molecular motors*. These proteins, which bind to the structure being moved, also bind to a microtubule and move along its length. The direction of movement depends on which of several known motor proteins is involved. For example, the molecular motors *kinesin* and *dynein* carry materials in opposite directions: Kinesin moves toward one end of a microtubule, dynein toward the other. Regardless of the direction of transport or the nature of the motor, the process requires ATP and is essential to normal cellular function.

4. During cell division, microtubules form the *spindle apparatus*, which distributes duplicated chromosomes to opposite ends of the dividing cell. We will consider this process in more detail in a later section.

5. Microtubules form structural components of organelles, such as *centrioles* and *cilia*.

Thick Filaments **Thick filaments** are relatively massive bundles of subunits composed of the protein **myosin**. Thick filaments, which may reach 15 nm in diameter, appear only in muscle cells, where they interact with actin filaments to produce powerful contractions.

Microvilli

Many cells have small, finger-shaped projections of the cell membrane on their exposed surfaces (see Figure 3–3b•). These projections, called **microvilli**, greatly increase the surface area of the cell exposed to the extracellular environment. Accordingly, they cover the surfaces of cells that are actively absorbing materials from the extracellular fluid, such as the cells lining the digestive tract. Microvilli have extensive connections with the cytoskeleton: A core of microfilaments stiffens each microvillus and anchors it to the cytoskeleton at the terminal web.

Centrioles

All animal cells capable of undergoing cell division contain a pair of **centrioles**, cylindrical structures composed of short microtubules (Figure 3–4a•). The microtubules form nine groups, three in each group. Each of these nine “triplets” is connected to its nearest neighbors on either side. Because there are no central microtubules, this organization is called a *9 + 0 array*. (An axial structure with radial spokes leading toward the microtubular groups has also been observed, but its function is not known.)

During cell division, the centrioles form the spindle apparatus associated with the movement of DNA strands. Mature red blood cells, skeletal muscle cells, cardiac muscle cells, and typical neurons have no centrioles; as a result, these cells are incapable of dividing.

Centrioles are intimately associated with the cytoskeleton. The **centrosome**, the cytoplasm surrounding the centrioles, is the heart of the cytoskeletal system. Microtubules of the cytoskeleton generally begin at the centrosome and radiate through the cytoplasm.

Cilia

Cilia (singular, *cilium*) are relatively long, slender extensions of the cell membrane. They are found on cells lining the respiratory tract, on cells lining the reproductive tract, and at various other locations in the body. Cilia have an internal arrangement similar to that of centrioles. However, in cilia, nine *pairs* of microtubules (rather than triplets) surround a central pair (Figure 3–4b•)— an organization known as a *9 + 2 array*. The microtubules are anchored to a compact **basal body** situated just beneath the cell surface. The organization of microtubules in the basal body resembles the 9 + 0 array of a centriole: nine triplets with no central pair.

Cilia are important because they can “beat” rhythmically to move fluids or secretions across the cell surface (Figure 3–4c•). The cilium is relatively stiff during the effective *power stroke* and flexible during the *return stroke*. The ciliated cells along your trachea beat their cilia in synchronized waves to move sticky mucus and trapped dust particles toward the throat and away from delicate respiratory surfaces. If the cilia are damaged or immobilized by heavy smoking or a metabolic problem, the cleansing action is lost and the irritants will no longer be removed. As a result, a chronic cough and respiratory infections develop. Ciliated cells also move oocytes along the uterine tubes, and waft sperm from the testes into the male reproductive tract.

Ribosomes

Proteins are produced within cells, using information provided by the DNA of the nucleus. The organelles responsible for protein synthesis are called **ribosomes**. The number of ribosomes in a particular cell varies with the type of cell and its demand for new proteins. For example, liver cells, which manufacture blood proteins, contain far more ribosomes than do fat cells, which primarily synthesize lipids.

Individual ribosomes are not visible with the light microscope. In an electron micrograph, they appear as dense granules approximately 25 nm in diameter. Each ribosome is roughly 60 percent RNA and 40 percent protein.

A functional ribosome consists of two subunits that are normally separate and distinct. One is called a **small ribosomal subunit** and the other a **large ribosomal subunit**. These subunits contain special proteins and **ribosomal RNA** (**rRNA**), one of the RNA types introduced in Chapter 2. l**p. 55** Before protein synthesis can begin, a small and a large ribosomal subunit must join together with a strand of *messenger RNA* (*mRNA*, another type of RNA).

Two major types of functional ribosomes are found in cells: free ribosomes and fixed ribosomes (see Figure 3–1•, p. 64). **Free ribosomes** are scattered throughout the cytoplasm. The proteins they manufacture enter the cytosol. **Fixed ribosomes** are attached to the *endoplasmic reticulum* (*ER*), a membranous organelle. Proteins manufactured by fixed ribosomes enter the ER, where they are modified and packaged for secretion. We will examine ribosomal structure and functions in later sections, when we discuss the endoplasmic reticulum and protein synthesis.

Proteasomes

Free ribosomes produce proteins within the cytoplasm; proteasomes remove them. **Proteasomes** are organelles that contain an assortment of protein-digesting enzymes, or *proteases*. Cytoplasmic enzymes attach chains of *ubiquitin*, a molecular “tag,” to proteins destined for recycling. Tagged proteins are quickly transported into the proteasome. Once inside, they are rapidly disassembled into amino acids and small peptides, which can be released into the cytoplasm.

Proteasomes are responsible for removing and recycling damaged or denatured proteins, and for breaking down abnormal proteins, such as those produced within cells infected by viruses. They also play a key role in the immune response, as we will see in Chapter 22.

Table 3–1 provides a review of the characteristics of nonmembranous organelles.

Concept Check

Cells lining the small intestine have numerous fingerlike projections on their free surface. What are these structures, and what is their function?

What are the major differences between cytosol and extracellular fluid?

Answers begin on p. A–1

The Endoplasmic Reticulum

The **endoplasmic reticulum** (en-d
¯o
-PLAZ-mik re-TIK-
¯u
-lum), or **ER**, is a network of intracellular membranes connected to the
nuclear envelope, which surrounds the nucleus. The name *endoplasmic reticulum* is very descriptive. *Endo*-means “within,” *plasm* refers to the cytoplasm, and a *reticulum* is a network. The ER has four major functions:

1. *Synthesis.* Specialized regions of the ER synthesize proteins, carbohydrates, and lipids.

2. *Storage.* The ER can store synthesized molecules or materials absorbed from the cytosol without affecting other cellular operations.

3. *Transport.* Materials can travel from place to place in the ER.

4. *Detoxification.* Drugs or toxins can be absorbed by the ER and neutralized by enzymes within it.

The ER (Figure 3–5•) forms hollow tubes, flattened sheets, and chambers called **cisternae** (sis-TUR-n ; singular, *cisterna*, a reservoir for water). Two types of ER exist: *smooth endoplasmic reticulum* and *rough endoplasmic reticulum*.

Smooth Endoplasmic Reticulum The term “smooth” refers to the fact that no ribosomes are associated with the **smooth endoplasmic reticulum (SER)**. The SER has the following functions, all associated with the synthesis of lipids and carbohydrates:

- Synthesis of the phospholipids and cholesterol needed for maintenance and growth of the cell membrane, ER, nuclear mem
brane, and Golgi apparatus in all cells
¯e
- Synthesis of steroid hormones, such as *androgens* and *estrogens* (the dominant sex hormones in males and in females, respectively) in the reproductive organs

- Synthesis and storage of glycerides, especially triacylglycerides, in liver cells and fat cells
- Synthesis and storage of glycogen in skeletal muscle and liver cells

In muscle cells, neurons, and many other types of cells, the SER also adjusts the composition of the cytosol by absorbing and storing ions, such as Ca^{2+}, or larger molecules. In addition, the SER in liver and kidney cells is responsible for the detoxification or inactivation of drugs.

Rough Endoplasmic Reticulum The **rough endoplasmic reticulum (RER)** functions as a combination workshop and shipping depot. It is where many newly synthesized proteins are chemically modified and packaged for export to their next destination, the *Golgi apparatus*.

The ribosomes on the outer surface of the rough endoplasmic reticulum are fixed ribosomes (see Figure 3–5•). Their presence gives the RER a beaded, grainy, or rough appearance. Both free and fixed ribosomes synthesize proteins using instructions provided by messenger RNA. The new polypeptide chains produced at fixed ribosomes are released into the cisternae of the RER. In

side the RER, each protein assumes its secondary and tertiary structures. l**p. 50** Some of the proteins are enzymes that will function inside the endoplasmic reticulum. Other proteins are chemically modified by the attachment of carbohydrates, creating glycoproteins. Most of the proteins and glycoproteins produced by the RER are packaged into small membranous sacs that pinch off from the tips of the cisternae. These **transport vesicles** subsequently deliver their contents to the Golgi apparatus.

The amount of endoplasmic reticulum and the proportion of RER to SER vary with the type of cell and its ongoing activities. For example, pancreatic cells that manufacture digestive enzymes contain an extensive RER, but the SER is relatively small. The situation is just the reverse in reproductive system cells that synthesize steroid hormones.

The Golgi Apparatus

When a transport vesicle carries a newly synthesized protein or glycoprotein that is destined for export from the cell, it travels from the ER to an organelle that looks a bit like a stack of dinner plates. This organelle, the **Golgi** (G¯O L-j¯e) **apparatus** (Figure 3–6•), typically consists of five or six flattened membranous discs called *cisternae*. A single cell may contain several of these organelles, most often near the nucleus.

The Golgi apparatus has three major functions: It (1) modifies and packages secretions, such as hormones or enzymes, for release through exocytosis, (2) renews or modifies the cell membrane, and (3) packages special enzymes within vesicles for use in the cytosol.

Figure 3–7a• diagrams the role of the Golgi apparatus in packaging secretions. Some proteins and glycoproteins synthesized in the RER are delivered to the Golgi apparatus by transport vesicles. The vesicles generally arrive at a cisterna known as the *forming* (or *cis*) *face*. The transport vesicles then fuse with the Golgi membrane, emptying their contents into the cisternae. Inside the Golgi apparatus, enzymes modify the arriving proteins and glycoproteins. For example, the enzymes may change the carbohydrate structure of a glycoprotein, or they may attach a phosphate group, sugar, or fatty acid to a protein.

One of the unique things about this organelle is that compounds that enter the cisternae are constantly in motion, traveling up the stack from the ER toward the cell membrane. Small vesicles move material from one cisterna to the next. Ultimately, the product arrives at the *maturing* (or *trans*) *face*, which usually faces the cell surface. Three types of vesicles that carry materials away from the Golgi apparatus form at the maturing face:

1. *Secretory Vesicles.* **Secretory vesicles** contain secretions that will be discharged from the cell. These vesicles fuse with the cell membrane and empty their contents into the extracellular environment (Figure 3–7b•). This process, known as *exocytosis*, is discussed in greater detail later in this chapter.

2. *Membrane Renewal Vesicles.* When vesicles produced at the Golgi apparatus fuse with the surface of the cell, they are adding new lipids and proteins to the cell membrane. At the same time, other areas of the cell membrane are being removed and recycled. The Golgi apparatus can thus change the properties of the cell membrane over time. For example, new glycoprotein receptors can be added, making the cell more sensitive to a particular stimulus. Alternatively, receptors can be removed and not replaced, making the cell less sensitive to specific ligands. Such changes can profoundly alter the sensitivity and functions of the cell.

3. *Lysosomes.* Vesicles called *lysosomes* that remain in the cytoplasm contain digestive enzymes. Their varied functions will be detailed next.

Lysosomes

Cells often need to break down and recycle large organic molecules and even complex structures like organelles. The breakdown process requires the use of powerful enzymes, and it often generates toxic chemicals that could damage or kill the cell. **Lysosomes**

(L

¯I

-s
¯o
-s
¯o
mz; *lyso*-, dissolution + *soma*, body) are special vesicles that provide an isolated environment for potentially danger

ous chemical reactions. These vesicles, produced at the Golgi apparatus, contain digestive enzymes. Lysosomes are small, often spherical bodies with contents that look dense and dark in electron micrographs (see Figure 3–7b•).

Lysosomes have several functions (Figure 3–8•). *Primary lysosomes* contain inactive enzymes. When these lysosomes fuse with the membranes of damaged organelles (such as mitochondria or fragments of the ER), the enzymes are activated and *secondary lysosomes* are formed. These enzymes then break down the lysosomal contents. The cytosol reabsorbs released nutrients, and the remaining material is eliminated from the cell by exocytosis.

Lysosomes also function in the destruction of bacteria (as well as liquids and organic debris) that enter the cell from the extracellular fluid. The cell encloses these substances in a small portion of the cell membrane, which is then pinched off to form a transport vesicle in the cytoplasm. (This method of transporting substances into the cell, called *endocytosis*, will be discussed later in this chapter.) When a primary lysosome fuses with the vesicle, activated enzymes in the secondary lysosome break down the contents and release usable substances, such as sugars or amino acids. In this way, the cell both protects itself against harmful substances and obtains valuable nutrients.

Lysosomes also perform essential cleanup and recycling functions inside the cell. For example, when muscle cells are inactive, lysosomes gradually break down their contractile proteins. (This mechanism accounts for the reduction in muscle mass seen among retired athletes.) The process is usually precisely controlled, but in a damaged or dead cell the regulatory mechanism fails. Lysosomes then disintegrate, releasing enzymes that become activated within the cytosol. These enzymes rapidly destroy the cell’s proteins and organelles in a process called **autolysis** (aw-TOL-i-sis; *auto*-, self). We do not know how to control lysosomal activities or why the enclosed enzymes do not digest the lysosomal walls unless the cell is damaged.

Problems with lysosomal enzyme production cause more than 30 serious diseases affecting children. In these conditions, called *lysosomal storage diseases*, the lack of a specific lysosomal enzyme results in the buildup of waste products and debris normally removed and recycled by lysosomes. Affected individuals may die when vital cells, such as those of the heart, can no longer function. AM: Lysosomal Storage Diseases

Peroxisomes

Peroxisomes are smaller than lysosomes and carry a different group of enzymes. In contrast to lysosomes, which are produced at the Golgi apparatus, new peroxisomes are produced by the growth and subdivision of existing peroxisomes. Their enzymes are produced at free ribosomes and transported from the cytosol into the peroxisomes by carrier proteins.

Peroxisomes absorb and break down fatty acids and other organic compounds. As they do so, peroxisomes generate hydrogen peroxide (H2O2), a potentially dangerous free radical. l**p. 32** Other enzymes within the peroxisome then break down the hydrogen peroxide to oxygen and water. Peroxisomes thus protect the cell from the potentially damaging effects of free radicals produced during catabolism. While these organelles are present in all cells, their numbers are highest in metabolically active cells, such as liver cells.

Membrane Flow

When the temperature changes markedly, you change your clothes. Similarly, when a cell’s environment changes, it alters the structure and properties of its cell membrane. With the exception of mitochondria, all membranous organelles in the cell are either interconnected or in communication through the movement of vesicles. The RER and SER are continuous and are connected to the nuclear envelope. Transport vesicles connect the ER with the Golgi apparatus, and secretory vesicles link the Golgi apparatus with the cell membrane. Finally, vesicles forming at the exposed surface of the cell remove and recycle segments of the cell membrane. This continuous movement and exchange is called **membrane flow**. In an actively secreting cell, an area equal to the entire membrane surface may be replaced each hour.

Membrane flow is an example of the dynamic nature of cells. It provides a mechanism by means of which cells change the characteristics of their cell membranes—the lipids, receptors, channels, anchors, and enzymes—as they grow, mature, or respond to a specific environmental stimulus.

100 Keys | A cell is the basic structural and functional unit of life. Cells respond directly to their environment and help

maintain homeostasis at the cellular level. They can also change their internal structure and physiological functions over

time.

Mitochondria

Cells, like other living things, require energy to carry out the functions of life. The organelles responsible for energy production

are the **mitochondria** (m

–

ı vary widely in shape, from long and slender to short and fat. The number of mitochondria in a particular cell varies with the cell’s energy demands. Red blood cells lack mitochondria altogether, whereas these organelles may account for 20 percent of the volume of an active liver cell.

Mitochondria have an unusual double membrane (Figure 3–9a•). The outer membrane surrounds the organelle. The inner membrane contains numerous folds called **cristae**. Cristae increase the surface area exposed to the fluid contents, or **matrix**, of the mitochondrion. Metabolic enzymes in the matrix catalyze the reactions that provide energy for cellular functions.

–
o

-KON-dr

–
e

-uh; singular, *mitochondrion*; *mitos*, thread *chondrion*, granule). These small structures

+

-t

Most of the chemical reactions that release energy occur in the mitochondria, but most of the cellular activities that require energy occur in the surrounding cytoplasm. Cells must therefore store energy in a form that can be moved from place to place. Recall from Chapter 2 that cellular energy is stored and transferred in the form of *high-energy bonds*, such as those that attach a phos

phate group ($PO4^{3-}$) to adenosine diphosphate (ADP), creating the high-energy compound *adenosine triphosphate* (ATP). Cells can break the high-energy bond under controlled conditions, reconverting ATP to ADP and phosphate and thereby releasing energy for the cell’s use.

Mitochondrial Energy Production Most cells generate ATP and other high-energy compounds through the breakdown of carbohydrates, especially glucose. We will examine the entire process in Chapter 25, but a few basic concepts now will help you follow discussions of muscle contraction, neuron function, and endocrine function in Chapters 10–18.

Although most ATP production occurs inside mitochondria, the first steps take place in the cytosol (Figure 3–9b•). In this reaction sequence, called **glycolysis** (*glycos*, sugar + -*lysis*, splitting), each glucose molecule is broken down into two molecules of *pyruvic acid*. The pyruvic acid molecules are then absorbed by mitochondria.

In the mitochondrial matrix, a CO2 molecule is removed from each absorbed pyruvic acid molecule; the remainder enters the **tricarboxylic acid cycle**, or **TCA cycle** (also known as the *Krebs cycle* and the *citric acid cycle*). The TCA cycle is an enzymatic pathway that systematically breaks down the absorbed pyruvic acid in the presence of oxygen. The remnants of pyruvic acid molecules contain carbon, oxygen, and hydrogen atoms. The carbon and oxygen atoms are released as carbon dioxide, which diffuses out of the cell. The hydrogen atoms are delivered to carrier proteins in the cristae. The electrons from the hydrogen atoms are then removed and passed along a chain of coenzymes. The energy released during these steps performs the enzymatic conversion of

ADP to ATP. l**p. 56** Because mitochondrial activity requires oxygen, this method of ATP production is known as **aerobic metabolism** (*aero*-, air

+ *bios*, life), or *cellular respiration*. Aerobic metabolism in mitochondria produces about 95 percent of the ATP needed to keep a cell alive. (Enzymatic reactions in the cytosol produce the rest.)

100 Keys | Mitochondria provide most of the energy needed to keep your cells (and you) alive. They require oxygen and

organic substrates, and they generate carbon dioxide and ATP.

Clinical Note

Several inheritable disorders result from abnormal mitochondrial activity. While not totally self-sufficient, mitochondria do carry their

own DNA and manufacture many of their own proteins under the direction of the genes on this DNA. The mitochondria involved in

congenital diseases contain abnormal DNA, and the enzymes they produce reduce the efficiency of ATP production. Cells throughout

the body may be affected, but symptoms involving muscle cells, neurons, and the receptor cells in the eye are most common,

because these cells have especially high energy demands. AM: Mitochondrial DNA, Disease, and Evolution

Concept Check

Certain cells in the ovaries and testes contain large amounts of smooth endoplasmic reticulum (SER). Why?

What does the presence of many mitochondria imply about a cell's energy requirements?

Answers begin on p. A–1

The Nucleus

Objectives

- Explain the functions of the cell nucleus.
- Discuss the nature and importance of the genetic code.
- Summarize the process of protein synthesis.

The **nucleus** is usually the largest and most conspicuous structure in a cell; under a light microscope, it is often the only organelle visible. The nucleus serves as the control center for cellular operations. A single nucleus stores all the information needed to direct the synthesis of the more than 100,000 different proteins in the human body. The nucleus determines the structure of the cell and what functions it can perform by controlling which proteins are synthesized, under what circumstances, and in what amounts. A cell without a nucleus cannot repair itself, and it will disintegrate within three or four months.

Most cells contain a single nucleus, but exceptions exist. For example, skeletal muscle cells have many nuclei, whereas mature red blood cells have none. Figure 3–10• details the structure of a typical nucleus. Surrounding the nucleus and separating it from the cytosol is a **nuclear envelope**, a double membrane with its two layers separated by a narrow **perinuclear space** (*peri-*, around). At several locations, the nuclear envelope is connected to the rough endoplasmic reticulum (see Figure 3–1•, p. 64).

To direct processes that take place in the cytosol, the nucleus must receive information about conditions and activities in other parts of the cell. Chemical communication between the nucleus and the cytosol occurs through **nuclear pores**. These pores, which cover about 10 percent of the surface of the nucleus, are large enough to permit the movement of ions and small molecules, but are too small for the free passage of proteins or DNA. Each nuclear pore contains regulatory proteins that govern the transport of specific proteins and RNA into or out of the nucleus.

Contents of the Nucleus

The fluid contents of the nucleus are called the *nucleoplasm*. The nucleoplasm contains the **nuclear matrix**, a network of fine filaments that provides structural support and may be involved in the regulation of genetic activity. The nucleoplasm also contains ions, enzymes, RNA and DNA nucleotides, small amounts of RNA, and DNA.

¯E

-l ; singular, *nucleolus*). Nucleoli are transient nu-

ı clear organelles that synthesize ribosomal RNA. They also assemble the ribosomal subunits, which reach the cytoplasm by carrier-mediated transport at the nuclear pores. Nucleoli are composed of RNA, enzymes, and proteins called **histones**. The nucleoli form around portions of DNA that contain the instructions for producing ribosomal proteins and RNA when those instructions are being carried out. Nucleoli are most prominent in cells that manufacture large amounts of proteins, such as liver, nerve, and muscle cells, because those cells need large numbers of ribosomes.

It is the DNA in the nucleus that stores the instructions for protein synthesis. Interactions between the DNA and the histones help determine the information available to the cell at any moment. The organization of DNA within the nucleus is shown in Figure 3–11•. At intervals, the DNA strands wind around the histones, forming a complex known as a **nucleosome**. Such wind

–

ing allows a great deal of DNA to be packaged in a small space. The entire chain of nucleosomes may coil around other proteins. The degree of coiling varies depending on whether cell division is under way. In cells that are not dividing, the nucleosomes are loosely coiled within the nucleus, forming a tangle of fine filaments known as **chromatin**. Chromatin gives the nucleus a clumped, grainy appearance. Just before cell division begins, the coiling becomes tighter, forming distinct structures called **chromosomes** (*chroma*, color). In humans, the nuclei of somatic cells contain 23 pairs of chromosomes. One member of each pair is derived from the mother, and one from the father.

100 Keys | The nucleus contains the genetic instructions needed to synthesize the proteins that determine cell structure and function. This information is stored in chromosomes, which consist of DNA and various proteins involved in controlling and accessing the genetic information.

Information Storage in the Nucleus

As we saw in Chapter 2, each protein molecule consists of a unique sequence of amino acids. l**p. 49** Any “recipe” for a protein, therefore, must specify the order of amino acids in the polypeptide chain. This information is stored in the chemical structure of the DNA strands in the nucleus. The chemical “language” the cell uses is known as the **genetic code**. An understanding of the genetic code has enabled us to determine how cells build proteins and how various structural and functional characteristics are inherited from generation to generation.

To understand how the genetic code works, recall the basic structure of nucleic acids described in Chapter 2. l**p. 54** A single DNA molecule consists of a pair of DNA strands held together by hydrogen bonding between complementary nitrogenous bases. Information is stored in the sequence of nitrogenous bases along the length of the DNA strands. Those nitrogenous bases are adenine (A), thymine (T), cytosine (C), and guanine (G). The genetic code is called a *triplet code*, because a sequence of three nitrogenous bases specifies the identity of a single amino acid. Thus, the information encoded in the sequence of nitrogenous bases must be read in groups of three. For example, the triplet thymine–guanine–thymine (TGT) on one DNA strand (the *coding strand*) codes for the amino acid cysteine. More than one triplet may represent the same amino acid, however. For example, the DNA triplet thymine–guanine–cytosine (TGC) also codes for cysteine.

A **gene** is the functional unit of heredity; it contains all the DNA triplets needed to produce specific proteins. The number of triplets in a gene depends on the size of the polypeptide represented. A relatively short polypeptide chain might require fewer than 100 triplets, whereas the instructions for building a large protein might involve 1000 or more triplets. Not all of the DNA molecule carries instructions for proteins; some segments contain instructions for the synthesis of transfer RNA or ribosomal RNA, some have a regulatory function, and others have no apparent function.

Clinical Note

Every nucleated somatic cell in the body carries a set of 46 chromosomes that are copies of the set formed at fertilization. Not all the DNA of these chromosomes codes for proteins, however; a significant percentage of DNA segments have no known function. Some of the “useless” segments contain the same nucleotide sequence repeated over and over. The number of segments and the number of repetitions vary among individuals. The chance that any two individuals, other than identical twins, will have the same pattern of repeating DNA segments is less than one in 9 billion. Individuals can therefore be identified on the basis of their DNA pattern, just as they can on the basis of a fingerprint. Skin scrapings, blood, semen, hair, or other tissues can be used as the DNA source. Information from DNA fingerprinting has been used to convict (and to acquit) people accused of violent crimes, such as rape or murder. The science of molecular biology has thus become a useful addition to the crime-fighting arsenal.

Most nuclei contain several dark-staining areas called **nucleoli** (noo-KL

¯o

-

Gene Activation and Protein Synthesis

Each DNA molecule contains thousands of genes and therefore holds the information needed to synthesize thousands of proteins. Normally, the genes are tightly coiled, and bound histones keep the genes inactive. Before a gene can affect a cell, the portion of the

DNA molecule containing that gene must be uncoiled and the histones temporarily removed.

The factors controlling this process, called **gene activation**, are only partially understood. We know, however, that every gene contains segments responsible for regulating its own activity. In effect, these are triplets that say “do (or do not) read this message,” “message starts here,” or “message ends here.” The “read me,” “don’t read me,” and “start” signals form a special region of DNA called the *promoter*, or control segment, at the start of each gene. Each gene ends with a “stop” signal. Gene activation begins with the temporary disruption of the weak bonds between the nitrogenous bases of the two DNA strands and the removal of the histone that guards the promoter.

After the complementary strands have separated and the histone has been removed, the enzyme **RNA polymerase** binds to the promoter of the gene. This binding is the first step in the process of **transcription**, the production of RNA from a DNA template. The term *transcription* is appropriate, as it means “to copy” or “rewrite.” All three types of RNA are formed through the transcription of DNA, but we will focus here on the transcription of mRNA, which carries the information needed to synthesize proteins. **Messenger RNA (mRNA)** is absolutely vital, because the DNA cannot leave the nucleus. Instead, its information is copied to messenger RNA, which *can* leave the nucleus and carry the information to the cytoplasm, where protein synthesis occurs.

The Transcription of mRNA

The two DNA strands in a gene are complementary. The strand containing the triplets that specify the sequence of amino acids in the polypeptide is the **coding strand**. The other strand, called the **template strand**, contains complementary triplets that will be used as a template for mRNA production. The resulting mRNA will have a nucleotide sequence identical to that of the coding strand, but with uracil substituted for thymine. Figure 3–12• illustrates the steps in transcription:

Step 1 Once the DNA strands have separated and the promoter has been exposed, transcription can begin. The key event is the attachment of RNA polymerase to the template strand.

Step 2 RNA polymerase promotes hydrogen bonding between the nitrogenous bases of the template strand and complementary nucleotides in the nucleoplasm. This enzyme begins at a “start” signal in the promoter region. It then strings nucleotides together by covalent bonding. The RNA polymerase interacts with only a small portion of the template strand at any one time as it travels along the DNA strand. The complementary strands separate in front of the enzyme as it moves one nucleotide at a time, and they reassociate behind it. The enzyme collects additional nucleotides and attaches them to the growing chain. The nucleotides involved are those characteristic of RNA, not of DNA; RNA polymerase can attach adenine, guanine, cytosine, or uracil, but never thymine. Thus, wherever an A occurs in the DNA strand, the polymerase will attach a U rather than a T to the growing mRNA strand. In this way, RNA polymerase assembles a complete strand of mRNA. The nucleotide sequence of the template strand determines the nucleotide sequence of the mRNA strand. Thus, each DNA triplet corresponds to a sequence of three nucleotide bases in the mRNA strand. Such a three-base mRNA sequence is called a **codon** (KO-don). Codons contain nitrogenous bases that are complementary to those of the triplets in the template strand. For example, if the DNA triplet is TCG, the corresponding mRNA codon will be AGC. This method of copying ensures that the mRNA exactly matches the coding strand of the gene.

Step 3 At the “stop” signal, the enzyme and the mRNA strand detach from the DNA strand, and transcription ends. The complementary DNA strands now complete their reassociation as hydrogen bonding occurs between complementary base pairs.

Each gene includes a number of triplets that are not needed to build a functional protein. As a result, the mRNA strand assembled during transcription, sometimes called immature mRNA or *pre-mRNA*, must be “edited” before it leaves the nucleus to direct protein synthesis. In this **RNA processing**, nonsense regions, called **introns**, are snipped out, and the remaining, coding segments, or **exons**, are spliced together. The process creates a much shorter, functional strand of mRNA that then enters the cytoplasm through a nuclear pore.

Intron removal is extremely important and tightly regulated. This is understandable because an error in the editing will produce an abnormal protein with potentially disastrous results. Moreover, we now know that by changing the editing instructions and removing different introns, a single gene can produce mRNAs that code for several different proteins. How this variable editing is regulated remains a mystery.

Translation

Protein synthesis is the assembling of functional polypeptides in the cytoplasm. Protein synthesis occurs through **translation**, the formation of a linear chain of amino acids, using the information provided by an mRNA strand. Again, the name is appropriate: To *translate* is to present the same information in a different language; in this case, a message written in the “language” of nucleic acids (the sequence of nitrogenous bases) is translated by ribosomes into the “language” of proteins (the sequence of amino acids in a polypeptide chain). Each mRNA codon designates a particular amino acid to be incorporated into the polypeptide chain.

The amino acids are provided by **transfer RNA (tRNA)**, a relatively small and mobile type of RNA. Each tRNA molecule binds and delivers an amino acid of a specific type. More than 20 kinds of transfer RNA exist—at least one for each of the amino acids used in protein synthesis.

A tRNA molecule has a tail that binds an amino acid. Roughly midway along its length, the nucleotide chain of the tRNA forms a tight loop that can interact with an mRNA strand. The loop contains three nitrogenous bases that form an **anticodon**. During translation, the anticodon bonds complementarily with an appropriate mRNA codon. The base sequence of the anticodon indicates the type of amino acid carried by the tRNA. For example, a tRNA with the anticodon GGC always carries the amino acid *proline*, whereas a tRNA with the anticodon CGG carries *alanine*. Table 3–2 lists examples of several codons and anticodons that specify individual amino acids and summarizes the relationships among DNA, codons, and anticodons.

The tRNA molecules thus provide the physical link between codons and amino acids. During translation, each codon along the mRNA strand binds a complementary anticodon on a tRNA molecule. Thus, if the mRNA has the codons AUG–CCG–AGC, it will bind to tRNAs with anticodons UAC–GGC–UCG. The amino acid sequence of the polypeptide chain created is determined by the sequence of delivery by tRNAs, and that sequence depends on the arrangement of codons along the mRNA strand. In this case, the amino acid sequence in the resulting polypeptide would be methionine–proline–serine.

The translation process is illustrated in Figure 3–13•:

Step 1 Translation begins as the mRNA strand binds to a small ribosomal subunit. The first codon, or *start codon*, of the mRNA strand always has the base sequence AUG. It binds a tRNA with the complementary anticodon sequence UAC. This tRNA, which carries the amino acid *methionine,* attaches to the first of two tRNA binding sites on the small ribosomal subunit. (The initial methionine will be removed from the finished protein.)

Step 2 When this tRNA binding occurs, a large ribosomal subunit joins the complex to create a complete ribosome. The mRNA strand nestles in the gap between the small and the large ribosomal subunits.

Step 3 A second tRNA now arrives at the second tRNA binding site of the ribosome, and its anticodon binds to the next codon of the mRNA strand.

Step 4 Enzymes of the large ribosomal subunit then break the linkage between the tRNA and its amino acid. At the same time, the enzymes attach the amino acid to its neighbor by means of a peptide bond. The ribosome then moves one codon down the mRNA strand. The cycle is then repeated with the arrival of another molecule of tRNA. The tRNA stripped of its amino acid drifts away. It will soon bind to another amino acid and be available to participate in protein synthesis again.

Step 5 The polypeptide chain continues to grow by the addition of amino acids until the ribosome reaches a “stop” signal, or *stop codon,* at the end of the mRNA strand. The ribosomal subunits now detach, leaving an intact strand of mRNA and a completed polypeptide.

Translation proceeds swiftly, producing a typical protein in about 20 seconds. The mRNA strand remains intact, and it can interact with other ribosomes to create additional copies of the same polypeptide chain. The process does not continue indefinitely, however, because after a few minutes to a few hours, mRNA strands are broken down and the nucleotides are recycled. However, large numbers of protein chains can be produced during that time. Although only two mRNA codons are “read” by a ribosome at any one time, the entire strand may contain thousands of codons. As a result, many ribosomes can bind to a single mRNA strand. At any moment, each ribosome will be reading a different part of the same message, but each will end up constructing a copy of the same protein as the others. The arrangement is similar to a line of people who make identical choices at a buffet lunch; all the people will assemble the same meal, but each person is always a step behind the person ahead. A series of ribosomes attached to the same mRNA strand is called a *polyribosome*, or *polysome* (see Figure 3–3a•, p. 69).

100 Keys | Genes are the functional units of DNA that contain the instructions for making one or more proteins. The creation of specific proteins involves multiple enzymes and three types of RNA.

Clinical Note

Mutations are permanent changes in a cell’s DNA that affect the nucleotide sequence of one or more genes. The simplest is a *point mutation*, a change in a single nucleotide that affects one codon. The triplet code has some flexibility, because several different codons can specify the same amino acid. But a point mutation that produces a codon that specifies a different amino acid will usually change the structure of the completed protein. A single change in the amino acid sequence of a structural protein or enzyme can prove fatal. Certain cancers and two potentially lethal blood disorders discussed in Chapter 19, *thalassemia* and *sickle cell anemia*, result from variations in a single nucleotide.

More than 100 inherited disorders have been traced to abnormalities in enzyme or protein structure that reflect single changes in nucleotide sequence. More elaborate mutations, such as additions or deletions of nucleotides, can affect multiple codons in one gene or in several adjacent genes, or they can affect the structure of one or more chromosomes.

Most mutations occur during DNA replication, when cells are duplicating their DNA in preparation for cell division. A single cell, a group of cells, or an entire individual may be affected. This last prospect occurs when the changes are made early in development. For example, a mutation affecting the DNA of an individual's sex cells will be inherited by that individual's children. Our understanding of genetic structure is opening the possibility of diagnosing and correcting some of these problems. AM: Genetic Engineering and Gene Therapy

100 Keys | A mutation is a change in the nucleotide sequence of a gene. Mutations can occur at any time, due to chemical or radiation exposure, but they also occur during DNA replication. Mistakes in copying are usually detected and corrected, but any that persist may alter or disrupt gene function.

How the Nucleus Controls Cell Structure and Function

As we noted at the start of this section, the DNA of the nucleus controls the cell by directing the synthesis of specific proteins. Through the control of protein synthesis, virtually every aspect of cell structure and function can be regulated. Two levels of control are involved:

1. The DNA of the nucleus has *direct* control over the synthesis of structural proteins, such as cytoskeletal components, membrane proteins (including receptors), and secretory products. By issuing appropriate instructions, in the form of mRNA strands, the nucleus can alter the internal structure of the cell, its sensitivity to substances in its environment, or its secretory functions to meet changing needs.

2. The DNA of the nucleus has *indirect* control over all other aspects of cellular metabolism, because it regulates the synthesis of enzymes. By ordering or stopping the production of appropriate enzymes, the nucleus can regulate all metabolic activities and functions of the cell. For example, the nucleus can accelerate the rate of glycolysis by increasing the number of needed enzymes in the cytoplasm.

This brings us to a central question: How does the nucleus “know” what genes to activate? Although we don’t have all the answers, we know that in many cases gene activation or deactivation is triggered by changes in the surrounding cytoplasm. Such changes in the intracellular environment can, in turn, affect the nucleoplasm enough to turn specific genes on or off. Alternatively, messengers or hormones may enter the nucleus through nuclear pores and bind to specific receptors or promoters along the DNA strands. Thus, continual chemical communication occurs between the cytoplasm and the nucleus. That communication is relatively selective, thanks to the restrictive characteristics of the nuclear pores and the barrier posed by the nuclear envelope.

Of course, continual communication also occurs between the cytoplasm and the extracellular fluid across the cell membrane, and what crosses the cell membrane today may alter gene activity tomorrow. In the next section, we will examine how the cell membrane selectively regulates the passage of materials in and out of the cell.

Concept Check

How does the nucleus control the activities of a cell?

What process would be affected by the lack of the enzyme RNA polymerase?

Answers begin on p. A–1

How Things Get Into and Out of Cells

Objectives

- Specify the routes by which different ions and molecules can enter or leave a cell, and the factors that may restrict such movement.

- Describe the various transport mechanisms cells use to facilitate the absorption or removal of specific substances.
- Explain the origin and significance of the transmembrane potential.

The cell membrane is a barrier that isolates the cytoplasm from the extracellular fluid. Because the cell membrane is an effective barrier, conditions inside the cell can be considerably different from conditions outside the cell. However, the barrier cannot be perfect, because cells are not self-sufficient. Each day they require nutrients to provide the energy they need to stay alive and function normally. They also generate waste products that must be eliminated. Whereas your body has passageways and openings for nutrients, gases, and wastes, the cell is surrounded by a continuous, relatively uniform membrane. So how do materials—whether nutrients or waste products—get across the cell membrane without damaging it or reducing its effectiveness as a barrier? To answer this question, we must take a closer look at the structure and function of the cell membrane.

Permeability of the cell membrane is the property of the cell membrane that determines precisely which substances can enter or leave the cytoplasm. A membrane through which nothing can pass is described as **impermeable**. A membrane through which any substance can pass without difficulty is **freely permeable**. The permeability of cell membranes lies somewhere between those extremes, so cell membranes are said to be **selectively permeable**.

A selectively permeable membrane permits the free passage of some materials and restricts the passage of others. The distinction may be based on size, electrical charge, molecular shape, lipid solubility, or other factors. Cells differ in their permeabilities, depending on what lipids and proteins are present in the cell membrane and how these components are arranged.

Passage across the membrane is either passive or active. *Passive processes* move ions or molecules across the cell membrane with no expenditure of energy by the cell. *Active processes* require that the cell expend energy, generally in the form of ATP.

Transport processes are also categorized by the mechanism involved. The three major categories are as follows:

1. *Diffusion*, which results from the random motion and collisions of ions and molecules. Diffusion is a passive process.

2. *Carrier-mediated transport*, which requires the presence of specialized integral membrane proteins. Carrier-mediated transport can be passive or active, depending on the substance transported and the nature of the transport mechanism.

3. *Vesicular transport*, which involves the movement of materials within small membranous sacs, or *vesicles*. Vesicular transport is always an active process.

Diffusion

Ions and molecules are constantly in motion, colliding and bouncing off one another and off obstacles in their paths. The movement is random: A molecule can bounce in any direction. One result of this continuous random motion is that, over time, the molecules in any given space will tend to become evenly distributed. This distribution process is called **diffusion**. As the molecules move around, there will be a net movement of material from areas of higher concentration to areas of lower concentration. The difference between the high and low concentrations is a **concentration gradient** (and thus a potential energy gradient). Diffusion tends to eliminate that gradient.

After the gradient has been eliminated, the molecular motion continues, but net movement no longer occurs in any particular direction. (For convenience, we restrict use of the term *diffusion* to the directional movement that eliminates concentration gradients—a process sometimes called *net diffusion*.) Because diffusion tends to spread materials from a region of higher concentration to one of lower concentration, it is often described as proceeding “down a concentration gradient” or “downhill.”

All of us have experienced the effects of diffusion, which occurs in air as well as in water. The scent of fresh flowers in a vase sweetens the air in the whole room; a drop of ink spreads to color an entire glass of water. Each case begins with a very high concentration of molecules in a localized area. Consider a colored sugar cube dropped in water (Figure 3–14•). Placing the cube in a large volume of clear water establishes a steep concentration gradient for the ingredients as they dissolve: The sugar and dye concentration is high near the cube and negligible elsewhere. As diffusion proceeds, the sugar and dye molecules spread through the solution until they are distributed evenly.

Diffusion is important in body fluids because it tends to eliminate local concentration gradients. For example, every cell in the body generates carbon dioxide, and the intracellular concentration is relatively high. Carbon dioxide concentrations are lower in the surrounding interstitial fluid, and lower still in the circulating blood. Because cell membranes are freely permeable to carbon dioxide, it can diffuse down its concentration gradient—traveling from the cell's interior into the interstitial fluid and then into the bloodstream, for eventual delivery to the lungs.

To be effective, the diffusion of nutrients, waste products, and dissolved gases must keep pace with the demands of active cells. Important factors that influence diffusion rates include the following:

- **Distance.** The shorter the distance, the more quickly concentration gradients are eliminated. In the human body, diffusion distances are generally small. For example, few cells are farther than 125mm from a blood vessel.
- **Molecule Size.** Ions and small organic molecules such as glucose diffuse more rapidly than do large proteins.
- **Temperature.** The higher the temperature, the faster the diffusion rate. Diffusion proceeds somewhat more rapidly at human body temperature (about 37°C, or 98.6°F) than at cooler environmental temperatures.
- **Gradient Size.** The larger the concentration gradient, the faster diffusion proceeds. When cells become more active, the intracellular concentration of oxygen declines. This change increases the concentration gradient for oxygen between the inside of the cell (relatively low) and the interstitial fluid outside (relatively high). The rate of oxygen diffusion into the cell then increases.

- **Electrical Forces.** Opposite electrical charges (+ and -) attract each other; like charges (+ and + *or* -and -) repel each other. The interior of the cell membrane has a net negative charge relative to the exterior surface, due in part to the high concentration of proteins in the cell. This negative charge tends to pull positive ions from the extracellular fluid into the cell, while

opposing the entry of negative ions. For example, interstitial fluid contains higher concentrations of sodium ions (Na^+) and chloride ions (Cl^-) than does cytosol. Diffusion of the positively charged sodium ions into the cell is therefore favored by both the concentration gradient, or *chemical gradient*, and the electrical gradient. In contrast, diffusion of the negatively charged chloride ions into the cell is favored by the chemical gradient, but opposed by the electrical gradient. For any ion, the net result of the chemical and electrical forces acting on it is called the *electrochemical gradient*.

Diffusion across Cell Membranes

In extracellular fluids, water and dissolved solutes diffuse freely. A cell membrane, however, acts as a barrier that selectively restricts diffusion: Some substances pass through easily, while others cannot penetrate the membrane. An ion or a molecule can diffuse across a cell membrane only by (1) crossing the lipid portion of the membrane or (2) passing through a membrane channel (Figure 3–15•).

Simple Diffusion Alcohol, fatty acids, and steroids can enter cells easily, because they can diffuse through the lipid portions of the membrane. Dissolved gases, such as oxygen and carbon dioxide, and lipid-soluble drugs also enter and leave our cells by diffusing through the phospholipid bilayer. The situation is more complicated for ions and water-soluble compounds, which are not lipid-soluble. To enter or leave the cytoplasm, these substances must pass through a membrane channel.

Clinical Note

Many clinically important drugs affect cell membranes. In general, the potency of an anesthetic is directly correlated with its lipid solubility. Presumably, high lipid solubility accelerates the drug’s entry into cells and enhances its ability to block ion channels or change other properties of cell membranes. The most important clinical result is a reduction in the sensitivity and responsiveness of neurons and muscle cells. Local anesthetics, such as *procaine* and *lidocaine,* affect nerve cells by blocking sodium channels in their cell membranes. This blockage reduces or eliminates the responsiveness of these cells to painful (or any other) stimuli. Lipid solubility is also involved in the action of general anesthetics, such as *chloroform, ether, halothane and nitrous oxide.* AM: Drugs and the Cell Membrane

Channel-Mediated Diffusion Membrane channels are very small passageways created by transmembrane proteins. On average, the channel is about 0.8 nm in diameter. Water molecules can enter or exit freely, but even a small organic molecule, such as glucose, is too big to fit through the channels. Whether an ion can transit a particular membrane channel depends on many factors, including the size and charge of the ion, the size of the hydration sphere, and interactions between the ion and the channel walls. The mechanics of diffusion through membrane channels is therefore more complex than simple diffusion. For example, the rate at which a particular ion diffuses across the membrane can be limited by the availability of suitable channels. However, for many ions, including sodium, potassium, and chloride, movement across the cell membrane occurs at rates comparable to those one would predict if relying on simple diffusion.

Osmosis: A Special Case of Diffusion

–

The net diffusion of water across a membrane is so important that it is given a special name: **osmosis** (oz-MO-sis; *osmos,* thrust).

For convenience, we will always use the term *osmosis* for the movement of water, and the term *diffusion* for the movement of solutes.

Intracellular and extracellular fluids are solutions that contain a variety of dissolved materials. Each solute diffuses as though it were the only material in solution. The diffusion of sodium ions, for example, occurs only in response to the existence of a concentration gradient for sodium. A concentration gradient for another ion will have no effect on the rate or direction of sodium ion diffusion.

Some solutes diffuse into the cytoplasm, others diffuse out, and a few (such as proteins) are unable to diffuse across the cell membrane at all. Yet if we ignore the individual identities and simply count ions and molecules, we find that the *total* concentration of dissolved ions and molecules on either side of the cell membrane stays the same. This state of equilibrium persists because a typical cell membrane is freely permeable to water.

To understand the basis for such equilibrium, consider that whenever a solute concentration gradient exists, a concentration gradient for *water* exists also. Because dissolved solute molecules occupy space that would otherwise be taken up by water molecules, the higher the solute concentration, the lower the water concentration. As a result, *water molecules tend to flow across a membrane toward the solution containing the higher solute concentration*, because this movement is down the concentration gradient for water. Water movement will continue until water concentrations—and thus solute concentrations—are the same on either side of the membrane.

Remember these three characteristics of osmosis:

1. Osmosis is the movement of water molecules across a membrane.

2. Osmosis occurs across a selectively permeable membrane that is freely permeable to water, but not freely permeable to solutes.

3. In osmosis, water flows across a membrane toward the solution that has the higher concentration of solutes, because that is where the concentration of water is lower.

Osmosis and Osmotic Pressure Figure 3–16• diagrams the process of osmosis. STEP 1 shows two solutions (A and B), with different solute concentrations, separated by a selectively permeable membrane. As osmosis occurs, water molecules cross the membrane until the solute concentrations in the two solutions are identical (STEP 2a). Thus, the volume of solution B increases while that of solution A decreases. The greater the initial difference in solute concentrations, the stronger is the osmotic flow. The **osmotic pressure** of a solution is an indication of the force with which pure water moves into that solution as a result of its solute concentration. We can measure a solution's osmotic pressure in several ways. For example, an opposing pressure can prevent the osmotic flow of water into the solution. Pushing against a fluid generates **hydrostatic pressure**. In STEP 2b, hydrostatic pressure opposes the osmotic pressure of solution B, so no net osmotic flow occurs.

Osmosis eliminates solute concentration differences much more quickly than solute diffusion. In large part this is because water molecules cross a membrane in groups held together by hydrogen bonding, whereas solute molecules usually diffuse through membrane channels one at a time. These differences result in a higher membrane permeability for water compared to solutes.

Osmolarity and Tonicity The total solute concentration in an aqueous solution is the solution's **osmolarity**, or **osmotic concentration**. The nature of the solutes, however, is often as important as the total osmolarity. Therefore, when we describe the effects of various osmotic solutions on cells, we usually use the term **tonicity** instead of osmolarity. A solution that does not cause an osmotic flow of water into or out of a cell is called **isotonic** (*iso*-, same + *tonos,* tension).

Although often used interchangeably, the terms *osmolarity* and *tonicity* do not always mean the same thing. Osmolarity refers to the solute concentration of the solution, while tonicity is a description of how the solution affects a cell. Consider a solution that has the same osmolarity as the intracellular fluid, but a higher concentration of one or more individual ions. If any of those ions can cross the cell membrane and diffuse into the cell, the osmolarity of the intracellular fluid will increase, and that of the extracellular solution will decrease. Osmosis will then occur, moving water into the cell. If the process continues, the cell will gradually inflate like a water balloon. In this case, the extracellular solution and the intracellular fluid were initially equal in osmolarity, but they were not isotonic.

Figure 3–17a• shows a red blood cell in an isotonic solution. If a red blood cell is in a **hypotonic** solution, water will flow into the cell, causing it to swell up like a balloon (Figure 3–17b•). The cell may eventually burst, releasing its contents. This event is **hemolysis** (*hemo*-, blood + *lysis*, dissolution). A cell in a **hypertonic** solution will lose water by osmosis. As it does, the cell shrivels and dehydrates. The shrinking of red blood cells is called **crenation** (Figure 3–17c•).

It is often necessary to give patients large volumes of fluid to combat severe blood loss or dehydration. One fluid frequently administered is a 0.9 percent (0.9 g > dl) solution of sodium chloride (NaCl). This solution, which approximates the normal osmotic concentration of extracellular fluids, is called *normal saline*. It is used because sodium and chloride are the most abundant ions in the extracellular fluid. Little net movement of either ion across cell membranes occurs; thus, normal saline is essentially isotonic with respect to body cells. An alternative treatment involves the use of an isotonic saline solution containing *dextran*, a carbohydrate that cannot cross cell membranes. The dextran molecules elevate the osmolarity of the blood, and as osmosis draws water into the blood vessels from the extracellular fluid, blood volume increases further.

100 Keys | *Things tend to even out*, unless something— like a cell membrane—prevents this from happening. In the absence of a cell membrane, or across a freely permeable membrane, diffusion will quickly eliminate concentration gradients. Osmosis acts to eliminate concentration gradients across membranes that are permeable to water but not permeable to the solutes involved.

Concept Check

How would a decrease in the concentration of oxygen in the lungs affect the diffusion of oxygen into the blood? Some pediatricians recommend the use of a 10 percent salt solution to relieve congestion for infants with stuffy noses. What effect would such a solution have on the cells lining the nasal cavity, and why?

Answers begin on p. A–1

Carrier-Mediated Transport

In **carrier-mediated transport**, integral proteins bind specific ions or organic substrates and carry them across the cell membrane. All forms of carrier-mediated transport have the following characteristics, which they share with enzymes:

1. *Specificity.* Each carrier protein in the cell membrane will bind and transport only certain substances. For example, the carrier protein that transports glucose will not transport other simple sugars.

2. *Saturation Limits.* The availability of substrate molecules and carrier proteins limits the rate of transport into or out of the cell, just as enzymatic reaction rates are limited by the availability of substrates and enzymes. When all the available carrier proteins are operating at maximum speed, the carriers are said to be *saturated*. The rate of transport cannot increase further, regardless of the size of the concentration gradient.

3. *Regulation.* Just as enzyme activity often depends on the presence of cofactors, the binding of other molecules, such as hormones, can affect the activity of carrier proteins. Hormones thus provide an important means of coordinating carrier protein activity throughout the body. The interplay between hormones and cell membranes will be examined when we consider the endocrine system (Chapter 18) and metabolism (Chapter 25).

Many examples of carrier-mediated transport involve the movement of a single substrate molecule across the cell membrane. A few carrier mechanisms transport more than one substrate at a time. In **cotransport**, or *symport*, the carrier transports two substances in the same direction simultaneously, either into or out of the cell. In **countertransport**, or *antiport*, one substance moves into the cell and the other moves out.

We will consider two major examples of carrier-mediated transport here: *facilitated diffusion* and *active transport*.

Facilitated Diffusion

Many essential nutrients, such as glucose and amino acids, are insoluble in lipids and too large to fit through membrane channels. These substances can be passively transported across the membrane by carrier proteins in a process called **facilitated diffusion** (Figure 3–

18•). The molecule to be transported must first bind to a **receptor site** on the protein. The shape of the protein then changes, moving the molecule across the cell membrane, where it is released into the cytoplasm.

As in the case of simple or channel-mediated diffusion, no ATP is expended in facilitated diffusion: The molecules simply move from an area of higher concentration to one of lower concentration. However, once the carrier proteins are saturated, the rate of transport cannot increase, regardless of further increases in the concentration gradient.

All cells move glucose across their membranes through facilitated diffusion. However, several different carrier proteins are involved. In muscle cells, fat cells, and many other types of cell, the glucose transporter functions only when stimulated by the hormone *insulin*. Inadequate production of this hormone is one cause of *diabetes mellitus*, a metabolic disorder that we will discuss in Chapter 18.

Active Transport

In **active transport**, a high-energy bond (in ATP or another high-energy compound) provides the energy needed to move ions or molecules across the membrane. Despite the energy cost, active transport offers one great advantage: It is not dependent on a concentration gradient. As a result, the cell can import or export specific substrates, *regardless of their intracellular or extracellular concentrations*.

All cells contain carrier proteins called **ion pumps**, which actively transport the cations sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}) across their cell membranes. Specialized cells can transport additional ions, such as iodide (I^-), chloride (Cl^-), and iron (Fe^{2+}). Many of these carrier proteins move a specific cation or anion in one direction only, either into or out of the cell. In a few instances, one carrier protein will move more than one kind of ion at the same time. If counter-transport occurs, the carrier protein is called an **exchange pump**.

The Sodium–Potassium Exchange Pump Sodium and potassium ions are the principal cations in body fluids. Sodium ion concentrations are high in the extracellular fluids, but low in the cytoplasm. The distribution of potassium in the body is just the opposite: low in the extracellular fluids and high in the cytoplasm. As a result, sodium ions slowly diffuse into the cell, and potassium ions diffuse out through leak channels. Homeostasis within the cell depends on the ejection of sodium ions and the recapture of lost potassium ions. This exchange is accomplished through the activity of a **sodium–potassium exchange pump**. The carrier protein involved in the process is called *sodium–potassium ATPase*.

The sodium–potassium exchange pump exchanges intracellular sodium for extracellular potassium (Figure 3–19•). On average, for each ATP molecule consumed, three sodium ions are ejected and two potassium ions are reclaimed by the cell. If ATP is readily available, the rate of transport depends on the concentration of sodium ions in the cytoplasm. When the concentration rises, the pump becomes more active. The energy demands are impressive: Sodium–potassium ATPase may use up to 40 percent of the ATP produced by a resting cell!

Secondary Active Transport In **secondary active transport**, the transport mechanism itself does not require energy, but the cell often needs to expend ATP at a later time to preserve homeostasis. As does facilitated transport, a secondary active transport mechanism moves a specific substrate down its concentration gradient. Unlike the proteins in facilitated transport, however, these carrier proteins can also move another substrate at the same time, without regard to its concentration gradient. In effect, the concentration gradient for one substance provides the driving force needed by the carrier protein, and the second substance gets a “free ride.”

The concentration gradient for sodium ions most often provides the driving force for cotransport mechanisms that move materials into the cell. For example, sodium-linked cotransport is important in the absorption of glucose and amino acids along the intestinal tract. Although the initial transport activity proceeds without direct energy expenditure, the cell must expend ATP to pump the arriving sodium ions out of the cell by using the sodium–potassium exchange pump (Figure 3–20•). Sodium ions are also involved with many countertransport mechanisms. Sodium–calcium countertransport is responsible for keeping intracellular calcium ion concentrations very low.

Vesicular Transport

In **vesicular transport**, materials move into or out of the cell in **vesicles**, small membranous sacs that form at, or fuse with, the cell membrane. Because large volumes of fluid and solutes are transported in this way, this process is also known as *bulk transport*. The two major categories of vesicular transport are *endocytosis* and *exocytosis*.

Endocytosis

As we saw earlier in this chapter, extracellular materials can be packaged in vesicles at the cell surface and imported into the cell

(p. 75). This process, called **endocytosis**, involves relatively large volumes of extracellular material and requires energy in the form of ATP. The three major types of endocytosis are (1) *receptor-mediated endocytosis*, (2) *pinocytosis*, and (3) *phagocytosis*. All three are active processes that require energy in the form of ATP.

Vesicles produced by receptor-mediated endocytosis or by pinocytosis are called *endosomes*; those produced by phagocytosis are called *phagosomes*. The contents of endosomes and phagosomes remain isolated from the cytoplasm, trapped within the vesicle. The movement of materials into the surrounding cytoplasm may involve active transport, simple or facilitated diffusion, or the destruction of the vesicle membrane.

Receptor-Mediated Endocytosis A selective process, **receptor-mediated endocytosis** involves the formation of small vesicles at the surface of the membrane. This process produces vesicles that contain a specific target molecule in high concentrations. Receptor-mediated endocytosis begins when materials in the extracellular fluid bind to receptors on the membrane surface (Figure 3–21•). Most receptor molecules are glycoproteins, and each binds to a specific ligand, or target, such as a transport protein or a hormone. Some receptors are distributed widely over the surface of the cell membrane; others are restricted to specific regions or in depressions on the cell surface.

Receptors bound to ligands cluster together. Once an area of the cell membrane has become covered with ligands, it forms grooves or pockets that move to one area of the cell and then pinch off to form an endosome. The endosomes produced in this way are called **coated vesicles**, because they are surrounded by a protein–fiber network that originally carpeted the inner membrane surface beneath the receptor–ligand clusters. This coating is essential to endosome formation and movement. Inside the cell, the coated vesicles fuse with primary lysosomes filled with digestive enzymes, creating secondary lysosomes (p. 75). The lysosomal enzymes then free the ligands from their receptors, and the ligands enter the cytosol by diffusion or active transport. The vesicle membrane detaches from the secondary lysosome and returns to the cell surface, where its receptors are available to bind more ligands.

Many important substances, including cholesterol and iron ions (Fe^{2+}) are distributed through the body attached to special transport proteins. These proteins are too large to pass through membrane pores, but they can and do enter cells by receptor-me-diated endocytosis.

Pinocytosis “Cell drinking,” or **pinocytosis** (pi-n

¯O

-T

-sis), is the formation of endosomes filled with extracellular fluid.

ı This process is not as selective as receptor-mediated endocytosis, because no receptor proteins are involved. The target appears to be the fluid contents in general, rather than specific bound ligands. In pinocytosis, a deep groove or pocket forms in the cell membrane and then pinches off (Figure 3–22a•). The steps involved in the formation and fate of an endosome created by pinocytosis are similar to the steps in receptor-mediated endocytosis, except that ligand binding is not the trigger.

–

¯o

-s

Phagocytosis “Cell eating,” or **phagocytosis** (fag-

¯O

-T

-sis), produces phagosomes containing solid objects that may be as

ı large as the cell itself. In this process, cytoplasmic extensions called **pseudopodia** (soo-d

–

¯o

-s

¯o

-P

–

O

-d

¯e

-ah; *pseudo-*, false + *podon*,

foot; singular *pseudopodium*) surround the object, and their membranes fuse to form a phagosome (Figure 3–22b•). This vesicle then fuses with many lysosomes, whereupon its contents are digested by lysosomal enzymes. Although most cells display pinocytosis, phagocytosis is performed only by specialized cells, such as the *macrophages* that protect tissues by engulfing bacteria, cell debris, and other abnormal materials.

Exocytosis

¯O

Exocytosis (ek-s

-T

-sis), introduced in our discussion of the Golgi apparatus (p. 74), is the functional reverse of endocyı tosis. In exocytosis, a vesicle created inside the cell fuses with the cell membrane and discharges its contents into the extracellular environment (see Figure 3–22b•). The ejected material may be secretory products, such as mucins or hormones, or waste products, such as those accumulating in endocytic vesicles. In a few specialized cells, endocytosis produces vesicles on one side of the cell that are discharged through exocytosis on the opposite side. This method of bulk transport is common in cells lining capillaries, which use a combination of pinocytosis and exocytosis to transfer fluid and solutes from the bloodstream into the surrounding tissues.

Many different mechanisms are moving materials into and out of the cell at any moment. Before proceeding further, review and compare the mechanisms summarized in Table 3–3.

The Transmembrane Potential

As noted previously, the inside of the cell membrane has a slight negative charge with respect to the outside. The cause is a slight excess of positively charged ions outside the cell membrane, and a slight excess of negatively charged ions (especially proteins)

–

inside the cell membrane. This unequal charge distribution is created by differences in the permeability of the membrane to various ions, as well as by active transport mechanisms.

Although the positive and negative charges are attracted to each other and would normally rush together, they are kept apart by the phospholipid membrane. When positive and negative charges are held apart, a **potential difference** is said to exist between them. We refer to the potential difference across a cell membrane as the **transmembrane potential**.

The unit of measurement of potential difference is the *volt* (V). Most cars, for example, have 12-V batteries. The transmembrane potentials of cells are much smaller, typically in the vicinity of 0.07 V. Such a value is usually expressed as 70 mV, or 70 *millivolts* (thousandths of a volt). The transmembrane potential in an undisturbed cell is called the **resting potential**. Each type of cell has a characteristic resting potential between -10 mV (-0.01 V) and -100 mV (-0.1 V), with the minus sign signifying that the inside of the cell membrane contains an excess of negative charges compared with the outside. Examples include fat cells (-40 mV), thyroid cells (-50 mV), neurons (-70 mV), skeletal muscle cells (-85 mV), and cardiac muscle cells (-90 mV).

If the lipid barrier were removed, the positive and negative charges would rush together and the potential difference would be eliminated. The cell membrane thus acts like a dam across a stream. Just as a dam resists the water pressure that builds up on the upstream side, a cell membrane resists electrochemical forces that would otherwise drive ions into or out of the cell. The water retained behind a dam and the ions held on either side of the cell membrane have *potential energy*—stored energy that can be released to do work. People have designed many ways to use the potential energy stored behind a dam—for example, turning a mill wheel or a turbine. Similarly, cells have ways of utilizing the potential energy stored in the transmembrane potential. For example, it is the transmembrane potential that makes possible the transmission of information in the nervous system, and thus our perceptions and thoughts. As we will see in later chapters, changes in the transmembrane potential also trigger the contraction of muscles and the secretion of glands.

Concept Check

During digestion in the stomach, the concentration of hydrogen ions (H^+) rises to many times that in cells of the stomach. Which transport process could be responsible? If the cell membrane were freely permeable to sodium ions (Na^+), how would the transmembrane potential be affected?

¯o

When they encounter bacteria, certain types of white blood cells engulf the bacteria and bring them into the cell. What is this process called?

Answers begin on p. A–1

The Cell Life Cycle

Objectives

- Describe the stages of the cell life cycle.
- Describe the process of mitosis and explain its significance.
- Discuss the regulation of the cell life cycle and the relationship between cell division and cancer.
- Define differentiation and explain its importance.

The period between fertilization and physical maturity involves tremendous changes in organization and complexity. At fertilization, a single cell is all there is; at maturity, your body has roughly 75 trillion cells. This amazing transformation involves a form of cellular reproduction called **cell division**. The division of a single cell produces a pair of **daughter cells**, each half the size of the original. Before dividing, each of the daughter cells will grow to the size of the original cell.

Even when development is complete, cell division continues to be essential to survival. Cells are highly adaptable, but they can be damaged by physical wear and tear, toxic chemicals, temperature changes, and other environmental stresses. And, like individuals, cells age. The life span of a cell varies from hours to decades, depending on the type of cell and the stresses involved. Many cells apparently self-destruct after a certain period of time as a result of the activation of specific “suicide genes” in the nu

cleus. The genetically controlled death of cells is called **apoptosis** (ap-op-T

¯O

-sis or ap-

¯o

-T

¯O

-sis; *apo*-, separated from + *ptosis*,
a falling away). Several genes involved in the regulation of this process have been identified. For example, a gene called *bcl-2* appears to prevent apoptosis and to keep a cell alive and functional. If something interferes with the function of this gene, the cell self-destructs.

Because a typical cell does not live nearly as long as a typical person, cell populations must be maintained over time by cell division. For cell division to be successful, the genetic material in the nucleus must be duplicated accurately, and one copy must be distributed to each daughter cell. The duplication of the cell’s genetic material is called **DNA replication**, and nuclear division is called **mitosis**
(m -T ı **is** (mı
–
–

¯O

-sis). Mitosis occurs during the division of somatic cells. The production of sex cells involves a different process, **meios**
-
–

O
-sis), described in Chapter 28.

Figure 3–23• depicts the life cycle of a typical cell. That life cycle includes a fairly brief period of mitosis alternating with an *interphase* of variable duration.

Interphase

Most cells spend only a small part of their time actively engaged in cell division. Somatic cells spend the majority of their functional lives in a state known as **interphase**. During interphase, a cell performs all its normal functions and, if necessary, prepares for cell division. In a cell preparing to divide, interphase can be divided into the *G*1, *S*, and *G*2 *phases*. An interphase cell in the *G*0 *phase* is not preparing for division, but is performing all of the other functions appropriate for that particular cell type. Some mature cells, such as skeletal muscle cells and most neurons, remain in G0 indefinitely and never divide. In contrast, *stem cells*, which divide repeatedly with very brief interphase periods, never enter G0.

The G_1 Phase

A cell that is ready to divide first enters the **G_1 phase**. In this phase, the cell makes enough mitochondria, cytoskeletal elements, endoplasmic reticula, ribosomes, Golgi membranes, and cytosol for two functional cells. Centriole replication begins in G1 and commonly continues until G2. In cells dividing at top speed, G1 may last just 8–12 hours. Such cells pour all their energy into mitosis, and all other activities cease. If G1 lasts for days, weeks, or months, preparation for mitosis occurs as the cells perform their normal functions.

The S Phase

When the activities of G1 have been completed, the cell enters the **S phase**. Over the next 6–8 hours, the cell duplicates its chromosomes. This involves DNA replication and the synthesis of histones and other proteins in the nucleus. The goal of DNA replication, which occurs in cells preparing to undergo either mitosis or meiosis, is to copy the genetic information in the nucleus. The cell ends up with two identical sets of chromosomes. In mitosis, one set is given to each of the two daughter cells.

DNA Replication Each DNA molecule consists of a pair of DNA strands joined by hydrogen bonding between complementary nitrogenous bases. l**p. 55** Figure 3–24• diagrams DNA replication. The process begins when enzymes called *helicases* unwind the strands and disrupt the weak bonds between the bases. As the strands unwind, molecules of **DNA polymerase** bind to the exposed nitrogenous bases. This enzyme (1) promotes bonding between the nitrogenous bases of the DNA strand and complementary DNA nucleotides dissolved in the nucleoplasm and (2) links the nucleotides by covalent bonds.

Many molecules of DNA polymerase work simultaneously along the DNA strands (see Figure 3–24•). DNA polymerase can work in only one direction along a strand of DNA, but the two strands in a DNA molecule are oriented in opposite directions. As a result, the DNA polymerase on one strand works toward the site where the strands are unzipping, but those on the other strand work away from it. As the two original strands gradually separate, the DNA polymerase bound to one strand (the upper strand in the figure) adds nucleotides to make a single, continuous complementary copy of that strand. This copy grows toward the "zipper" from right to left, adding nucleotides 1 through 9 in sequence; the 1 is added first, then 2 to the left of 1, and so on.

DNA polymerase on the other original strand, however, can work only away from the unzipping site. In the lower strand in Figure 3–24•, the first DNA polymerase to bind to it must work from left to right, adding nucleotides in the sequence 1 ¡ 2 ¡ 3 ¡ 4 ¡ 5. But as the original strands continue to unzip, additional nucleotides are continuously exposed. This molecule of DNA polymerase cannot go into reverse; it can only continue working from left to right. Thus, a second molecule of DNA polymerase must bind closer to the point of unzipping and assemble a complementary copy that grows in the sequence 6 ¡ 7 ¡ 8 ¡ 9, until it bumps into the segment created by the first DNA polymerase. The two segments are then spliced together by enzymes called **ligases** (L -g
I¯
¯a
s-ez; *liga*, to tie). Eventually, the unzipping completely separates the original strands. The copying ends, the last splicing is done, and two identical DNA molecules have formed.

The G_2 Phase

Once DNA replication has ended, there is a brief (2–5-hour) **G_2 phase** devoted to last-minute protein synthesis and to the completion of centriole replication. The cell then enters the **M phase**, and mitosis begins.

Mitosis

Mitosis separates the duplicated chromosomes of a cell into two identical nuclei. The term *mitosis* specifically refers to the division and duplication of the cell’s nucleus; division of the cytoplasm to form two distinct new cells involves a separate, but related,

E¯

process known as **cytokinesis** (s

ı the four stages of mitosis: *prophase* (early and late), *metaphase*, *anaphase*, and *telophase*. Bear in mind that, although we describe mitosis in stages, it is really one smooth, continuous process.

Stage 1: Prophase

–

¯o

-ki-N

-sis; *cyto*-, cell *kinesis*, motion). Figure 3–25• depicts interphase and summarizes

+

-t

Prophase (PR

¯O

-f

¯a

z; *pro*, before) begins when the chromosomes coil so tightly that they become visible as individual structures

under a light microscope. As a result of DNA replication during the S phase, two copies of each chromosome now exist. Each copy,

called a **chromatid** (KR

¯O

-ma-tid), is physically connected to its duplicate copy at a single point, the **centromere** (SEN-tr
¯o
-m
¯e
r). The centromere is surrounded by a protein complex known as the **kinetochore** (ki-NE-t
¯o
-kor). (These structures can be seen
in Figure 3–11•, p. 79.)

As the chromosomes appear, the nucleoli disappear. The disappearance occurs in late prophase, often called *prometaphase*. Around this time, the two pairs of centrioles replicated during the G1 –G2 period move toward opposite poles of the nucleus. An array of microtubules called **spindle fibers** extends between the centriole pairs. Smaller microtubules called *astral rays* radiate into the surrounding cytoplasm. Late in prophase, the nuclear envelope disappears. The spindle fibers now form among the chromosomes, and the kinetochore of each chromatid becomes attached to a spindle fiber. Once that attachment occurs, the spindle fiber is called a *chromosomal microtubule*.

Stage 2: Metaphase

Metaphase (MET-a-f
¯a
z; *meta*, after) begins as the chromatids move to a narrow central zone called the **metaphase plate**.

Metaphase ends when all the chromatids are aligned in the plane of the metaphase plate.

Stage 3: Anaphase

Anaphase (AN-a-f
¯a
z; *ana*-, apart) begins when the centromere of each chromatid pair splits and the chromatids separate. The two

daughter chromosomes are now pulled toward opposite ends of the cell along the chromosomal microtubules. This movement involves an interaction between the kinetochore and the microtubule. Anaphase ends when the daughter chromosomes arrive near the centrioles at opposite ends of the cell.

Stage 4: Telophase

During **telophase** (T
¯E

L-

¯o
-f
¯a
z; *telo*-, end), each new cell prepares to return to the interphase state. The nuclear membranes re
form, the nuclei enlarge, and the chromosomes gradually uncoil. Once the chromosomes have relaxed and the fine filaments of chromatin become visible again, the nucleoli reappear and the nuclei resemble those of interphase cells. This stage marks the end of mitosis.

100 Keys | Mitosis is the duplication of the chromosomes in the nucleus and their separation into two identical sets in
the process of somatic cell division.

Cytokinesis

Cytokinesis is the cytoplasmic division of the daughter cells. This process usually begins in late anaphase. As the daughter chromosomes approach the ends of the spindle apparatus, the cytoplasm constricts along the plane of the metaphase plate, forming a *cleavage furrow*. Cytokinesis continues throughout telophase and is usually completed sometime after a nuclear membrane has reformed around each daughter nucleus. The completion of cytokinesis marks the end of cell division, creating two separate and complete cells, each surrounded by its own cell membrane.

The Mitotic Rate and Energy Use

The preparations for cell division that occur between G1 and the M phase are difficult to recognize in a light micrograph. However, the start of mitosis is easy to recognize, because the chromosomes become condensed and highly visible. The frequency of cell division can thus be estimated by the number of cells in mitosis at any time. As a result, we often use the term **mitotic rate** when we discuss rates of cell division. In general, the longer the life expectancy of a cell type, the slower the mitotic rate. Long-lived cells, such as muscle cells and neurons, either never divide or do so only under special circumstances. Other cells, such as those covering the surface of the skin or the lining of the digestive tract, are subject to attack by chemicals, pathogens, and abrasion. They survive for only days or even hours. Special cells called **stem cells** maintain these cell populations through repeated cycles of cell division.

Stem cells are relatively unspecialized; their only function is the production of daughter cells. Each time a stem cell divides, one of its daughter cells develops functional specializations while the other prepares for further stem cell divisions. The rate of stem cell division can vary with the type of tissue and the demand for new cells. In heavily abraded skin, stem cells may divide more than once a day, but stem cells in adult connective tissues may remain inactive for years.

Dividing cells use an unusually large amount of energy. For example, they must synthesize new organic materials and move organelles and chromosomes within the cell. All these processes require ATP in substantial amounts. Cells that do not have adequate energy sources cannot divide. In a person who is starving, normal cell growth and maintenance grind to a halt. For this reason, prolonged starvation stunts childhood growth, slows wound healing, lowers resistance to disease, thins the skin, and changes the lining of the digestive tract.

Regulation of the Cell Life Cycle

In normal tissues, the rate of cell division balances the rate of cell loss or destruction. Mitotic rates are genetically controlled, and many different stimuli may be responsible for activating genes that promote cell division. Some of the stimuli are internal, and many cells set their own pace of mitosis and cell division. An important internal trigger is the level of **M-phase promoting factor (MPF)**, also known as *maturation-promoting factor*. MPF is assembled from two parts: a cell division cycle protein called *Cdc2* and a second protein called *cyclin*. Cyclin levels climb as the cell life cycle proceeds. When levels are high enough, MPF appears in the cytoplasm and mitosis gets under way.

Various extracellular compounds—generally, peptides—can stimulate the division of specific types of cells. These compounds include several hormones and a variety of **growth factors**. Table 3–4 lists some of the stimulatory compounds and their target tissues; we will discuss these hormones and factors in later chapters.

Genes that inhibit cell division have recently been identified. Such genes are known as *repressor genes*. One gene, called *p53*, controls a protein that resides in the nucleus and activates genes that direct the production of growth-inhibiting factors inside the cell. Roughly half of all cancers are associated with abnormal forms of the *p53* gene.

There are indications that in humans, the *number* of cell divisions performed by a cell and its descendants is regulated at the chromosome level by structures called **telomeres**. Telomeres are terminal segments of DNA with associated proteins. These DNA-protein complexes bend and fold repeatedly to form caps at the ends of chromosomes. Telomeres have several functions, notably to attach chromosomes to the nuclear matrix and to protect the ends of the chromosomes from damage during mitosis. The telomeres themselves, however, are subject to wear and tear over the years. Each time a cell divides during adult life, some of the repeating segments break off, and the telomeres get shorter. When they get too short, repressor gene activity tells the cell to stop dividing. AM: Telomeres, Aging, and Cancer

Cell Division and Cancer

When the rates of cell division and growth exceed the rate of cell death, a tissue begins to enlarge. A **tumor**, or *neoplasm,* is a mass or swelling produced by abnormal cell growth and division. In a *benign tumor,* the cells usually remain within the epithelium or a connective-tissue capsule. Such a tumor seldom threatens an individual's life and can usually be surgically removed if its size or position disturbs tissue function.

Cells in a *malignant tumor* no longer respond to normal control mechanisms. These cells do not remain confined within the epithelium or a connective tissue capsule, but spread into surrounding tissues. The tumor of origin is called the *primary tumor* (or *primary neoplasm*), and the spreading process is called **invasion**. Malignant cells may also travel to distant tissues and organs and establish *secondary tumors*. This dispersion, called **metastasis** (me-TAS-ta-sis; *meta-*, after + *stasis*, standing still), is very difficult to control.

Cancer is an illness characterized by mutations that disrupt normal control mechanisms and produce potentially malignant cells. Cancer develops in the series of steps diagrammed in Figure 3–26•. Initially, the cancer cells are restricted to the primary tumor. In most cases, all the cells in the tumor are the daughter cells of a single malignant cell. Normal cells often become malignant when a mutation occurs in a gene involved with cell growth, differentiation, or division. The modified genes are called **oncog**

enes (ON-k

¯o

-g

¯e

nz; *oncos*, tumor). AM: Cancer: A Closer Look

Cancer cells gradually lose their resemblance to normal cells. They change shape and typically become abnormally large or small. At first, the growth of the primary tumor distorts the tissue, but the basic tissue organization remains intact. Metastasis begins with invasion as tumor cells "break out" of the primary tumor and invade the surrounding tissue. They may then enter the lymphatic system and accumulate in nearby lymph nodes. When metastasis involves the penetration of blood vessels, the cancer cells circulate throughout the body.

Responding to cues that are as yet unknown, cancer cells in the bloodstream ultimately escape out of blood vessels to establish secondary tumors at other sites. These tumors are extremely active metabolically, and their presence stimulates the growth of blood vessels into the area. The increased circulatory supply provides additional nutrients to the cancer cells and further accelerates tumor growth and metastasis.

As malignant tumors grow, organ function begins to deteriorate. The malignant cells may no longer perform their original functions, or they may perform normal functions in an abnormal way. For example, endocrine cancer cells may produce normal hormones, but in excessively large amounts. Cancer cells do not use energy very efficiently. They grow and multiply at the expense of healthy tissues, competing for space and nutrients with normal cells. This competition contributes to the starved appearance of many patients in the late stages of cancer. Death may occur as a result of the compression of vital organs when nonfunctional cancer cells have killed or replaced the healthy cells in those organs, or when the cancer cells have starved normal tissues of essential nutrients. We will return to the subject of cancer in later chapters that deal with specific systems.

100 Keys | Cancer results from mutations that disrupt the control mechanism that regulates cell growth and division.

Cancers most often begin where stem cells are dividing rapidly, because the more times chromosomes are copied, the greater
the chances of error.

Cell Diversity and Differentiation

An individual’s liver cells, fat cells, and neurons all contain the same set of chromosomes and genes, but in each case a different set of genes has been turned *off*. In other words, liver cells and fat cells differ because liver cells have one set of genes accessible for transcription, and fat cells another.

When a gene is functionally eliminated, the cell loses the ability to produce a particular protein—and thus to perform any functions involving that protein. Each time another gene switches off, the cell's functional abilities become more restricted. This specialization process is called **differentiation**.

Fertilization produces a single cell with all its genetic potential intact. Repeated cell divisions follow, and differentiation begins as the number of cells increases. Differentiation produces specialized cells with limited capabilities. These cells form organized collections known as *tissues*, each with discrete functional roles. In Chapter 4, we will examine the structure and function of tissues and will consider the role of tissue interactions in the maintenance of homeostasis.

Clinical Note

In most cases, differentiation is irreversible: Once genes are turned off, they won't be turned back on. However, some cells, such as

stem cells, are relatively undifferentiated. These cells can differentiate into any of several different types of cell, depending on local

conditions. For example, when more nutrients are consumed than the body can use, stem cells in many parts of the body can differentiate into fat cells. Researchers are gradually discovering what chemical cues are responsible for controlling the differentiation of

specific cell types. The ability to take a person's stem cells and create new heart muscle cells or neurons on demand may one day

revolutionize the treatment of heart attacks and strokes.

100 Keys | All cells in your body (except sex cells, which form sperm or oocytes) contain the same 46 chromosomes.

What makes one cell different from another is which genes are active, and which are inactive.

Concept Check

A cell is actively manufacturing enough organelles to serve two functional cells. This cell is probably in which phase of its life cycle? During DNA replication, a nucleotide is deleted from a sequence that normally codes for a polypeptide. What effect will this deletion have on the amino acid sequence of the polypeptide? What would happen if spindle fibers failed to form in a cell during mitosis?

Answers begin on p. A–1

Chapter Review

Selected Clinical Terminology

benign tumor: A mass or swelling in which the cells usually remain within a connective-tissue capsule; rarely life threatening. (p. 98)

cancer: An illness caused by mutations leading to the uncontrolled growth and replication of affected cells. (p. 100)

dextran: A carbohydrate that cannot cross cell membranes; commonly administered in solution to patients after blood loss or dehydration. (p. 89)

DNA fingerprinting: Identifying an individual on the basis of repeating nucleotide sequences in his or her DNA. (p. 80)

invasion: The spread of cancer cells from a primary tumor into surrounding tissues. (p. 100)

malignant tumor: A mass or swelling in which the cells no longer respond to normal control mechanisms, but divide rapidly. (p. 98)

metastasis: The spread of malignant cells into distant tissues and organs, where secondary tumors subsequently develop. (p. 100)

normal saline: A NaCl solution that approximates the normal osmotic concentration of extracellular fluids. (p. 89)

oncogene: A cancer-causing gene created by a somatic mutation in a normal gene involved with growth, differentiation, or cell division.

(p. 100) **primary tumor** *(primary neoplasm):* The mass of cells in which a cancer cell initially developed. (p. 100) **secondary tumor:** A colony of cancerous cells formed by metastasis. (p. 100) **tumor (neoplasm):** A mass or swelling produced by abnormal cell growth and division. (p. 98)

Study Outline

An Introduction to Cells p. 63

1. Contemporary *cell theory* incorporates several basic concepts: (1) Cells are the building blocks of all plants and animals; (2) cells are produced by the division of preexisting cells; (3) cells are the smallest units that perform all vital physiological functions; (4) each cell maintains homeostasis at the cellular level; and (5) homeostasis at the tissue, organ, organ system, and organism levels reflects the combined and coordinated actions of many cells. *(Figure 3–1)*

2. **Cytology**, the study of cellular structure and function, is part of **cell biology**.

3. The human body contains two types of cells: **sex cells** (*sperm* and *oocytes*) and **somatic cells** (all other cells). *(Figure 3–1; Table 3–1)*

The Cell Membrane p. 63

1. A typical cell is surrounded by **extracellular fluid**—specifically, the **interstitial fluid** of the tissue. The cell's outer boundary is the **cell membrane**, or **plasma membrane**.

2. The cell membrane's functions include physical isolation, regulation of exchange with the environment, sensitivity to the environment, and structural support. *(Figure 3–2)*

Membrane Lipids p. 66

3. The cell membrane, which is a **phospholipid bilayer**, contains other lipids, proteins, and carbohydrates.

Membrane Proteins p. 66

4. **Integral proteins** are part of the membrane itself; **peripheral proteins** are attached to, but can separate from, the membrane.

5. Membrane proteins can act as anchors (**anchoring proteins**), identifiers (**recognition proteins**), enzymes, receptors (**receptor proteins**), carriers (**carrier proteins**), or **channels**.

Membrane Carbohydrates p. 67

6. The **glycocalyx** is formed by the carbohydrate portions of the *proteoglycans*, *glycoproteins*, and *glycolipids*. Functions include lubrication and protection, anchoring and locomotion, specificity in binding, and recognition.

The Cytoplasm p. 68

1. The **cytoplasm** contains the fluid **cytosol** and the **organelles** suspended in the cytosol.

The Cytosol p. 68

2. Cytosol differs from extracellular fluid in composition and in the presence of **inclusions**.

The Organelles p. 68

3. **Nonmembranous organelles** are not completely enclosed by membranes, and all of their components are in direct contact with the cytosol. They include the *cytoskeleton*, *microvilli*, *centrioles*, *cilia*, *ribosomes*, and *proteasomes*. *(Table 3–1)*

4. **Membranous organelles** are surrounded by phospholipid membranes that isolate them from the cytosol. They include the *endoplasmic reticulum*, the *Golgi apparatus*, *lysosomes*, *peroxisomes*, and *mitochondria*. *(Table 3–1)*

5. The **cytoskeleton** gives the cytoplasm strength and flexibility. It has four components: **microfilaments** (typically made of **actin**), **intermediate filaments**, **microtubules** (made of **tubulin**), and **thick filaments** (made of **myosin**). *(Figure 3–3)*

6. **Microvilli** are small projections of the cell membrane that increase the surface area exposed to the extracellular environment.

(Figure 3–3)

7. **Centrioles** direct the movement of chromosomes during cell division and organize the cytoskeleton. The **centrosome** is the cytoplasm surrounding the centrioles. *(Figure 3–4)*

8. **Cilia**, anchored by a **basal body**, beat rhythmically to move fluids or secretions across the cell surface. *(Figure 3–4)*

9. **Ribosomes**, responsible for manufacturing proteins, are composed of a **small** and a **large ribosomal subunit**, both of which contain **ribosomal RNA (rRNA)**. **Free ribosomes** are in the cytoplasm, and **fixed ribosomes** are attached to the endoplasmic reticulum. *(Figure 3–1)*

10. **Proteasomes** remove and break down damaged or abnormal proteins that have been tagged with *ubiquitin*.

11. The **endoplasmic reticulum (ER)** is a network of intracellular membranes that function in synthesis, storage, transport, and detoxification. The ER forms hollow tubes, flattened sheets, and chambers called **cisternae**. **Smooth endoplasmic reticulum (SER)** is involved in lipid synthesis; **rough endoplasmic reticulum (RER)** contains ribosomes on its outer surface and forms **transport vesicles**. *(Figure 3–5)*

12. The **Golgi apparatus** forms **secretory vesicles** and new membrane components, and packages *lysosomes*. Secretions are discharged from the cell by exocytosis. *(Figures 3–6, 3–7)*

13. **Lysosomes**, vesicles filled with digestive enzymes, are responsible for the **autolysis** of injured cells. *(Figures 3–6, 3–8)*

14. **Peroxisomes** carry enzymes that neutralize potentially dangerous free radicals.

15. **Membrane flow** refers to the continuous movement and recycling of the membrane among the ER, vesicles, the Golgi apparatus, and the cell membrane.

100 Keys | p. 76

16. Mitochondria are responsible for ATP production through aerobic metabolism. The **matrix**, or fluid contents of a mitochondrion, lies inside the **cristae**, or folds of an inner membrane. *(Figure 3–9)*

100 Keys | p. 77

The Nucleus p. 77

1. The **nucleus** is the control center of cellular operations. It is surrounded by a **nuclear envelope** (a double membrane with a **perinuclear space**), through which it communicates with the cytosol by way of **nuclear pores**. *(Figures 3–1, 3–10)*

Contents of the Nucleus p. 78

2. The nucleus contains a supportive **nuclear matrix**; one or more **nucleoli** typically are present.

3. The nucleus controls the cell by directing the synthesis of specific proteins, using information stored in **chromosomes**, which consist of DNA bound to **histones**. In nondividing cells, DNA and associated proteins form a tangle of filaments called **chromatin**.

(Figure 3–11)

100 Keys | p. 79

Information Storage in the Nucleus p. 79

4. The cell’s information storage system, the **genetic code**, is called a *triplet code* because a sequence of three nitrogenous bases specifies the identity of a single amino acid. Each **gene** contains all the DNA triplets needed to produce a specific polypeptide chain.

Gene Activation and Protein Synthesis p. 80

5. As **gene activation** begins, **RNA polymerase** must bind to the gene.

6. **Transcription** is the production of RNA from a DNA template. After transcription, a strand of **messenger RNA (mRNA)** carries instructions from the nucleus to the cytoplasm. *(Figure 3–12)*

7. During **translation**, a functional polypeptide is constructed using the information contained in the sequence of **codons** along an mRNA strand. The sequence of codons determines the sequence of amino acids in the polypeptide.

8. By complementary base pairing of **anticodons** to mRNA codons, **transfer RNA (tRNA)** molecules bring amino acids to the ribosomal complex. *(Figure 3–13; Table 3–2)*

100 Keys | pp. 83 and 84

How the Nucleus Controls Cell Structure and Function p. 84

9. The DNA of the nucleus has both direct and indirect control over protein synthesis.

How Things Get Into and Out of Cells p. 84

1. The **permeability** of a barrier such as the cell membrane is an indication of the barrier's effectiveness. Nothing can pass through an **impermeable** barrier; anything can pass through a **freely permeable** barrier. Cell membranes are **selectively permeable**.

Diffusion p. 85

2. **Diffusion** is the net movement of material from an area of higher concentration to an area of lower concentration. Diffusion occurs until the **concentration gradient** is eliminated. *(Figures 3–14, 3–15)*

3. Most lipid-soluble materials and gases freely diffuse across the phospholipid bilayer of the cell membrane. Water and small ions rely on channel-mediated diffusion through passageways bounded by transmembrane proteins.

4. **Osmosis** is the net flow of water across a membrane in response to differences in osmotic pressure. **Osmotic pressure** is the force of water movement into a solution resulting from solute concentration. **Hydrostatic pressure** can oppose osmotic pressure.

(Figure 3–16)

5. **Tonicity** describes the effects of osmotic solutions on cells. A solution that does not cause an osmotic flow is **isotonic**. A solution that causes water to flow into a cell is **hypotonic** and can lead to **hemolysis** of red blood cells. A solution that causes water to flow out of a cell is **hypertonic** and can lead to **crenation**. *(Figure 3–17)*

100 Keys | p. 89

Carrier-Mediated Transport p. 89

6. Carrier-mediated transport involves the binding and transporting of specific ions by integral proteins. **Cotransport** moves two substances in the same direction; **countertransport** moves them in opposite directions.

7. In **facilitated diffusion**, compounds are transported across a membrane after binding to a **receptor site** on a carrier protein.

(Figure 3–18)

8. **Active transport** mechanisms consume ATP, and are not dependent on concentration gradients. Some **ion pumps** are **exchange pumps**. **Secondary active transport** may involve cotransport or countertransport. *(Figures 3–19, 3–20)*

Vesicular Transport p. 92

9. In **vesicular transport**, materials move into or out of the cell in membranous **vesicles**. Movement into the cell is accomplished through **endocytosis**, an active process that can take three forms: **receptor-mediated endocytosis** (by means of **coated vesicles**), **pinocytosis**, or **phagocytosis** (using **pseudopodia**). The ejection of materials from the cytoplasm is accomplished by **exocytosis**.

(Figures 3–21, 3–22; Summary Table 3–3)

The Transmembrane Potential p. 94

10. The **potential difference** between the two sides of a cell membrane is a **transmembrane potential**. The transmembrane potential in an undisturbed cell is the cell's **resting potential**.

The Cell Life Cycle p. 95

1. **Cell division** is the reproduction of cells. **Apoptosis** is the genetically controlled death of cells. **Mitosis** is the nuclear division of somatic cells. Sex cells are produced by **meiosis**. *(Figure 3–23)*

Interphase p. 95

2. Most somatic cells spend most of their time in **interphase**, which includes the **G1**, **S (DNA replication)**, and **G2 phases**.

(Figures 3–23, 3–24)

Mitosis p. 96

3. Mitosis proceeds in four stages: **prophase**, **metaphase**, **anaphase**, and **telophase**. *(Figure 3–25)*

100 Keys | p. 98

Cytokinesis p. 98

4. During **cytokinesis**, the cytoplasm is divided and cell division ends. *(Figure 3–25)*

The Mitotic Rate and Energy Use p. 98

5. In general, the longer the life expectancy of a cell type, the slower is the **mitotic rate**. **Stem cells** undergo frequent mitosis to replace other, more specialized cells.

Regulation of the Cell Life Cycle p. 99

6. A variety of **growth factors** can stimulate cell division and growth. *(Table 3–4)*

Cell Division and Cancer p. 99

7. Produced by abnormal cell growth and division, a **tumor**, or **neoplasm**, can be **benign** or **malignant**. Malignant cells may spread locally (by **invasion**) or to distant tissues and organs (through **metastasis**). The resultant illness is called **cancer**. Malignancy is often caused by modified genes called **oncogenes**. *(Figure 3–26)*

100 Keys | p. 100

Cell Diversity and Differentiation p. 100

8. **Differentiation**, a process of specialization, results from the inactivation of particular genes in different cells, producing populations of cells with limited capabilities. Specialized cells form organized collections called *tissues*, each of which has certain functional roles.

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The process by which containing solid objects such as bacteria are formed on the surface of a cell for transport into the cell is called

(a) pinocytosis

(b) phagocytosis

(c) exocytosis

(d) receptor-mediated endocytosis

(e) channel-mediated transport

2. Cell membranes are said to be

(a) impermeable

(b) freely permeable

(c) selectively permeable

(d) actively permeable

(e) slightly permeable

3. _____ ion concentrations are high in the extracellular fluids, and _____ ion concentrations are high in the cytoplasm.

(a) Calcium, magnesium

(b) Chloride, sodium

(c) Potassium, sodium

(d) Sodium, potassium

4. In a resting transmembrane potential, the inside of the cell is _____, and the cell exterior is _____.

(a) slightly negative, slightly positive

(b) slightly positive, slightly negative

(c) slightly positive, neutral

(d) slightly negative, neutral

5. The organelle responsible for a variety of functions centering around the synthesis of lipids and carbohydrates is

(a) the Golgi apparatus

(b) the rough endoplasmic reticulum

(c) the smooth endoplasmic reticulum

(d) mitochondria

6. The construction of a functional polypeptide by using the information in an mRNA strand is

(a) translation **(b)** transcription

(c) replication **(d)** gene activation

7. Our somatic cell nuclei contain _____ pairs of chromosomes.

(a) 8 **(b)** 16

(c) 23 **(d)** 46

8. The movement of water across a membrane from an area of low solute concentration to an area of higher solute concentration is known as

(a) osmosis **(b)** active transport

(c) diffusion **(d)** facilitated transport

(e) filtration

9. The interphase of the cell life cycle is divided into

(a) prophase, metaphase, anaphase, and telophase

(b) G0, G1, S, and G2

(c) mitosis and cytokinesis

(d) a, b, and c are correct

10. List the five basic concepts that make up the modern-day cell theory.

11. What are four general functions of the cell membrane?

12. What are the primary functions of membrane proteins?

13. By what three major transport mechanisms do substances get into and out of cells?

14. List four important factors that influence diffusion rates.

15. What are the four major functions of the endoplasmic reticulum?

LEVEL 2 Reviewing Concepts

16. Diffusion is important in body fluids because it tends to

(a) increase local concentration gradients

(b) eliminate local concentration gradients

(c) move substances against concentration gradients

(d) create concentration gradients

17. Microvilli are found

(a) mostly in muscle cells

(b) on the inside of cell membranes

(c) in large numbers on cells that secrete hormones

(d) in cells that are actively engaged in absorption

(e) only on cells lining the reproductive tract

18. When a cell is placed in a(n) _____ solution, the cell will lose water through osmosis. This process results in the _____ of red blood cells.

(a) hypotonic, crenation **(b)** hypertonic, crenation

(c) isotonic, hemolysis **(d)** hypotonic, hemolysis

19. Suppose that a DNA segment has the following nucleotide sequence: CTC–ATA–CGA–TTC–AAG–TTA. Which nucleotide sequences would a complementary mRNA strand have?

(a) GAG–UAU–GAU–AAC–UUG–AAU

(b) GAG–TAT–GCT–AAG–TTC–AAT

(c) GAG–UAU–GCU–AAG–UUC–AAU

(d) GUG–UAU–GGA–UUG–AAC–GGU

20. How many amino acids are coded in the DNA segment in Review Question 19?

(a) 18 **(b)** 9

(c) 6 **(d)** 3

21. The sodium-potassium exchange pump

(a) is an example of facilitated diffusion

(b) does not require the input of cellular energy in the form of ATP

(c) moves the sodium and potassium ions along their concentration gradients

(d) is composed of a carrier protein located in the cell membrane

(e) is not necessary for the maintenance of homeostasis

22. If a cell lacked ribosomes, it would not be able to

23. When a sodium ion is moved across the cell membrane against its concentration gradient

(a) diffusion occurs

(b) osmosis occurs

(c) cellular ATP is used

(d) vesicles are formed

(e) the cell membrane changes shape

24. List, in sequence, the phases of the interphase stage of the cell life cycle, and briefly describe what happens in each.

25. List the stages of mitosis, and briefly describe the events that occur in each.

26. **(a)** What is cytokinesis?

(a) move **(b)** synthesize proteins

(c) produce DNA **(d)** metabolize sugar

(e) divide

(b) What is its role in the cell cycle?

LEVEL 3 Critical Thinking and Clinical Applications

27. The transport of a certain molecule exhibits the following characteristics: (1) The molecule moves down its concentration gradient;

(2) at concentrations above a given level, the rate of transport does not increase; and (3) cellular energy is not required for transport to occur. Which transport process is at work?

28. Solutions A and B are separated by a selectively permeable barrier. Over time, the level of fluid on side A increases. Which solution initially had the higher concentration of solute?

29. A molecule that blocks the ion channels in integral proteins in the cell membrane would interfere with

(a) cell recogniton

(b) the movement of lipid soluble molecules

(c) the ability of the cell membrane to depolarize

(d) the ability of protein hormones to stimulate the cell

(e) the cell's ability to divide

30. What is the benefit of having some of the cellular organelles enclosed by a membrane similar to the cell membrane?

TABLE 3–2 Examples of the Triplet Code

DNA Triplets				
Coding Strand	**Template Strand**	**mRNA Codon**	**tRNA Anticodon**	**Amino Acid**
TTT	AAA	UUU	AAA	Phenylalanine
TTA	AAT	UUA	AAU	Leucine
TGT	ACA	UGU	ACA	Cysteine
GTT	CAA	GUU	CAA	Valine
ATG	TAC	AUG	UAC	Methionine
AGC	TCG	AGC	UCG	Serine
CCG	GGC	CCG	GGC	Proline
GCC	CGG	GCC	CGG	Alanine

| SUMMARY TABLE 3–3 | MECHANISMS INVOLVED IN MOVEMENT ACROSS CELL MEMBRANES

Mechanism Process Factors Affecting Rate Substances Involved (Sites)

Diffusion Molecular movement of solutes; (includes direction determined by relative simple diffusion concentrations and channel-mediated diffusion)

Size of gradient; size Small inorganic ions; lipid-soluble of molecules; charge; lipid materials (all cells) solubility, temperature; additional factors apply to channel-mediated diffusion

Osmosis Movement of water molecules toward Concentration gradient; opposing Water only (all cells) solution containing relatively osmotic or hydrostatic pressure; higher solute concentration; requires number of aquaporins selectively permeable membrane (water channels)

Carrier-Mediated Transport

Facilitated diffusion Carrier proteins passively transport Size of gradient, temperature Glucose and amino acids (all cells, solutes across a membrane down a and availability of carrier protein but several different regulatory concentration gradient mechanisms exist)

Active transport Carrier proteins actively transport Availability of carrier, Na^+, K^+, Ca^{2+}, Mg^{2+} (all cells); other solutes across a membrane, often substrates, and ATP solutes by specialized cells against a concentration gradient

Secondary active Carrier proteins passively transport Availability of carrier, Glucose and amino acids

transport two solutes, with one (normally Na^+) substrates, and ATP (specialized cells)

moving down its concentration

gradient; the cell must later expend

ATP to eject the Na^+

Vesicular Transport Endocytosis Creation of membranous vesicles containing fluid or solid material **Exocytosis** Fusion of vesicles containing fluids or solids (or both) with the cell membrane

Stimulus and mechanics incompletely Fluids, nutrients (all cells); debris, understood; requires ATP pathogens (specialized cells)

Stimulus and mechanics Fluids, debris (all cells) incompletely understood; requires ATP

TABLE 3–4 Representative Chemical Factors Affecting Cell Division

Factor Source(s) Effect(s) Target(s)

M-phase promoting factor Forms within cytoplasm from Triggers start of mitosis Regulatory mechanism active in all **(maturation-promoting** Cdc2 and cyclin dividing cells **factor)**

Growth hormone Anterior lobe of the Stimulation of growth, cell All cells, especially in epithelia and pituitary gland division, differentiation connective tissues

Prolactin Anterior lobe of the Stimulation of cell growth, Gland and duct cells of mammary pituitary gland division, development glands

Nerve growth factor (NGF) Salivary glands; other Stimulation of nerve cell Neurons and neuroglia sources suspected repair and development

Epidermal growth factor (EGF) Duodenal glands; other Stimulation of stem cell Epidermis sources suspected divisions and epithelial repairs

Fibroblast growth factor (FGF) Unknown Division and differentiation of Connective tissues

fibroblasts and related cells

Erythropoietin Kidneys (primary source) Stimulation of stem cell Bone marrow

divisions and maturation

of red blood cells

Thymosins and related Thymus Stimulation of division and Thymus and other lymphoid tissues

compounds differentiation of lymphocytes and organs

(especially T cells)

Chalones Many tissues Inhibition of cell division Cells in the immediate area

- **FIGURE 3–1** The Anatomy of a Model Cell. See Table 3–1 for a summary of the functions associated with the various cell structures.
- **FIGURE 3–2** The Cell Membrane
- **FIGURE 3–3** The Cytoskeleton. **(a)** The cytoskeleton provides strength and structural support for the cell and its organelles. Interactions between cytoskeletal components are also important in moving organelles and in changing the shape of the cell. **(b)** The microfilaments and microvilli of an intestinal cell. Such an image, produced by a scanning electron microscope, is called an SEM.
- **FIGURE 3–4** Centrioles and Cilia. **(a)** A centriole consists of nine microtubule triplets (known as a 9 + 0 array). A pair of centrioles oriented at right angles to one another occupies the centrosome. The photograph, produced by a transmission electron microscope, is called a *TEM*. **(b)** A cilium contains nine pairs of microtubules surrounding a central pair (9 + 2 array). The basal body to which the cilium is anchored has a structure similar to that of a centriole. **(c)** Action of a single cilium. During the power stroke, the cilium is relatively stiff; during the return stroke, it bends and returns to its original position.
- **FIGURE 3–5** The Endoplasmic Reticulum. **(a)** The three-dimensional relationships between the rough and smooth endoplasmic reticula.

(b) Rough endoplasmic reticulum and free ribosomes in the cytoplasm of a cell.

- **FIGURE 3–6** The Golgi Apparatus. **(a)** A three-dimensional view of the Golgi apparatus with a cut edge corresponding to **(b)**, a sectional view of the Golgi apparatus of an active secretory cell, produced by a transmission electron microscope (TEM).
- **FIGURE 3–7** Functions of the Golgi Apparatus. **(a)** Transport vesicles carry the secretory product from the endoplasmic reticulum to the Golgi apparatus (simplified to clarify the relationships between the membranes). Small vesicles move membrane and materials between the Golgi cisternae. At the maturing face, three functional categories of vesicles develop. Lysosomes, which remain in the cytoplasm, are vesicles filled with digestive enzymes. Secretory vesicles carry the secretion from the Golgi to the cell surface,

where exocytosis releases the contents into the extracellular fluid. Other vesicles add surface area and integral proteins to the cell membrane. **(b)** Exocytosis at the surface of a cell.

- **FIGURE 3–8** Lysosome Functions. Primary lysosomes, formed at the Golgi apparatus, contain inactive enzymes. Activation may occur under any of three basic conditions indicated here.
- **FIGURE 3–9** Mitochondria. **(a)** The three-dimensional organization and a color-enhanced TEM of a typical mitochondrion in section.

(b) An overview of the role of mitochondria in energy production. Mitochondria absorb short carbon chains (such as pyruvic acid) and oxygen and generate carbon dioxide and ATP.

- **FIGURE 3–10** The Nucleus. **(a)** Important nuclear structures. **(b)** This cell was frozen and then broken apart to make its internal structures visible. The technique, called *freeze fracture* or *freeze-etching*, provides a unique perspective on the internal organization of cells. The nuclear envelope and nuclear pores are visible. The fracturing process broke away part of the outer membrane of the nuclear envelope, and the cut edge of the nucleus can be seen.
- **FIGURE 3–11** The Organization of DNA within the Nucleus. DNA strands are coiled around histones to form nucleosomes. Nucleosomes form coils that may be very tight or rather loose. In cells that are not dividing, the DNA is loosely coiled, forming a tangled network known as chromatin. When the coiling becomes tighter, as it does in preparation for cell division, the DNA becomes visible as distinct structures called chromosomes.
- **FIGURE 3–12** mRNA Transcription. A small portion of a single DNA molecule, containing a single gene available for transcription. STEP 1: The two DNA strands separate, and RNA polymerase binds to the promoter of the gene. STEP 2: The RNA polymerase moves from one nucleotide to another along the length of the template strand. At each site, complementary RNA nucleotides form hydrogen bonds with the DNA nucleotides of the template strand. The RNA polymerase then strings the arriving

nucleotides together into a strand of mRNA. STEP 3: On reaching the stop signal at the end of the gene, the RNA polymerase and the mRNA strand detach, and the two DNA strands reassociate.

- **FIGURE 3–13** The Process of Translation. For clarity, the components are not drawn to scale and their three-dimensional relationships have been simplified.
- **FIGURE 3–14** Diffusion. Placing a colored sugar cube in a glass of water establishes a steep concentration gradient. As the cube dissolves, many sugar and dye molecules are in one location, and none are elsewhere. As diffusion occurs, the molecules spread through the solution. Eventually, diffusion eliminates the concentration gradient. The sugar cube has dissolved completely, and the molecules are distributed evenly. Molecular motion continues, but there is no net directional movement.
- **FIGURE 3–15** Diffusion across the Cell Membrane
- **FIGURE 3–16** Osmosis. The osmotic pressure of solution B is equal to the amount of hydrostatic pressure required to stop the osmotic flow.
- **FIGURE 3–17** Osmotic Flow across a Cell Membrane. Black arrows indicate an equilibrium with no net water movement. Blue arrows indicate the direction of osmotic water movement. **(a)** In an isotonic saline solution, no osmotic flow occurs, and these red blood cells appear normal.

(b) Immersion in a hypotonic saline solution results in the osmotic flow of water into the cells. The swelling may continue until the cell membrane
ruptures, or lyses. **(c)** Exposure to a hypertonic solution results in the movement of water out of the cells. The red blood cells shrivel and become crenated.

- **FIGURE 3–18** Facilitated Diffusion. In facilitated diffusion, an extracellular molecule, such as glucose, binds to a receptor site on a carrier protein. The binding alters the shape of the protein, which then releases the molecule to diffuse into the cytoplasm.
- **FIGURE 3–19** The Sodium–Potassium Exchange Pump. The operation of the sodium–potassium exchange pump is an example of active transport. For each ATP converted to

ADP, the protein called sodium– potassium ATPase carries three Na^+ out of the cell and two K^+ into the cell.

• **FIGURE 3–20** Secondary Active Transport. In secondary active transport, glucose transport by a carrier protein will occur only after the carrier has bound a sodium ion. In three cycles, three glucose molecules and three sodium ions are transported into the cytoplasm. The cell then pumps the sodium ions across the cell membrane via the sodium–potassium exchange pump, at a cost of one ATP molecule.

• **FIGURE 3–21** Receptor-Mediated Endocytosis

• **FIGURE 3–22** Pinocytosis and Phagocytosis. **(a)** An electron micrograph showing pinocytosis at the surface of a cell. **(b)** In phagocytosis, material is brought into the cell enclosed in a phagosome that is subsequently exposed to lysosomal enzymes. After nutrients are absorbed from the vesicle, the residue is discharged by exocytosis.

• **FIGURE 3–23** The Cell Life Cycle

• **FIGURE 3–24** DNA Replication. In DNA replication, the DNA strands unwind, and DNA polymerase begins attaching complementary DNA nucleotides along each strand. On one original strand, the complementary copy is produced as a continuous strand. Along the other original strand, the copy begins as a series of short segments spliced together by ligases. This process ultimately produces two identical copies of the original DNA molecule.

Tissues of the Body: An Introduction

Objective

- Identify the four major types of tissues in the body and describe their roles.

Although the human body contains trillions of cells, differentiation produces only about 200 types of cells. To work efficiently, several different types of cells must coordinate their efforts. The combination of different cell types creates **tissues**—collections of specialized cells and cell products that perform a relatively limited number of functions. The study of tissues is called **histology**. Histologists recognize four basic types of tissue:

1. *Epithelial tissue*, which covers exposed surfaces, lines internal passageways and chambers, and forms glands.

2. *Connective tissue*, which fills internal spaces, provides structural support for other tissues, transports materials within the body, and stores energy reserves.

3. *Muscle tissue*, which is specialized for contraction and includes the skeletal muscles of the body, the muscle of the heart, and the muscular walls of hollow organs.

4. *Neural tissue*, which carries information from one part of the body to another in the form of electrical impulses. ATLAS: Embryology Summary 1: The Formation of Tissues

This chapter will introduce the basic characteristics of these tissues. You will need this information to understand the descriptions of organs and organ systems in later chapters. Additionally, a working knowledge of basic histology will help you make the connections between anatomical structures and their physiological functions.

100 Keys | Tissues are collections of cells and cell products that perform a specific but limited range of functions. There are four tissue types in varying combinations that form all of the structures of the human body: epithelial, connective, muscle, and neural tissue.

Epithelial Tissue

Objectives

- Discuss the types and functions of epithelial cells.
- Describe the relationship between form and function for each type of epithelium.

It is convenient to begin our discussion with **epithelial tissue**, because it includes the surface of your skin, a relatively familiar feature. Epithelial tissue includes *epithelia* and *glands*. **Epithelia** (ep-i-THĒ-lē-a; singular, *epithelium*) are layers of cells that cover internal or external surfaces. **Glands** are structures that produce fluid secretions; they are either attached to or derived from epithelia.

Epithelia cover every exposed surface of the body. Epithelia form the surface of the skin and line the digestive, respiratory, reproductive, and urinary tracts—in fact, they line all passageways that communicate with the outside world. The more delicate epithelia line internal cavities and passageways, such as the chest cavity, fluid-filled spaces in the brain, the inner surfaces of blood vessels, and the chambers of the heart.

Epithelia have several important characteristics:

- **Cellularity.** Epithelia are composed almost entirely of cells bound closely together by interconnections known as *cell junctions*. In other tissue types, the cells are often widely separated by extracellular materials.
- **Polarity.** An epithelium has an exposed surface, which faces the exterior of the body or some internal space, and a base, which is attached to adjacent tissues. The term **polarity** refers to the presence of structural and functional differences between the exposed and attached surfaces. In an epithelium consisting of a single layer of cells, exposed (*apical*) and attached (*basal*) surfaces differ in terms of membrane structure and function, and between the two surfaces the organelles and other cytoplasmic components are unevenly distributed.
- **Attachment.** The base of an epithelium is bound to a thin **basal lamina**, or *basement membrane*. The basal lamina is a complex structure produced by the basal surface of the epithelium and the underlying connective tissue.

- **Avascularity.** Epithelia are **avascular** (ā-VAS-kū-lar; *a*-, without + *vas*, vessel); that is, they lack blood vessels. Epithelial cells must therefore obtain nutrients by diffusion or absorption across either the exposed or the attached epithelial surface.
- **Regeneration.** Epithelial cells that are damaged or lost at the exposed surface are continuously replaced through the divisions of stem cells in the epithelium. Although regeneration is a characteristic of other tissues as well, the rates of cell division and replacement are typically much higher in epithelia than in other tissues.

Functions of Epithelial Tissue

Epithelia perform four essential functions:

1. *Provide Physical Protection.* Epithelia protect exposed and internal surfaces from abrasion, dehydration, and destruction by
chemical or biological agents.

2. *Control Permeability.* Any substance that enters or leaves your body must cross an epithelium. Some epithelia are relatively impermeable; others are easily crossed by compounds as large as proteins. Many epithelia contain the molecular "machinery" needed for selective absorption or secretion. The epithelial barrier can be regulated and modified in response to stimuli. For example, hormones can affect the transport of ions and nutrients through epithelial cells. Even physical stress can alter the structure and properties of epithelia; for example, calluses form on your hands when you do manual labor for a while.

3. *Provide Sensation.* Most epithelia are extremely sensitive to stimulation, because they have a large sensory nerve supply. These sensory nerves continually provide information about the external and internal environments. For example, the lightest touch of a mosquito will stimulate sensory neurons that tell you where to swat. A *neuroepithelium* is an epithelium that is specialized to perform a particular sensory function; neuroepithelia contain sensory cells that provide the sensations of smell, taste, sight, equilibrium, and hearing.

4. *Produce Specialized Secretions.* Epithelial cells that produce secretions are called *gland cells*. Individual gland cells are typically scattered among other cell types in an epithelium. In a **glandular epithelium**, most or all of the epithelial cells produce secretions, which are either discharged onto the surface of the epithelium (to provide physical protection) or released into the surrounding interstitial fluid and blood (to act as chemical messengers).

Specializations of Epithelial Cells

Epithelial cells have several structural specializations that distinguish them from other body cells. For the epithelium as a whole to perform the functions just listed, individual epithelial cells may be specialized for (1) the movement of fluids over the epithelial surface, providing protection and lubrication; (2) the movement of fluids through the epithelium, to control permeability; or

(3) the production of secretions that provide physical protection or act as chemical messengers. Specialized epithelial cells generally possess a strong polarity; one common type of epithelial polarity is shown in Figure 4–1•.

The cell is often divided into two functional regions: (1) the *apical surface*, where the cell is exposed to an internal or external environment; and (2) the *basolateral surfaces*, which include both the base, where the cell attaches to underlying epithelial cells or deeper tissues, and the sides, where the cell contacts its neighbors.

Many epithelial cells that line internal passageways have microvilli on their exposed surfaces. l**p. 70** Just a few may be present, or microvilli may carpet the entire surface. Microvilli are especially abundant on epithelial surfaces where absorption and secretion take place, such as along portions of the digestive and urinary tracts. The epithelial cells in these locations are transport specialists; each cell has at least 20 times more surface area than it would have if it lacked microvilli.

Cilia are characteristic of surfaces covered by a **ciliated epithelium**. A typical ciliated cell contains about 250 cilia that beat in a coordinated fashion. As though on an escalator, substances are moved over the epithelial surface by the synchronized beating of the cilia. The ciliated epithelium that lines the respiratory tract, for example, moves mucus up from the lungs and toward the throat. The sticky mucus traps inhaled particles, including dust, pollen, and pathogens; the ciliated epithelium carries the mucus and the trapped debris to the throat, where they can be swallowed. Injury to the cilia or to the epithelial cells, most commonly by abrasion or exposure to toxic compounds such as nicotine in cigarette smoke, can stop ciliary movement and block the protective flow of mucus.

Maintaining the Integrity of Epithelia

To be effective as a barrier, an epithelium must form a complete cover or lining. Three factors help maintain the physical integrity of an epithelium: (1) intercellular connections, (2) attachment to the basal lamina, and (3) epithelial maintenance and repair.

Intercellular Connections

Cells in an epithelium are firmly attached to one another, and the epithelium as a unit is attached to extracellular fibers of the basal lamina. Many cells in your body form permanent or temporary bonds with other cells or extracellular material. Epithelial cells, however, are specialists in intercellular connection (Figure 4–2•).

Intercellular connections involve either extensive areas of opposing cell membranes or specialized attachment sites, discussed shortly. Large areas of opposing cell membranes are interconnected by transmembrane proteins called **cell adhesion molecules (CAMs)**, which bind to each other and to extracellular materials. For example, CAMs on the basolateral surface of an epithelium help bind the cell to the underlying basal lamina. The membranes of adjacent cells may also be bonded by **intercellular cement**, a thin layer of proteoglycans that contain polysaccharide derivatives known as *glycosaminoglycans*, most notably **hyaluronan** (*hyaluronic acid*).

Cell junctions are specialized areas of the cell membrane that attach a cell to another cell or to extracellular materials. The three most common types of cell junctions are (1) tight junctions, (2) gap junctions, and (3) desmosomes.

At a **tight junction**, the lipid portions of the two cell membranes are tightly bound together by interlocking membrane proteins (Figure 4–2b•). A continuous *adhesion belt* forms a band that encircles cells and binds them to their neighbors. The bands are attached to the microfilaments of the terminal web. l**p. 69** This kind of attachment is so tight that these junctions prevent the passage of water and solutes between the cells. When the epithelium lines a tube, such as the intestinal tract, the apical surfaces of the epithelial cells are exposed to the space inside the tube, a passageway called the **lumen** (LOO-men). Tight junctions effectively isolate the contents of the lumen from the basolateral surfaces of the cell. For example, tight junctions near the apical surfaces of cells that line the digestive tract help keep enzymes, acids, and wastes in the lumen from reaching the basolateral surfaces and digesting or otherwise damaging the underlying tissues and organs.

Some epithelial functions require rapid intercellular communication. At a **gap junction** (Figure 4–2c•), two cells are held together by interlocking junctional proteins called *connexons*. Because these are channel proteins, they form a narrow passageway that lets small molecules and ions pass from cell to cell. Gap junctions are common among epithelial cells, where the movement of ions helps coordinate functions such as the beating of cilia. Gap junctions are also common in other tissues. For example, gap junctions in cardiac muscle tissue and smooth muscle tissue are essential to the coordination of muscle cell contractions.

Most epithelial cells are subject to mechanical stresses—stretching, bending, twisting, or compression—so they must have durable interconnections. At a **desmosome** (DEZ-mō-sōm; *desmos*, ligament + *soma*, body), CAMs and proteoglycans link the opposing cell membranes. Desmosomes are very strong and can resist stretching and twisting.

A typical desmosome is formed by two cells. Within each cell is a complex known as a *dense area*, which is connected to the cytoskeleton (Figure 4–2d•). It is this connection to the cytoskeleton that gives the desmosome—and the epithelium—its strength. For example, desmosomes are abundant between cells in the superficial layers of the skin. As a result, damaged skin cells are usually lost in sheets rather than as individual cells. (That is why your skin peels rather than comes off as a powder after a sunburn.)

There are two types of desmosomes:

- *Button desmosomes* are small discs connected to bands of intermediate fibers. The intermediate fibers function as cross-braces to stabilize the shape of the cell.
- *Hemidesmosomes* resemble half of a button desmosome. Rather than attaching one cell to another, a hemidesmosome attaches a cell to extracellular filaments in the basal lamina (Figure 4–2e•). This attachment helps stabilize the position of the epithelial cell and anchors it to underlying tissues.

Attachment to the Basal Lamina

Not only do epithelial cells hold onto one another, but they also remain firmly connected to the rest of the body. The inner surface of each epithelium is attached to a two-part basal lamina. The layer closer to the epithelium, the *lamina lucida* (LAM-i-nah LOO-si-dah; *lamina*, thin layer + *lucida*, clear), contains glycoproteins and a network of fine protein filaments (see Figure 4–2e•). Secreted by the adjacent layer of epithelial cells, the lamina lucida acts as a barrier that restricts the movement of proteins and other large molecules from the underlying connective tissue into the epithelium.

The deeper layer of the basal lamina, the *lamina densa*, contains bundles of coarse protein fibers produced by connective tissue cells. The lamina densa gives the basement membrane its strength. Attachments between the fibers of the lamina lucida and those of the lamina densa hold the two layers together, and hemidesmosomes attach the epithelial cells to the composite basal lamina. The lamina densa also acts as a filter that determines what substances can diffuse between the adjacent tissues and the epithelium.

Epithelial Maintenance and Repair

Epithelial cells lead hard lives, for they are exposed to disruptive enzymes, toxic chemicals, pathogenic bacteria, and mechanical abrasion. Thus, an epithelium must continuously repair and renew itself. Consider the lining of the small intestine, where epithelial cells are exposed to a variety of enzymes and abraded by partially digested food. In this extreme environment, an epithelial cell may last just a day or two before it is shed or destroyed. The only way the epithelium can maintain its structure over time

is by the continual division of *stem cells*. l**p. 97** Most stem cells, also called **germinative cells**, are located near the basal lamina, in a relatively protected location. ATLAS: Embryology Summary 2: The Development of Epithelia

Concept Check

List five important characteristics of epithelial tissue.

An epithelial surface bears many microvilli. What is the probable function of this epithelium?

What is the functional significance of gap junctions?

Answers begin on p. A–1

Classification of Epithelia

There are many different specialized types of epithelia. You can easily sort these into categories based on (1) the cell shape, and

(2) the number of cell layers between the base and the exposed surface of the epithelium. Using these two criteria—cell shape and number of cell layers—we can describe almost every epithelium in the body (Table 4–1).

Three cell shapes are identified: *squamous*, *cuboidal*, and *columnar*. For classification purposes, one looks at the superficial cells in a section perpendicular to both the exposed surface and the basal lamina. In sectional view, squamous cells appear thin and flat, cuboidal cells look like little boxes, and columnar cells are tall and relatively slender rectangles.

Once you have determined whether the superficial cells are squamous, cuboidal, or columnar, you then look at the number of cell layers. There are only two options: *simple* or *stratified*. If only one layer of cells covers the basal lamina, that layer is a **simple epithelium**. Simple epithelia are necessarily thin. All

the cells have the same polarity, so the distance from the nucleus to the basal lamina does not change from one cell to the next. Because they are so thin, simple epithelia are also fragile. A single layer of cells cannot provide much mechanical protection, so simple epithelia are located only in protected areas inside the body. They line internal compartments and passageways, including the ventral body cavities, the heart chambers, and blood vessels.

Simple epithelia are also characteristic of regions in which secretion or absorption occurs, such as the lining of the intestines and the gas-exchange surfaces of the lungs. In these places, thinness is an advantage, for it reduces the time required for materials to cross the epithelial barrier.

In a **stratified epithelium**, several layers of cells cover the basal lamina. Stratified epithelia are generally located in areas that need protection from mechanical or chemical stresses, such as the surface of the skin and the lining of the mouth.

Squamous Epithelia

The cells in a **squamous epithelium** (SKW

¯A

-mus; *squama*, plate or scale) are thin, flat, and somewhat irregular in shape, like

pieces of a jigsaw puzzle (Figure 4–3•). From the surface, the cells resemble fried eggs laid side by side. In sectional view, the disc-shaped nucleus occupies the thickest portion of each cell.

A **simple squamous epithelium** is the body’s most delicate type of epithelium. This type of epithelium is located in protected regions where absorption or diffusion takes place, or where a slick, slippery surface reduces friction. Examples are the respiratory exchange surfaces (*alveoli*) of the lungs, the lining of the ventral body cavities (Figure 4–3a•), and the lining of the heart and blood vessels. Smooth linings are extremely important; for example, any irregularity in the lining of a blood vessel will result in the formation of a potentially dangerous blood clot.

Special names have been given to the simple squamous epithelia that line chambers and passageways that do not communicate with the outside world. The simple squamous epithelium that lines the ventral body cavities is a **mesothelium** (mez-

¯o

-THE

¯e

-um; *mesos*, middle). The pleura, peritoneum, and pericardium each contain a superficial layer of mesothelium. The simple squamous epithelium lining the inner surface of the heart and all blood vessels is an **endothelium** (en-d

¯o

-TH

¯E

-l

¯e

-um; *endo*-, in side).

A **stratified squamous epithelium** (Figure 4–3b•) is generally located where mechanical stresses are severe. The cells form a series of layers, like the layers in a sheet of plywood. The surface of the skin and the lining of the mouth, esophagus, and anus are areas where this type of epithelium protects against physical and chemical attacks. On exposed body surfaces, where mechanical stress and dehydration are potential problems, apical layers of epithelial cells are packed with filaments of the protein *keratin*. As a result, superficial layers are both tough and water resistant; the epithelium is said to be *keratinized*. A *nonkeratinized* stratified squamous epithelium resists abrasion, but will dry out and deteriorate unless kept moist. Nonkeratinized stratified squamous epithelia are situated in the oral cavity, pharynx, esophagus, anus, and vagina.

Cuboidal Epithelia

The cells of a **cuboidal epithelium** resemble hexagonal boxes. (In typical sectional views they appear square.) The spherical nuclei are near the center of each cell, and the distance between adjacent nuclei is roughly equal to the height of the epithelium. A **simple**

cuboidal epithelium provides limited protection and occurs where secretion or absorption takes place. Such an epithelium lines portions of the kidney tubules (Figure 4–4a•). **Stratified cuboidal epithelia** are relatively rare; they are located along the ducts of sweat glands (Figure 4–4b•) and in the larger ducts of the mammary glands.

Transitional Epithelia

A **transitional epithelium** (Figure 4–4c•) is unusual because, unlike most epithelia, it tolerates repeated cycles of stretching and recoil without damage. It is called transitional because the appearance of the epithelium changes as stretching occurs. A transitional epithelium is situated in regions of the urinary system, such as the urinary bladder, where large changes in volume occur. In an empty urinary bladder, the epithelium seems to have many layers, and the superficial cells are typically plump cuboidal cells. The multilayered appearance results from overcrowding. In a full urinary bladder, when the volume of urine has stretched the lining to its limits, the epithelium appears flattened, and more like a simple epithelium.

Clinical Note

¯are examined for a variety of reasons—for example, to check for cellular changes that indicate cancer, or for genetic screening of a fetus. Cells are collected by sampling the fluids that cover the epithelia lining the respiratory, digestive, urinary, or reproductive tract; by removing fluid from one of the ventral body cavities; or by removing cells from an epithelial surface. One common sampling procedure is called a *Pap test*, named after Dr. George Papanicolaou, who pioneered its use. The most familiar Pap test is that for cervical cancer; it involves the scraping of cells from the tip of the *cervix*, the portion of the uterus that projects into the vagina. *Amniocentesis* is another important test based on exfoliative cytology. In this procedure, shed epithelial cells are collected from a sample of *amniotic fluid*, which surrounds and protects a developing fetus. Examination of these cells can determine whether the fetus has a genetic abnormality, such as *Down syndrome*, that affects the number or structure of chromosomes.

Exfoliative cytology (eks-F O -l ¯e -a-tiv; *ex*-from + *folium*, leaf) is the study of cells shed or removed from epithelial surfaces. The cells

Columnar Epithelia

In a typical sectional view, **columnar epithelial cells** appear rectangular. In reality, the apical and basal surfaces of the densely packed cells are hexagonal, but they are taller and more slender than cells in a cuboidal epithelium (Figure 4–5•). The elongated nuclei are crowded into a narrow band close to the basal lamina. The height of the epithelium is several times the distance between adjacent nuclei. A **simple columnar epithelium** is typically found where absorption or secretion occurs, such as in the small intestine (Figure 4–5a•). In the stomach and large intestine, the secretions of simple columnar epithelia protect against chemical stresses.

Portions of the respiratory tract contain a **pseudostratified columnar epithelium**, a columnar epithelium that includes several types of cells with varying shapes and functions. The distances between the cell nuclei and the exposed surface vary, so the epithelium appears to be layered, or stratified (Figure 4–5b•). It is not truly stratified, though, because every epithelial cell contacts the basal lamina. Pseudostratified columnar epithelial cells typically possess cilia. Epithelia of this type line most of the nasal cavity, the trachea (windpipe), the bronchi (branches of the trachea leading to the lungs), and portions of the male reproductive tract.

Stratified columnar epithelia are relatively rare, providing protection along portions of the pharynx, epiglottis, anus, and urethra, as well as along a few large excretory ducts. The epithelium has either two layers (Figure 4–5c•) or multiple layers. In the latter case, only the superficial cells are columnar.

Glandular Epithelia

Many epithelia contain gland cells that are specialized for secretion. Collections of epithelial cells (or structures derived from epithelial cells) that produce secretions are called *glands*. They range from scattered cells to complex glandular organs. Some of these glands, called **endocrine glands**, release their secretions into the interstitial fluid. Others, known as **exocrine glands**, release their secretions into passageways called **ducts** that open onto an epithelial surface.

Endocrine Glands

An endocrine gland produces *endocrine* (*endo*-, inside + *krinein*, to secrete) *secretions*, which are released directly into the surrounding interstitial fluid. These secretions, also called *hormones*, enter the bloodstream for distribution throughout the body. Hormones regulate or coordinate the activities of various tissues, organs, and organ systems. Examples of endocrine glands include the thyroid gland and the pituitary gland. Because their secretions are not released into ducts, endocrine glands are often called *ductless glands*.

Endocrine cells may be part of an epithelial surface, such as the lining of the digestive tract, or they may be found in separate organs, such as the pancreas, thyroid gland, thymus, and pituitary gland. We will consider endocrine cells, organs, and hormones further in Chapter 18.

Exocrine Glands

Exocrine glands produce *exocrine* (*exo*-, outside) *secretions*, which are discharged onto an epithelial surface. Most exocrine secretions reach the surface through tubular ducts, which empty onto the skin surface or onto an epithelium lining an internal passageway that communicates with the exterior. Examples of exocrine secretions delivered to epithelial surfaces by ducts are enzymes entering the digestive tract, perspiration on the skin, tears in the eyes, and milk produced by mammary glands.

Exocrine glands exhibit several different methods of secretion; therefore, they are classified by their mode and type of secretion, and by the structure of the gland cells and associated ducts.

Modes of Secretion A glandular epithelial cell releases its secretions by (1) merocrine secretion, (2) apocrine secretion, or

(3) holocrine secretion.

In **merocrine secretion** (MER-u-krin; *meros*, part), the product is released from secretory vesicles by exocytosis (Figure 4–6a•). This is the most common mode of secretion. One type of merocrine secretion, *mucin*, mixes with water to form **mucus**, an effective lubricant, a protective barrier, and a sticky trap for foreign particles and microorganisms. The mucous secretions of the salivary glands coat food and reduce friction during swallowing. In the skin, merocrine sweat glands produce the watery perspiration that helps cool you on a hot day.

Apocrine secretion (AP-
ō
-krin; *apo-*, off) involves the loss of cytoplasm as well as the secretory product (Figure 4–6b•). The
apical portion of the cytoplasm becomes packed with secretory vesicles and is then shed. Milk production in the mammary glands involves a combination of merocrine and apocrine secretions.

Merocrine and apocrine secretions leave a cell relatively intact and able to continue secreting. **Holocrine secretion** (HOL-
ō
-

krin; *holos*, entire), by contrast, destroys the gland cell. During holocrine secretion, the entire cell becomes packed with secretory products and then bursts (Figure 4–6c•), releasing the secretion, but killing the cell. Further secretion depends on the replacement of destroyed gland cells by the division of stem cells. Sebaceous glands, associated with hair follicles, produce an oily hair coating by means of holocrine secretion.

Types of Secretions Exocrine glands are also categorized by the types of secretion produced:

1. *Serous glands* secrete a watery solution that contains enzymes. The parotid salivary glands are serous glands.

2. *Mucous glands* secrete mucins that hydrate to form mucus. The sublingual salivary glands and the submucosal glands of the small intestine are mucous glands.

3. *Mixed exocrine glands* contain more than one type of gland cell and may produce two different exocrine secretions, one serous and the other mucous. The submandibular salivary glands are mixed exocrine glands.

Gland Structure The final method of classifying exocrine glands is by structure. In epithelia that have independent, scattered gland cells, the individual secretory cells are called **unicellular glands**. **Multicellular glands** include glandular epithelia and aggregations of gland cells that produce exocrine or endocrine secretions.

The only **unicellular exocrine glands** in the body are **goblet cells**, which secrete mucins. Goblet cells are scattered among other epithelial cells. Both the pseudostratified ciliated columnar epithelium that lines the trachea and the columnar epithelium of the small and large intestines have an abundance of goblet cells.

The simplest **multicellular exocrine gland** is a *secretory sheet*, in which gland cells form an epithelium that releases secretions into an inner compartment. The continuous secretion of mucin-secreting cells that line the stomach, for instance, protects that organ from its own acids and enzymes. Most other multicellular exocrine glands are in pockets set back from the epithelial surface; their secretions travel through one or more ducts to the surface. Examples include the salivary glands, which produce mucins and digestive enzymes.

Three characteristics are used to describe the structure of multicellular exocrine glands (Figure 4–7•):

1. *The Structure of the Duct.* A gland is *simple* if it has a single duct that does not divide on its way to the gland cells. The gland is *compound* if the duct divides one or more times on its way to the gland cells.

2. *The Shape of the Secretory Portion of the Gland.* Glands whose glandular cells form tubes are *tubular*; the tubes may be straight or coiled. Those that form blind pockets are *alveolar* (al-VE¯-o¯-lar; *alveolus*, sac) or *acinar* (AS-i-nar; *acinus*, chamber). Glands whose secretory cells form both tubes and pockets are called *tubuloalveolar* or *tubuloacinar*.

3. *The Relationship between the Ducts and the Glandular Areas.* A gland is *branched* if several secretory areas (tubular or acinar) share a duct. ("Branched" refers to the glandular areas and not to the duct.)

The vast majority of glands in the body produce either exocrine or endocrine secretions. However, a few complex organs, including the digestive tract and the pancreas, produce both kinds of secretions. We will consider the organization of these glands in Chapters 18 and 24.

Concept Check

Using a light microscope, you examine a tissue and see a simple squamous epithelium on the outer surface. Can this be a sample of the skin surface?

Why do the pharynx, esophagus, anus, and vagina have the same epithelial organization?

The secretory cells of sebaceous glands fill with secretions and then rupture, releasing their contents. Which mode of secretion is this?

A gland has no ducts to carry the glandular secretions, and the gland's secretions are released directly into the extracellular fluid. Which type of gland is this?

Answers begin on p. A–1

Connective Tissues

Objective

- Compare the structures and functions of the various types of connective tissues.

It is impossible to discuss epithelial tissue without mentioning an associated type of tissue: **connective tissue**. Recall that the reticular layer of the basal lamina of all epithelial tissues is created by connective tissue; in essence, connective tissue connects the epithelium to the rest of the body. Other connective tissues include bone, fat, and blood, which provide structure, store energy reserves, and transport materials throughout the body. Connective tissues vary widely in appearance and function, but they all share three basic components: (1) specialized cells, (2) extracellular protein fibers, and (3) a fluid known as **ground substance**. The extracellular fibers and ground substance together constitute the **matrix**, which surrounds the cells. Whereas cells make up the bulk of epithelial tissue, the matrix typically accounts for most of the volume of connective tissues. ATLAS: Embryology Summary 3: The Origins of Connective Tissues

Connective tissues are situated throughout the body, but are never exposed to the outside environment. Many connective tissues are highly vascular (that is, they have many blood vessels) and contain sensory receptors that detect pain, pressure, temperature, and other stimuli. Among the specific functions of connective tissues are the following:

- Establishing a structural framework for the body.
- Transporting fluids and dissolved materials.
- Protecting delicate organs.
- Supporting, surrounding, and interconnecting other types of tissue.
- Storing energy reserves, especially in the form of lipids.
- Defending the body from invading microorganisms.

Classification of Connective Tissues

Connective tissues are classified on the basis of their physical properties. The three general categories of connective tissue are connective tissue proper, fluid connective tissues, and supporting connective tissues:

1. Connective tissue proper includes those connective tissues with many types of cells and extracellular fibers in a syrupy ground substance. This broad category contains a variety of connective tissues that are divided into (a) *loose connective tissues* and

(b) *dense connective tissues* based on the number of cell types present, and on the relative properties and proportions of fibers and ground substance. Both *adipose tissue* or fat (a loose connective tissue) and *tendons* (a dense connective tissue) are connective tissue proper, but they have very different structural and functional characteristics.

2. Fluid connective tissues have distinctive populations of cells suspended in a watery matrix that contains dissolved proteins. Two types exist: *blood* and *lymph*.

3. Supporting connective tissues differ from connective tissue proper in having a less diverse cell population and a matrix containing much more densely packed fibers. Supporting connective tissues protect soft tissues and support the weight of part or all of the body. The two types of supporting connective tissues are *cartilage* and *bone*. The matrix of cartilage is a gel whose characteristics vary with the predominant type of fiber. The matrix of bone is said to be **calcified**, because it contains mineral deposits (primarily calcium salts) that provide rigidity.

Connective Tissue Proper

Connective tissue proper contains extracellular fibers, a viscous (syrupy) ground substance, and a varied cell population (Figure 4–8•). Some of the cells, including *fibroblasts*, *adipocytes*, and *mesenchymal cells*, function in local maintenance, repair, and energy storage. These cells are permanent residents of the connective tissue. Other cells, including *macrophages*, *mast cells*, *lymphocytes*, *plasma cells*, and *microphages*, defend and repair damaged tissues. These cells are not permanent residents; they migrate through healthy connective tissues and aggregate at sites of tissue injury. The number of cells and cell types in a tissue at any moment varies with local conditions.

Components of Connective Tissue Proper

The Cell Populations

¯I

Fibroblasts (F -br the only cells that are *always* present in it. Fibroblasts secrete hyaluronan (a polysaccharide derivative) and proteins. (Recall that hyaluronan is one of the ingredients in the intercellular cement that helps lock epithelial cells together.) In connective tissue proper, extracellular fluid, hyaluronan, and proteins interact to form the proteoglycans that make ground substance viscous. Each fibroblast

also secretes protein subunits that interact to form large extracellular fibers. l**p. 52** In addition to fibroblasts, connective tissues proper may contain several other cell types:

¯o

-blasts) are the most abundant permanent residents of connective tissue proper, and

Macrophages (MAK-r

¯o

-f

¯a

-jez; *phagein*, to eat) are large amoeboid cells scattered throughout the matrix. These scavengers en

•

gulf pathogens or damaged cells that enter the tissue. (The name literally means “big eater.”) Although not abundant, macrophages are important in mobilizing the body’s defenses. When stimulated, they release chemicals that activate the immune system and attract large numbers of additional macrophages and other cells involved in tissue defense. The two classes of macrophage are *fixed macrophages*, which spend long periods in a tissue, and *free macrophages*, which migrate rapidly through tissues. In effect, fixed macrophages provide a “frontline” defense that can be reinforced by the arrival of free macrophages and other specialized cells.

¯

ı droplet. The nucleus, other organelles, and cytoplasm are squeezed to one side, making a sectional view of the cell resemble a class ring. The number of fat cells varies from one type of connective tissue to another, from one region of the body to another, and among individuals.

- **Mesenchymal cells** are stem cells that are present in many connective tissues. These cells respond to local injury or infection by dividing to produce daughter cells that differentiate into fibroblasts, macrophages, or other connective tissue cells.

Adipocytes (AD-i-p

¯o

ts) are also known as *adipose cells*, or fat cells. A typical adipocyte contains a single, enormous lipid

¯e

–

ı Melanocytes are common in the epithelium of the skin, where they play a major role in determining skin color. Melanocytes are also abundant in connective tissues of the eye and the dermis of the skin, although the number present differs by body region and among individuals.

- **Mast cells** are small, mobile connective tissue cells that are common near blood vessels. The cytoplasm of a mast cell is filled with granules containing **histamine** (HIS-tuh-m n) and **heparin** (HEP-uh-rin). These chemicals, released after injury or in-

Melanocytes (me-LAN-

¯o

ts) synthesize and store the brown pigment **melanin** (MEL-a-nin), which gives tissues a dark color.

•

-s

fection, stimulate local inflammation. (You are likely familiar with the inflammatory effects of histamine; people often take antihistamines to reduce cold symptoms.) *Basophils*, blood cells that enter damaged tissues and enhance the inflammation process, also contain histamine and heparin.

- **Lymphocytes** (LIM-fo¯-s ¯ı ts) migrate throughout the body, traveling through connective tissues and other tissues. Their numbers increase markedly wherever tissue damage occurs. Some lymphocytes may develop into **plasma cells**, which produce *antibodies*—proteins involved in defending the body against disease.
- **Microphages** (*neutrophils* and *eosinophils*) are phagocytic blood cells that normally move through connective tissues in small numbers. When an infection or injury occurs, chemicals released by macrophages and mast cells attract numerous microphages to the site.

Connective Tissue Fibers Three types of fibers occur in connective tissue: *collagen*, *reticular*, and *elastic*. Fibroblasts form all three by secreting protein subunits that interact in the matrix.

1. Collagen fibers are long, straight, and unbranched. They are the most common fibers in connective tissue proper. Each collagen fiber consists of a bundle of fibrous protein subunits wound together like the strands of a rope. Like a rope, a collagen fiber is flexible, but it is stronger than steel when pulled from either end. *Tendons*, which connect skeletal muscles to bones, consist almost entirely of collagen fibers. Typical *ligaments* are similar to tendons, but they connect one bone to another. Tendons and ligaments can withstand tremendous forces. Uncontrolled muscle contractions or skeletal movements are more likely to break a bone than to snap a tendon or a ligament.

2. Reticular fibers (*reticulum*, network) contain the same protein subunits as do collagen fibers, but arranged differently. Thinner than collagen fibers, reticular fibers form a branching, interwoven framework that is tough yet flexible. Because they form a network rather than share a common alignment, reticular fibers resist forces applied from many directions. This interwoven network, called a *stroma*, stabilizes the relative positions of the functional cells, or **parenchyma** (pa-RENG-ki-ma), of organs such as the liver. Reticular fibers also stabilize the positions of an organ’s blood vessels, nerves, and other structures, despite changing positions and the pull of gravity.

3. Elastic fibers contain the protein *elastin*. Elastic fibers are branched and wavy. After stretching, they will return to their original length. **Elastic ligaments**, which are dominated by elastic fibers, are relatively rare but have important functions, such as interconnecting vertebrae.

Ground Substance Ground substance fills the spaces between cells and surrounds connective tissue fibers (see Figure 4–8•). In connective tissue proper, ground substance is clear, colorless, and viscous (due to the presence of proteoglycans and glycoproteins). l**p. 53** Ground substance is dense enough that bacteria have trouble moving through it—imagine swimming in molasses. This density slows the spread of pathogens and makes them easier for phagocytes to catch.

Clinical Note

Marfan's syndrome is an inherited condition caused by the production of an abnormal form of *fibrillin*, a glycoprotein that imparts strength and elasticity to connective tissues. Because most organs contain connective tissues, the effects of this defect are widespread. The most visible sign of Marfan's syndrome involves the skeleton; most individuals with the condition are tall and have abnormally long limbs and fingers. The most serious consequences involve the cardiovascular system; roughly 90 percent of people with Marfan's syndrome have structural abnormalities in their cardiovascular system. The most dangerous possibility is that the weakened elastic connective tissues in the walls of major arteries, such as the aorta, may burst, causing a sudden, fatal loss of blood.

Embryonic Connective Tissues

Mesenchyme, or *embryonic connective tissue*, is the first connective tissue to appear in a developing embryo. Mesenchyme contains an abundance of star-shaped stem cells (mesenchymal cells) separated by a matrix with very fine protein filaments (Figure 4–9a•). Mesenchyme gives rise to all other connective tissues. **Mucous connective tissue** (Figure 4–9b•), or Wharton's jelly, is a loose connective tissue found in many parts of the embryo, including the umbilical cord.

Adults have neither form of embryonic connective tissue. However, many adult connective tissues contain scattered mesenchymal stem cells that can assist in tissue repair after an injury.

Loose Connective Tissues

Loose connective tissues are the "packing materials" of the body. They fill spaces between organs, cushion and stabilize specialized cells in many organs, and support epithelia. These tissues surround and support blood vessels and nerves, store lipids, and provide a route for the diffusion of materials. Loose connective tissues include mucous connective tissue in embryos and *areolar tissue, adipose tissue,* and *reticular tissue* in adults.

Areolar Tissue **Areolar tissue** (*areola*, little space) is the least specialized connective tissue in adults. It may contain all the cells and fibers of any connective tissue proper in a very loosely organized array (see Figure 4–8•). Areolar tissue has an open framework. A viscous ground substance accounts for most of its volume and absorbs shocks. Because its fibers are loosely organized, areolar tissue can distort without damage. The presence of elastic fibers makes it resilient, so areolar tissue returns to its original shape after external pressure is relieved.

Areolar tissue forms a layer that separates the skin from deeper structures. In addition to providing padding, the elastic properties of this layer allow a considerable amount of independent movement. Thus, if you pinch the skin of your arm, you will not affect the underlying muscle. Conversely, contractions of the underlying muscle do not pull against your skin; as the muscle bulges, the areolar tissue stretches. Because this tissue has an extensive blood supply, the areolar tissue layer under the skin is a common injection site for drugs.

The capillaries (thin-walled blood vessels) in areolar tissue deliver oxygen and nutrients and remove carbon dioxide and waste products. They also carry wandering cells to and from the tissue. Epithelia commonly cover areolar tissue; fibroblasts maintain the reticular lamina of the basal lamina that separates the two kinds of tissue. The epithelial cells rely on the diffusion of oxygen and nutrients across that membrane from capillaries in the underlying connective tissue.

Adipose Tissue The distinction between areolar tissue and fat, or **adipose tissue**, is somewhat arbitrary. Adipocytes account for most of the volume of adipose tissue (Figure 4–10a•), but only a fraction of the volume of areolar tissue. Adipose tissue provides padding, absorbs shocks, acts as an insulator to slow heat loss through the skin, and serves as packing or filler around structures. Adipose tissue is common under the skin of the flanks, buttocks, and breasts. It fills the bony sockets behind the eyes, surrounds the kidneys, and is common beneath the mesothelial lining of the pericardial and abdominal cavities.

Most of the adipose tissue in the body is called **white fat**, because it has a pale, yellow-white color. In infants and young children, however, the adipose tissue between the shoulder blades, around the neck, and possibly elsewhere in the upper body is highly vascularized, and the individual adipocytes contain numerous mitochondria. Together, these characteristics give the tissue a deep, rich color from which the name **brown fat** is derived. When these cells are stimulated by the nervous system, lipid breakdown accelerates. The cells do not capture the energy that is released. Instead, it is absorbed by the surrounding tissues as heat. The heat warms the circulating blood, which distributes the heat throughout the body. In this way, an infant can increase metabolic heat generation by 100 percent very quickly. (In adults, who have little if any brown fat, body temperature is elevated primarily by shivering.)

Adipocytes are metabolically active cells; their lipids are constantly being broken down and replaced. When nutrients are scarce, adipocytes deflate like collapsing balloons. Because the cells are not killed but merely reduced in size, the lost weight can easily be regained in the same areas of the body. In adults, adipocytes are incapable of dividing. The number of fat cells in peripheral tissues is established in the first few weeks of a newborn’s life, perhaps in response to the amount of fats in the diet. However, that is not the end of the story, because loose connective tissues also contain mesenchymal cells. If circulating-lipid levels are chronically elevated, the mesenchymal cells will divide, giving rise to cells that differentiate into fat cells. As a result, areas of areolar tissue can become adipose tissue in times of nutritional plenty, even in adults.

In the procedure known as **liposuction**, unwanted adipose tissue is surgically removed. Because adipose tissue can regenerate through the differentiation of mesenchymal cells, liposuction provides only a temporary and potentially risky solution to the problem of excess weight.

Reticular Tissue As mentioned earlier, organs such as the spleen and liver contain **reticular tissue**, in which reticular fibers create a complex three-dimensional stroma (Figure 4–10b•). The stroma supports the parenchyma (functional cells) of these organs. This fibrous framework is also found in the lymph nodes and bone marrow. Fixed macrophages and fibroblasts are associated with the reticular fibers, but these cells are seldom visible, because the organs are dominated by specialized cells with other functions.

Dense Connective Tissues

Most of the volume of **dense connective tissues** is occupied by fibers. Dense connective tissues are often called **collagenous** (ko-LAJ-e-nus) **tissues**, because collagen fibers are the dominant type of fiber in them. The body has two types of dense connective tissues: dense regular connective tissue and dense irregular connective tissue.

In **dense regular connective tissue**, the collagen fibers are parallel to each other, packed tightly, and aligned with the forces applied to the tissue. **Tendons** are cords of dense regular connective tissue that attach skeletal muscles to bones (Figure 4–11a•). The collagen fibers run along the longitudinal axis of the tendon and transfer the pull of the contracting muscle to the bone. **Ligaments** resemble tendons, but connect one bone to another or stabilize the positions of internal organs. An **aponeurosis** (AP-

‾o

-

noo-R

‾O

-sis; plural, *aponeuroses*) is a tendinous sheet that attaches a broad, flat muscle to another muscle or to several bones of

the skeleton. It can also stabilize the positions of tendons and ligaments. Aponeuroses are associated with large muscles of the lower back and abdomen, and with the tendons and ligaments of the palms of the hands and the soles of the feet. Large numbers of fibroblasts are scattered among the collagen fibers of tendons, ligaments, and aponeuroses.

In contrast, the fibers in **dense irregular connective tissue** form an interwoven meshwork in no consistent pattern (Figure 4–11b•). These tissues strengthen and support areas subjected to stresses from many directions. A layer of dense irregular connective tissue gives skin its strength. Cured leather (animal skin) is an excellent illustration of the interwoven nature of this tissue. Except at joints, dense irregular connective tissue forms a sheath around cartilages (the *perichondrium*) and bones (the *periosteum*). Dense irregular connective tissue also forms a thick fibrous layer called a **capsule**, which surrounds internal organs such as the liver, kidneys, and spleen and encloses the cavities of joints.

Dense regular and dense irregular connective tissues contain variable amounts of elastic fibers. When elastic fibers outnumber collagen fibers, the tissue has a springy, resilient nature that allows it to tolerate cycles of extension and recoil. Abundant elastic fibers are present in the connective tissue that supports transitional epithelia, in the walls of large blood vessels such as the aorta, and around the respiratory passageways.

Elastic tissue is a dense regular connective tissue dominated by elastic fibers. Elastic ligaments, which are almost completely dominated by elastic fibers, help stabilize the positions of the vertebrae of the spinal column (Figure 4–11c•).

Fluid Connective Tissues

Blood and *lymph* are connective tissues with distinctive collections of cells. The fluid matrix that surrounds the cells also includes many types of suspended proteins that do not form insoluble fibers under normal conditions.

In **blood**, the watery matrix is called **plasma**. Plasma contains blood cells and fragments of cells, collectively known as *formed elements* (Figure 4–12•). There are three types of formed elements: red blood cells, white blood cells, and platelets.

–

ı the volume of blood and is the reason we associate the color red with blood. Red blood cells are responsible for the transport of oxygen (and, to a lesser degree, of carbon dioxide) in the blood.

A single cell type—the **red blood cell**, or **erythrocyte** (e-RITH-r

–
o

t; *erythros,* red *cyte*, cell)—accounts for almost half

+

-s
–

ı clude the phagocytic microphages (*neutrophils* and *eosinophils*), *basophils*, *lymphocytes*, and *monocytes,* cells related to the macrophages found in other connective tissues. White blood cells are important components of the immune system, which protects the body from infection and disease.

The third type of formed element in blood consists not of whole cells, but of tiny membrane-enclosed packets of cytoplasm called **platelets**. These cell fragments, which contain enzymes and special proteins, function in the clotting response that seals breaks in the endothelial lining.

Recall from Chapter 3 that the human body contains a large volume of extracellular fluid. This fluid includes three major subdivisions: *plasma*, *interstitial fluid*, and *lymph*. Plasma is normally confined to the vessels of the cardiovascular system, and contractions of the heart keep it in motion. **Arteries** carry blood away from the heart and into the tissues of the body. In those tissues, blood pressure forces water and small solutes out of the bloodstream across the walls of **capillaries**, the smallest blood vessels. This is the origin of the interstitial fluid that bathes the body’s cells. The remaining blood flows from the capillaries into **veins** that return it to the heart.

Lymph forms as interstitial fluid enters **lymphatic vessels**. As fluid passes along the lymphatic vessels, cells of the immune system monitor the composition of the lymph and respond to signs of injury or infection. The lymphatic vessels ultimately return the lymph to large veins near the heart. This recirculation of fluid—from the cardiovascular system, through the interstitial fluid, to the lymph, and then back to the cardiovascular system—is a continuous process that is essential to homeostasis. It helps eliminate local differences in the levels of nutrients, wastes, or toxins; maintains blood volume; and alerts the immune system to infections that may be under way in peripheral tissues.

Supporting Connective Tissues

Cartilage and *bone* are called supporting connective tissues because they provide a strong framework that supports the rest of the body. In these connective tissues, the matrix contains numerous fibers and, in bone, deposits of insoluble calcium salts.

Cartilage

The matrix of **cartilage** is a firm gel that contains polysaccharide derivatives called **chondroitin sulfates** (kon-DROY-tin; *chondros*, cartilage). Chondroitin sulfates form complexes with proteins in the ground substance, producing proteoglycans. Cartilage cells, Blood also contains small numbers of **white blood cells**, or **leukocytes** (LOO-k

¯o

ts; *leuko-*, white). White blood cells in--s

or **chondrocytes** (KON-dr

–

ı ; *lacus*, pool). The physical properties of cartilage depend on the proteoglycans of the matrix, and on the type and abun-

¯o

ts), are the only cells in the cartilage matrix. They occupy small chambers known as **lacunae** (la--s

KOO-n

¯e

dance of extracellular fibers.

Unlike other connective tissues, cartilage is avascular, so all exchange of nutrients and waste products must occur by diffusion through the matrix. Blood vessels do not grow into cartilage because chondrocytes produce a chemical that discourages their formation. This chemical, named **antiangiogenesis factor** (*anti-*, against + *angeion*, vessel + *genno*, to produce), is now being tested as a potential anticancer agent.

¯e

A cartilage is generally set apart from surrounding tissues by a fibrous **perichondrium** (per-i-KON-dr -um); *peri-*, around). The perichondrium contains two distinct layers: an outer, fibrous region of dense irregular connective tissue, and an inner, cellular layer. The fibrous layer provides mechanical support and protection and attaches the cartilage to other structures. The cellular layer is important to the growth and maintenance of the cartilage.

Cartilage Growth Cartilage grows by two mechanisms: *interstitial growth* and *appositional growth* (Figure 4–13•).

In **interstitial growth**, chondrocytes in the cartilage matrix undergo cell division, and the daughter cells produce additional matrix (Figure 4–13a•). This process enlarges the cartilage from within. Interstitial growth is most important during development. The process begins early in embryonic development and continues through adolescence.

In **appositional growth**, new layers of cartilage are added to the surface (Figure 4–13b•). In this process, cells of the inner layer of the perichondrium undergo repeated cycles of division. The innermost cells then differentiate into immature chondrocytes, which begin producing cartilage matrix. As they become surrounded by and embedded in new matrix, they differentiate into mature chondrocytes. Appositional growth gradually increases the size of the cartilage by adding to its outer surface.

Both interstitial and appositional growth occur during development, although interstitial growth contributes more to the mass of the adult cartilage. Neither interstitial nor appositional growth occurs in the cartilages of normal adults. However, appositional growth may occur in unusual circumstances, such as after cartilage has been damaged or excessively stimulated by *growth hormone* from the pituitary gland. Minor damage to cartilage can be repaired by appositional growth at the damaged surface. After more severe damage, the injured portion of the cartilage will be replaced by a dense fibrous patch.

Types of Cartilage The body contains three major types of cartilage: hyaline cartilage, elastic cartilage, and fibrocartilage.

1. Hyaline cartilage (H -uh-lin; *hyalos*, glass) is the most common type of cartilage. Except inside joint cavities, a dense perichondrium surrounds hyaline cartilages. The matrix of hyaline cartilage contains closely packed collagen fibers, making it tough but somewhat flexible. Because the fibers are not in large bundles and do not stain darkly, they are not always apparent in light microscopy (Figure 4–14a•). Examples in adults include the connections between the ribs and the sternum; the nasal cartilages and the supporting cartilages along the conducting passageways of the respiratory tract; and the *articular cartilages*, which cover opposing bone surfaces within many joints, such as the elbow and knee.

2. Elastic cartilage (Figure 4–14b•) contains numerous elastic fibers that make it extremely resilient and flexible. These cartilages usually have a yellowish color on gross dissection. Elastic cartilage forms the external flap (the *auricle*, or *pinna*) of the outer ear, the epiglottis, a passageway to the middle ear cavity (the *auditory tube*), and small cartilages in the larynx (the *cuneiform cartilages*).

3. Fibrocartilage has little ground substance, and its matrix is dominated by densely interwoven collagen fibers (Figure 4–14c•), making this tissue extremely durable and tough. Fibrocartilaginous pads lie between the spinal vertebrae, between the pubic bones of the pelvis, and around tendons and within or around joints. In these positions, fibrocartilage resists compression, absorbs shocks, and prevents damaging bone-to-bone contact. Cartilage heals poorly, and damaged fibrocartilage in joints such as the knee can interfere with normal movements. AM: Fibrocartilage on Demand

Several complex joints, including the knee, contain both hyaline cartilage and fibrocartilage. The hyaline cartilage covers bony
¯I
surfaces, and fibrocartilage pads in the joint prevent contact between bones during movement. Injuries to these joints can produce tearing in the fibrocartilage pads that does not heal. Eventually, joint mobility is severely reduced. Surgery generally produces only a temporary or incomplete repair.

Bone

Because we will examine the detailed histology of **bone**, or **osseous** (OS-
¯e
-us; *os*, bone) **tissue**, in Chapter 6, here we focus only
on significant differences between cartilage and bone. The volume of ground substance in bone is very small. Roughly two-thirds of the matrix of bone consists of a mixture of calcium salts—primarily calcium phosphate, with lesser amounts of calcium carbonate. The rest of the matrix is dominated by collagen fibers. This combination gives bone truly

remarkable properties. By themselves, calcium salts are hard but rather brittle, whereas collagen fibers are stronger but relatively flexible. In bone, the presence of the minerals surrounding the collagen fibers produces a strong, somewhat flexible combination that is highly resistant to shattering. In its overall properties, bone can compete with the best steel-reinforced concrete. In essence, the collagen fibers in bone act like the steel reinforcing rods, and the mineralized matrix acts like the concrete.

–

ı bone cells. The lacunae are typically organized around blood vessels that branch through the bony matrix. Although diffusion cannot occur through the hard matrix, osteocytes communicate with the blood vessels and with one another by means of slender cy-

Figure 4–15• shows the general organization of osseous tissue. Lacunae in the matrix contain **osteocytes** (OS-t

¯e ¯o

ts), or-

-s

toplasmic extensions. These extensions run through long, slender passageways in the matrix called **canaliculi** (kan-a-LIK-

¯u ¯e

;

little canals). These passageways form a branching network for the exchange of materials between blood vessels and osteocytes. Except in joint cavities, where they are covered by a layer of hyaline cartilage, bone surfaces are sheathed by a **periosteum**

(per-

¯e

-OS-t

¯e

-um), a layer composed of fibrous (outer) and cellular (inner) layers. The periosteum assists in the attachment of a bone to surrounding tissues and to associated tendons and ligaments. The cellular layer functions in appositional bone growth and participates in repairs after an injury. Unlike cartilage, bone undergoes extensive remodeling throughout life, and complete repairs can be made even after severe damage has occurred. Bones also respond to the stresses placed on them, growing thicker and stronger with exercise and becoming thin and brittle with inactivity.

Table 4–2 summarizes the similarities and differences between cartilage and bone.

Which two types of connective tissue have a fluid matrix?

Answers begin on p. A–1

Membranes

Objective

- Explain how epithelial and connective tissues combine to form four types of membranes, and specify the functions of each.

A membrane is a physical barrier. There are many different types of anatomical membranes—you encountered cell membranes in Chapter 3, and you will find many other kinds of membranes in later chapters. The membranes we are concerned with here line or cover body surfaces. Each consists of an epithelium supported by connective tissue. Four such membranes occur in the body:

(1) *mucous membranes*, (2) *serous membranes*, (3) the *cutaneous membrane*, and (4) *synovial membranes* (Figure 4–16•).

Mucous Membranes

Mucous membranes, or **mucosae** (m
–
u
-K

–

O
-s
–
e
), line passageways and chambers that communicate with the exterior, including
those in the digestive, respiratory, reproductive, and urinary tracts (Figure 4–16a•). The epithelial surfaces of these passageways must be kept moist to reduce friction and, in many cases, facilitate absorption or secretion. The epithelial surfaces are lubricated either by mucus, produced by goblet cells or multicellular glands, or by exposure to fluids such as urine or semen. The areolar tis
–

sue component of a mucous membrane is called the **lamina propria** (PRO
-pr
–
e
-uh). We will consider the organization of specific
mucous membranes in greater detail in later chapters.

Many mucous membranes are lined by simple epithelia that perform absorptive or secretory functions, such as the simple columnar epithelium of the digestive tract. Other types of epithelia may be involved, however. For example, a stratified squamous epithelium is part of the mucous membrane of the mouth, and the mucous membrane along most of the urinary tract has a transitional epithelium.

Serous Membranes

Serous membranes line the sealed, internal subdivisions of the ventral body cavity—cavities that are not open to the exterior. These membranes consist of a mesothelium supported by areolar tissue (Figure 4–16b•). As you may recall from Chapter 1, the three types of serous membranes are (1) the *pleura*, which lines the pleural cavities and covers the lungs; (2) the *peritoneum*, which lines the peritoneal cavity and covers the surfaces of the enclosed organs; and (3) the *pericardium*, which lines the pericardial cavity and covers the heart. l**p. 22** Serous membranes are very thin, but they are firmly attached to the body wall and to the organs they cover. When looking at an organ such as the heart or stomach, you are really seeing the tissues of the organ through a transparent serous membrane.

Each serous membrane can be divided into a *parietal portion*, which lines the inner surface of the cavity, and an opposing *visceral portion*, or **serosa**, which covers the outer surfaces of visceral organs. These organs often move or change shape as they perform their various functions, and the parietal and visceral surfaces of a serous membrane are in close contact at all times. Thus, the primary function of any serous membrane is to minimize friction between the opposing parietal and visceral surfaces. Friction is kept to a minimum because mesothelia are very thin and permeable; tissue fluids continuously diffuse onto the exposed surface, keeping it moist and slippery.

The fluid formed on the surfaces of a serous membrane is called a *transudate* (TRAN-sū-dāt; *trans*-, across). In healthy individuals, the total volume of transudate is extremely small—just enough to prevent friction between the walls of the cavities and the surfaces of internal organs. However, after an injury or in certain disease states, the volume of transudate may increase dramatically, complicating existing medical problems or producing new ones. AM: Problems with Serous Membranes

The Cutaneous Membrane

The **cutaneous membrane**, or skin, covers the surface of the body. It consists of a stratified squamous epithelium and a layer of areolar tissue reinforced by underlying dense irregular connective tissue (Figure 4–16c•). In contrast to serous and mucous membranes, the cutaneous membrane is thick, relatively waterproof, and usually dry. We will examine the cutaneous membrane further in Chapter 5.

Synovial Membranes

Adjacent bones often interact at joints, or *articulations*. At an articulation, the two articulating bones are very close together if not in contact. Joints that permit significant amounts of movement are complex structures. Such a joint is surrounded by a fibrous capsule, and the ends of the articulating bones lie within a *joint cavity* filled with **synovial** (si-NO-v -ul) **fluid**. (Figure 4–16d•). The synovial fluid is produced by a **synovial membrane**, which lines the joint cavity. A synovial membrane consists of an extensive area of areolar tissue containing a matrix of interwoven collagen fibers, proteoglycans, and glycoproteins. An incomplete layer of macrophages and specialized fibroblasts separates the areolar tissue from the joint cavity. These cells regulate the composition of the synovial fluid. Although this lining is often called an epithelium, it differs from true epithelia in four respects: (1) It develops within a connective tissue, (2) no basal lamina is present, (3) gaps of up to 1 mm may separate adjacent cells, and (4) fluid

¯e

and solutes are continuously exchanged between the synovial fluid and capillaries in the underlying connective tissue.

Even though the adjacent ends of the bones are covered by a smooth layer of articular cartilage, the surfaces must be lubricated to keep friction from damaging the opposing surfaces. The necessary lubrication is provided by the synovial fluid, which is similar in composition to the ground substance in loose connective tissues. Synovial fluid circulates from the areolar tissue into the joint cavity and percolates through the articular cartilages, providing oxygen and nutrients to the chondrocytes. Joint movement is important in stimulating the formation and circulation of synovial fluid: If a synovial joint is immobilized for long periods, the articular cartilages and the synovial membrane undergo degenerative changes.

The Connective Tissue Framework of the Body

Objective

- Describe how connective tissue establishes the framework of the body.

Connective tissues create the internal framework of the body. Layers of connective tissue connect the organs within the dorsal and ventral body cavities with the rest of the body. These layers (1) provide strength and stability, (2) maintain the relative positions of internal organs, and (3) provide a route for the distribution of blood vessels, lymphatic vessels, and nerves. **Fasciae** (FASH-

¯e

-

¯e

; singular, *fascia*) are connective tissue layers and wrappings that support and surround organs. We can divide the fasciae into three types of layers: the superficial fascia, the deep fascia, and the subserous fascia (Figure 4–17•).

1. The **superficial fascia**, or **subcutaneous layer** (*sub*-, below + *cutis*, skin) is also termed the *hypodermis* (*hypo*, below + *dermis*, skin). This layer of areolar tissue and fat separates the skin from underlying tissues and organs, provides insulation and padding, and lets the skin and underlying structures move independently.

2. The **deep fascia** consists of dense irregular connective tissue. The organization of the fibers resembles that of plywood: In each layer all the fibers run in the same direction, but the orientation of the fibers changes from layer to layer. This arrangement helps the tissue resist forces applied from many directions. The tough capsules that surround most organs, including the kidneys and the organs in the thoracic and peritoneal cavities, are bound to the deep fascia. The perichondrium around cartilages, the periosteum around bones and the ligaments that interconnect them, and the connective tissues of muscle (including tendons) are also connected to the deep fascia. The dense connective tissue components are interwoven. For example, the deep fascia around a muscle blends into the tendon, whose fibers intermingle with those of the periosteum. This arrangement creates a strong, fibrous network and ties structural elements together.

3. The **subserous fascia** is a layer of areolar tissue that lies between the deep fascia and the serous membranes that line body cavities. Because this layer separates the serous membranes from the deep fascia, movements of muscles or muscular organs do not severely distort the delicate lining.

Concept Check

Which cavities in the body are lined by serous membranes?

The lining of the nasal cavity is normally moist, contains numerous goblet cells, and rests on a layer of connective tissue called the lamina propria. Which type of membrane is this?

A sheet of tissue has many layers of collagen fibers that run in different directions in successive layers. Which type of tissue is this?

Answers begin on p. A–1

Muscle Tissue

Objective

- Describe the three types of muscle tissue and the special structural features of each type.

Epithelia cover surfaces and line passageways; connective tissues support weight and interconnect parts of the body. Together, these tissues provide a strong, interwoven framework within which the organs of the body can function. Several vital functions involve movement of one kind or another—movement of materials along the digestive tract, movement of blood around the cardiovascular system, or movement of the body from one place to another. Movement is produced by **muscle tissue**, which is specialized for contraction. Muscle cells possess organelles and properties distinct from those of other cells.

There are three types of muscle tissue: (1) *skeletal muscle*, which forms the large muscles responsible for gross body movements and locomotion; (2) *cardiac muscle*, found only in the heart and responsible for the circulation of blood; and (3) *smooth muscle*, found in the walls of visceral organs and a variety of other locations, where it provides elasticity, contractility, and support. The contraction mechanism is similar in all three types of muscle tissue, but the muscle cells differ in internal organization. We will examine only general characteristics at this point, because each type of muscle is described more fully in Chapter 10.

Skeletal Muscle Tissue

Skeletal muscle tissue contains very large muscle cells—up to 0.3 m (1 ft) or more in length. Because the individual muscle cells are relatively long and slender, they are usually called **muscle fibers**. Each muscle fiber is described as *multinucleate*, because it has several hundred nuclei distributed just inside the cell membrane (Figure 4–18a•). Skeletal muscle fibers are incapable of dividing, but new muscle fibers are produced through the divisions of **satellite cells**, stem cells that persist in adult skeletal muscle tissue. As a result, skeletal muscle tissue can at least partially repair itself after an injury.

As noted in Chapter 3, the cytoskeleton contains actin and myosin filaments. l**p. 69** In skeletal muscle fibers, however, these filaments are organized into repeating groups that give the cells a *striated*, or banded, appearance. The *striations*, or bands, are readily apparent in light micrographs. Skeletal muscle fibers do not usually contract unless stimulated by nerves, and the nervous system provides voluntary control over their activities. Thus, skeletal muscle is called **striated voluntary muscle**.

A *skeletal muscle* is an organ of the muscular system, and although muscle tissue predominates, it contains all four types of body tissue. Within a skeletal muscle, adjacent skeletal muscle fibers are tied together by collagen and elastic fibers that blend into the attached tendon or aponeurosis. The tendon or aponeurosis conducts the force of contraction, often to a bone of the skeleton. Thus, when the muscles contract, they pull on the attached bone, producing movement.

Cardiac Muscle Tissue

Cardiac muscle tissue is located only in the heart. A typical cardiac muscle cell, also known as a **cardiocyte**, is smaller than a skeletal muscle cell (Figure 4–18b•). A typical cardiac muscle cell has one centrally positioned nucleus, but some cardiocytes have as many as five. Prominent striations resemble those of skeletal muscle; the actin and myosin filaments are arranged the same way in both cell types.

Cardiac muscle cells form extensive connections with one another. As a result, cardiac muscle tissue consists of a branching network of interconnected muscle cells. The connections occur at specialized regions known as **intercalated discs**. At an intercalated disc, the membranes are locked together by desmosomes, intercellular cement, and gap junctions. Ion movement through gap junctions helps coordinate the contractions of the cardiac muscle cells, and the desmosomes and intercellular cement lock the cells together during a contraction. Cardiac muscle tissue has a very limited ability to repair itself. Although some cardiac muscle cells do divide after an injury to the heart, the repairs are incomplete and some heart function is usually lost.

Cardiac muscle cells do not rely on nerve activity to start a contraction. Instead, specialized cardiac muscle cells called *pacemaker cells* establish a regular rate of contraction. Although the nervous system can alter the rate of pacemaker cell activity, it does not provide voluntary control over individual cardiac muscle cells. Therefore, cardiac muscle is called **striated involuntary muscle**.

Smooth Muscle Tissue

Smooth muscle tissue is located in the walls of blood vessels, around hollow organs such as the urinary bladder, and in layers around the respiratory, circulatory, digestive, and reproductive tracts. A smooth muscle cell is a small, spindle-shaped cell with tapering ends and a single, oval nucleus (Figure 4–18c•). Smooth muscle cells can divide; hence, smooth muscle tissue can regenerate after an injury.

The actin and myosin filaments in smooth muscle cells are organized differently from those of skeletal and cardiac muscles. One result of this difference is that smooth muscle tissue has no striations. Smooth muscle cells may contract on their own, with gap junctions between adjacent cells coordinating the contractions of individual cells. The contraction of some smooth muscle tissue can be controlled by the nervous system, but contractile activity is not under voluntary control. (Imagine the degree of effort that would be required to exert conscious control over the smooth muscles along the 8 m of digestive tract, not to mention the miles of blood vessels!) Because the nervous system usually does not provide voluntary control over smooth muscle contractions, smooth muscle is known as **nonstriated involuntary muscle**.

Neural Tissue

Objective

- Discuss the basic structure and role of neural tissue.

Neural tissue, which is also known as *nervous tissue* or *nerve tissue*, is specialized for the conduction of electrical impulses from one region of the body to another. Ninety-eight percent of the neural tissue in the body is concentrated in the brain and spinal
cord, which are the control centers of the nervous system.

Neural tissue contains two basic types of cells: (1) **neurons** (NOOR-onz; *neuro*, nerve) and (2) several kinds of supporting

cells, collectively called **neuroglia** (noo-ROG-l

¯e

-uh or noo-r

‾o

-GL

-uh), or *glial cells* (*glia*, glue). Our conscious and unconscious

E thought processes reflect the communication among neurons in the brain. Such communication involves the propagation of electrical impulses, in the form of changes in the transmembrane potential. Information is conveyed both by the frequency and by the pattern of the impulses. Neuroglia support and repair neural tissue and supply nutrients to neurons.

The longest cells in your body are neurons, many of which are as much as a meter (39 in.) long. Most neurons cannot divide under normal circumstances, so they have a very limited ability to repair themselves after injury. A typical neuron has a large **cell body** with a large nucleus and a prominent nucleolus (Figure 4–19•). Extending from the cell body are many branching processes

‾

(projections or outgrowths) termed **dendrites** (DEN-dr ts; *dendron*, a tree), and one **axon**. The dendrites receive information, typ-

ı ically from other neurons, and the axon conducts that information to other cells. Because axons tend to be very long and slender, they are also called **nerve fibers**. In Chapter 12, we will further examine the properties of neural tissue.

Concept Check

Which type of muscle tissue has small, tapering cells with single nuclei and no obvious striations?

A tissue contains irregularly shaped cells with many fibrous projections, some several centimeters long. These are probably which type of cell?

If skeletal muscle cells in adults are incapable of dividing, how is new skeletal muscle formed?

Answers begin on p. A–1

–

Tissue Injuries and Repair

Objective

- Describe how injuries affect the tissues of the body.

Tissues are not isolated; they combine to form organs with diverse functions. Therefore, any injury affects several types of tissue simultaneously. These tissues must respond in a coordinated way to preserve homeostasis. The restoration of homeostasis after a tissue has been injured involves two related processes: inflammation and regeneration.

Inflammation and Regeneration

Immediately after the injury, the area is isolated while damaged cells, tissue components, and any dangerous microorganisms are cleaned up. This phase, which coordinates the activities of several types of tissue, is called **inflammation**, or the **inflammatory response**. It produces several familiar signs and symptoms of injury, including swelling, redness, warmth, and pain. Inflammation may also result from the presence of pathogens, such as harmful bacteria, within the tissues; the presence of these pathogens constitutes an **infection**.

Second, the damaged tissues are replaced or repaired to restore normal function. The repair process is called **regeneration**. Inflammation and regeneration are controlled at the tissue level. The two phases overlap; isolation establishes a framework that guides the cells responsible for reconstruction, and repairs are under way well before cleanup operations have ended.

Next we consider the basics of the repair process after an injury. At this time, we will focus on the interaction among different tissues. Our example includes two connective tissues (areolar tissue and blood), an epithelium (the endothelia of blood vessels), a muscle tissue (smooth muscle in the vessel walls), and neural tissue (sensory nerve endings). In later chapters, especially Chapters 5 and 22, we will examine inflammation and regeneration in more detail.

First Phase: Inflammation

Many stimuli—including impact, abrasion, distortion, chemical irritation, infection by pathogenic organisms (such as bacteria or viruses), and extreme temperatures (hot or cold)—can produce inflammation. Each of these stimuli kills cells, damages fibers, or injures the tissue in some other way. Such changes alter the chemical composition of the interstitial fluid: Damaged cells release prostaglandins, proteins, and potassium ions, and the injury itself may have introduced foreign proteins or pathogens into the body.

Tissue conditions soon become even more abnormal. **Necrosis** (ne-KRŌ-sis), the tissue destruction that occurs after cells have been hurt or killed, begins several hours after the original injury. The damage is caused by lysosomal enzymes. Through widespread autolysis, lysosomes release enzymes that first destroy the injured cells and then attack surrounding tissues. l**p. 75** The result may be an accumulation of debris, fluid, dead and dying cells, and necrotic tissue components collectively known as **pus**. An accumulation of pus in an enclosed tissue space is an **abscess**.

These tissue changes trigger the inflammatory response by stimulating mast cells—connective tissue cells introduced on p. 119. Figure 4–20• depicts the events set in motion by the activation of mast cells. Although in this example the injury has occurred in areolar tissue, the process would be basically the same after an injury to any connective tissue proper. Because all organs have connective tissues, inflammation can occur anywhere in the body.

When an injury occurs that damages fibers and cells, mast cells release a variety of chemicals. These chemicals, including histamine and prostaglandins, trigger changes in local circulation. In response, the smooth muscle tissue that surrounds local blood vessels relaxes, and the vessels *dilate*, or enlarge in diameter. This dilation increases blood flow through the tissue, turning the region red and making it warm to the touch. The combination of abnormal tissue conditions and chemicals released by mast cells stimulates sensory nerve endings that produce sensations of pain. At the same time, the chemicals released by mast cells make the endothelial cells of local capillaries more permeable. Plasma, including blood proteins, now diffuses into the injured tissue, so the area becomes swollen.

The increased blood flow accelerates the delivery of nutrients and oxygen and the removal of dissolved waste products and toxic chemicals. It also brings white blood cells to the region. These phagocytic cells migrate to the site of the injury and assist in defense and cleanup operations. Macrophages and microphages protect the tissue from infection and perform cleanup by engulfing both debris and bacteria. Over a period of hours to days, the cleanup process generally succeeds in eliminating the inflammatory stimulus.

Second Phase: Regeneration

By the time the inflammation phase is over, the situation is under control and no further damage will occur. However, many cells in the area either have already died or will soon die as a consequence of the original injury. As tissue conditions return to normal, fibroblasts move into the necrotic area, laying down a network of collagen fibers that stabilizes the injury site. This process produces a dense, collagenous framework known as *scar tissue* or *fibrous tissue*. Over time, scar tissue is usually “remodeled” and gradually assumes a more normal appearance. The cell population in the area gradually increases; some cells migrate to the site, and others are produced by the division of mesenchymal stem cells.

Each organ has a different ability to regenerate after injury—an ability that can be directly linked to the pattern of tissue organization in the injured organ. Epithelia, connective tissues (except cartilage), and smooth muscle tissue usually regenerate well, whereas other muscle tissues and neural tissue regenerate relatively poorly if at all. The skin, which is dominated by epithelia and connective tissues, regenerates rapidly and completely after injury. (We will consider the process in Chapter 5.) In contrast, damage to the heart is much more serious. Although the connective tissues of the heart can be repaired, the majority of damaged cardiac muscle cells are replaced only by fibrous tissue. The permanent replacement of normal tissue by fibrous tissue is called *fibrosis*

(f -BRO-sis). Fibrosis in muscle and other tissues may occur in response to injury, disease, or aging. AM: Tissue Structure and Disease

—

1

Aging and Tissue Structure

Tissues change with age, and the speed and effectiveness of tissue repairs decrease. Repair and maintenance activities throughout the body slow down; the rate of energy consumption in general declines. All these changes reflect various hormonal alterations occurring with age, often coupled with a reduction in physical activity and the adoption of a more sedentary lifestyle. These factors combine to alter the structure and chemical composition of many tissues. Epithelia get thinner and connective tissues more fragile. Individuals bruise easily and bones become brittle; joint pain and broken bones are common in the elderly. Because cardiac muscle cells and neurons cannot be replaced, cumulative damage can eventually cause major health problems, such as cardiovascular disease or a deterioration in mental functioning.

In later chapters, we will consider the effects of aging on specific organs and systems. Some of these effects are genetically programmed. For example, the chondrocytes of older individuals produce a slightly different form of proteoglycan than do those of younger people. This difference probably accounts for the thinner and less resilient cartilage of older people. In some cases, the tissue degeneration can be temporarily slowed or even reversed. Age-related reduction in bone strength, a condition called *osteoporosis*, typically results from a combination of inactivity, low dietary calcium levels, and a reduction in circulating sex hormones. A program of exercise, calcium supplements, and hormone replacement therapies can generally maintain healthy bone structure for many years.

Aging and Cancer Incidence

Cancer rates increase with age, and roughly 25 percent of all people in the United States develop cancer at some point in their lives. It has been estimated that 70–80 percent of cancer cases result from chemical exposure, environmental factors, or some combination of the two, and 40 percent of those cancers are caused by cigarette smoke. Each year in the United States, more than 500,000 individuals die of cancer, making it second only to heart disease as a cause of death. We discussed the development and

growth of cancer in Chapter 3. l**p. 100** AM: Cancer: A Closer Look

This chapter concludes the introductory portion of this text. In combination, the four basic tissue types described here form all of the organs and systems discussed in subsequent chapters. The *Systems Overview* that follows this chapter will help you make the transition from atoms, molecules, cells, and tissues to organ systems. One of the most important themes in this text is that organ systems interact continuously—they do not function in isolation. Thus, to understand specifics about one system, you need to know something about all of the others. The *Systems Overview* section provides a general orientation in more detail than was possible in Chapter 1. You will find this section useful as a reference throughout the remainder of the text.

Chapter Review

Selected Clinical Terminology

abscess: The accumulation of pus within an enclosed tissue space. (p. 136)

adhesions: Restrictive fibrous connections that can result from surgery, infection, or other injuries to serous membranes. [AM]

anaplasia: An irreversible change in the size and shape of tissue cells. [AM]

antiangiogenesis factor: A secretion, produced by chondrocytes, that inhibits the growth of blood vessels. (p. 125)

ascites: The accumulation of fluid in the peritoneal cavity, usually caused by liver or kidney disease or heart failure. [AM]

dysplasia: A reversible change in the normal shape, size, and organization of tissue cells. [AM]

exfoliative cytology: The study of cells shed or collected from epithelial surfaces. (p. 114)

liposuction: A surgical procedure to remove unwanted adipose tissue by sucking it out through a tube. (p. 123)

metaplasia: A reversible structural change that alters the character of a tissue. [AM]

necrosis: Tissue destruction that occurs after cells have been injured or destroyed; a result of the release of lysosomal enzymes through

autolysis. (p. 136) **pathologists:** Physicians who specialize in the study of disease processes. [AM] **pericarditis:** An inflammation of the pericardial lining that may lead to the accumulation of pericardial fluid (a *pericardial effusion*). [AM] **peritonitis:** An inflammation of the peritoneum after infection or injury. [AM] **pleural effusion:** The accumulation of fluid within the pleural cavities as a result of chronic infection or inflammation of the pleura.

[AM]

pleuritis *(pleurisy)***:** An inflammation of the pleural cavities. This condition may cause the production of a sound known as a *pleural rub*. [AM] **regeneration:** The repairing of injured tissues that follows inflammation. (p. 135)

Study Outline

Tissues of the Body: An Introduction p. 107

1. **Tissues** are collections of specialized cells and cell products that perform a relatively limited number of functions. The four *tissue types* are *epithelial tissue*, *connective tissue*, *muscle tissue*, and *neural tissue*.

2. **Histology** is the study of tissues.

100 Keys | p. 107

Epithelial Tissue p. 107

1. **Epithelial tissue** includes epithelia and glands. An **epithelium** is an **avascular** layer of cells that forms a barrier that provides protection and regulates permeability. **Glands** are secretory structures derived from epithelia. Epithelial cells may show **polarity**, an uneven distribution of cytoplasmic components.

2. A **basal lamina** attaches epithelia to underlying connective tissues.

Functions of Epithelial Tissue p. 107

3. Epithelia provide physical protection, control permeability, provide sensation, and produce specialized secretions. Gland cells are epithelial cells that produce secretions. In **glandular epithelia**, most cells produce secretions.

Specializations of Epithelial Cells p. 108

4. Epithelial cells are specialized to perform secretory or transport functions and to maintain the physical integrity of the epithelium.

(Figure 4–1)

5. Many epithelial cells have microvilli.

6. The coordinated beating of the cilia on a **ciliated epithelium** moves materials across the epithelial surface.

Maintaining the Integrity of Epithelia p. 108

7. Cells can attach to other cells or to extracellular protein fibers by means of **cell adhesion molecules** (**CAM**s) or at specialized attachment sites called **cell junctions**. The three major types of cell junctions are **tight junctions**, **gap junctions**, and **desmosomes**.

(Figure 4–2)

8. The inner surface of each epithelium is connected to a two-part basal lamina consisting of a *lamina lucida* and a *lamina densa*. Divisions by **germinative cells** continually replace the short-lived epithelial cells.

Classification of Epithelia p. 111

9. Epithelia are classified on the basis of the number of cell layers and the shape of the cells at the apical surface.

10. A **simple epithelium** has a single layer of cells covering the basal lamina; a **stratified epithelium** has several layers. The cells in a **squamous epithelium** are thin and flat. Cells in a **cuboidal epithelium** resemble hexagonal boxes; those in a **columnar epithelium** are taller and more slender. *(Table 4–1; Figures 4–3 to 4–5)*

Glandular Epithelia p. 114

11. Exocrine glands discharge secretions onto the body surface or into **ducts**, which communicate with the exterior. *Hormones*, the secretions of **endocrine glands**, are released by gland cells into the surrounding interstitial fluid.

12. A glandular epithelial cell may release its secretions by merocrine, apocrine, or holocrine modes. In **merocrine secretion**, the most common mode, the product is released through exocytosis. **Apocrine secretion** involves the loss of both the secretory product and cytoplasm. Unlike the other two methods, **holocrine secretion** destroys the gland cell, which becomes packed with secretions and bursts. *(Figure 4–6)*

13. In epithelia that contain scattered gland cells, individual secretory cells are called **unicellular glands**. **Multicellular glands** are organs that contain glandular epithelia that produce exocrine or endocrine secretions.

14. Exocrine glands can be classified on the basis of structure as **unicellular exocrine glands** (**goblet cells**) or as **multicellular exocrine glands**. Multicellular exocrine glands can be further classified according to structure. *(Figure 4–7)*

Connective Tissues p. 118

1. **Connective tissues** are internal tissues with many important functions: establishing a structural framework; transporting fluids and dissolved materials; protecting delicate organs; supporting, surrounding, and interconnecting tissues; storing energy reserves; and defending the body from microorganisms.

2. All connective tissues contain specialized cells and a **matrix**, composed of extracellular protein fibers and a **ground substance**.

Classification of Connective Tissues p. 118

3. **Connective tissue proper** is connective tissue that contains varied cell populations and fiber types surrounded by a syrupy ground substance. *(Figure 4–8)*

4. **Fluid connective tissues** have distinctive populations of cells suspended in a watery matrix that contains dissolved proteins. The two types of fluid connective tissues are *blood* and *lymph*.

5. **Supporting connective tissues** have a less diverse cell population than connective tissue proper and a dense matrix with closely packed fibers. The two types of supporting connective tissues are *cartilage* and *bone*.

Connective Tissue Proper p. 119

6. Connective tissue proper contains fibers, a viscous ground substance, and a varied population of cells, including **fibroblasts**, **macrophages**, **adipocytes**, **mesenchymal cells**, **melanocytes**, **mast cells**, **lymphocytes**, and **microphages**.

7. The three types of fibers in connective tissue are **collagen fibers**, **reticular fibers**, and **elastic fibers**.

8. The first connective tissue to appear in an embryo is **mesenchyme**, or *embryonic connective tissue*.

9. Connective tissue proper is classified as **loose connective tissue** or **dense connective tissue**. Loose connective tissues are mesenchyme and **mucous connective tissues** in the embryo; **areolar tissue**; **adipose tissue**, including **white fat** and **brown fat**; and **reticular tissue**. Most of the volume in dense connective tissue consists of fibers. The two types of dense connective tissue are **dense regular connective tissue** and **dense irregular connective tissue** in the adult. *(Figures 4–9 to 4–11)*

Fluid Connective Tissues p. 123

10. Blood and **lymph** are connective tissues that contain distinctive collections of cells in a fluid matrix.

11. Blood contains *formed elements*: **red blood cells** (*erythrocytes*), **white blood cells** (*leukocytes*), and **platelets**. The watery matrix of blood is called **plasma**. *(Figure 4–12)*

12. Arteries carry blood away from the heart and toward **capillaries**, where water and small solutes move into the interstitial fluid of surrounding tissues. **Veins** return blood to the heart.

13. Lymph forms as interstitial fluid enters the **lymphatic vessels**, which return lymph to the cardiovascular system.

Supporting Connective Tissues p. 125

14. Cartilage and bone are called supporting connective tissues because they support the rest of the body.

15. The matrix of cartilage is a firm gel that contains **chondroitin sulfates** (used to form proteoglycans) and cells called **chondrocytes**. Chondrocytes occupy chambers called **lacunae**. A fibrous **perichondrium** separates cartilage from surrounding tissues. The three types of cartilage are **hyaline cartilage**, **elastic cartilage**, and **fibrocartilage**. *(Figure 4–14)*

16. Chondrocytes rely on diffusion through the avascular matrix to obtain nutrients.

17. Cartilage grows by two mechanisms: **interstitial growth** and **appositional growth**. *(Figure 4–13)*

18. Bone, or **osseous tissue**, consists of **osteocytes**, little ground substance, and a dense, mineralized matrix. Osteocytes are situated in lacunae. The matrix consists of calcium salts and collagen fibers, giving it unique properties. *(Figure 4–15; Table 4–2)*

19. Osteocytes depend on diffusion through **canaliculi** for nutrient intake.

20. Each bone is surrounded by a **periosteum** with fibrous and cellular layers.

Membranes p. 129

1. Membranes form a barrier or interface. Epithelia and connective tissues combine to form membranes that cover and protect other structures and tissues. The four types of membranes are *mucous*, *serous*, *cutaneous*, and *synovial*. *(Figure 4–16)*

Mucous Membranes p. 129

2. **Mucous membranes** line cavities that communicate with the exterior. They contain areolar tissue called the **lamina propria**.

Serous Membranes p. 129

3. **Serous membranes** line the body's sealed internal cavities. They form a fluid called a *transudate*.

The Cutaneous Membrane p. 130

4. The **cutaneous membrane**, or skin, covers the body surface.

Synovial Membranes p. 131

5. **Synovial membranes** form an incomplete lining within the cavities of synovial joints.

The Connective Tissue Framework of the Body p. 131

1. Internal organs and systems are tied together by a network of connective tissue proper. This network consists of the **superficial fascia** (the **subcutaneous layer**, or *hypodermis*, separating the skin from underlying tissues and organs), the **deep fascia** (dense connective tissue), and the **subserous fascia** (the layer between the deep fascia and the serous membranes that line body cavities). *(Figure 4–17)*

Muscle Tissue p. 132

1. **Muscle tissue** is specialized for contraction. The three types of muscle tissue are *skeletal muscle*, *cardiac muscle*, and *smooth muscle*. *(Figure 4–18)*

Skeletal Muscle Tissue p. 132

2. The cells of **skeletal muscle tissue** are *multinucleate*. Skeletal muscle, or **striated voluntary muscle**, produces new fibers by the division of **satellite cells**.

Cardiac Muscle Tissue p. 134

3. **Cardiocytes**, the cells of **cardiac muscle tissue**, occur only in the heart. Cardiac muscle, or **striated involuntary muscle**, relies on *pacemaker cells* for regular contraction.

Smooth Muscle Tissue p. 134

4. **Smooth muscle tissue**, or **nonstriated involuntary muscle**, is not striated. Smooth muscle cells can divide and therefore regenerate after injury has occurred.

Neural Tissue p. 134

1. **Neural tissue** conducts electrical impulses, which convey information from one area of the body to another.

2. Cells in neural tissue are either neurons or neuroglia. **Neurons** transmit information as electrical impulses. Several kinds of **neuroglia** exist, and their basic functions include supporting neural tissue and helping supply nutrients to neurons. *(Figure 4–19)*

3. A typical neuron has a **cell body**, **dendrites**, and an **axon**, or **nerve fiber**. The axon carries information to other cells.

Tissue Injuries and Repair p. 135 Inflammation and Regeneration p. 135

1. Any injury affects several types of tissue simultaneously, and they respond in a coordinated manner. Homeostasis after an injury is restored by two processes: inflammation and regeneration.

2. **Inflammation**, or the **inflammatory response**, isolates the injured area while damaged cells, tissue components, and any dangerous microorganisms (which could cause **infection**) are cleaned up. **Regeneration** is the repair process that restores normal function.

(Figure 4–20)

Aging and Tissue Structure p. 137

3. Tissues change with age. Repair and maintenance become less efficient, and the structure and chemical composition of many tissues are altered.

Aging and Cancer Incidence p. 137

4. The incidence of cancer increases with age, with roughly three-quarters of all cases caused by exposure to chemicals or by other environmental factors, such as cigarette smoke.

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. Collections of specialized cells and cell products that perform a relatively limited number of functions are called

(a) cellular aggregates **(b)** tissues

(c) organs **(d)** organ systems

(e) organisms

2. A type of junction common in cardiac and smooth muscle tissues is the

(a) hemidesmosome **(b)** basal lamina

(c) tight junction **(d)** gap junction

3. The most abundant connections between cells in the superficial layers of the skin are

(a) connexons **(b)** gap junctions

(c) desmosomes **(d)** tight junctions

4. ___ membranes have an epithelium that is stratified and supported by dense connective tissue.

(a) Synovial **(b)** Serous

(c) Cutaneous **(d)** Mucous

5. Mucous secretions that coat the passageways of the digestive and respiratory tracts result from **___** secretion.

(a) apocrine **(b)** merocrine

(c) holocrine **(d)** endocrine

6. Matrix is a characteristic of which type of tissue?

(a) epithelial **(b)** neural

(c) muscle **(d)** connective

7. Functions of connective tissue include

(a) establishing a structural framework for the body

(b) storing energy reserves

(c) providing protection for delicate organs

(d) all of the above

(e) a and c only

8. Which of the following epithelia most easily permits diffusion?

(a) stratified squamous **(b)** simple squamous

(c) transitional **(d)** simple columnar

9. The three major types of cartilage in the body are

(a) collagen, reticular, and elastic

(b) areolar, adipose, and reticular

(c) hyaline, elastic, and fibrocartilage

(d) tendons, reticular, and elastic

10. The primary function of serous membranes in the body is to

(a) minimize friction between opposing surfaces

(b) line cavities that communicate with the exterior

(c) perform absorptive and secretory functions

(d) cover the surface of the body

11. The type of cartilage growth characterized by adding new layers of cartilage to the surface is

(a) interstitial growth **(b)** appositional growth

(c) intramembranous growth **(d)** longitudinal growth

12. Tissue changes with age can result from

(a) hormonal changes **(b)** increased need for sleep

(c) improper nutrition **(d)** all of the above

(e) both a and c only

13. Axons, dendrites, and a cell body are characteristic of cells located in

(a) neural tissue **(b)** muscle tissue

(c) connective tissue **(d)** epithelial tissue

14. The repair process necessary to restore normal function in damaged tissues is

(a) isolation **(b)** regeneration

(c) reconstruction **(d)** a, b, and c are correct

15. What are the four essential functions of epithelial tissue?

16. Differentiate between endocrine and exocrine glands.

17. What three methods do various glandular epithelial cells use to release their secretions?

18. List three basic components of connective tissues.

19. What are the four kinds of membranes composed of epithelial and connective tissue that cover and protect other structures and tissues in the body?

20. What two cell populations make up neural tissue? What is the function of each?

LEVEL 2 Reviewing Concepts

21. What is the difference between an exocrine and an endocrine secretion?

22. A significant structural feature in the digestive system is the presence of tight junctions near the exposed surfaces of cells lining the digestive tract. Why are these junctions so important?

23. Describe the fluid connective tissues in the human body. Compare them with the supporting connective tissues. What are the main differences?

24. Why are infections always a serious threat after a severe burn or abrasion?

25. A layer of glycoproteins and a network of fine protein filaments that prevents the movement of proteins and other large molecules from the connective tissue to the epithelium describes

(a) interfacial canals **(b)** the basal lamina

(c) the reticular lamina **(d)** areolar tissue

(e) squamous epithelium

26. Why does damaged cartilage heal slowly?

(a) Chondrocytes cannot be replaced if killed, and other cell types must take their place.

(b) Cartilage is avascular so nutrients and other molecules must diffuse to the site of injury.

(c) Damaged cartilage becomes calcified, thus blocking the movement of materials required for healing.

(d) Chondrocytes divide more slowly than other cell types, delaying the healing process.

(e) Damaged collagen cannot be quicly replaced, thus slowing the healing process.

27. Compare the three types of muscle tissue. List three similarities and three differences among them.

LEVEL 3 Critical Thinking and Clinical Applications

28. Assuming that you had the necessary materials to perform a detailed chemical analysis of body secretions, how could you determine whether a secretion was merocrine or apocrine?

29. During a lab pratical, a student examines a tissue that is composed of densely packed protein fibers that are running parallel and form a cord. There are no striations, but small nuclei are visible. The student identifies the tissue as skeletal muscle. Why is the stu-dent’s choice wrong, and what tissue is he probably observing?

30. While in a chemistry lab, Jim accidentally spills a small amount of a caustic chemical on his arm. What changes in the characteristics of the skin would you expect to observe and what would cause these changes?

Systems Overview

Our perspective has gradually changed over the preceding chapters. Atoms can only be imagined or indirectly examined through experimental procedures. Cellular details often escape detection unless an electron microscope is used. Tissue structure, however, can be examined with a light microscope, and based on your experiences in the laboratory you may already be able to identify some tissues with the unaided eye. For example, once you have handled adipose tissue, with its lumpy, greasy texture, it would be difficult to mistake it for any other type of tissue.

Organs are combinations of tissues that perform complex functions. A great deal of information concerning organs and organ structure can be obtained by dissection and direct examination. In organ systems, several organs work together in a coordinated fashion. We can easily observe the functions of intact organ systems as they perform, direct, or moderate the activities of individual human beings. As a result, at the start of this course you probably knew much more about the major organs and systems than you did about cells and tissue structure.

Figure 1• presents four views of the composition of the human body, reflecting the changes in our perspective over the last four chapters. In Chapter 2 the body was treated as a collection of chemical elements (Figure 1a•) that combine to form molecules. Cells, described in Chapter 3, are composed of organic molecules, inorganic molecules, ions, and water. Figure 1b• indicates the proportions of water and organic molecules in the body as a whole.

Chapter 4 described the association of roughly 200 types of cells in four types of body tissues (Figure 1c•). These four tissue types combine to form thousands of different organs. Some are quite large and distinctive; the liver, an organ of the digestive tract, weighs about 1.6 kg (3.5 lb), and some skeletal muscles can be even larger. Other organs are tiny and far more numerous; the skin contains roughly 3 million sweat glands that are barely large enough to see without a magnifying glass. Regardless of their size, all of these organs contain all four tissue types, although the proportions vary from organ to organ. For example, all four tissue types contribute extensively to the structure of the stomach, but most of the heart is composed of cardiac muscle tissue. Figure 1d• characterizes the human body at the organ system level, the focus of the rest of this textbook.

Despite their structural and functional differences, all organ systems share certain characteristics:

1. *Specialization for performing a limited number of functions.* In other words, there is a division of labor among organ systems.
2. *Functional independence* in responding to local environmental stimuli.
3. *Dependence on other organ systems* for nutrient supply, oxygen, and waste removal.
4. *Integration of activity* through neural and hormonal mechanisms.

Figure 2•, on the pages that follow, summarizes the components, organization, and functions of the 11 organ systems in the human body. This information will provide a framework for later chapters dealing with specific systems. Refer to them while you work through those chapters, whenever you need a reminder of the general functions or locations of specific organs.

TABLE 4–1 Clas

TABLE 4–2 A C

Characteristic	**Cartilage**	**Bone**	
Structural Features			
Cells	Chondrocytes in lacunae	Osteocytes in lacunae	
Ground substance	Chondroitin sulfate (in proteoglycan)		A s

	and water	of calcium salts (calcium phosphate and calcium carbonate)
Fibers	Collagen, elastic, and reticular fibers (proportions vary)	Coll
Vascularity	None	Extensive
Covering	Perichondrium (two layers)	Periosteum (two layers)

Strength Limited: bends easily, but hard to break Strong: resists distortion until breaking point

Metabolic Features

Oxygen demands Low

Nutrient delivery By diffusion through matrix

Growth Interstitial and appositional

Repair capabilities Limited

High By diffusion through cytoplasm and fluid in canaliculi Appositional only Extensive

• **FIGURE 4–1** The Polarity of Epithelial Cells. Many epithelial cells have an uneven distribution of organelles between the free surface (here, the top) and the basal lamina. Often, the free surface bears microvilli; sometimes it has cilia. In some epithelia, such as the lining of the kidney tubules, mitochondria are concentrated near the base of the cell, probably to provide energy for the cell's transport activities.

• **FIGURE 4–2** Intercellular Connections. **(a)** A diagrammatic view of an epithelial cell, showing the major types of intercellular connections.

(b) A tight junction is formed by the fusion of the outer layers of two cell membranes. Tight junctions prevent the diffusion of fluids and solutes between the cells. A continuous adhesion belt lies deep to the tight junction. This belt is tied to the microfilaments of the terminal web. **(c)** Gap junctions permit the free diffusion of ions and small molecules between two cells. **(d)** A button desmosome ties adjacent cells together.

(e) Hemidesmosomes attach a cell to extracellular structures, such as the protein fibers in the basal lamina.

- **FIGURE 4–3** Squamous Epithelia. **(a)** A superficial view of the simple squamous epithelium (mesothelium) that lines the peritoneal cavity. The three-dimensional drawing shows the epithelium in superficial and sectional views. **(b)** Sectional and diagrammatic views of the stratified squamous epithelium that covers the tongue.
- **FIGURE 4–4** Cuboidal and Transitional Epithelia. **(a)** A section through the simple cuboidal epithelial cells of a kidney tubule. **(b)** A sectional view of the stratified cuboidal epithelium that lines a sweat gland duct in the skin. **(c)** Left: The lining of the empty urinary bladder, showing a transitional epithelium in the relaxed state. Right: The lining of the full bladder, showing the effects of stretching on the appearance of cells in the epithelium.
- **FIGURE 4–5** Columnar Epithelia. Note the thickness of the epithelium and the location and orientation of the nuclei. **(a)** The simple columnar epithelium lining the small intestine. **(b)** The pseudostratified ciliated columnar epithelium of the respiratory tract. Note that despite the uneven layering of the nuclei, all of the cells contact the basal lamina. **(c)** A stratified columnar epithelium occurs along some large ducts, such as this salivary gland duct.
- **FIGURE 4–6** Modes of Glandular Secretion. **(a)** In merocrine secretion, secretory vesicles are discharged at the apical surface of the gland cell by exocytosis. **(b)** Apocrine secretion involves the loss of apical cytoplasm. Inclusions, secretory vesicles, and other cytoplasmic components are shed in the process. The gland cell then undergoes growth and repair before it releases additional secretions. **(c)** Holocrine secretion occurs as superficial gland cells burst. Continued secretion involves the replacement of these cells through the mitotic division of underlying stem cells.

A Structural Classification of Exocrine Glands

- **FIGURE 4–8** The Cells and Fibers of Connective Tissue Proper. Diagrammatic and histological views of the cell types and fibers of connective tissue proper. (Microphages, not shown, are common only in damaged or abnormal tissues.)
- **FIGURE 4–9** Connective Tissues in Embryos. **(a)** Mesenchyme, the first connective tissue to appear in an embryo. **(b)** Mucous connective tissue, which is derived from mesenchyme. Shown here is mucous connective tissue in the umbilical cord of a fetus, where it is also known as *Wharton's jelly*.
- **FIGURE 4–10** Adipose and Reticular Tissues. **(a)** Adipose tissue is a loose connective tissue dominated by adipocytes. In standard histological preparations, the tissue looks empty because the lipids in the fat cells dissolve in the alcohol used in tissue processing. **(b)** Reticular tissue has an open framework of reticular fibers, which are usually very difficult to see because of the large numbers of cells around them.
- **FIGURE 4–11** Dense Connective Tissues. **(a)** The dense regular connective tissue in a tendon. Notice the densely packed, parallel bundles of collagen fibers. The fibroblast nuclei are flattened between the bundles. **(b)** The deep dermis of the skin contains a thick layer of dense irregular connective tissue. **(c)** An elastic ligament, an example of elastic tissue. Elastic ligaments extend between the vertebrae of the vertebral column. The bundles are fatter than those of a tendon or a ligament composed of collagen.
- **FIGURE 4–12** Formed Elements of the Blood
- **FIGURE 4–13** The Growth of Cartilage. **(a)** In interstitial growth, the cartilage expands from within as chondrocytes in the matrix divide, grow, and produce new matrix. **(b)** In appositional growth, the cartilage grows at its external surface as fibroblasts in the cellular layer of the perichondrium differentiate into chondrocytes.
- **FIGURE 4–14** The Types of Cartilage. **(a)** Hyaline cartilage. Note the translucent matrix and the absence of prominent fibers. **(b)** Elastic cartilage. The closely packed elastic fibers are visible between the chondrocytes. **(c)** Fibrocartilage. The collagen fibers are extremely dense, and the chondrocytes are relatively far apart.

- **FIGURE 4–15** Bone. The osteocytes in bone are generally organized in groups around a central space that contains blood vessels. Bone dust produced during preparation of the section fills the lacunae and the central canal, making them appear dark in the micrograph.
- **FIGURE 4–16** Membranes. **(a)** Mucous membranes are coated with the secretions of mucous glands. These membranes line the digestive, respiratory, urinary, and reproductive tracts. **(b)** Serous membranes line the ventral body cavities (the peritoneal, pleural, and pericardial cavities). **(c)** The cutaneous membrane, or skin, covers the outer surface of the body. **(d)** Synovial membranes line joint cavities and produce the fluid within the joint.
- **FIGURE 4–17** The Fasciae. The relationships among the connective tissue elements in the body.
- **FIGURE 4–18** Muscle Tissue. **(a)** Skeletal muscle fibers are large unbranched cells with multiple, peripherally located nuclei and prominent striations (banding). **(b)** Cardiac muscle cells differ from skeletal muscle fibers in three major ways: They are smaller, they branch, and they have one centrally placed nucleus. The striations of both skeletal and cardiac muscle cells result from an organized array of actin and myosin filaments. **(c)** Smooth muscle cells are small and spindle shaped, with a central nucleus. They lack branches and striations.
- **FIGURE 4–19** Neural Tissue
- **FIGURE 4–20** An Introduction to Inflammation. Inflammation is triggered by mast cell activation in response to tissue injury. It creates the conditions under which the regeneration of tissues can occur.

- **FIGURE 1** Composition of the Human Body
- **FIGURE 1** Composition of the Human Body *(continued)*

Organ/Component	**Primary Functions**
Bones, Cartilages,	Support, protect soft tissues; bones store

and Joints minerals

Axial Skeleton (skull, Protects brain, spinal cord, sense organs,
vertebrae, ribs, sternum, and soft tissues of thoracic cavity;
sacrum, cartilages, and supports the body weight over the lower
ligaments) limbs

Appendicular Skeleton Provides internal support and positioning
(supporting bones, of the limbs; supports and moves axial
cartilages, and ligaments skeleton
of the limbs)

Bone Marrow Acts as primary site of blood cell
production (red blood cells, white blood
cells); stores lipid reserves

Organ/Component Primary Functions
Skeletal Muscles (700) Provide skeletal movement; control
entrances and exits of digestive tract;
produce heat; support skeletal position;
protect soft tissues

Axial Muscles Support and position axial skeleton
Appendicular Muscles Support, move, and brace limbs

Tendons, Aponeuroses Harness forces of contraction to perform
specific tasks

Organ/Component	Primary Functions
Central Nervous System (CNS)	Acts as control center for nervous system: processes information; provides short-term control over activities of other systems
Brain	Performs complex integrative functions; controls both voluntary and autonomic activities
Spinal Cord	Relays information to and from brain; performs less-complex integrative functions; directs many simple involuntary activities
Peripheral Nervous System (PNS)	Links CNS with other systems and with sense organs

Organ/Component	Primary Functions
Pineal Gland	May control timing of reproduction and set day-night rhythms
Pituitary Gland	Controls other endocrine glands; regulates growth and fluid balance
Thyroid Gland	Controls tissue metabolic rate; regulates calcium levels

Parathyroid Glands	Regulate calcium levels (with thyroid)
Thymus	Controls maturation of lymphocytes
Adrenal Glands	Adjust water balance, tissue metabolism, cardiovascular and respiratory activity
Kidneys	Control red blood cell production and assist in calcium regulation
Pancreas	Regulates blood glucose levels
Gonads	
Testes	Support male sexual characteristics and reproductive functions *(see part k)*
Ovaries	Support female sexual characteristics and reproductive functions *(see part l)*

Organ/Component	**Primary Functions**
Heart	Propels blood; maintains blood pressure
Blood Vessels	Distribute blood around the body
Arteries	Carry blood from heart to capillaries
Capillaries	Permit diffusion between blood and interstitial fluids
Veins	Return blood from capillaries to the heart
Blood	Transports oxygen, carbon dioxide, and blood cells; delivers nutrients and hormones; removes waste products; assists in temperature regulation and defense against disease

Organ/Component	**Primary Functions**
Lymphatic Vessels	Carry lymph (water and proteins) and lymphocytes from peripheral tissues to veins of the cardiovascular system
Lymph Nodes	Monitor the composition of lymph;

	macrophages engulf pathogens; stimulate immune response
Spleen	Monitors circulating blood; macrophages engulf pathogens; stimulates immune response
Thymus	Controls development and maintenance of one class of lymphocytes (T cells)

Organ/Component	**Primary Functions**
Nasal Cavities, Paranasal Sinuses	Filter, warm, humidify air; detect smells
Pharynx	Conducts air to larynx; is a chamber shared with the digestive tract *(see part i)*
Larynx	Protects opening to trachea and contains vocal cords
Trachea	Filters air, traps particles in mucus; cartilages keep airway open
Bronchi	(Same functions as trachea)
Lungs	Responsible for air movement through volume changes during movements of ribs and diaphragm; include airways and alveoli
Alveoli	Act as sites of gas exchange between air and blood

Organ/Component	**Primary Functions**
Salivary Glands	Provide buffers and lubrication; produce enzymes that begin digestion
Pharynx	Conducts solid food and liquids to esophagus; is a chamber shared with respiratory tract *(see part h)*
Esophagus	Delivers food to stomach
Stomach	Secretes acids and enzymes

Small Intestine Secretes digestive enzymes, buffers, and hormones; absorbs nutrients

Liver Secretes bile; regulates nutrient composition of blood

Gallbladder Stores bile for release into small intestine

Pancreas Secretes digestive enzymes and buffers; contains endocrine cells *(see part e)*

Large Intestine Removes water from fecal material; stores wastes

Organ/Component Primary Functions

Kidneys Form and concentrate urine; regulate blood pH and ion concentrations; perform endocrine functions *(see part e)*

Ureters Conduct urine from kidneys to urinary bladder

Urinary Bladder Stores urine for eventual elimination

Urethra Conducts urine to exterior

Organ/Component Primary Functions

Testes Produce sperm and hormones *(see part e)*

Accessory Organs Epididymis Acts as site of sperm maturation **Ductus Deferens** Conducts sperm between epididymis and

(Sperm Duct)	prostate gland
Seminal Vesicles	Secrete fluid that makes up much of the volume of semen
Prostate Gland	Secretes fluid and enzymes
Urethra	Conducts semen to exterior
External Genitalia	
Penis	Contains erectile tissue; deposits sperm in vagina of female; produces pleasurable sensations during sexual activities
Scrotum	Surrounds the testes and controls their temperature
Organ/Component	**Primary Functions**

Ovaries	Produce oocytes and hormones *(see part e)*
Uterine Tubes	Deliver oocyte or embryo to uterus; normal site of fertilization
Uterus	Site of embryonic development and exchange between maternal and embryonic bloodstreams
Vagina	Site of sperm deposition; acts as birth canal during delivery; provides passageway for fluids during menstruation
External Genitalia	
Clitoris	Contains erectile tissue; produces pleasurable sensations during sexual activities
Labia	Contain glands that lubricate entrance to vagina
Mammary Glands	Produce milk that nourishes newborn infant

2

Support and Movement

Chapter 5, The Integumentary System, considers the many and varied functions of the skin, the organ system with which you are probably most familiar.

Chapter 6, Osseous Tissue and Skeletal Structure, expands upon the introduction to bone, presented in Chapter 4, by examining the mechanisms involved with the growth, remodeling, and repair of the skeleton.

Chapter 7, The Axial Skeleton, turns our attention to the functional anatomy of the bones that form the longitudinal axis of the body: the skull and associated bones, the thoracic cage, and the vertebral column.

Chapter 8, The Appendicular Skeleton, focuses on the functional anatomy of the bones of the limbs and of the supporting elements (or girdles) that connect the limbs to the body.

Chapter 9, Articulations, considers the ways bones interact wherever they interconnect at joints, or articulations.

Chapter 10, Muscle Tissue, discusses one of the four primary tissue types, with particular attention to skeletal muscle tissue; this chapter also examines the histological and physiological characteristics of skeletal muscle cells, and relates those features to the functional properties of the entire tissue.

Chapter 11, The Muscular System, describes the gross anatomy of the muscular system and considers functional relationships between muscles and bones of the body.

The End of Chapter questions within this unit include critical thinking questions about both normal and abnormal functions. For comprehensive exercises covering material in the unit as a whole, see the Clinical Problems at the end of the corresponding unit in the *Applications Manual* [AM].

The Integumentary System: An Overview

Objectives

- List the components of the integumentary system, and describe their physical relationship to each other and to the subcutaneous layer.
- Specify the general functions of the integumentary system.

No other organ system is as accessible, large, varied in function, and underappreciated as the integumentary system. Often referred to simply as the **integument** (in-TEG-u¯-ment), this system accounts for about 16 percent of your total body weight. Its surface, 1.5–2 m^2 in area, is continually abraded, attacked by microorganisms, irradiated by sunlight, and exposed to environmental chemicals. The integumentary system is your body’s first line of defense against an often hostile environment—the place where you and the outside world meet. AM: Examination of the Skin

The integumentary system has two major components: the **cutaneous membrane** or skin, and the **accessory structures** (Figure 5–1•).

1. The cutaneous membrane has two components: the **epidermis** (*epi-*, above) or superficial epithelium, and the **dermis**, an underlying area of connective tissues.

2. The accessory structures include hair, nails, and multicellular exocrine glands. These structures are located primarily in the dermis and protrude through the epidermis to the skin surface.

The integument does not function in isolation. An extensive network of blood vessels branches through the dermis, and sensory receptors that monitor touch, pressure, temperature, and pain provide valuable information to the central nervous system about the state of the body. Deep to the dermis, the loose connective tissue of the **subcutaneous layer**, also known as the superficial fascia or *hypodermis*, separates the integument from the deep fascia around other organs, such as muscles and bones.

l**p. 131** Although the subcutaneous layer is often considered separate from the integument, we will consider it in this chapter because its connective tissue fibers are interwoven with those of the dermis. The general functions of the skin and subcutaneous layer include the following:

- *Protection* of underlying tissues and organs against impact, abrasion, fluid loss, and chemical attack.
- *Excretion* of salts, water, and organic wastes by integumentary glands.
- *Maintenance* of normal body temperature through either insulation or evaporative cooling, as needed.
- *Synthesis of vitamin D*3 , a steroid that is subsequently converted to calcitriol, a hormone important to normal calcium metabolism.
- *Storage* of lipids in adipocytes in the dermis and in adipose tissue in the subcutaneous layer.
- *Detection* of touch, pressure, pain, and temperature stimuli, and the relaying of that information to the nervous system. (These *general senses*, which provide information about the external environment, will be considered further in Chapter 15.)

In the next two sections we will consider the various components of the integument.

The Epidermis

Objectives

- Describe the main structural features of the epidermis, and explain the functional significance of each.
- Explain what accounts for individual differences in skin color.
- Describe the effects of ultraviolet radiation on the skin, and discuss the role of melanocytes in exposure to sunlight.

The epidermis consists of a stratified squamous epithelium. Recall from Chapter 4 that such an epithelium provides considerable mechanical protection and also helps keep microorganisms outside the body. l**p. 112** Like all other epithelia, the epidermis is avascular. Because there are no local blood vessels, the epidermal cells rely on the diffusion of nutrients and oxygen from capillaries within the dermis. As a result, the epidermal cells with the highest metabolic demands are found close to the basal lamina, where the diffusion distance is short. The superficial cells, far removed from the source of nutrients, are either inert or dead.

The epidermis is dominated by **keratinocytes** (ke-RAT-i-no¯-s ¯ı ts), the body's most abundant epithelial cells. These cells, which form several layers, contain large amounts of the protein *keratin* (discussed shortly). **Thin skin** (Figure 5–2a,b•), which covers most of the body surface, contains four layers of keratinocytes, and is about as thick as the wall of a plastic sandwich bag (roughly

0.08 mm). **Thick skin** (Figure 5–2c•), which occurs on the palms of the hands and the soles of the feet, contains five layers and is about as thick as a standard paper towel (roughly 0.5 mm). Note that the terms *thick* and *thin* refer to the relative thickness of the epidermis, not to the integument as a whole. Next we examine the layers of the epidermis in greater detail.

Layers of the Epidermis

Figure 5–3• shows the layers of keratinocytes in a section of the epidermis in an area of thick skin. The boundaries between the layers are often difficult to see in a standard light micrograph. You will notice that the various layers have Latin names. The word *stratum* (plural, *strata*) means "layer"; the rest of the name refers to the function or appearance of the layer. The strata, in order from the basal lamina toward the free surface, are the *stratum germinativum*, the *stratum spinosum*, the *stratum granulosum*, the *stratum lucidum*, and the *stratum corneum*.

Stratum Germinativum

The innermost epidermal layer is the **stratum germinativum** (STRA-tum jer-mi-na-T

¯E

-vum), or *stratum basale* (see Figure 5–3•).

Hemidesmosomes attach the cells of this layer to the basal lamina that separates the epidermis from the areolar tissue of the adjacent dermis. l**p. 110** The stratum germinativum and the underlying dermis interlock, increasing the strength of the bond between the epidermis and dermis. The stratum germinativum forms **epidermal ridges**, which extend into the dermis and are adjacent to dermal projections called **dermal papillae** (singular, *papilla*; a nipple-shaped mound) that project into the epidermis (see Figure 5–2a•). These ridges and papillae are significant because the strength of the attachment is proportional to the surface area of the basal lamina: The more folds, the larger the surface area becomes.

The contours of the skin surface follow the ridge patterns, which vary from small conical pegs (in thin skin) to the complex whorls seen on the thick skin of the palms and soles. Ridges on the palms and soles increase the surface area of the skin and increase friction, ensuring a secure grip. Ridge shapes are genetically determined. The pattern of your epidermal ridges is unique and does not change during your lifetime. The ridge patterns on the tips of the fingers are the basis of fingerprints (Figure 5–4•), which have been used to identify individuals in criminal investigations for more than a century.

Large **basal cells**, or *germinative cells*, dominate the stratum germinativum. Basal cells are stem cells whose divisions replace the more superficial keratinocytes that are lost or shed at the epithelial surface. Skin surfaces that lack hair also contain specialized epithelial cells known as *Merkel cells* scattered among the cells of the stratum germinativum. Merkel cells are sensitive to touch; when compressed, they release chemicals that stimulate sensory nerve endings. (The skin contains many other kinds of sensory receptors, as we will see in later sections.) The brown tones of skin result from the synthetic activities of pigment cells called *melanocytes*, l**p. 120** which are distributed throughout the stratum germinativum, with cell processes extending into more superficial layers.

Stratum Spinosum

Each time a stem cell divides, one of the daughter cells is pushed superficial to the stratum germinativum into the **stratum spinosum** (see Figure 5–3•), which consists of 8 to 10

layers of keratinocytes bound together by desmosomes. l**p. 110** The name *stratum spinosum*, which means “spiny layer,” refers to the fact that the cells look like miniature pincushions in standard histological sections. They look that way because the keratinocytes were exposed to chemicals that shrank the cytoplasm but left the cytoskeletal elements and desmosomes intact. Some of the cells entering this layer from the stratum germinativum continue to divide, further increasing the thickness of the epithelium. The stratum spinosum also contains *Langerhans cells,* which participate in the immune response by stimulating a defense against (1) microorganisms that manage to penetrate the superficial layers of the epidermis and (2) superficial skin cancers. Langerhans cells and other cells of the immune response will be considered in Chapter
22.

Stratum Granulosum

The region superficial to the stratum spinosum is the **stratum granulosum**, or “grainy layer” (see Figure 5–3•). The stratum granulosum consists of three to five layers of keratinocytes displaced from the stratum spinosum. By the time cells reach this layer, most have stopped dividing and have started making large amounts of the proteins **keratin** (KER-a-tin; *keros*, horn) and **keratoh**
yalin (ker-a-t
¯o
-H

¯I

-a-lin). Keratin, a tough, fibrous protein, is the basic structural component of hair and nails in humans.

l**p. 112** As keratin fibers develop, the cells grow thinner and flatter, and their membranes thicken and become less permeable. Keratohyalin forms dense cytoplasmic granules that promote dehydration of the cell as well as aggregation and cross-linking of the keratin fibers. The nuclei and other organelles then disintegrate, and the cells die. Further dehydration creates a tightly interlocked layer of cells that consist of keratin fibers surrounded by keratohyalin.

Stratum Lucidum

In the thick skin of the palms and soles, a glassy **stratum lucidum** (“clear layer”) covers the stratum granulosum (see Figure 5–3•). The cells in the stratum lucidum are flattened, densely packed, and filled with keratin.

Stratum Corneum

At the exposed surface of both thick skin and thin skin is the **stratum corneum** (KOR-n ¯e -um; *cornu*, horn) (see Figure 5–3•). It normally contains 15 to 30 layers of keratinized cells. **Keratinization**, or *cornification*, is the formation of protective, superficial layers of cells filled with keratin. This process occurs on all exposed skin surfaces except the anterior surfaces of the eyes. The dead cells in each layer of the stratum corneum remain tightly interconnected by desmosomes. The connections are so secure that keratinized cells are generally shed in large groups or sheets rather than individually.

It takes 15 to 30 days for a cell to move from the stratum germinativum to the stratum corneum. The dead cells generally remain in the exposed stratum corneum for an additional two weeks before they are shed or washed away. This arrangement places the deeper portions of the epithelium and underlying tissues beneath a protective barrier of dead, durable, and expendable cells. Normally, the surface of the stratum corneum is relatively dry, so it is unsuitable for the growth of many microorganisms. Maintenance of this barrier involves coating the surface with lipid secretions from sebaceous glands.

The stratum corneum is water resistant, but not waterproof. Water from interstitial fluids slowly penetrates the surface, to be evaporated into the surrounding air. You lose roughly 500 ml (about 1 pt) of water in this way each day. The process is called **insensible perspiration**, because you are unable to see or feel the water loss. In contrast, you are usually very aware of the **sensible perspiration** produced by active sweat glands. Damage to the epidermis can increase the rate of insensible perspiration. If the damage breaks connections between superficial and deeper layers of the epidermis, fluid will accumulate in pockets, or *blisters*, within the epidermis. (Blisters also form between the epidermis and dermis if the basal lamina is damaged.) If damage to the stratum corneum reduces its effectiveness as a water barrier, the rate of insensible perspiration skyrockets, and a potentially dangerous fluid loss occurs. This is a serious consequence of severe burns and a complication in the condition known as *xerosis* (excessively dry skin). AM: Disorders of Keratin Production

When the skin is immersed in water, osmotic forces may move water into or out of the epithelium. l**p. 87** Sitting in a freshwater bath causes water to move into the epidermis, because fresh water is hypotonic (has fewer dissolved materials) compared with body fluids. The epithelial cells may swell to four times their normal volumes, a phenomenon particularly noticeable in the thickly keratinized areas of the palms and soles. Swimming in the ocean reverses the direction of osmotic flow; because the ocean is a hypertonic solution, water leaves the body, crossing the epidermis from the underlying tissues. The process is slow, but long-term exposure to seawater endangers survivors of a shipwreck by accelerating dehydration.

Concept Check

Dandruff is caused by excessive shedding of cells from the outer layer of skin in the scalp. Thus dandruff is composed of cells from which epidermal layer?

A splinter that penetrates to the third layer of the epidermis of the palm is lodged in which layer?

Why does swimming in fresh water for an extended period cause epidermal swelling?

Some criminals sand the tips of their fingers so as not to leave recognizable fingerprints. Would this practice permanently remove fingerprints? Why or why not?

Answers begin on p. A-1

The Basis of Skin Color

The color of your skin is a result of an interaction between (1) epidermal pigmentation and (2) the dermal circulation.

The Role of Epidermal Pigmentation

The epidermis contains variable quantities of two pigments: carotene and melanin. **Carotene** (KAR-uh-t n) is an orange-yellow pigment that normally accumulates in epidermal cells. It is most apparent in cells

e¯of the stratum corneum of light-skinned individuals, but it also accumulates in fatty tissues in the deep dermis and subcutaneous layer. Carotene is found in a variety of orange vegetables, such as carrots and squashes, and thus the skin of individuals with a special fondness for carrots can actually turn orange from an overabundance of carotenes. The color change is very striking in pale-skinned individuals, but less obvious in people with darker skin pigmentation. Carotene can be converted to vitamin A, which is required for both the normal maintenance of epithelia and the synthesis of photoreceptor pigments in the eye.

Melanin is a brown, yellow-brown, or black pigment produced by melanocytes, pigment cells introduced in Chapter 4. The **melanocytes** involved are located in the stratum germinativum, squeezed between or deep to the epithelial cells (Figure 5–5•). Melanocytes manufacture melanin from the amino acid *tyrosine*, and package it in intracellular vesicles called *melanosomes*. These vesicles travel within the processes of melanocytes and are transferred intact to keratinocytes. The transfer of pigmentation colors the keratinocyte temporarily, until the melanosomes are destroyed by fusion with lysosomes. In individuals with pale skin, this transfer occurs in the stratum germinativum and stratum spinosum, and the cells of more superfical layers lose their pigmentation. In dark-skinned people, the melanosomes are larger and the transfer may occur in the stratum granulosum as well; skin pigmentation is thus darker and more persistent.

The ratio of melanocytes to germinative cells ranges between 1 : 4 and 1 : 20, depending on the region of the body. The skin covering most areas of the body has about 1000 melanocytes per square millimeter. The cheeks and forehead, the nipples, and the genital region (the scrotum of males and the labia majora of females) have higher concentrations (about 2000 per square millimeter). The differences in skin pigmentation among individuals do not reflect different numbers of melanocytes, but merely different levels of synthetic activity. Even the melanocytes of *albino* individuals are distributed normally, although the cells are incapable of producing melanin. There can also be localized differences in the rates of melanin production by your melanocytes. *Freckles* are small pigmented areas on relatively pale skin. These spots, which typically have an irregular border, represent the areas serviced by melanocytes that are producing larger-than-average amounts of melanin. Freckles tend to be most abundant on surfaces such as the face, probably owing to its greater exposure to the sun. *Lentigos* are similar to freckles, but have regular borders and contain abnormal melanocytes. *Senile lentigos*, or *liver spots*, are variably pigmented areas that develop on sun-exposed skin in older individuals with pale skin.

The melanin in keratinocytes protects your epidermis and dermis from the harmful effects of sunlight, which contains significant amounts of **ultraviolet (UV) radiation**. A small amount of UV radiation is beneficial, because it stimulates the epidermal production of a compound required for calcium ion homeostasis (a process discussed in a later section). However, UV radiation can also damage DNA, causing mutations and promoting the development of cancer. Within keratinocytes, melanosomes become concentrated in the region around the nucleus, where the melanin pigments provide some UV protection for the DNA in those cells.

UV radiation can also produce some immediate effects—burns, which if severe can damage both the epidermis and the dermis. Thus, the presence of pigment layers in the epidermis helps protect both epidermal and dermal tissues. However, although melanocytes respond to UV exposure by increasing their activity, the response is not rapid enough to prevent sunburn the first day you spend at the beach. Melanin synthesis accelerates slowly, peaking about 10 days after the initial exposure. Individuals of any skin color can suffer sun damage to the integument, but dark-skinned individuals have greater initial protection against the effects of UV radiation.

Over time, cumulative damage to the integument by UV exposure can harm fibroblasts, causing impaired maintenance of the dermis. The resulting structural alterations lead to premature wrinkling. In addition, skin cancers can develop from chromosomal damage in germinative cells or melanocytes. One of the major consequences of the global depletion of the ozone layer in Earth's upper atmosphere is likely the sharp increase in the rates of skin cancers (such as *malignant melanoma*) that has been seen in recent years. Such increased cancer rates have been reported in Australia, which has already experienced a significant loss of ozone, as well as in the United States, Canada, and parts of Europe, which have experienced a more moderate ozone loss. For this reason, limiting UV exposure through a combination of protective clothing and sunscreens (or, better yet, sunblocks) is recommended during outdoor activities.

The Role of Dermal Circulation

Blood contains red blood cells filled with the pigment *hemoglobin*, which binds and transports oxygen in the bloodstream. When bound to oxygen, hemoglobin is bright red, giving capillaries in the dermis a reddish tint that is most apparent in lightly pigmented individuals. If those vessels are dilated, the red tones become much more pronounced. For example, your skin becomes flushed and red when your body temperature rises because the superficial blood vessels dilate so that the skin can act like a radiator and
lose heat. l**p. 12**

When its blood supply is temporarily reduced, the skin becomes relatively pale; a light-skinned individual who is frightened may "turn white" as a result of a sudden drop in blood supply to the skin. During a sustained reduction in circulatory supply, the oxygen levels in the tissues decline, and under these conditions hemoglobin releases oxygen and turns a much darker red. Seen

ı

from the surface, the skin then takes on a bluish coloration called **cyanosis** (s -uh-N skin color, cyanosis is most apparent in areas of very thin skin, such as the lips or beneath the nails. It can occur in response to extreme cold or as a result of cardiovascular or respiratory disorders, such as heart failure or severe asthma. Parenting guides often tell parents to watch for “blue lips,” because it is a sign that their young children are cold.

Because the skin is easily observed, changes in skin appearance can be useful in diagnosing diseases that primarily affect other body systems. Several diseases can produce secondary effects on skin color and pigmentation:

- In *jaundice* (JAWN-dis), the liver is unable to excrete bile, so a yellowish pigment accumulates in body fluids. In advanced stages, the skin and whites of the eyes turn yellow.
- Some tumors affecting the pituitary gland result in the secretion of large amounts of *melanocyte-stimulating hormone (MSH)*. This hormone causes a darkening of the skin, as if the individual has an extremely deep bronze tan.
- In *Addison’s disease*, the pituitary gland secretes large quantities of *adrenocorticotropic hormone (ACTH)*, which is structurally similar to MSH. The effect of ACTH on skin color is similar to that of MSH.

-sis; *kyanos*, blue). In individuals of any

¯I

In *vitiligo* (vit-i-L -g its incidence increases among individuals with thyroid gland disorders, Addison’s disease, or several other disorders. It is suspected that vitiligo develops when the immune defenses malfunction and antibodies attack normal melanocytes. The primary problem with vitiligo is cosmetic, especially for individuals with darkly pigmented skin.

The Epidermis and Steroid Production

Although too much sunlight can damage epithelial cells and deeper tissues, limited exposure to sunlight is beneficial. When exposed to ultraviolet radiation, epidermal cells in the stratum spinosum and stratum germinativum convert a cholesterol-related

¯o

), individuals lose their melanocytes. The condition develops in about 1 percent of the population, and

•

-le-kal-SIF-er-ol), or **vitamin D3.** The liver then converts cholecalciferol into an intermediary product used by the kidneys to synthesize the hormone **calcitriol** (kal-si-TR -ol). Calcitriol is essential for the normal absorption I¯

steroid into **cholecalciferol** (k

¯o

of calcium and phosphorus by the small intestine; an inadequate supply leads to impaired bone maintenance and growth.

The term *vitamin* is usually reserved for essential organic nutrients that must be obtained from the diet because the body either cannot make them or makes them in insufficient amounts. If present in the diet, cholecalciferol can be absorbed by the digestive tract, and if the skin cannot make enough cholecalciferol, a dietary supply will maintain normal bone development. Under these circumstances, dietary cholecalciferol acts like a vitamin, and this accounts for the alternative name for cholecalciferol: *vitamin D*3 . If cholecalciferol cannot be produced by the skin and is not included in the diet, bone development is abnormal and bone maintenance is inadequate. For example, children who live in areas with overcast skies and whose diet lacks cholecalciferol can have abnormal bone development. This condition, called *rickets*, has largely been eliminated in the United States because dairy companies add cholecalciferol, usually identified as “vitamin D,” to the milk sold in grocery stores. In Chapter 6, we will consider the hormonal control of bone growth in greater detail.

The Roles of Epidermal Growth Factor

Epidermal growth factor (EGF) is one of the peptide growth factors introduced in Chapter 3. l**p. 99** Although named for its effects on the epidermis, we now know that EGF has widespread effects on epithelia throughout the body, and that it is produced by the salivary glands and glands of the duodenum. Among the roles of EGF are the following:

- Promoting the divisions of germinative cells in the stratum germinativum and stratum spinosum
- Accelerating the production of keratin in differentiating keratinocytes
- Stimulating epidermal development and epidermal repair after injury
- Stimulating synthetic activity and secretion by epithelial glands

In the procedure known as tissue culture, cells are grown under laboratory conditions for experimental or therapeutic use. Epidermal growth factor has such a pronounced effect that it can be used in tissue culture to stimulate the growth and division of epidermal cells (or other epithelial cells). It is now possible to grow sheets of epidermal cells for use in the treatment of severe or extensive burns. The burned areas can be covered by epidermal sheets “grown” from a small sample of intact skin from another part of the burn victim’s body. (We will consider this treatment later in the chapter when we discuss burns.)

100 Keys | The epidermis is a multilayered, flexible, self-repairing barrier that prevents fluid loss, provides protection

from UV radiation, produces vitamin D3 , and resists damage from abrasion, chemicals, and pathogens.

Why does exposure to sunlight or sunlamps darken skin?

Why does the skin of a fair-skinned person appear red during exercise in hot weather?

In some cultures, women must be covered completely, except for their eyes, when they go outside. Explain why these women exhibit a high incidence of problems with their bones.

Answers begin on p. A-1

The Dermis

Objective

- Describe the structure and functions of the dermis.

The dermis lies between the epidermis and the subcutaneous layer (see Figure 5–1•, p. 154). In this section we will discuss the organization and properties of the dermis, and dermal circulation and innervation.

Dermal Organization

The dermis has two major components: (1) a superficial *papillary layer* and (2) a deeper *reticular layer* (see Figure 5–1•, p. 154).

The **papillary layer**, which consists of areolar tissue, contains the capillaries, lymphatics, and sensory neurons that supply the surface of the skin. The papillary layer derives its name from the dermal papillae that project between the epidermal ridges (see Figure 5–2a•, p. 155).

The **reticular layer**, deep to the papillary layer, consists of an interwoven meshwork of dense irregular connective tissue containing both collagen and elastic fibers. l**p. 123** Bundles of collagen fibers extend superficially beyond the reticular layer to blend into those of the papillary layer, so the boundary between the two layers is indistinct. Collagen fibers of the reticular layer also extend into the deeper subcutaneous

layer. In addition to extracellular protein fibers, the dermis contains all the cells of connective tissue proper. l**p. 119–123** Accessory organs of epidermal origin, such as hair follicles and sweat glands, extend into the dermis. In addition, the reticular and papillary layers of the dermis contain networks of blood vessels, lymph vessels, and nerve fibers (see Figure 5–1•).

Because of the abundance of sensory receptors in the skin, regional infection or inflammation can be very painful. **Dermatitis** (der-muh-T -tis) is an inflammation of the skin that primarily involves the papillary layer. The inflammation typically begins

I¯in a part of the skin exposed to infection or irritated by chemicals, radiation, or mechanical stimuli. Dermatitis may cause no discomfort, or it may produce an annoying itch, as in poison ivy. Other forms of the condition can be quite painful, and the inflammation can spread rapidly across the entire integument. AM: Dermatitis

Dermal Strength and Elasticity

The presence of two types of fibers—*collagen fibers*, which are very strong and resist stretching but are easily bent or twisted, and *elastic fibers*, which permit stretching and then recoil to their original length—enables the dermis to tolerate limited stretching. The elastic fibers provide flexibility, and the collagen fibers limit that flexibility to prevent damage to the tissue.

The water content of the skin also helps maintain its flexibility and resilience, properties collectively known as *skin turgor*. One of the symptoms of dehydration is the loss of skin turgor, revealed by pinching the skin on the back of the hand. A dehydrated dermis will remain peaked when pinched, whereas hydrated skin will flatten out. Aging, hormones, and the destructive effects of ultraviolet radiation permanently reduce the amount of elastin in the dermis; the result is wrinkles and sagging skin. The extensive distortion of the dermis that occurs over the abdomen during pregnancy or after substantial weight gain can exceed the elastic capabilities of the skin. The resulting damage to the dermis prevents it from recoiling to its original size after delivery or weight loss. The skin then wrinkles and creases, creating a network of **stretch marks**.

Tretinoin (Retin-A) is a derivative of vitamin A that can be applied to the skin as a cream or gel. This drug was originally developed to treat acne, but it also increases blood flow to the dermis and stimulates dermal repair. As a result, the rate of wrinkle formation decreases, and existing wrinkles become smaller. The degree of improvement varies among individuals.

Lines of Cleavage

Most of the collagen and elastic fibers at any location are arranged in parallel bundles oriented to resist the forces applied to the skin during normal movement. The resulting pattern of fiber bundles establishes **lines of cleavage** of the skin (Figure 5–7•). Lines of cleavage are clinically significant: A cut parallel to a cleavage line will usually remain closed and heal with little scarring, whereas a cut at right angles to a cleavage line will be pulled open as severed elastic fibers recoil and will result in greater scarring. For these reasons, surgeons choose to make neat incisions parallel to the lines of cleavage.

The Dermal Blood Supply

Arteries supplying the skin form networks in the subcutaneous layer along its border with the reticular layer of the dermis. This network is called the *cutaneous plexus* (Figure 5–8•). Tributaries of these arteries supply both the adipose tissues of the subcutaneous layer and the tissues of the integument. As small arteries travel toward the epidermis, branches supply the hair follicles, sweat glands, and other structures in the dermis. On reaching the papillary layer, the small arteries form another branching network, the *papillary plexus*, which provides arterial blood to capillary loops that follow the contours of the epidermis–dermis boundary (see Figure 5–8•). These capillaries empty into a network of small veins that form a venous plexus deep to the papillary plexus. This network is in turn connected to a larger venous plexus in the subcutaneous layer. Trauma to the skin often results in a *contusion*, or bruise. As a result of the rupture of dermal blood vessels, blood leaks into the dermis, and the area develops the familiar "black and blue" color. AM: Drug Absorption through the Skin

Clinical Note

Problems with dermal circulation affect both the epidermis and the dermis. An *ulcer* is a localized shedding of an epithelium. *Decubitis ulcers*, or
bedsores, affect patients whose circulation is restricted, especially when a splint, a cast, or lying in bed continuously compresses superficial blood
vessels. Such sores most commonly affect the skin covering joints or bony prominences, where dermal blood vessels are pressed against deeper
structures. The chronic lack of circulation kills epidermal cells, removing a barrier to bacterial infection; eventually, dermal tissues deteriorate as
well. (Cell death and tissue destruction, or *necrosis*, can occur in any tissue deprived of adequate blood flow.) Bedsores can be prevented or treated

by frequently changing the position of the body, to vary the pressures applied to local blood vessels.

Innervation of the Skin

The integument is filled with sensory receptors, and anything that comes in contact with the skin—from the lightest touch of a mosquito to the weight of a loaded backpack—initiates a nerve impulse that can reach our conscious awareness. Nerve fibers in the skin control blood flow, adjust gland secretion rates, and monitor sensory receptors in the dermis and the deeper layers of the epidermis. We have already noted that the deeper layers of the epidermis contain Merkel cells; these cells are monitored by sensory terminals known as *tactile discs*. The epidermis also contains the extensions of sensory neurons that provide sensations of pain and temperature. The dermis contains similar receptors, as well as other, more specialized receptors. Examples shown in Figure 5–1• include receptors sensitive to light touch—*tactile corpuscles*, located in dermal papillae—and receptors sensitive to deep pressure and vibration—*lamellated corpuscles*, in the reticular layer.

Even this partial list of the receptors found in the skin is enough to highlight the importance of the integument as a sensory structure. We will return to this topic in Chapter 15, where we consider not only what receptors are present, but how they function.

100 Keys | The dermis provides mechanical strength, flexibility, and protection for underlying tissues. It is highly vascular and contains a variety of sensory receptors that provide information about the external environment.

Concept Check

Where are the capillaries and sensory neurons that supply the epidermis located?

What accounts for the ability of the dermis to undergo repeated stretching?

Answers begin on p. A-1

The Subcutaneous Layer

Objective

- Describe the structure and functions of the subcutaneous layer.

The connective tissue fibers of the reticular layer are extensively interwoven with those of the subcutaneous layer, or **hypodermis**. The boundary between the two is generally indistinct (see Figure 5–1•, p. 154). Although the subcutaneous layer is not a part of the integument, it is important in stabilizing the position of the skin in relation to underlying tissues, such as skeletal muscles or other organs, while permitting independent movement.

The subcutaneous layer consists of areolar and adipose tissues and is quite elastic. Only its superficial region contains large arteries and veins. The venous circulation of this region contains a substantial amount of blood, and much of this volume will shift to the general circulation if these veins constrict. For that reason, the skin is often described as a *blood reservoir*. The rest of the subcutaneous layer contains a limited number of capillaries and no vital organs. This last characteristic makes **subcutaneous injection—**by means of a **hypodermic needle—**a useful method of administering drugs.

Most infants and small children have extensive “baby fat,” which provides extra insulation and helps reduce heat loss. Subcutaneous fat also serves as a substantial energy reserve and as a shock absorber for the rough-and-tumble activities of our early years. As we grow, the distribution of subcutaneous fat changes. The greatest changes occur in response to circulating sex hormones. Beginning at puberty, men accumulate subcutaneous fat at the neck, on the arms, along the lower back, and over the buttocks. In contrast, women accumulate subcutaneous fat at the breasts, buttocks, hips, and thighs. In adults of either gender, the subcutaneous layer of the backs of the hands and the upper surfaces of the feet contain few fat cells, whereas distressing amounts of adipose tissue can accumulate in the abdominal region, producing a prominent “potbelly.”

Clinical Note

The accumulation of excessive amounts of adipose tissue increases the risks of diabetes, stroke, and other serious conditions. Dietary restrictions and increased activity levels are often successful in promoting weight loss and reducing these risks. However, a “quick fix” is often promised by a

surgical procedure called **liposuction**. In this procedure, subcutaneous adipose tissue is removed through a tube inserted deep to the skin.

Adipose tissue tears relatively easily, and suction applied to the tube rips chunks of adipose tissue from the body. After liposuction, the skin is loose fitting, and until it recoils, a tight-fitting garment is usually worn. Liposuction is relatively common and is increasing in popularity. In 2002, an estimated 373,000 liposuction procedures were performed in the United States.

Although it might sound like an easy way to remove unwanted fat, in practice liposuction can be dangerous. There are risks from anesthesia, bleeding (adipose tissue is quite vascular), infection, and fluid loss. The death rate from liposuction procedures is 1 in 5000, very high for what is basically cosmetic surgery that provides only a temporary solution to a chronic problem. As noted in Chapter 4, unless there are changes in diet and lifestyle, the damaged adipose tissue will repair itself, and areas of areolar tissue will convert to adipose tissue. Over time, the surgery will have to be repeated.

Accessory Structures

Objectives

- Describe the mechanisms of hair production, and explain the structural basis for hair texture and color.
- Discuss the various kinds of glands in the skin and the secretions of each.
- Explain how the sweat glands play a major role in regulating body temperature.
- Describe the anatomical structure of nails, and explain how they are formed.

The accessory structures of the integument include hair and hair follicles, sebaceous and sweat glands, and nails. During embryological development, these structures originate from the epidermis, so they are also known as *epidermal derivatives*. Although located in the dermis, they project through the epidermis to the integumentary surface. ATLAS: Embryology Summary 5: The Development of the Integumentary System

Hair and Hair Follicles

Hairs project above the surface of the skin almost everywhere, except over the sides and soles of the feet, the palms of the hands, the sides of the fingers and toes, the lips, and portions of the external genitalia. The human body has about 2.5 million hairs, and 75 percent of them are on the general body surface, not on the head. Hairs are nonliving structures produced in organs called **hair follicles**.

The hairs and hair follicles on your body have important functions. The roughly 500,000 hairs on your head protect your scalp from ultraviolet radiation, help cushion light blows to the head, and insulate the skull. The hairs guarding the entrances to your nostrils and external ear canals help prevent the entry of foreign particles and insects, and your eyelashes perform a similar function for the surface of the eye. However, hairs are also extremely important as sensory receptors.

Figure 5–9• illustrates important details about the structure of hairs and hair follicles. Each hair follicle opens onto the surfaces of the epidermis but extends deep into the dermis and usually into the subcutaneous layer. Deep to the epidermis, each follicle is wrapped in a dense connective tissue sheath. A **root hair plexus** of sensory nerves surrounds the base of each hair follicle (Figure 5–9a•). As a result, you can feel the movement of the shaft of even a single hair. This sensitivity provides an early-warning system that may help prevent injury; for example, you may be able to swat a mosquito before it reaches your skin.

A bundle of smooth muscle cells forms the **arrector pili** (a-REK-tor PI-l ; plural, *arrectores pilorum*), muscle, which extends from the papillary layer of the dermis to the connective tissue sheath surrounding the hair follicle. When stimulated, the arrector pili muscle contracts, pulling on the follicle and forcing the hair to stand erect. Contraction may be the result of emotional states, such as fear or rage, or a response to cold, producing “goose bumps.” In a furry mammal, this action increases the thickness of its insulating coat. Although humans do not receive any comparable insulating benefits, the response persists.

Hair Structure

Each hair is a long, cylindrical structure that extends outward, past the epidermal surface (Figure 5–9a,b•). The **hair root**—the portion that anchors the hair into the skin—begins at the base of the hair, at the *hair bulb*, and extends distally to the point at which the internal organization of the hair is complete, about halfway to the skin surface. The **hair shaft**, part of which we see on the surface, extends from this halfway point to the exposed tip of the hair.

Hair Production

Hair production begins at the base of a hair follicle (Figure 5–9b,c•). Here a mass of epithelial cells forms a cap, called the **hair**

¯e

bulb, that surrounds a small **hair papilla**, a peg of connective tissue containing capillaries and nerves. The superficial cells of the hair bulb are responsible for producing the hair; they form a layer called the **hair matrix**. Basal cells near the center of the hair matrix divide, producing daughter cells that are gradually pushed toward the surface. Daughter cells closest to the center of the matrix form the **medulla**, or core, of the hair. Daughter cells farther from the center of the hair matrix form the **cortex**, an intermediate layer. Those at the edges of the hair matrix form the **cuticle**, which will be the surface of the hair.

As cell divisions continue at the hair matrix, the daughter cells are pushed toward the surface of the skin, and the hair gets longer. Keratinization is completed by the time these cells approach the surface. At this level, which corresponds to the start of the hair shaft, the cells of the medulla, cortex, and cuticle are dead, and the keratinization process is at an end. The medulla contains a flexible **soft keratin**; the cortex and cuticle contain thick layers of **hard keratin**, which give the hair its stiffness. The cuticle consists of overlapping layers of dead, flattened, heavily keratinized cells.

The epithelial cells of the follicle walls are organized into several concentric layers (see Figure 5–9c,d•). Moving outward from the hair cuticle, these layers include:

- The **internal root sheath**, which surrounds the hair root and the deeper portion of the shaft. The internal root sheath is produced by the cells at the periphery of the hair matrix. The cells of this sheath disintegrate quickly. This layer does not extend the entire length of the follicle.
- The **external root sheath**, which in longitudinal section extends from the skin surface to the hair matrix. Over most of that distance, it has all the cell layers found in the superficial epidermis. However, where the external root sheath joins the hair matrix, all the cells resemble those of the stratum germinativum.
- The **glassy membrane**, a thickened basal lamina wrapped in a dense connective tissue sheath. This membrane is in contact with the surrounding connective tissues of the dermis.

The Hair Growth Cycle

Hairs grow and are shed according to a **hair growth cycle**. A hair in the scalp grows for two to five years, at a rate of about 0.33 mm per day. Variations in the growth rate and in the duration of the hair growth cycle account for individual differences in the length of uncut hair.

While hair is growing, the cells of the hair root absorb nutrients and incorporate them into the hair structure. As a result, clipping or collecting hair for analysis can be helpful in diagnosing several disorders. For example, hairs of individuals with lead poisoning or other heavy-metal poisoning contain high levels of those metal ions. Hair samples containing nucleated cells can also

be used for identification purposes through DNA fingerprinting. l**p. 80**

As it grows, the root is firmly attached to the matrix of the follicle. At the end of the growth cycle, the follicle becomes inactive. The hair is now termed a **club hair**. The follicle gets smaller, and over time the connections between the hair matrix and the club hair root break down. When another cycle begins, the follicle produces a new hair; the old club hair is pushed to the surface and is shed.

If you are a healthy adult, you lose about 50 hairs from your head each day. Sustained losses of more than 100 hairs per day generally indicate that a net loss of hairs is under way, and noticeable hair loss will eventually result. Temporary increases in hair loss can result from drugs, dietary factors, radiation, an excess of vitamin A, high fever, stress, or hormonal factors related to pregnancy. In males, changes in the level of the sex hormones circulating in the blood can affect the scalp, causing a shift from terminal to vellus hair production, beginning at the temples and the crown of the head. This alteration is called *male pattern baldness*. Some cases of male pattern baldness respond to drug therapies, such as the topical application of *minoxidyl (Rogaine)*. AM: Baldness and Hirsutism

Types of Hairs

Hairs first appear after roughly three months of embryonic development. These hairs, collectively known as *lanugo* (la-NOO-gō), are extremely fine and unpigmented. Most lanugo hairs are shed before birth. They are replaced by one of two types of hairs in the adult integument: vellus hairs or terminal hairs. **Vellus hairs** are the fine “peach fuzz” hairs located over much of the body surface. **Terminal hairs** are heavy, more deeply pigmented, and sometimes curly. The hairs on your head, including your eyebrows and eyelashes, are terminal hairs that are present throughout life. Hair follicles may alter the structure of the hairs in response to circulating hormones. For example, vellus hairs are present at the armpits, pubic area, and limbs until puberty; thereafter, the follicles produce terminal hairs, in response to circulating sex hormones.

Hair Color

Variations in hair color reflect differences in structure and variations in the pigment produced by melanocytes at the hair papilla. Different forms of melanin give a dark brown, yellow-brown, or red color to the hair. These structural and biochemical characteristics are genetically determined, but hormonal and environmental factors also influence the condition of your hair. As pigment production decreases with age, hair color lightens. White hair results from the combination of a lack of pigment and the presence of air bubbles in the medulla of the hair shaft. As the proportion of white hairs increases, the individual’s overall hair color is described as gray. Because hair itself is dead and inert, any changes in its coloration are gradual. We are able to change our hair color by using harsh chemicals that disrupt the cuticle and permit dyes to enter and stain the cortex and medulla. These color treatments damage the hair by disrupting the protective cuticle layer and dehydrating and weakening the hair shaft. As a result, the hair becomes thin and brittle. Cream rinses, conditioners, and oil treatments attempt to reduce the effects of this structural damage by rehydrating and recoating the shaft.

Concept Check

What happens when the arrector pili muscle contracts?

Once a burn on the forearm that destroys the epidermis and extensive areas of the deep dermis heals, will hair grow again in the affected area?

Answers begin on p. A-1

Glands in the Skin

The skin contains two types of exocrine glands: *sebaceous glands* and *sweat glands*.

Sebaceous (Oil) Glands

Sebaceous (se-BA¯-shus) **glands**, or *oil glands*, are holocrine glands that discharge an oily lipid secretion into hair follicles (Figure 5–10•). Sebaceous glands that communicate with a single follicle share a duct and thus are classified as simple branched alveolar glands. l**p. 117** The gland cells produce large quantities of lipids as they mature. The lipid product is released through holocrine secretion, a process that involves the rupture of the secretory cells. l**p. 117**

The lipids released from gland cells enter the lumen (open passageway) of the gland. The arrector pili muscles that erect the hair then contract, squeezing the sebaceous gland and forcing the lipids into the hair follicle and onto the surface of the skin. The secreted lipid product, called **sebum** (SE¯-bum), is a mixture of triacylglycerides, cholesterol, proteins, and electrolytes. Sebum inhibits the growth of bacteria, lubricates and protects the keratin of the hair shaft, and conditions the surrounding skin. Keratin is a tough protein, but dead, keratinized cells become dry and brittle once exposed to the environment. It is interesting to reflect on our custom of washing and shampooing to remove the oily secretions of sebaceous glands, only to add other lipids to the hair in the form of conditioners, and to the skin in the form of creams and lotions.

Sebaceous follicles are large sebaceous glands that are not associated with hair follicles; their ducts discharge sebum directly onto the epidermis (see Figure 5–10•). Sebaceous follicles are located on the face, back, chest, nipples, and external genitalia.

Surprisingly, sebaceous glands are very active during the last few months of fetal development. Their secretions, mixed with shed epidermal cells, form a protective superficial layer—the *vernix caseosa*—that coats the skin surface. Sebaceous gland activity all but ceases after birth, but it increases again at puberty in response to rising levels of sex hormones.

Seborrheic dermatitis is an inflammation around abnormally active sebaceous glands, most often those of the scalp. The affected area becomes red, and some epidermal scaling usually occurs. In infants, mild cases are called *cradle cap*. Seborrheic dermatitis is a common cause of dandruff in adults. Anxiety, stress, and food allergies can aggravate the problem.

AM: Folliculitis and Acne

Sweat Glands

The skin contains two types of sweat glands, or **sudoriferous glands:** *apocrine sweat glands* and *merocrine sweat glands* (Figure 5–11•).

Apocrine Sweat Glands In the armpits (axillae), around the nipples, and in the pubic region, **apocrine sweat glands** secrete their products into hair follicles (Figure 5–11a•). These coiled, tubular glands produce a sticky, cloudy, and potentially odorous secretion. The name *apocrine* was originally chosen because it was thought the gland cells use an apocrine method of secretion.

l**p. 116** Although we now know that they rely on merocrine secretion, the name has not changed.

Apocrine sweat glands begin secreting at puberty. The sweat produced is a nutrient source for bacteria, which intensify its odor. Surrounding the secretory cells in these glands are special **myoepithelial cells** (*myo-*, muscle), which by contracting squeeze the gland and discharge the accumulated secretion into the hair follicles. The secretory activities of the gland cells and the contractions of myoepithelial cells are controlled by the nervous system and by circulating hormones.

Merocrine (Eccrine) Sweat Glands Merocrine sweat glands are, also known as **eccrine** (EK-rin) **sweat glands.** These are coiled, tubular glands that discharge their secretions directly onto the surface of the skin (see Figure 5–11b•). Eccrine sweat glands are far more numerous and widely distributed than apocrine sweat glands. The adult integument contains 2–5 million merocrine sweat glands, which are smaller than apocrine sweat glands and do not extend as deeply into the dermis. The palms and soles have the highest numbers, with the palm possessing an estimated 500 merocrine sweat glands per square centimeter (3000 per square inch).

As noted earlier, the sweat produced by merocrine sweat glands is called sensible perspiration. Sweat is 99 percent water, but it also contains some electrolytes (chiefly sodium chloride), a number of organic nutrients, a peptide with antibiotic properties, and various waste products. It has a pH of 4.0–6.8, and the presence of sodium chloride gives sweat a salty taste. (See Appendix IV for a complete analysis of the composition of normal sweat.)

The functions of merocrine sweat gland activity include the following:

- **Cooling the Surface of the Skin to Reduce Body Temperature.** This is the primary function of sensible perspiration. The degree of secretory activity is regulated by neural and hormonal mechanisms; when all the merocrine sweat glands are working at their maximum, the rate of perspiration can exceed a gallon per hour, and dangerous fluid and electrolyte losses can occur. For this reason, athletes participating in endurance sports must drink fluids at regular intervals.
- **Excreting Water and Electrolytes.** A number of ingested drugs are excreted as well.

- **Providing Protection from Environmental Hazards.** Sweat dilutes harmful chemicals in contact with the skin and discourages the growth of microorganisms in two ways: (1) by either flushing them from the surface or making it difficult for them to adhere to the epidermal surface, and (2) through the action of *dermicidin*, a small peptide that has powerful antibiotic properties.

Other Integumentary Glands

As we have seen, merocrine sweat glands are widely distributed across the body surface, sebaceous glands are located wherever there are hair follicles, and apocrine sweat glands are located in relatively restricted areas. The skin also contains a variety of specialized glands that are restricted to specific locations. Two examples of particular importance are the following:

1. The **mammary glands** of the breasts are anatomically related to apocrine sweat glands. A complex interaction between sex hormones and pituitary hormones controls their development and secretion. We will discuss mammary gland structure and function in Chapter 28.

2. Ceruminous (se-ROO-mi-nus) **glands** are modified sweat glands in the passageway of the external ear. Their secretions combine with those of nearby sebaceous glands, forming a mixture called **cerumen**, or earwax. Together with tiny hairs along the ear canal, earwax helps trap foreign particles, preventing them from reaching the eardrum.

Control of Glandular Secretions and the Homeostatic Role of the Integument

The autonomic nervous system (ANS) controls the activation and deactivation of sebaceous glands and apocrine sweat glands at the subconscious level. Regional control is not possible; the commands issued by the ANS affect all the glands of that type, everywhere on the body surface. Merocrine sweat glands are much more precisely controlled, and the amount of secretion and the area of the body involved can vary independently. For example, when you are nervously awaiting an anatomy and physiology exam, only your palms may begin to sweat.

As we noted earlier, the primary function of sensible perspiration is to cool the surface of the skin and to reduce body temperature. When the environmental temperature is high, this is a key component of *thermoregulation*, the process of maintaining temperature homeostasis. When you sweat in the hot sun, all your merocrine glands are working together. The blood vessels beneath your epidermis are dilated and filled with blood, your skin reddens, and the surface of your skin is warm and wet. As the moisture evaporates, your skin cools. If your body temperature subsequently falls below normal, sensible perspiration ceases, blood flow to the skin is reduced, and the skin surface cools and dries, releasing little heat into the environment. Chapter 1 introduced the negative feedback mechanisms of thermoregulation (pp. 12–13); additional details will be found in Chapter 25.

100 Keys | The skin plays a major role in controlling body temperature by acting as a radiator. The heat delivered by the dermal circulation is removed primarily by the evaporation of sensible perspiration.

Concept Check

What are the functions of sebaceous secretions?

Deodorants are used to mask the effects of secretions from which type of skin gland?

Which type of skin gland is most affected by the hormonal changes that occur during puberty?

Answers begin on p. A-1

Nails

Nails protect the exposed dorsal surfaces of the tips of the fingers and toes (Figure 5–12a•). They also help limit distortion of the digits when they are subjected to mechanical stress—for example, when you run or grasp objects. The **nail body**, the visible portion of the nail, covers an area of epidermis called the **nail bed** (Figure 5–12b•). The nail body is recessed deep to the level of the surrounding epithelium and is bounded on either side by **lateral**

nail grooves (depressions) and **lateral nail folds**. The **free edge** of the nail—the distal portion that continues past the nail bed—extends over the **hyponychium**

(h -p

Nail production occurs at the **nail root**, an epidermal fold not visible from the surface. The deepest portion of the nail root lies very close to the bone of the fingertip. A portion of the stratum corneum of the nail root extends over the exposed nail, form

–

ı

¯o

-NIK-

¯e

-um), an area of thickened stratum corneum (Figure 5–12c•).

ing the **eponychium** (ep-

¯o

-NIK-

¯e

-um; *epi*-, over + *onyx*, nail), or **cuticle**. Underlying blood vessels give the nail its characteristic pink color. Near the root, these vessels may be obscured, leaving a pale crescent known as the **lunula** (LOO-n

¯u

-la; *luna*, moon)

(see Figure 5–12a•).

The body of the nail consists of dead, tightly compressed cells packed with keratin. The cells producing the nails can be affected by conditions that alter body metabolism, so changes in the shape, structure, or appearance of the nails can provide useful diagnostic information. For example, the nails may turn yellow in individuals who have chronic respiratory disorders, thyroid gland disorders, or AIDS. Nails may become pitted and distorted as a result of *psoriasis* (a condition marked by rapid stem cell division in the stratum germinativum) and concave as a result of some blood disorders. AM: Disorders of Keratin Production

The Response of the Integument to Injury

Objective

- Explain how the skin responds to injury and repairs itself.

The integumentary system displays a significant degree of functional independence—it often responds directly and automatically to local influences without the involvement of the nervous or endocrine systems. For example, when the skin is continually subjected to mechanical stresses, stem cells in the stratum germinativum divide more rapidly, and the depth of the epithelium increases. That is why calluses form on your palms when you perform manual labor. A more dramatic display of local regulation can be seen after an injury to the skin.

Repair of Localized Injuries to the Skin

The skin can regenerate effectively, even after considerable damage has occurred, because stem cells persist in both the epithelial and connective tissue components. Germinative cell divisions replace lost epidermal cells, and mesenchymal cell divisions replace lost dermal cells. The process can be slow. When large surface areas are involved, problems of infection and fluid loss complicate the situation. The relative speed and effectiveness of skin repair vary with the type of wound involved. A slender, straight cut, or *incision,* may heal relatively quickly compared with a deep scrape, or *abrasion*, which involves a much greater surface area to be repaired. AM: Trauma to the Skin

Figure 5–13• illustrates the four stages in the regeneration of the skin after an injury. When damage extends through the epidermis and into the dermis, bleeding generally occurs (STEP 1). The blood clot, or **scab**, that forms at the surface temporarily restores the integrity of the epidermis and restricts the entry of additional microorganisms into the area (STEP 2). The bulk of the clot consists of an insoluble network of *fibrin,* a fibrous protein that forms from blood proteins during the clotting response. The clot's color reflects the presence of trapped red blood cells. Cells of the stratum germinativum undergo rapid divisions and begin to migrate along the edges of the wound in an attempt to replace the missing epidermal cells. Meanwhile, macrophages patrol the damaged area of the dermis, phagocytizing any debris and pathogens.

If the wound occupies an extensive area or involves a region covered by thin skin, dermal repairs must be under way before epithelial cells can cover the surface. Divisions by fibroblasts and mesenchymal cells produce mobile cells that invade the deeper areas of injury. Endothelial cells of damaged blood vessels also begin to divide, and capillaries follow the fibroblasts, enhancing circulation. The combination of blood clot, fibroblasts, and an extensive capillary network is called **granulation tissue**.

Over time, deeper portions of the clot dissolve, and the number of capillaries declines. Fibroblast activity leads to the appearance of collagen fibers and typical ground substance (STEP 3). The repairs do not restore the integument to its original condition, however, because the dermis will contain an abnormally large number of collagen fibers and relatively few blood vessels. Severely damaged hair follicles, sebaceous or sweat glands, muscle cells, and nerves are seldom repaired, and they too are replaced by fibrous tissue. The formation of this rather inflexible, fibrous, noncellular **scar tissue** completes the repair process but fails to restore the tissue to its original condition (STEP 4).

We do not know what regulates the extent of scar tissue formation, and the process is highly variable. For example, surgical procedures performed on a fetus do not leave scars, perhaps because damaged fetal tissues do not produce the same types of growth factors that adult tissues do. In some adults, most often those with dark skin, scar tissue formation may continue beyond the requirements of tissue repair. The result is a thickened mass of scar tissue that begins at the site of injury and grows into the sur

rounding dermis. This thick, raised area of scar tissue, called a **keloid** (KE¯-loyd), is covered by a shiny, smooth epidermal surface. Keloids most commonly develop on the upper back, shoulders, anterior chest, or earlobes. They are harmless; in fact, some aboriginal cultures intentionally produce keloids as a form of body decoration.

In fact, people in societies around the world adorn the skin with culturally significant markings of one kind or another. Tattoos, piercings, keloids and other scar patterns, and even high-fashion makeup are all used to “enhance” the appearance of the integument. Scarification is performed in several African cultures, resulting in a series of complex, raised scars on the skin. Polynesian cultures have long preferred tattoos as a sign of status and beauty. A dark pigment is inserted deep within the dermis of the skin by tapping on a needle, shark tooth, or bit of bone. Because the pigment is inert, if infection does not occur (a potentially serious complication), the markings remain for the life of the individual, clearly visible through the overlying epidermis. American popular culture has recently rediscovered tattoos as a fashionable form of body adornment. The colored inks that are commonly used are less durable than those used by the Polynesians, and today’s tattoos can gradually fade or lose their definition.

Tattoos can now be partially or completely removed. The removal process takes time (10 or more sessions may be required to remove a large tattoo), and scars often remain. To remove the tattoo, an intense, narrow beam of light from a laser breaks down the ink molecules in the dermis. Each blast of the laser that destroys the ink also burns the surrounding dermal tissue. Although the burns are minor, they accumulate and result in the formation of localized scar tissue.

Concept Check

What do you call the combination of fibrin clots, fibroblasts, and the extensive network of capillaries in healing tissue?

Why can skin regenerate effectively even after considerable damage?

Answers begin on p. A-1

Aging and the Integumentary System

Objective

- Summarize the effects of the aging process on the skin.

Aging affects all the components of the integumentary system:

- The epidermis thins as germinative cell activity declines, making older people more prone to injury and skin infections.
- The number of Langerhans cells decreases to about 50 percent of levels seen at maturity (roughly age 21). This decrease may reduce the sensitivity of the immune system and further encourage skin damage and infection.
- Vitamin D_3 production declines by about 75 percent. The result can be reduced calcium and phosphate absorption, eventually leading to muscle weakness and a reduction in bone strength and density.
- Melanocyte activity declines, and in light-skinned individuals the skin becomes very pale. With less melanin in the skin, people become more sensitive to exposure to the sun and more likely to experience sunburn.
- Glandular activity declines. The skin becomes dry and often scaly, because sebum production is reduced. Merocrine sweat glands are also less active, and with impaired perspiration, older people cannot lose heat as fast as younger people can. Thus, the elderly are at greater risk of overheating in warm environments.
- The blood supply to the dermis is reduced. Reduction in blood flow makes the skin become cool, which in turn can stimulate thermoreceptors, making a person feel cold even in a warm room. However, because reduced circulation and sweat gland function in the elderly lessens their ability to lose body heat, overexertion or exposure to high temperatures (such as those in a sauna or hot tub) can cause body temperatures to soar dangerously high.

- Hair follicles stop functioning or produce thinner, finer hairs. With decreased melanocyte activity, these hairs are gray or white.
- The dermis thins, and the elastic fiber network decreases in size. The integument therefore becomes weaker and less resilient, and sagging and wrinkling occur. These effects are most pronounced in areas of the body that have been exposed to the sun.
- With changes in levels of sex hormones, secondary sexual characteristics in hair and body-fat distribution begin to fade. As a consequence, people age 90–100 of both sexes tend to look alike.
- Skin repairs proceed more slowly. Thus, whereas repairs to an uninfected blister might take three to four weeks in a young adult, the same repairs could take six to eight weeks at age 65–75. And because healing occurs more slowly, recurring infections may result.

Concept Check

Older individuals do not tolerate the summer heat as well as they did when they were young, and they are more prone to heat-related illness. What accounts for these changes?

Answers begin on p. A-1

Integration with Other Systems

The integumentary system forms the external surface of the body and provides protection from dehydration, environmental chemicals, and impacts. The integument is separated and insulated from the rest of the body by the subcutaneous layer, but is interconnected with the rest of the body by an extensive circulatory network of blood and lymphatic vessels and is richly supplied with sensory nerve endings. As a result, although the protective mechanical functions of the skin can be discussed independently, its physiological activities are always closely integrated with those of other systems.

Figure 5–15• reviews the components and functions of the integumentary system and diagrams the major functional relationships between that system and other systems.

Clinical Patterns

Because the skin is the most visible organ of the body, abnormalities are easily recognized. A bruise, for example, is typically a swollen and discolored area where the walls of blood vessels have been damaged. Changes in skin color, skin tone, and the overall condition of the skin commonly accompany illness or disease and can assist in the diagnosis of conditions involving other systems. For example, extensive bruising without any obvious cause may indicate a blood-clotting disorder; yellowish skin and mucous membranes may signify *jaundice*, which generally indicates some type of liver disorder. The general condition of the skin can also be significant. In addition to color changes, changes in the flexibility, elasticity, dryness, or sensitivity of the skin commonly follow malfunctions in other organ systems.

The *Applications Manual* [AM] discusses the diagnosis and treatment of major conditions affecting the integumentary system.

Chapter Review

Selected Clinical Terminology

basal cell carcinoma: A skin cancer caused by malignant stem cells within the stratum germinativum. (p. 160)

cutaneous anthrax: An infection resulting when spores of the anthrax bacterium enter a break in the skin. [AM]

cyanosis: Bluish skin color as a result of reduced oxygenation of the blood in superficial vessels. (p. 159)

decubitis ulcers *(bedsores)***:** Ulcers that occur in areas subject to restricted circulation; are especially common in bedridden people.

(p. 163) **dermatitis:** An inflammation of the skin that primarily involves the papillary region of the dermis. (p. 162) **granulation tissue:** A combination of fibrin, fibroblasts, and capillaries that forms during tissue repair after inflammation. (p. 171) **hypodermic needle:** A needle used to administer drugs via subcutaneous injection. (p. 163) **keloid:** A thickened area of scar tissue covered by a shiny, smooth epidermal surface. (p. 171) **male pattern baldness:** Hair loss in an adult male due to changes in levels of circulating sex hormones. (p. 166) **malignant melanoma:** A skin cancer originating in melanocytes. (p. 160 and AM) **scab:** A blood clot that forms at the surface of a wound to the skin. (p. 171) **seborrheic dermatitis:** An inflammation around abnormally active sebaceous glands. (p. 167) **sepsis:** A dangerous, widespread bacterial infection; the leading cause of death in burn patients. (p. 172) **skin graft:** The transplantation of a section of skin (either partial thickness or full thickness) to cover an extensive injury, such as a

third-degree burn. (p. 172) **squamous cell carcinoma:** A skin cancer resulting from chronic exposure to excessive amounts of UV radiation in sunlight. (p. 160) **ulcer:** A localized shedding of an epithelium. (p. 163)

Study Outline

The Integumentary System: An Overview p. 154

1. The **integument**, or **integumentary system**, consists of the **cutaneous membrane** or *skin* (which includes the **epidermis** and the **dermis**) and the **accessory structures**. Beneath the dermis lies the **subcutaneous layer**. *(Figure 5–1)*

2. Functions of the integument include *protection, excretion, temperature maintenance, vitamin* D_3 *synthesis, nutrient storage, and sensory detection*.

The Epidermis p. 155

1. **Thin skin**, formed by four layers of **keratinocytes**, covers most of the body. Heavily abraded body surfaces may be covered by **thick skin**, formed by five layers of keratinocytes. *(Figure 5–2)*

2. The epidermis provides mechanical protection, prevents fluid loss, and helps keep microorganisms out of the body.

Layers of the Epidermis p. 155

3. Cell divisions in the **stratum germinativum**, the innermost epidermal layer, replace more superficial cells. *(Figure 5–3)*

4. As epidermal cells age, they pass through the **stratum spinosum**, the **stratum granulosum**, the **stratum lucidum** (in thick skin), and the **stratum corneum**. In the process, they accumulate large amounts of **keratin**. Ultimately, the cells are shed or lost. *(Figure*

5–3)

5. **Epidermal ridges**, interlocked with **dermal papillae** of the underlying dermis, improve the gripping ability of the palms and soles and increase the skin's sensitivity. *(Figure 5–4)*

6. *Langerhans cells* in the stratum spinosum are part of the immune system. *Merkel cells* in the stratum germinativum provide sensory information about objects that touch the skin.

The Basis of Skin Color p. 158

7. The color of the epidermis depends on two factors: blood supply and epidermal pigmentation.

8. The epidermis contains the pigments **carotene** and **melanin**. **Melanocytes**, which produce melanin, protect us from **ultraviolet (UV) radiation**. *(Figure 5–5)*

9. Interruptions of the dermal blood supply can lead to **cyanosis**.

The Epidermis and Steroid Production p. 159

10. Epidermal cells synthesize **vitamin** $\mathbf{D_3}$ or **cholecalciferol**, when exposed to the UV radiation in sunlight.

The Roles of Epidermal Growth Factor p. 161

11. Epidermal growth factor (EGF) promotes growth, division, and repair of the epidermis and the secretion of epithelial glands.

100 Keys | p. 161

The Dermis p. 161 Dermal Organization p. 161

1. The dermis consists of the superficial **papillary layer** and the deeper **reticular layer**. *(Figures 5–1, 5–2)*

2. The papillary layer of the dermis contains blood vessels, lymphatics, and sensory nerves that supply the epidermis. The reticular layer consists of a meshwork of collagen and elastic fibers oriented to resist tension in the skin.

3. Extensive distension of the dermis can cause **stretch marks**.

4. The pattern of collagen and elastic fiber bundles forms **lines of cleavage**. *(Figure 5–7)*

5. Arteries to the skin form the **cutaneous plexus** and the **papillary plexus** in the subcutaneous layer and the papillary dermis, respectively. *(Figure 5–8)*

6. Integumentary sensory receptors detect both light touch and pressure.

100 Keys | p. 163

The Subcutaneous Layer p. 163

1. The subcutaneous layer, or **hypodermis**, stabilizes the skin’s position against underlying organs and tissues. *(Figure 5–1)*

Accessory Structures p. 164 Hair and Hair Follicles p. 164

1. **Hairs** originate in complex organs called **hair follicles**. Each hair has a **root** and a **shaft**. At the base of the root are a **hair papilla**, surrounded by a **hair bulb**, and a **root hair plexus** of sensory nerves. Hairs have a **medulla**, or core of soft keratin, surrounded by a

cortex of hard keratin. The **cuticle** is a superficial layer of dead cells that protects the hair. *(Figure 5–9)*

2. Our bodies have both **vellus hairs** (“peach fuzz”) and heavy **terminal hairs**. A hair that has stopped growing is called a **club hair**.

3. Each **arrector pili** muscle can erect a single hair.

(Figure 5–9)

4. Our hairs grow and are shed according to the **hair growth cycle**. A typical hair on the head grows for two to five years and is subsequently shed.

Glands in the Skin p. 167

5. A typical **sebaceous gland** discharges the waxy **sebum** into a lumen and, ultimately, into a hair follicle. **Sebaceous follicles** are large sebaceous glands that discharge sebum directly onto the epidermis. *(Figure 5–10)*

6. The two types of sweat glands, or **sudoriferous glands**, are apocrine and merocrine sweat glands. **Apocrine sweat glands** produce an odorous secretion. The more numerous **merocrine**, or **eccrine**, **sweat glands** produce a watery secretion known as sensible perspiration. *(Figure 5–11)*

7. **Mammary glands** of the breasts are structurally similar to sweat glands. **Ceruminous glands** in the ear produce a waxy substance called **cerumen**.

100 Keys | p. 169

Nails p. 169

8. The **nail body** of a **nail** covers the **nail bed**. Nail production occurs at the **nail root**, which is overlain by the **cuticle**, or **eponychium**. The **free edge** of the nail extends over the **hyponychium**. *(Figure 5–12)*

The Response of the Integument to Injury p. 170 Repair of Localized Injuries to the Skin p. 170

1. The skin can regenerate effectively even after considerable damage. The process includes the formation of a **scab**, **granulation tissue**, and **scar tissue**. *(Figure 5–13)*

Aging and the Integumentary System p. 173

1. With aging, the integument thins, blood flow decreases, cellular activity decreases, and repairs occur more slowly.

Integration with Other Systems p. 174

1. The integumentary system has extensive anatomical and physiological connections with other body systems. *(Figure 5–15)*

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A-1.

LEVEL 1 Reviewing Facts and Terms

1. The two major components of the integumentary system are

(a) the cutaneous membrane and the accessory structures

(b) the epidermis and the hypodermis

(c) the hair and the nails

(d) the dermis and the subcutaneous layer

2. Beginning at the basal lamina and traveling toward the free surface, the epidermis includes the following layers:

(a) corneum, lucidum, granulosum, spinosum, germinativum

(b) granulosum, lucidum, spinosum, germinativum, corneum

(c) germinativum, spinosum, granulosum, lucidum, corneum

(d) lucidum, granulosum, spinosum, germinativum, corneum

3. Each of the following is a function of the integumentary system, *except*

(a) protection of underlying tissue

(b) excretion of salts and wastes

(c) maintenance of body temperature

(d) synthesis of vitamin C

(e) storage of nutrients

4. Exposure of the skin to ultraviolet light

(a) can result in increased numbers of melanocytes
forming in the skin

(b) can result in decreased melanin production in melanocytes

(c) can cause destruction of vitamin D

(d) can result in damage to the DNA of cells in the stratum germinativum

(e) has no effect on the skin cells

5. The two major components of the dermis are the

(a) superficial fascia and cutaneous membrane

(b) epidermis and hypodermis

(c) papillary layer and reticular layer

(d) stratum germinativum and stratum corneum

6. The cutaneous plexus and papillary plexus consist of

(a) a network of arteries providing the dermal blood supply

(b) a network of nerves providing dermal sensations

(c) specialized cells for cutaneous sensations

(d) gland cells that release cutaneous secretions

7. The accessory structures of the integument include the

(a) blood vessels, glands, muscles, and nerves

(b) Merkel cells, lamellated corpuscles, and tactile corpuscles

(c) hair, skin, and nails

(d) hair follicles, nails, sebaceous glands, and sweat glands

8. The portion of the hair follicle where cell divisions occur is the

(a) shaft **(b)** matrix

(c) root hair plexus **(d)** cuticle

9. The two types of exocrine glands in the skin are

(a) merocrine and sweat glands

(b) sebaceous and sweat glands

(c) apocrine and sweat glands

(d) eccrine and sweat glands

10. Apocrine sweat glands can be controlled by

(a) the autonomic nervous system

(b) regional control mechanisms

(c) the endocrine system

(d) a and c are correct

11. The primary function of sensible perspiration is to

(a) get rid of wastes

(b) protect the skin from dryness

(c) maintain electrolyte balance

(d) reduce body temperature

12. The stratum corneum of the nail root, which extends over the exposed nail, is called the

(a) hyponychium **(b)** eponychium

(c) cuticle **(d)** cerumen

13. Muscle weakness and a reduction in bone strength in the elderly result from decreased

(a) vitamin D_3 production

(b) melanin production

(c) sebum production

(d) dermal blood supply

14. In which layer(s) of the epidermis does cell division occur?

15. What is the function of the arrector pili muscle?

16. What widespread effects does epidermal growth factor (EGF) have on the integument?

17. What two major layers constitute the dermis, and what components are in each layer?

18. List the four stages in the regeneration of the skin after an injury.

LEVEL 2 Reviewing Concepts

19. How do insensible perspiration and sensible perspiration differ?

20. In clinical practice, drugs can be delivered by diffusion across the skin; this delivery method is called transdermal administration. Why are fat-soluble drugs more suitable for transdermal administration than drugs that are water soluble?

21. In our society, a tan body is associated with good health. However, medical research constantly warns about the dangers of excessive exposure to the sun. What are the benefits of a tan?

22. Why is it important for a surgeon to choose an incision pattern according to the lines of cleavage of the skin?

23. The fibrous protein that is responsible for the strengh and water resistance of the skin surface is

24. The darker an individual's skin color

(a) the more melanocytes they have in their skin

(b) the more layers they have in their epidermis

(c) the more melanin their melanocytes produce

(d) the more superficial their blood vessels are

25. In order for bacteria on the skin to cause an infection in the skin, they must accomplish all of the following, *except*

(a) survive the bactericidal components of sebum

(b) avoid being flushed from the surface of the skin by sweat

(c) penetrate the stratum corneum

(d) penetrate to the level of the capillaries

(e) escape the Langherans cells

(a) collagen **(b)** eleidin

(c) keratin **(d)** elastin

(e) keratohyalin

LEVEL 3 Critical Thinking and Clinical Applications

26. In the elderly, blood supply to the dermis is reduced and sweat glands are less active. This combination of factors would most affect

(a) the ability to thermoregulate

(b) the ability to heal injured skin

(c) the ease with which the skin is injured

(d) the physical characteristics of the skin

(e) the ability to grow hair

27. Two patients are brought to the emergency room. One has cut his finger with a knife; the other has stepped on a nail. Which wound has a greater change of becoming infected? Why?

28. Exposure to optimum amounts of sunlight is necessary for proper bone maintenance and growth in children.

(a) What does sunlight do to promote bone maintenance and growth?

(b) If a child lives in an area where exposure to sunlight is rare because of pollution or overcast skies, what can be done to minimize impaired maintenance and growth of bone?

29. One of the factors to which lie detectors respond is an increase in skin conductivity due to the presence of moisture. Explain the physiological basis for the use of this indicator.

30. Many people change the natural appearance of their hair, either by coloring it or by altering the degree of curl in it. Which layers of the hair do you suppose are affected by the chemicals added during these procedures? Why are the effects of the procedures not permanent?

Clinical Note

Skin Cancers, Melanomas, and Sunblocks

Almost everyone has several benign tumors of the skin; moles are a common example. However, skin cancers, which are more dangerous, are the most common form of cancer.

An *actinic keratosis* is a scaly area on sun-damaged skin. It is an indication that sun damage is occurring, but it is not a sign of skin cancer. In contrast, *basal cell carcinoma* (Figure 5–6a•), a cancer that originates in the stratum germinativum, is the most common skin cancer. Roughly two-thirds of these cancers appear in body areas subjected to chronic UV exposure. Researchers have identified genetic factors that predispose people to this condition. *Squamous cell carcinomas* are less common, but almost totally restricted to areas of sun-exposed skin. Metastasis seldom occurs in squamous cell carcinomas and virtually never in basal cell carcinomas, and most people survive these cancers. The usual treatment involves the surgical removal of the tumor, and 95 percent of patients survive for five years or longer after treatment. (This statistic, the 5-year survival rate, is a common method of reporting long-term outcomes.)

Unlike these common and seldom life-threatening cancers, *malignant melanomas* (mel-a-N O -maz) (Figure 5–6b•) are extremely danger
–

ous. In this condition, cancerous melanocytes grow rapidly and metastasize through the lymphatic system. The outlook for long-term survival is in many cases determined by how early the condition is diagnosed. If the cancer is detected early, while it is still localized, the 5year survival rate is 99 percent; if it is not detected until extensive metastasis has occurred, the survival rate drops to 14 percent.

To detect melanoma at an early stage, you must examine your skin, and you must know what to look for. The mnemonic ABCD makes it easy to remember this cancer’s key characteristics:

- A is for *asymmetry:* Melanomas tend to be irregular in shape. Typically, they are raised; they may also ooze or bleed.
- B is for *border:* The border of a melanoma is generally indistinct, irregular, and in some cases notched.
- C is for *color:* A melanoma is generally mottled, with any combination of tan, brown, black, red, pink, white, and blue tones.

- D is for *diameter:* Any skin growth more than about 5 mm (0.2 in.) in diameter, or roughly the area covered by the eraser on a pencil, is dangerous.

Fair-skinned individuals who live in the tropics are most susceptible to all forms of skin cancer, because their melanocytes are unable to shield them from UV radiation. Sun damage can be prevented by avoiding exposure to the sun during the middle of the day and by using a sunblock (not a tanning oil)—a practice that also delays the cosmetic problems of aging and wrinkling. *Everyone* who spends any time out in the sun should choose a broad-spectrum sunblock with a sun protection factor (SPF) of at least 15; blondes, redheads, and people with very pale skin are better off with an SPF of 20 to 30. (The risks are the same for those who spend time in a tanning salon or tanning bed.) The protection offered by these "sunscreens" is afforded by both organic molecules that absorb UV and inorganic pigments that absorb, scatter, and reflect UV. The higher the SPF factor, the more of these chemicals the product contains, and the fewer UV rays are able to penetrate to the skin's surface. Wearing a hat with a brim and panels to shield the neck and face provides added protection.

The use of sunblocks will be even more important as the ozone gas in the upper atmosphere is further destroyed by our industrial emissions. Ozone absorbs UV radiation before it reaches Earth's surface; in doing so, ozone assists the melanocytes in preventing skin cancer. Australia, the continent that is most affected by the depletion of ozone above the South Pole (the "ozone hole"), is already reporting an increased incidence of skin cancers.

- **FIGURE 5–6** Skin Cancers. **(a)** Basal cell carcinoma. **(b)** Melanoma.

Clinical Note

Burns and Grafts

Burns are significant injuries in that they can damage the integrity of large areas of the skin. The integumentary functions of protection, excretion, maintenance, sensory detection, and storage and synthesis of vitamin D are all compromised. Burns result from the exposure of skin to heat, friction, radiation, electrical shock, or strong chemical agents. The severity of the burn depends on the depth of penetration and the total area affected.

First- and second-degree burns are also called *partial-thickness burns*, because damage is restricted to the superficial layers of the skin. Only the surface of the epidermis is affected by a *first-degree burn*. In this type of burn, which includes most sunburns, the skin reddens and can be painful. The redness, a sign called **erythema** (er-i-TH E -ma), results from inflammation of the sun-damaged tissues. In a *second-degree burn*, the entire epidermis and perhaps some of

¯the dermis are damaged. Accessory structures such as hair follicles and glands are generally not affected, but blistering, pain, and swelling occur. If the blisters rupture at the surface, infection can easily develop. Healing typically takes one to two weeks, and some scar tissue may form. *Full-thickness burns*, or *third-degree burns*, destroy the epidermis and dermis, extending into subcutaneous tissues. Despite swelling, these burns are less painful than second-degree burns, because sensory nerves are destroyed along with accessory structures, blood vessels, and other dermal components. Extensive third-degree burns cannot repair themselves, because granulation tissue cannot form and epithelial cells are unable to cover the injury. As a result, the affected area remains open to infection. Extensive third-degree burns often require skin grafts, discussed shortly.

Each year in the United States, roughly 10,000 people die from the effects of burns. The larger the area burned, the more significant are the effects on integumentary function. Figure 5–14• presents a standard reference for calculating the percentage of total surface area damaged. Burns that cover more than 20 percent of the skin surface represent serious threats to life, because they affect the following functions:

- Fluid and Electrolyte Balance. Even areas with partial-thickness burns lose their effectiveness as barriers to fluid and electrolyte losses. In full-thickness burns, the rate of fluid loss through the skin may reach five times the normal level.
- Thermoregulation. Increased fluid loss means increased evaporative cooling. As a result, more energy must be expended to keep body temperature within acceptable limits.

- Protection from Infection. The dampness of the epidermal surface, resulting from uncontrolled fluid loss, encourages bacterial growth. If the skin is broken at a blister or at the site of a third-degree burn, infection is likely. Widespread bacterial infection, or **sepsis** (*septikos*, rotting), is the leading cause of death in burn victims.

Effective treatment of full-thickness burns focuses on the following four procedures:

1. Replacing lost fluids and electrolytes.

2. Providing sufficient nutrients to meet increased metabolic demands for thermoregulation and healing.

3. Preventing infection by cleaning and covering the burn while administering antibiotic drugs.

4. Assisting tissue repair.

Because large full-thickness burns cannot heal unaided, surgical procedures are necessary to encourage healing. In a **skin graft**, areas of intact skin are transplanted to cover the site of the burn. A *split-thickness graft* involves a transfer of the epidermis and superficial portions of the dermis; a *full-thickness graft* involves the epidermis and both layers of the dermis.

With fluid-replacement therapies, infection control methods, and grafting techniques, young patients with burns over 80 percent of the body have about a 50 percent chance of recovery. Recent advances in cell culturing may improve survival rates further. After a postage-stamp-sized section of undamaged epidermis is removed and grown in the laboratory, germinative cell divisions produce large sheets of epidermal cells—up to several square meters in area—that can be transplanted to cover the burn area. Although questions remain about the strength and flexibility of the repairs, skin cultivation is a substantial advance in the treatment of serious burns. AM: Synthetic Skin

• **FIGURE 5–14** A Quick Method of Estimating the Percentage of Surface Area Affected by Burns. This method is called the *rule of nines*, because the surface area in adults is divided into multiples of 9. The rule must be modified for children, because their proportions are quite different.

An Introduction to the Skeletal System

Objective

- Describe the functions of the skeletal system.

The skeletal system includes the bones of the skeleton and the cartilages, ligaments, and other connective tissues that stabilize or connect the bones. Skeletal elements are more than just props, or racks from which muscles hang; they have a great variety of vital functions. In addition to supporting the weight of the body, bones work together with muscles to maintain body position and to produce controlled, precise movements. Without the skeleton to pull against, contracting muscle fibers could not make us sit, stand, walk, or run.

The skeletal system has five primary functions:

1. *Support.* The skeletal system provides structural support for the entire body. Individual bones or groups of bones provide a framework for the attachment of soft tissues and organs.

2. *Storage of Minerals and Lipids.* As we will learn in Chapter 25, minerals are inorganic ions that contribute to the osmotic concentration of body fluids. Minerals also participate in various physiological processes, and several are important as enzyme cofactors. Calcium is the most abundant mineral in the human body. The calcium salts of bone are a valuable mineral reserve that maintains normal concentrations of calcium and phosphate ions in body fluids. In addition to acting as a mineral reserve, the bones of the skeleton store energy reserves as lipids in areas filled with *yellow marrow*.

3. *Blood Cell Production.* Red blood cells, white blood cells, and other blood elements are produced in *red marrow*, which fills the internal cavities of many bones. We will describe the role of bone marrow in blood cell formation when we examine the cardiovascular and lymphatic systems (Chapters 19 and 22).

4. *Protection.* Many soft tissues and organs are surrounded by skeletal elements. The ribs protect the heart and lungs, the skull encloses the brain, the vertebrae shield the spinal cord, and the pelvis cradles delicate digestive and reproductive organs.

5. *Leverage*. Many bones function as levers that can change the magnitude and direction of the forces generated by skeletal muscles. The movements produced range from the dainty motion of a fingertip to changes in the position of the entire body.

Chapters 6–9 describe the structure and function of the skeletal system. We begin by describing bone, or osseous tissue, a supporting connective tissue introduced in Chapter 4. l**p. 128** All of the features and properties of the skeletal system ultimately depend on the unique and dynamic properties of bone. The bone specimens that you study in lab or that you are familiar with from skeletons of dead animals are only the dry remains of this living tissue. They bear the same relationship to the bone in a living organism as a kiln-dried 2-by-4 does to a living oak. AM: Examination of the Skeletal System

The Gross Anatomy of Bones

Objectives

. • Classify bones according to their shapes and internal tissues, and give examples of each type.

. • Identify the major types of bone markings, and explain the functional significance of each.

A description of a bone may indicate its general shape or the internal organization of its tissues. Before considering specific bones of the skeleton, you must be familiar with both classification schemes.

Bone Shapes

Every adult skeleton contains 206 major bones, which we can divide into six broad categories according to their individual shapes (Figure 6–1•):

1. **1. Long bones** are relatively long and slender (Figure 6–1a•). Long bones are located in the arm and forearm, thigh and leg, palms, soles, fingers, and toes. The femur, the long bone of the thigh, is the largest and heaviest bone in the body.

2. **2. Flat bones** have thin, roughly parallel surfaces. Flat bones form the roof of the skull (Figure 6–1b•), the sternum, the ribs, and the scapula. They provide protection for underlying soft tissues and offer an extensive surface area for the attachment of skeletal muscles.

3. **3. Sutural bones**, or *Wormian bones*, are small, flat, irregularly shaped bones between the flat bones of the skull (Figure 6–1c•). There are individual variations in the number, shape, and position of the sutural bones. Their borders are like pieces of a jigsaw puzzle, and they range in size from a grain of sand to a quarter.

4. **4. Irregular bones** have complex shapes with short, flat, notched, or ridged surfaces (Figure 6–1d•). The spinal vertebrae, the bones of the pelvis, and several skull bones are irregular bones.

5. **5. Short bones** are small and boxy (Figure 6–1e•). Examples of short bones include the carpal bones (wrists) and tarsal bones (ankles).

6. **6. Sesamoid bones** are generally small, flat, and shaped somewhat like a sesame seed (Figure 6–1f•). They develop inside tendons and are most commonly located near joints at the knees, the hands, and the feet. Everyone has sesamoid *patellae* (pa-TEL-e; singular, *patella*, a small shallow dish), or kneecaps, but individuals vary in the location and abundance of other sesamoid

–

bones. This variation accounts for disparities in the total number of bones in the skeleton. (Sesamoid bones may form in at least 26 locations.)

Bone Markings (Surface Features)

Each bone in the body has characteristic external and internal features. Elevations or projections form where tendons and ligaments attach, and where adjacent bones articulate (that is, at joints). Depressions, grooves, and tunnels in bone indicate sites where blood vessels or nerves lie alongside or penetrate the bone. Detailed examination of these **bone markings**, or *surface features*, can yield an abundance of anatomical information. For example, anthropologists, criminologists, and pathologists can often determine the size, age, sex, and general appearance of an individual on the basis of incomplete skeletal remains.

Table 6–1 presents an introduction to the prominent surface features of bones, using specific anatomical terms to describe the various projections, depressions, and openings. These markings provide fixed landmarks that can help us determine the position of the soft-tissue components of other organ systems.

Bone Structure

Figure 6–2a• introduces the anatomy of the femur, a representative long bone with an extended tubular shaft, or **diaphysis** (d
–

ı AF-i-sis). At each end is an expanded area known as the **epiphysis** (-PIF-i-sis). The diaphysis is connected to each epiphysis at a narrow zone known as the **metaphysis** (me-TAF-i-sis; *meta*, between). The wall of the diaphysis consists of a layer of compact bone, or *dense bone*. Compact bone, which is relatively solid, forms a sturdy protective layer that surrounds a central space called
(KAN-se-lus) *bone*. Spongy bone consists of an open network of struts and plates with a thin covering, or **cortex**, of compact bone.

Figure 6–2b• details the structure of a flat bone from the skull, such as one of the *parietal*

‾e

bones. A flat bone resembles a spongy

,

(*medulla*

medullary cavity

marrow cavity

the

cancellous

innermost part). The epiphyses consist largely of spongy bone, or

, or

bone sandwich, with layers of compact bone covering a core of spongy bone. The layer of spongy bone between the layers of com

-

pact bone is called the *diploë* (DIP-l

‾o

-

‾e

). Although bone marrow is present within the spongy bone, there is no marrow cavity.

Many people think of the skeleton as a rather dull collection of bony props. This is far from the truth. Our bones are complex, dynamic organs that constantly change to adapt to the demands we place on them. We will now consider the histological organization of a typical bone.

Bone Histology

Objectives

. • Identify the cell types in bone, and list their major functions.

. • Compare the structures and functions of compact bone and spongy bone.

Osseous tissue is a supporting connective tissue. (You may wish to review the sections on dense connective tissues, cartilage, and bone in Chapter 4.) l**pp. 123–129** Like other connective tissues, osseous tissue contains specialized cells and a matrix consisting of extracellular protein fibers and a ground substance. The matrix of bone tissue is solid and sturdy, owing to the deposition of calcium salts around the protein fibers.

In Chapter 4, which introduced the organization of bone tissue, we discussed the following four characteristics of bone:

1. **1.** The matrix of bone is very dense and contains deposits of calcium salts.

2. The matrix contains bone cells, or *osteocytes*, within pockets called *lacunae*. (The spaces that chondrocytes occupy in cartilage

are also called lacunae. l**p. 125**) The lacunae of bone are typically organized around blood vessels that branch through the bony matrix.

2. **3.** *Canaliculi,* narrow passageways through the matrix, extend between the lacunae and nearby blood vessels, forming a branching network for the exchange of nutrients, waste products, and gases.

3. **4.** Except at joints, the outer surfaces of bones are covered by a *periosteum*, which consists of outer fibrous and inner cellular layers. We now take a closer look at the organization of the matrix and cells of bone.

The Matrix of Bone

Calcium phosphate, $Ca_3(PO_4)_2$, accounts for almost two-thirds of the weight of bone. Calcium phosphate interacts with calcium hydroxide, $Ca(OH)_2$, to form crystals of **hydroxyapatite**, $Ca_{10}(PO_4)_6(OH)_2$. As they form, these crystals incorporate other calcium salts, such as calcium carbonate ($CaCO_3$), and ions such as sodium, magnesium, and fluoride. Roughly one-third of the weight of bone is contributed by collagen fibers. Cells account for only 2 percent of the mass of a typical bone.

Calcium phosphate crystals are very hard, but relatively inflexible and quite brittle. They can withstand compression, but are likely to shatter when exposed to bending, twisting, or sudden impacts. Collagen fibers, by contrast, are remarkably strong; when subjected to tension (pull), they are stronger than steel. Flexible as well as tough, they can easily tolerate twisting and bending, but offer little resistance to compression. When compressed, they simply bend out of the way.

The composition of the matrix in compact bone is the same as that in spongy bone. The collagen fibers provide an organic framework on which hydroxyapatite crystals can form. These crystals form small plates and rods that are locked into the collagen fibers. The result is a protein–crystal combination with properties intermediate between those of collagen and those of pure mineral crystals. The protein– crystal interactions allow bone to be strong, somewhat flexible, and highly resistant to shattering. In its overall properties, bone is on a par with the best steel-reinforced concrete. In fact, bone is far superior to concrete, because it can be remodeled easily and can repair itself after injury.

The Cells of Bone

Although osteocytes are most abundant, bone contains four types of cells: osteocytes, osteoblasts, osteoprogenitor cells, and osteoclasts (Figure 6–3•).

Osteocytes (*osteo-*, bone + *-cyte,* cell) are mature bone cells that account for most of the cell population. Each osteocyte oc

cupies a lacuna, a pocket sandwiched between layers of matrix. The layers are called **lamellae** (lah-MEL-l

;

¯e

singular, *lamella*, a

thin plate). Osteocytes cannot divide, and a lacuna never contains more than one osteocyte. Narrow passageways called **canaliculi** penetrate the lamellae, radiating through the matrix and connecting lacunae with one another and with sources of nutrients, such as the central canal.

Canaliculi contain cytoplasmic extensions of osteocytes. Neighboring osteocytes are linked by gap junctions, which permit the exchange of ions and small molecules, including nutrients and hormones, between the cells. The interstitial fluid that surrounds the osteocytes and their extensions provides an additional route for the diffusion of nutrients and waste products.

Osteocytes have two major functions:

1. **1.** *Osteocytes maintain the protein and mineral content of the surrounding matrix.* This is not a static process, as there is continual turnover of matrix components. Osteocytes secrete chemicals that dissolve the adjacent matrix, and the minerals released enter the circulation. Osteocytes then rebuild the matrix, stimulating the deposition of new hydroxyapatite crystals. The turnover rate varies from bone to bone; we will consider this process further in a later section.

2. **2.** *Osteocytes participate in the repair of damaged bone.* If released from their lacunae, osteocytes can convert to a less specialized type of cell, such as an osteoblast or an osteoprogenitor cell.

Osteoblasts (OS-t

¯e

-

¯o

-blasts; *blast*, precursor) produce new bone matrix in a process called **osteogenesis** (os-t

¯e

-

¯o

-JEN-e-

sis; *gennan*, to produce). Osteoblasts make and release the proteins and other organic components of the matrix. Before calcium

¯e

salts are deposited, this organic matrix is called **osteoid** (OS-t -oyd). Osteoblasts also assist in elevating local concentrations of calcium phosphate and promoting the deposition of calcium salts in the organic matrix. This process converts osteoid to bone. Osteocytes develop from osteoblasts that have become completely surrounded by bone matrix.

Bone contains small numbers of mesenchymal cells called **osteoprogenitor** (os-t

¯e

-

¯o

-pr

¯o

-JEN-i-tor) **cells** (*progenitor*, ances

tor). These stem cells divide to produce daughter cells that differentiate into osteoblasts. Osteoprogenitor cells maintain populations of osteoblasts and are important in the repair of a *fracture* (a break or a crack in a bone). Osteoprogenitor cells are located in the inner, cellular layer of the periosteum; in an inner layer, or *endosteum*, that lines marrow cavities; and in the lining of passageways, containing blood vessels, that penetrate the matrix of compact bone.

Osteoclasts (os-t

¯e

-

ō-clasts; *clast*, to break) are cells that remove and recycle bone matrix. These are giant cells with 50 or more nuclei. Osteoclasts are not related to osteoprogenitor cells or their descendants. Instead, they are derived from the same stem cells that produce monocytes and macrophages. Acids and proteolytic (protein-digesting) enzymes secreted by osteoclasts dissolve the matrix and release the stored minerals. This erosion process, called **osteolysis** (os-tē-OL-i-sis; *osteo*-, bone + *lysis*, dissolution) or *resorption*, is important in the regulation of calcium and phosphate concentrations in body fluids.

In living bone, osteoclasts are constantly removing matrix, and osteoblasts are always adding to it. The balance between the opposing activities of osteoblasts and osteoclasts is very important. When osteoclasts remove calcium salts faster than osteoblasts deposit them, bones weaken. When osteoblast activity predominates, bones become stronger and more massive. This opposition causes some interesting differences in skeletal components among individuals. Those who subject their bones to muscular stress through weight training or strenuous exercise develop not only stronger muscles, but also stronger bones. Alternatively, declining muscular activity due to immobility leads to a reduction in bone mass at sites of muscle attachment. We will investigate this phenomenon further in a later section of the chapter.

The Structure of Compact Bone

The basic functional unit of mature compact bone is the **osteon** (OS-tē-on), or *Haversian system* (Figures 6–4 and 6–5a•). In an osteon, the osteocytes are arranged in concentric layers around a **central canal**, or *Haversian canal*. This canal contains one or more blood vessels (normally a capillary and a *venule*, a very small vein) that carry blood to and from the osteon. Central canals generally run parallel to the surface of the bone. Other passageways, known as **perforating canals** or *canals of Volk-mann,* extend roughly perpendicular to the surface. Blood vessels in these canals supply blood to osteons deeper in the bone and to tissues of the marrow cavity.

The lamellae of each osteon form a series of nested cylinders around the central canal. In transverse section, these *concentric lamellae* create a targetlike pattern, with the central canal as the bull’s-eye. Collagen fibers within each lamella form a spiral that adds strength and resiliency. Canaliculi radiating through the lamellae interconnect the lacunae of the osteon with one another and with the central canal. *Interstitial lamellae* fill in the spaces between the osteons in compact bone. These lamellae are remnants of osteons whose matrix components have been almost completely recycled by osteoclasts. *Circumferential lamellae* (*circum-*, around + *ferre*, to bear) are found at the outer and inner surfaces of the bone, where they are covered by the periosteum and endosteum, respectively (Figure 6–5a,b•). These lamellae are produced during the growth of the bone, and this process will be described in a later section.

Compact bone is thickest where stresses arrive from a limited range of directions. All osteons in compact bone are aligned the same way, making such bones very strong when stressed along the axis of alignment. You might think of a single osteon as a drinking straw with very thick walls: When you attempt to push the ends of the straw together or to pull them apart, the straw is quite strong. But if you hold the ends and push from the side, the straw will break relatively easily.

The osteons in the diaphysis of a long bone are parallel to the long axis of the shaft. Thus, the shaft does not bend, even when extreme forces are applied to either end. (The femur can withstand 10–15 times the body’s weight without breaking.) Yet a much smaller force applied to the side of the shaft can break the femur. The majority of breaks that occur in this bone are caused by a sudden sideways force, such as those applied during a football tackle or a hockey check.

The Structure of Spongy Bone

In spongy bone, lamellae are not arranged in osteons. The matrix in spongy bone forms struts and plates called **trabeculae** (tra-BEK-ū-lē) (Figure 6–6•). The thin trabeculae branch, creating an open network. There are no capillaries or venules in the matrix of spongy bone. Nutrients reach the osteocytes by diffusion along canaliculi that open onto the surfaces of trabeculae. Red marrow is found between the trabeculae of spongy bone, and blood vessels within this tissue deliver nutrients to the trabeculae and remove wastes generated by the osteocytes.

Spongy bone is located where bones are not heavily stressed or where stresses arrive from many directions. The trabeculae are oriented along stress lines and are cross-braced extensively. In addition to being able to withstand stresses applied from many directions, spongy bone is much lighter than compact bone. Spongy bone thus reduces the weight of the skeleton and thereby makes it easier for muscles to move the bones. Finally, the framework of trabeculae supports and protects the cells of the bone marrow. Spongy bone within the epiphyses of long bones, such as the femur, and the interior of other large bones such as the sternum and ilium, contains **red bone marrow** responsible for blood cell formation. At other sites spongy bone may contain **yellow bone marrow—**adipose tissue important as an energy reserve.

Figure 6–7• shows the distribution of forces applied to the femur, and illustrates the functional relationship between compact bone and spongy bone. The head of the femur articulates with a corresponding socket on the lateral surface of the pelvis. At the proximal epiphysis of the femur, trabeculae transfer forces from the pelvis to the compact bone of the femoral shaft, across the hip joint; at the distal epiphysis, trabeculae transfer weight from the shaft to the leg, across the knee joint. The femoral head projects medially, and the body weight compresses the medial side of the shaft. However, because the force is applied off center, the bone must also resist the tendency to bend into a lateral bow. So while the medial portion of the shaft is under compression, the lateral portion of the shaft, which resists this bending, is placed under a stretching load, or *tension*. Because the center of the bone is subjected to neither compression nor tension, the presence of the marrow cavity does not reduce the bone's strength.

The Periosteum and Endosteum

Except within joint cavities, the superficial layer of compact bone that covers all bones is wrapped by a **periosteum**, a membrane with a fibrous outer layer and a cellular inner layer (Figure 6–8a•). The periosteum (1) isolates the bone from surrounding tissues, (2) provides a route for the circulatory and nervous supply, and (3) actively participates in bone growth and repair.

Near joints, the periosteum becomes continuous with the connective tissues that lock the bones together. At a synovial joint, the periosteum is continuous with the joint capsule. The fibers of the periosteum are also interwoven with those of the tendons attached to the bone. As the bone grows, these tendon fibers are cemented into the circumferential lamellae by osteoblasts from the cellular layer of the periosteum. Collagen fibers incorporated into bone tissue from tendons and ligaments, as well as from the superficial periosteum, are called *perforating fibers (Sharpey's fibers).* This method of attachment bonds the tendons and ligaments into the general structure of the bone, providing a much stronger attachment than would otherwise be possible. An extremely powerful pull on a tendon or ligament will usually break a bone rather than snap the collagen fibers at the bone surface.

The **endosteum**, an incomplete cellular layer, lines the marrow cavity (Figure 6–8b•). This layer, which is active during bone growth, repair, and remodeling, covers the trabeculae of spongy bone and lines the inner surfaces of the central canals. The endosteum consists of a simple flattened layer of osteoprogenitor cells that covers the bone matrix, generally without any intervening connective tissue fibers. Where the cellular layer is not complete, the matrix is exposed. At these exposed sites, osteoclasts and osteoblasts can remove or deposit matrix components. The osteoclasts generally occur in shallow depressions *(Howship's lacunae)* that they have eroded into the matrix.

Concept Check

How would the strength of a bone be affected if the ratio of collagen to hydroxyapatite increased? A sample of bone has concentric lamellae surrounding a central canal. Is the sample from the cortex or the marrow cavity of a long bone? If the activity of osteoclasts exceeds the activity of osteoblasts in a bone, how will the mass of the bone be affected?

Answers begin on p. A–1

Bone Formation and Growth

Objectives

. • Compare the mechanisms of intramembranous ossification and endochondral ossification.

. • Discuss the timing of bone formation and growth, and account for the differences in the internal structure of the bones of adults.

The growth of the skeleton determines the size and proportions of your body. The bony skeleton begins to form about six weeks after fertilization, when the embryo is approximately 12 mm (0.5 in.) long. (At this stage, the existing skeletal elements are cartilaginous.) During subsequent development, the bones undergo a tremendous increase in size. Bone growth continues through adolescence, and portions of the skeleton generally do not stop growing until roughly age 25. In this section, we consider the physical process of osteogenesis (bone formation) and bone growth.

The process of replacing other tissues with bone is called **ossification**. The term refers specifically to the formation of bone. The process of **calcification—**the deposition of calcium salts—occurs during ossification, but it can also occur in other tissues. When calcification occurs in tissues other than bone, the result is a calcified tissue (such as calcified cartilage) that does not resemble bone. Two major forms of ossification exist: endochondral and intramembranous. In *endochondral ossification*, bone replaces existing cartilage. In *intramembranous ossification*, bone develops directly from mesenchyme or fibrous connective tissue.

Endochondral Ossification

During development, most bones originate as hyaline cartilages that are miniature models of the corresponding bones of the adult skeleton. These cartilage models are gradually converted to bone through the process of **endochondral** (en-do¯-KON-drul) **ossification** (*endo*-, inside + *chondros*, cartilage). As an example, consider the steps in limb bone development. By the time an embryo is six weeks old, the proximal bone of the limb—either the humerus (arm) or femur (thigh)—is present but composed entirely of hyaline cartilage. This cartilage model continues to grow by expansion of the cartilage matrix (*interstitial growth*) and the production of new cartilage at the outer surface (*appositional growth*). l**p. 126** Steps in the growth and ossification of a limb bone are diagrammed in Figure 6–9•:

Step 1 As the cartilage enlarges, chondrocytes near the center of the shaft begin to increase greatly in size. As these cells enlarge, their lacunae expand and the matrix is reduced to a series of thin struts that soon begin to calcify. The enlarged chondrocytes are now deprived of nutrients, because diffusion cannot occur through calcified cartilage. These chondrocytes become surrounded by calcified cartilage, die, and disintegrate.

Step 2 Blood vessels grow into the perichondrium surrounding the shaft of the cartilage. (We introduced the structure of the perichondrium and its role in cartilage formation in Chapter 4. l**pp. 125–126**) The cells of the inner layer of the perichondrium in this region then differentiate into osteoblasts and begin producing a thin layer of bone around the shaft of the cartilage. The perichondrium is now technically a periosteum, because it covers bone rather than cartilage.

Step 3 While these changes are under way, the blood supply to the periosteum increases, and capillaries and fibroblasts migrate into the heart of the cartilage, invading the spaces left by the disintegrating chondrocytes. The calcified cartilaginous matrix breaks down; the fibroblasts differentiate into osteoblasts that replace it with spongy bone. Bone development begins at this site, called the **primary ossification center**, and spreads toward both ends of the cartilaginous model. While the diameter of the diaphysis is small, it is filled with spongy bone and there is no marrow cavity.

Step 4 As the bone enlarges, osteoclasts appear and begin eroding the trabeculae in the center of the diaphysis, creating a marrow cavity. Further growth involves two distinct processes: an increase in length, and an enlargement in diameter by appositional growth. (We will consider appositional growth in the next subsection.)

Step 5 The next major change occurs when the centers of the epiphyses begin to calcify. Capillaries and osteoblasts migrate into these areas, creating **secondary ossification centers**. The time of appearance of secondary ossification centers varies from one bone to another and from individual to individual. Secondary ossification centers may occur at birth in both ends of the humerus (arm), femur (thigh), and tibia (leg), but the ends of some other bones, such as those of the fingers and toes, remain cartilaginous until early adulthood.

Step 6 The epiphyses eventually become filled with spongy bone. A thin cap of the original cartilage model remains exposed to the joint cavity as the **articular cartilage**. This cartilage prevents damaging bone-to-bone contact within the joint. At the metaphysis, a relatively narrow cartilaginous region called the **epiphyseal cartilage**, or *epiphyseal plate*, now separates the epiphysis from the diaphysis. Figure 6–9b• shows the interface between the degenerating cartilage and the advancing osteoblasts.

As long as the epiphyseal cartilage continues to grow at its epiphyseal surface, the bone will continue to increase in length. On the shaft side, osteoblasts continuously invade the cartilage and replace it with bone. On the epiphyseal side, new cartilage is continuously added. The osteoblasts are therefore moving toward the epiphysis, which is being pushed away by the expansion of the epiphyseal cartilage. The situation is like a pair of joggers, one in front of the other. As long as they are running at the same speed, the one in back will never catch the one in front, no matter how far they travel. The osteoblasts don’t catch up to the epiphysis, as long as both the osteoblasts and the epiphysis “run away” from the primary ossification center at the same rate. Meanwhile, the bone grows longer and longer.

At puberty, the combination of rising levels of sex hormones, growth hormone, and thyroid hormones stimulates bone growth dramatically. Osteoblasts now begin producing bone faster than chondrocytes are producing new epiphyseal cartilage. As a result, the osteoblasts “catch up” and the epiphyseal cartilage gets narrower and narrower until it ultimately disappears. The timing of this event can be monitored by comparing the width of the epiphyseal cartilages in successive x-rays. In adults, the former location of this cartilage is often detectable in x-rays as a distinct **epiphyseal line**, which remains after epiphyseal growth has ended (Figure 6–10•). The completion of epiphyseal growth is called *epiphyseal closure*.

Appositional Growth

A superficial layer of bone forms early in endochondral ossification (see Figure 6–9a•, STEP 2). Thereafter, the developing bone increases in diameter through appositional growth at the outer surface. In this process, cells of the inner layer of the periosteum differentiate into osteoblasts and deposit superficial layers of bone matrix. Eventually, these osteoblasts become surrounded by matrix and differentiate into osteocytes. Over much of the surface, appositional growth adds a series of layers that form circumferential lamellae. In time, the deepest circumferential lamellae are recycled and replaced by osteons typical of compact bone. However, blood vessels and collagen fibers of the periosteum can sometimes become enclosed within the matrix produced by osteoblasts. Osteons may then form around the smaller vessels. While bone matrix is being added to the outer surface of the growing bone, osteoclasts are removing bone matrix at the inner surface, albeit at a slower rate. As a result, the marrow cavity gradually enlarges as the bone gets larger in diameter.

Intramembranous Ossification

Intramembranous (in-tra-MEM-bra-nus) **ossification** begins when osteoblasts differentiate within a mesenchymal or fibrous connective tissue. This type of ossification is also called *dermal ossification* because it normally occurs in the deeper layers of the dermis. The bones that result are called **dermal bones**. Examples of dermal bones are the flat bones of the skull, the mandible (lower jaw), and the clavicle (collarbone).

The steps in the process of intramembranous ossification (Figure 6–11•) can be summarized as follows:

Step 1 Mesenchymal cells first cluster together and start to secrete the organic components of the matrix. The resulting osteoid then becomes mineralized through the crystallization of calcium salts. (The enzyme *alkaline phosphatase* plays a role in this process.) As calcification occurs, the mesenchymal cells differentiate into osteoblasts. The location in a tissue where ossification begins is called an **ossification center**. The developing bone grows outward from the ossification center in small struts called **spicules**. As ossification proceeds, it traps some osteoblasts inside bony pockets; these cells differentiate into osteocytes. Meanwhile, mesenchymal cell divisions continue to produce additional osteoblasts.

Step 2 Bone growth is an active process, and osteoblasts require oxygen and a reliable supply of nutrients. Blood vessels begin to grow into the area. As spicules meet and fuse together, some of these blood vessels become trapped within the developing bone.

Step 3 Initially, the intramembranous bone consists only of spongy bone. Subsequent remodeling around trapped blood vessels can produce osteons typical of compact bone. As the rate of growth slows, the connective tissue around the bone becomes organized into the fibrous layer of the periosteum. The osteoblasts closest to the bone surface become less active, but remain as the inner, cellular layer of the periosteum.

In response to abnormal stresses, bone may form anywhere in the dermis or within tendons, around joints, in the kidneys, or in skeletal muscles. Dermal bones forming in abnormal locations are called *heterotopic bones* (*hetero*-, different + *topos*, place), or *ectopic bones* (*ektos*, outside). These bones can form in very odd places, such as the testes or the whites of the eyes. AM: Heterotopic Bone Formation

Concept Check

During intramembranous ossification, which type(s) of tissue is (are) replaced by bone?

In endochondral ossification, what is the original source of osteoblasts?

How could x-rays of the femur be used to determine whether a person has reached full height?

Answers begin on p. A–1

The Blood and Nerve Supplies

Osseous tissue is highly vascular, and the bones of the skeleton have an extensive blood supply. In a typical bone such as the humerus, three major sets of blood vessels develop (Figure 6–12•):

1. *The Nutrient Artery and Vein.* The blood vessels that supply the diaphysis form

by invading the cartilage model as endochondral ossification begins. Most bones have only one *nutrient artery* and one *nutrient vein*, but a few bones, including the femur, have more than one of each. The vessels enter the bone through one or more round passageways called *nutrient foramina* in the diaphysis. Branches of these large vessels form smaller perforating canals and extend along the length of the shaft into the osteons of the surrounding cortex.

2. **2.** *Metaphyseal Vessels.* The *metaphyseal vessels* supply blood to the inner (diaphyseal) surface of each epiphyseal cartilage, where that cartilage is being replaced by bone.

3. **3.** *Periosteal Vessels.* Blood vessels from the periosteum provide blood to the superficial osteons of the shaft. During endochondral bone formation, branches of periosteal vessels also enter the epiphyses, providing blood to the secondary ossification centers.

Following the closure of the epiphyses, all three sets of vessels become extensively interconnected.

The periosteum also contains an extensive network of lymphatic vessels and sensory nerves. The lymphatics collect lymph from branches that enter the bone and reach individual osteons via the perforating canals. The sensory nerves penetrate the cortex with the nutrient artery to innervate the endosteum, marrow cavity, and epiphyses. Because of the rich sensory innervation, injuries to bones are usually very painful.

In the next section, we examine the maintenance and replacement of mineral reserves in the adult skeleton.

The Dynamic Nature of Bone

Objectives

. • Describe the remodeling and homeostatic mechanisms of the skeletal system.

. • Discuss the effects of nutrition, hormones, exercise, and aging on bone development and on the skeletal system.

. • Describe the types of fractures and explain how they heal.

The organic and mineral components of the bone matrix are continuously being recycled and renewed through the process of **remodeling**. Bone remodeling goes on throughout life, as part of normal bone maintenance. Remodeling can replace the matrix but leave the bone as a whole unchanged, or it may change the shape, internal architecture, or mineral content of the bone. Through this remodeling process, older mineral deposits are removed from bone and released into the circulation at the same time that circulating minerals are being absorbed and deposited.

Bone remodeling involves an interplay among the activities of osteocytes, osteoblasts, and osteoclasts. In adults, osteocytes are continuously removing and replacing the surrounding calcium salts. Osteoclasts and osteoblasts also remain active, even after the epiphyseal cartilages have closed. Normally, their activities are balanced: As quickly as osteoblasts form one osteon, osteoclasts remove another by osteolysis. The turnover rate of bone is quite high. In young adults, almost one-fifth of the adult skeleton is recycled and replaced each year. Not every part of every bone is affected equally; the rate of turnover differs regionally and even locally. For example, the spongy bone in the head of the femur may be replaced two or three times each year, whereas the compact bone along the shaft remains largely unchanged.

Because of their biochemical similarity to calcium, heavy-metal ions such as strontium or cobalt, or more exotic forms such as uranium or plutonium, can be incorporated into the matrix of bone. Osteoblasts do not differentiate between these heavy-metal ions and calcium, and any heavy-metal ions present in the bloodstream will be deposited into the bone matrix. Some of these ions are potentially dangerous, and the turnover of bone matrix can have detrimental health effects as ions that are absorbed and accumulated are released into the circulation over a period of years. This was one of the major complications in the aftermath of the Chernobyl nuclear reactor incident in 1986. Radioactive compounds released in the meltdown of the reactor were deposited into the bones of exposed individuals. Over time, the radiation released by their own bones resulted in cases of leukemia and other potentially fatal cancers.

100 Keys | Bone is continually remodeled, recycled, and replaced. That rate of turnover varies from bone to bone and
from moment to moment. When deposition exceeds removal, bones get stronger; when removal exceeds deposition, bones
get weaker.

Effects of Exercise on Bone

The turnover and recycling of minerals give each bone the ability to adapt to new stresses. The sensitivity of osteoblasts to electrical events has been theorized as the mechanism that controls the internal organization and structure of bone. Whenever a bone is stressed, the mineral crystals generate minute electrical fields. Osteoblasts are apparently attracted to these electrical fields and, once in the area, begin to produce bone. This finding has led to the successful use of small electrical fields in stimulating the repair of severe fractures.

Because bones are adaptable, their shapes reflect the forces applied to them. For example, bumps and ridges on the surface of a bone mark the sites where tendons are attached. If muscles become more powerful, the corresponding bumps and ridges enlarge to withstand the increased forces. Heavily stressed bones become thicker and stronger, whereas bones that are not subjected to ordinary stresses become thin and brittle. Regular exercise is therefore an important stimulus for maintaining normal bone structure. Champion weight lifters have massive bones with thick, prominent ridges where muscles attach. In nonathletes (especially couch potatoes), moderate amounts of physical activity and weight-bearing activities are essential for stimulating normal bone maintenance and maintaining adequate bone strength.

Degenerative changes in the skeleton occur after relatively brief periods of inactivity. For example, you may use a crutch to take weight off an injured leg while you wear a cast. After a few weeks, your unstressed bones will lose up to a third of their mass. The bones rebuild just as quickly when you resume normal weight loading. However, the removal of calcium salts can be a serious health hazard both for astronauts remaining in a weightless environment and for bedridden or paralyzed patients who spend months or years without stressing their skeleton.

100 Keys | What you don’t use, you lose. The stresses applied to bones during physical activity are essential to maintain

ing bone strength and bone mass.

Hormonal and Nutritional Effects on Bone

Normal bone growth and maintenance depend on a combination of nutritional and hormonal factors:

. • Normal bone growth and maintenance cannot occur without a constant dietary source of calcium and phosphate salts. Lesser amounts of other minerals, such as magnesium, fluoride, iron, and manganese, are also required.

. • The hormone *calcitriol*, synthesized in the kidneys, is essential for normal calcium and phosphate ion absorption in the digestive tract. Calcitriol synthesis is dependent on the availability of a related steroid, *cholecalciferol* (vitamin D3), which may be synthesized in the skin or absorbed from the diet. l**p. 161**

. • Adequate levels of vitamin C must be present in the diet. This vitamin, which is required for certain key enzymatic reactions in collagen synthesis, also stimulates osteoblast differentiation. One of the signs of vitamin C deficiency—a condition called *scurvy*—is a loss of bone mass and strength.

. • Three other vitamins have significant effects on bone structure. Vitamin A, which stimulates osteoblast activity, is particularly important for normal bone growth in children. Vitamins K and B12 are required for the synthesis of proteins in normal bone.

. • *Growth hormone*, produced by the pituitary gland, and *thyroxine*, from the thyroid gland, stimulate bone growth. Growth hormone stimulates protein synthesis and cell growth throughout the body. Thyroxine stimulates cell metabolism and increases the rate of osteoblast activity. In proper balance, these hormones maintain normal activity at the epiphyseal cartilages until roughly the time of puberty.

. • At puberty, rising levels of sex hormones (*estrogens* in females and *androgens* in males) stimulate osteoblasts to produce bone faster than the rate at which epiphyseal cartilage expands. Over time, the epiphyseal cartilages narrow and eventually close. The timing of epiphyseal closure differs from bone to bone and from individual to individual. The toes may complete ossification by age 11, but parts of the pelvis or the wrist may continue to enlarge until roughly age 25. Differences in male and female sex hormones account for significant variations in body size and proportions. Because estrogens cause faster epiphyseal closure than do androgens, women are generally shorter than men at maturity.

–

Two other hormones—*calcitonin* (kal-si-TO-nin), from the thyroid gland, and *parathyroid hormone*, from the parathyroid gland—are important in the homeostatic control of calcium and phosphate levels in body fluids. We consider the interactions of these hormones in the next section. The major hormones affecting the growth and maintenance of the skeletal system are summarized in Table 6–2.

The skeletal system is unique in that it persists after life, providing clues to the sex, lifestyle, and environmental conditions experienced by the individual. Not only do the bones reflect the physical stresses placed on the body, but they also provide clues concerning the person’s health and diet. By using the appearance, strength, and composition of bone, forensic scientists and physical anthropologists can detect features characteristic of hormonal deficiencies. (For more on the effects of hormones on bone growth, see the Clinical Note “Abnormal Bone Growth and Development.”) Combining the physical clues provided by the skeleton with modern molecular techniques, such as DNA fingerprinting, can provide a wealth of information.

Concept Check

Why would you expect the arm bones of a weight lifter to be thicker and heavier than those of a jogger?

A child who enters puberty several years later than the average age is generally taller than average as an adult. Why?

A 7-year-old child has a pituitary gland tumor involving the cells that secrete growth hormone (GH), resulting in increased levels of GH. How will this condition affect the child’s growth?

Answers begin on p. A–1

The Skeleton as a Calcium Reserve

The chemical analysis shown in Figure 6–13• reveals the importance of bones as mineral reservoirs. For the moment, we will focus on the homeostatic regulation of calcium ion concentration in body fluids; we will consider other minerals in later chapters. Calcium is the most abundant mineral in the human body. A typical human body contains 1–2 kg (2.2–4.4 lb) of calcium, with roughly 99 percent of it deposited in the skeleton.

Calcium ions play a role in a variety of physiological processes, so the body must tightly control calcium ion concentrations in order to prevent damage to essential physiological systems. Even small variations from the normal concentration affect cellular operations; larger changes can cause a clinical crisis. Calcium ions are particularly important to both the membranes and the intracellular activities of neurons and muscle cells, especially cardiac muscle cells. If the calcium concentration of body fluids increases by 30 percent, neurons and muscle cells become relatively unresponsive. If calcium levels decrease by 35 percent, neurons become so excitable that convulsions can occur. A 50 percent reduction in calcium concentration generally causes death. Calcium ion concentration is so closely regulated, however, that daily fluctuations of more than 10 percent are highly unusual.

Hormones and Calcium Balance

Calcium ion homeostasis is maintained by a pair of hormones with opposing effects. These hormones, parathyroid hormone and calcitonin, coordinate the storage, absorption, and excretion of calcium ions. Three target sites and functions are involved: (1) the bones (storage), (2) the digestive tract (absorption), and (3) the kidneys (excretion). Figure 6–14a• indicates factors that elevate calcium levels in the blood; Figure 6–14b• indicates factors that depress blood calcium levels.

When calcium ion concentrations in the blood fall below normal, cells of the **parathyroid glands**, embedded in the thyroid gland in the neck, release **parathyroid hormone (PTH)** into the bloodstream. Parathyroid hormone has three major effects, all of which increase blood calcium levels:

1. **1.** *Stimulating osteoclast activity* and enhancing the recycling of minerals by osteocytes. (PTH also stimulates osteoblast activity, but to a lesser degree.)

2. **2.** *Increasing the rate of intestinal absorption of calcium ions* by enhancing the action of calcitriol. Under normal circumstances, calcitriol is always present, and parathyroid hormone controls its effect on the intestinal epithelium.

3. *Decreasing the rate of excretion of calcium ions at the kidneys*.

Under these conditions, more calcium ions enter body fluids, and losses are restricted. The calcium ion concentration increases to normal levels, and homeostasis is restored.

If the calcium ion concentration of the blood instead rises above normal, special cells (*parafollicular cells*, or *C cells*) in the thyroid gland secrete **calcitonin**. This hormone has two major functions, which together act to decrease calcium ion concentrations in body fluids:

1. **1.** *Inhibiting osteoclast activity*.

2. **2.** *Increasing the rate of excretion of calcium ions at the kidneys*.

Under these conditions, less calcium *enters* body fluids because osteoclasts leave the mineral matrix alone. More calcium *leaves* body fluids because osteoblasts continue to produce new bone matrix while calcium ion excretion at the kidneys accelerates. The net result is a decline in the calcium ion concentration of body fluids, restoring homeostasis.

By providing a calcium reserve, the skeleton plays the primary role in the homeostatic maintenance of normal calcium ion concentrations of body fluids. This function can have a direct effect on the shape and strength of the bones in the skeleton. When large numbers of calcium ions are mobilized in body fluids, the bones become weaker; when calcium salts are deposited, the bones become denser and stronger.

Because the bone matrix contains protein fibers as well as mineral deposits, changes in mineral content do not necessarily af

fect the shape of the bone. In *osteomalacia* (os-t

¯e

-

¯o

-ma-L

¯A

-sh

¯e

-uh; *malakia*, softness), the bones appear normal, although they are weak and flexible owing to poor mineralization. *Rickets*, a form of osteomalacia affecting children, generally results from a vitamin D3 deficiency caused by inadequate exposure to sunlight and an inadequate dietary supply of the vitamin. l**p. 161** The bones of children with rickets are so poorly mineralized that they become very flexible. Because the walls of each femur can no longer resist the tension and compression forces applied by the body weight (see Figure 6–7•), the bones bend laterally and affected individuals develop a bowlegged appearance. In the United States, homogenized milk is fortified with vitamin D specifically to prevent rickets.

100 Keys | Each day calcium and phosphate ions circulating in the blood are lost in the urine. To keep body fluid concentrations stable, those ions must be replaced; if they aren't obtained from the diet, they will be released from the skeleton, and the bones will become weaker as a result. If you want to keep your bones strong, you must exercise and make sure your diet contains vitamin D and plenty of calcium—at least enough to compensate for daily excretion.

Concept Check

Why does a child who has rickets have difficulty walking?

What effect would increased PTH secretion have on blood calcium levels?

How does calcitonin help lower the calcium ion concentration of blood?

Answers begin on p. A–1

Fracture Repair

Despite its mineral strength, bone can crack or even break if subjected to extreme loads, sudden impacts, or stresses from unusual directions. The damage produced constitutes a **fracture**. (See "FOCUS: Types of Fractures," p. 200.) Most fractures heal even after severe damage, provided that the blood supply and the cellular components of the endosteum and periosteum survive. Steps in the repair process are illustrated in Figure 6–15•:

Step 1 In even a small fracture, many blood vessels are broken and extensive bleeding occurs. A large blood clot, or **fracture hematoma**, soon closes off the injured vessels and leaves a fibrous meshwork in the damaged area. The disruption of circulation kills osteocytes around the fracture, broadening the area affected. Dead bone soon extends along the shaft in either direction from the break.

Step 2 In adults, the cells of the periosteum and endosteum are normally relatively inactive. When a fracture occurs, the cells of the intact endosteum and periosteum undergo rapid cycles of cell division, and the daughter cells migrate into the fracture zone. An **external callus** (*callum*, hard skin), or enlarged collar of cartilage and bone, forms and encircles the bone at the level of the fracture. An extensive **internal callus** organizes within the marrow cavity and between the broken ends of the shaft. At the center of the external callus, cells differentiate into chondrocytes and produce blocks of hyaline cartilage. At the edges of each callus, the cells differentiate into osteoblasts and begin creating a bridge between the bone fragments on either side of the fracture. At this point, the broken ends have been temporarily stabilized.

Step 3 As the repair continues, osteoblasts replace the central cartilage of the external callus with spongy bone. When this conversion is complete, the external and internal calluses form an extensive and continuous brace at the fracture site. Struts of spongy bone now unite the broken ends. The surrounding area is gradually reshaped as fragments of dead bone are removed and replaced. The ends of the fracture are now held firmly in place and can withstand normal stresses from muscle contractions. If the fracture required external support in the form of a cast, that support can be removed at this stage.

Step 4 Osteoclasts and osteoblasts continue to remodel the region of the fracture for a period ranging from four months to well over a year. When the remodeling is complete, the bone of the calluses is gone and only living compact bone remains. The repair may be “good as new” and leave no indications that a fracture ever occurred, or the bone may be slightly thicker and stronger than normal at the fracture site. Under comparable stresses, a second fracture will generally occur at a different site. AM: Stimulation of Bone Growth and Repair

Aging and the Skeletal System

Objective

- Summarize the effects of the aging process on the skeletal system.

The bones of the skeleton become thinner and weaker as a normal part of the aging process. Inadequate ossification is called **ost**
eopenia (os-t
¯e
-

¯o
-P

E¯

-n
¯e
-uh; *penia*, lacking), and all of us become slightly osteopenic as we age. This reduction in bone mass begins between ages 30 and 40. Over that period, osteoblast activity begins to decline, while osteoclast activity continues at previous levels. Once the reduction begins, women lose roughly 8 percent of their skeletal mass every decade, whereas the skeletons of men deteriorate at about 3 percent per decade. Not all parts of the skeleton are equally affected. Epiphyses, vertebrae, and the jaws lose more mass than other sites, resulting in fragile limbs, reduction in height, and loss of teeth.

When the reduction in bone mass is sufficient to compromise normal function, the condition is known as **osteoporosis** (os

t

¯e

-

¯o

-po-R

¯O

-sis; *porosus,* porous). The fragile bones that result are likely to break when exposed to stresses that younger individuals could easily tolerate. For example, a hip fracture can occur when a ninety-year-old simply tries to stand. Any fractures that occur in aged individuals lead to a loss of independence and an immobility that further weakens the skeleton. The extent of the loss of spongy bone mass due to osteoporosis is shown in Figure 6–17•; the reduction in compact bone mass is equally severe.

Sex hormones are important in maintaining normal rates of bone deposition. Over age 45, an estimated 29 percent of women and 18 percent of men have osteoporosis. In women, the condition accelerates after menopause, owing to a decline in circulating estrogens. Because men continue to produce androgens until relatively late in life, severe osteoporosis is less common in men below age 60 than in women in that same age group.

Osteoporosis can also develop as a secondary effect of many cancers. Cancers of the bone marrow, breast, or other tissues release a chemical known as **osteoclast-activating factor**. This compound increases both the number and activity of osteoclasts and produces severe osteoporosis. AM: Osteoporosis and Age-Related Skeletal Abnormalities

Concept Check

At which point in fracture repair would you find an external callus?

Why is osteoporosis more common in older women than in older men?

Answers begin on p. A–1

Chapter Review

Selected Clinical Terminology

acromegaly: A condition caused by excess secretion of growth hormone after puberty. Skeletal abnormalities develop, affecting the cartilages and various small bones. (p. 196) **external callus:** A toughened layer of connective tissue that encircles and stabilizes a bone at a fracture site. (p. 198) **fracture:** A crack or break in a bone. (p. 198) **fracture hematoma:** A large blood clot that closes off the injured vessels around a fracture and leaves a fibrous meshwork in the damaged area of bone; the first step in fracture repair. (p. 198) **gigantism:** A condition resulting from an overproduction of growth hormone before puberty. (p. 196) **internal callus:** A bridgework of bone trabeculae that unites the broken ends of a bone on the marrow side of a fracture. (p. 198) **Marfan's syndrome:** An inherited condition linked to defective production of *fibrillin*, a connective tissue glycoprotein. Extreme height and long, slender limbs are the most obvious physical indications of Marfan's syndrome; cardiovascular problems are the most dangerous aspects of the condition. (p. 196) **osteoclast-activating factor:** A compound, released by cancers of the bone marrow, breast, or other tissues, that produces severe osteoporosis. (p. 201) **osteomalacia:** A softening of bone due to a decrease in its mineral content. (p. 198) **osteopenia:** Inadequate ossification, leading to thinner, weaker bones. (p. 199) **osteoporosis:** A reduction in bone mass to a degree that compromises normal function. (p. 201) **pituitary growth failure** (*pituitary dwarfism*)**:** A disorder caused by inadequate production of growth hormone prior to puberty. (p. 196) **rickets:** A childhood disorder that reduces the amount of calcium salts in the skeleton; typically characterized by a bow-legged appearance, because the leg bones bend under the body's weight. (p. 198) **scurvy:** A condition involving weak, brittle bones as a result of a vitamin C deficiency. (p. 195)

Study Outline

An Introduction to the Skeletal System p. 180

1. The skeletal system includes the bones of the skeleton and the cartilages, ligaments, and other connective tissues that stabilize or connect the bones. The functions of the skeletal system include support, storage of minerals and lipids, blood cell production, protection, and leverage.

The Gross Anatomy of Bones p. 180 Bone Shapes p. 180

1. Bones may be categorized as **long bones**, **flat bones**, **sutural bones**, (*Wormian bones*), **irregular bones**, **short bones**, and **sesamoid bones**. *(Figure 6–1)*

Bone Markings (Surface Features) p. 181

2. Each bone has characteristic **bone markings**, including elevations, projections, depressions, grooves, and tunnels. *(Table 6–1)*

Bone Structure p. 183

3. The two types of bone tissue are compact (*dense*) bone and spongy (*cancellous*) bone.

4. A representative long bone has a **diaphysis**, **epiphyses**, **metaphyses**, **articular cartilages**, and a **marrow cavity**. *(Figure 6–2)*

5. The marrow cavity and spaces within spongy bone contain either **red bone marrow** (for blood cell formation) or **yellow bone marrow** (for lipid storage).

Bone Histology p. 184

1. Osseous tissue is a supporting connective tissue with a solid matrix and ensheathed by a *periosteum*.

The Matrix of Bone p. 184

2. Bone matrix consists largely of crystals of **hydroxyapatite**; the minerals are deposited in **lamellae**.

The Cells of Bone p. 184

3. **Osteocytes**, located in *lacunae*, are mature bone cells. Adjacent osteocytes are interconnected by **canaliculi**. **Osteoblasts** synthesize the bony matrix by **osteogenesis**. **Osteoclasts** dissolve the bony matrix through **osteolysis**. **Osteoprogenitor cells** differentiate into osteoblasts. *(Figure 6–3)*

The Structure of Compact Bone p. 185

1. **4.** The basic functional unit of compact bone is the **osteon**, containing osteocytes arranged around a **central canal**. **Perforating canals** extend perpendicularly to the bone surface. *(Figures 6–4, 6–5)*

2. **5.** Compact bone is located where stresses come from a limited range of directions, such as along the diaphysis of long bones.

1. The organic and mineral components of bone are continuously recycled and renewed through **remodeling.**

100 Keys | p. 194

Effects of Exercise on Bone p. 194

2. The shapes and thicknesses of bones reflect the stresses applied to them.

100 Keys | p. 194

Hormonal and Nutritional Effects on Bone p. 194

3. Normal osteogenesis requires a reliable source of minerals, vitamins, and hormones.

4. *Growth hormone* and *thyroxine* stimulate bone growth. Calcitonin and parathyroid hormone control blood calcium levels. *(Table 6–2)*

The Skeleton as a Calcium Reserve p. 196

5. Calcium is the most abundant mineral in the human body; roughly 99 percent of it is located in the skeleton. *(Figure 6–13)*

6. Interactions among the bones, digestive tract, and kidneys affect the calcium ion concentration. *(Figure 6–14)*

7. Two hormones, **calcitonin** and **parathyroid hormone (PTH)**, regulate calcium ion homeostasis. Calcitonin leads to a decline in the

calcium concentration in body fluids, whereas parathyroid hormone increases the calcium concentration in body fluids. *(Figure 6–14)*

100 Keys | p. 198

Fracture Repair p. 198

8. A **fracture** is a crack or a break in a bone. The repair of a fracture involves the formation of a **fracture hematoma**, an **external callus**, and an **internal callus**. *(Figure 6–15)*

Aging and the Skeletal System p. 199

1. The effects of aging on the skeleton include **osteopenia** and **osteoporosis**. *(Figure 6–17)*

TABLE 6–2

Hormone	**Primary Source**	**Effects on Skeletal System**

Calcitriol Kidneys Promotes calcium and phosphate ion absorption along the digestive tract

Growth hormone Pituitary gland Stimulates osteoblast activity and the synthesis of bone matrix
Thyroxine Thyroid gland (follicle cells) With growth hormone, stimulates osteoblast activity and the synthesis
of bone matrix

Sex hormones Ovaries (estrogens) Stimulate osteoblast activity and the synthesis of bone matrix
Testes (androgens)

Parathyroid hormone Parathyroid glands Stimulates osteoclast (and osteoblast) activity; elevates calcium ion
concentrations in body fluids

Calcitonin Thyroid gland (C cells) Inhibits osteoclast activity; promotes calcium loss at kidneys; reduces calcium ion
concentrations in body fluids

Types of Fractures

Fractures are named according to their external appearance, their location, and the nature of the crack or break in the bone. Important types of fractures are illustrated here by representative x-rays. The broadest general categories are closed fractures and open fractures. **Closed**, or *simple*, fractures are completely internal. They can be seen only on x-rays, because they do not involve a break in the skin. Closed fractures are usually relatively simple to treat, as the surrounding tissues keep the broken ends of the bone aligned. **Open**, or *compound*, fractures project through the skin. These fractures, which are obvious on inspection, are more dangerous than closed fractures, due to the possibility of infection or uncontrolled bleeding. The names of some fractures apply only to injuries at specific locations; a *Pott's fracture*, for example, occurs at the ankle. In other cases, the terms used are descriptive. A *transverse fracture* involves a break at right angles to the long axis of a bone, and a *comminuted fracture* involves a shattering of the affected bone(s). Many fractures fall into more than one category, because the terms overlap. For example, a *Colles' fracture* is a transverse fracture of the wrist that may be comminuted and, depending on the injury, either open or closed. Representative examples of the common types of fractures are shown in Figure 6–16•. Identifying the fracture in these images takes some practice. Look for the dark line that interrupts the homogenous appearance of the bone of the shaft.

The Axial Division of the Skeletal System

Objective

- Identify the bones of the axial skeleton and specify their functions.

The **axial skeleton** forms the longitudinal axis of the body (Figure 7–1•). The axial skeleton has 80 bones, roughly 40 percent of the bones in the human body. The axial components are as follows:

- The *skull* (8 *cranial bones* and 14 *facial bones*).
- Bones associated with the skull (6 *auditory ossicles* and the *hyoid bone*).
- The *vertebral column* (24 *vertebrae*, the *sacrum*, and the *coccyx*).
- The *thoracic cage* (the *sternum* and 24 *ribs*).

The axial skeleton provides a framework that supports and protects organs in the dorsal and ventral body cavities. It also provides an extensive surface area for the attachment of muscles that (1) adjust the positions of the head, neck, and trunk; (2) perform respiratory movements; and (3) stabilize or position parts of the **appendicular skeleton**, which supports the limbs. The joints of the axial skeleton permit limited movement, but they are very strong and heavily reinforced with ligaments.

We will now consider each of the components of the axial skeleton, beginning with the skull.

The Skull

Objectives

- Identify the bones of the cranium and face, and explain the significance of the markings on the individual bones.
- Describe the structure of the nasal complex and the functions of the individual bones.
- Explain the functions of the paranasal sinuses.
- Describe key structural differences among the skulls of infants, children, and adults.

The bones of the **skull** protect the brain and guard the entrances to the digestive and respiratory systems. The skull contains 22 bones: 8 form the **cranium**, or *braincase*, and 14 are associated with the face (Figure 7–2•). Seven additional bones are associated with the skull: Six auditory ossicles are situated within the *temporal bones* of the cranium, and the hyoid bone is connected to the inferior surfaces of the temporal bones by a pair of ligaments.

The cranium consists of 8 **cranial bones**: the *occipital bone*, *frontal bone*, *sphenoid*, *ethmoid,* and the paired *parietal* and *temporal bones*. Together, the cranial bones enclose the **cranial cavity**, a fluid-filled chamber that cushions and supports the brain. Blood vessels, nerves, and membranes that stabilize the position of the brain are attached to the inner surface of the cranium. Its outer surface provides an extensive area for the attachment of muscles that move the eyes, jaws, and head. A joint between the occipital bone and the first vertebra of the neck stabilizes the positions of the brain and spinal cord, while the joints between the vertebrae of the neck permit a wide range of head movements.

If the cranium is the house where the brain resides, the *facial complex* is the front porch. **Facial bones** protect and support the entrances to the digestive and respiratory tracts. The superficial facial bones (the paired *maxillary*, *lacrimal*, *nasal*, and *zygomatic bones,* and the *mandible*) (see Figure 7–2•) provide areas for the attachment of muscles that control facial expressions and assist in manipulating food. The deeper facial bones (the paired *palatine bones* and *inferior nasal conchae*, and the single median *vomer*) help separate the oral and nasal cavities, increase the surface area of the nasal cavities, or help form the **nasal septum** (*septum*, wall), which subdivides the nasal cavity.

Several bones of the skull contain air-filled chambers called **sinuses**. Sinuses have two major functions: (1) They make a bone much lighter than it would otherwise be, and (2) the mucous membrane lining them produces mucus that moistens and cleans the air in and adjacent to the sinus. We will consider the sinuses as we discuss specific bones.

Joints, or *articulations*, form where two bones interconnect. Except where the mandible contacts the cranium, the connections between the skull bones of adults are immovable joints called **sutures**. At a suture, bones are tied firmly together with dense fibrous connective tissue. Each suture of the skull has a name, but at this point you need to know only four major sutures:

1. *Lambdoid Suture.* The **lambdoid** (LAM-doyd) **suture** (Greek *lambda*, L + *eidos*, shape) arches across the posterior surface of the skull (Figure 7–3a•). This suture separates the occipital bone from the two parietal bones. One or more **sutural bones** (*Wormian bones*) may be present along the lambdoid suture. l**p. 180**

2. *Coronal Suture.* The **coronal suture** attaches the frontal bone to the parietal bones of either side (Figure 7–3b•). The occipital, parietal, and frontal bones form the **calvaria** (kal-VA-re¯-uh), or skullcap. A cut through the body that parallels the coronal suture produces a *coronal section*, or *frontal section* (see Figure 1–9•, p. 20).

3. *Sagittal Suture.* The **sagittal suture** extends from the lambdoid suture to the coronal suture, between the parietal bones (see

Figure 7–3b•). A cut along the midline of the suture produces a midsagittal section; a slice that parallels the sagittal suture produces a parasagittal section. l**p. 20**

4. *Squamous Sutures.* A **squamous** (SKWA¯-mus) **suture** on each side of the skull forms the boundary between the temporal bone

and the parietal bone of that side. Figure 7–3a• shows the intersection between the squamous sutures and the lambdoid suture. Figure 7–3c shows the path of the squamous suture on the right side of the skull.

Clinical Note

The *temporomandibular joint (TMJ)*, between each temporal bone and the mandible, is quite mobile, allowing your jaw to move while

you chew or talk. The disadvantage of such mobility is that your jaw can easily be dislocated by forceful forward or lateral displace

ment. The connective tissue sheath, or *capsule*, that surrounds the joint is relatively loose, and the opposing bone surfaces are sepa

rated by a fibrocartilage pad. In **TMJ syndrome**, or *myofacial pain syndrome*, the mandible is pulled slightly out of alignment, gener

ally by spasms in one of the jaw muscles. The individual experiences facial pain that radiates around the ear on the affected side and an inability to open the mouth fully. TMJ syndrome is a repeating cycle of muscle spasm ¡ misalignment ¡ pain ¡ muscle spasm. It has been linked to involuntary behaviors, such as grinding of the teeth during sleep (*bruxism*), and to emotional stress. Treatment focuses on breaking the cycle of muscle spasm and pain and, when necessary, providing emotional support. The application of heat to the affected joint, coupled with the use of anti-inflammatory drugs, local anesthetics, or both, may help. If teeth grinding is suspected, special mouth guards may be worn during sleep.

Concept Check

In which bone is the foramen magnum located?

Tomás suffers a blow to the skull that fractures the right superior lateral surface of his cranium. Which bone is fractured?

Which bone contains the depression called the sella turcica? What is located in this depression?

Answers begin on p. A–1 Summary: Foramina and Fissures of the Skull

Table 7–1 summarizes information about the foramina and fissures introduced thus far. This reference source will be especially important to you in later chapters when you study the nervous and cardiovascular systems.

The Orbital and Nasal Complexes

The facial bones not only protect and support the openings of the digestive and respiratory systems, but also protect the delicate sense organs responsible for vision and smell. Together, certain cranial bones and facial bones form the *orbital complex*, which surrounds each eye, and the *nasal complex*, which surrounds the nasal cavities.

The **orbits** are the bony recesses that contain the eyes. Each orbit is formed by the seven bones of the **orbital complex** (Figure 7–13•). The frontal bone forms the roof, and the maxillary bone provides most of the orbital floor. The orbital rim and the first portion of the medial wall are formed by the maxillary bone, the lacrimal bone, and the lateral mass of the ethmoid. The lateral mass articulates with the sphenoid and a small process of the palatine bone. Several prominent foramina and fissures penetrate the sphenoid or lie between it and the maxillary bone. Laterally, the sphenoid and maxillary bone articulate with the zygomatic bone, which forms the lateral wall and rim of the orbit.

The **nasal complex** (Figure 7–14•) includes the bones that enclose the nasal cavities and the **paranasal sinuses**, air-filled chambers connected to the nasal cavities. The frontal bone, sphenoid, and ethmoid form the superior wall of the nasal cavities. The lateral walls are formed by the maxillary bones and the lacrimal bones (not shown), the ethmoid (the superior and middle nasal conchae), and the inferior nasal conchae. Much of the anterior margin of the nasal cavity is formed by the soft tissues of the nose, but the bridge of the nose is supported by the maxillary and nasal bones.

Paranasal Sinuses

The sphenoid, ethmoid, frontal, palatine, and maxillary bones contain the paranasal sinuses. Figure 7–14a• shows the location of the frontal and sphenoidal sinuses. Ethmoidal air cells and maxillary sinuses are shown in Figure 7–14b•. (The tiny palatine sinuses, not shown, generally open into the sphenoidal sinuses.) The paranasal sinuses lighten the skull bones and provide an extensive area of mucous epithelium. The mucous secretions are released into the nasal cavities. The ciliated epithelium passes the mucus back toward the throat, where it is eventually swallowed or expelled by coughing. Incoming air is humidified and warmed as it flows across this thick carpet of mucus. Foreign particulate matter, such as dust or microorganisms, becomes trapped in the sticky mucus and is then swallowed or expelled. This mechanism helps protect the more delicate portions of the respiratory tract.

AM: Sinus Problems and Septal Defects

Anatomy 360 | Review the anatomy of the skull on the **Anatomy 360 CD-ROM: Skeletal System/Axial Skeleton/ Skull.**

The Skulls of Infants and Children

Many different centers of ossification are involved in the formation of the skull. As development proceeds, the centers fuse, producing a smaller number of composite bones. For example, the sphenoid begins as 14 separate ossification centers. At birth, fusion has not been completed: There are two frontal bones, four occipital bones, and several sphenoid and temporal elements.

The skull organizes around the developing brain. As the time of birth approaches, the brain enlarges rapidly. Although the bones of the skull are also growing, they fail to keep pace. At birth, the cranial bones are connected by areas of fibrous connective tissue (Figure 7–15•). The connections are quite flexible, so the skull can be distorted without damage. Such distortion normally occurs during delivery, and the changes in head shape ease the passage of the infant through the birth canal. The largest fibrous areas between the cranial bones are known as **fontanels** (fon-tuh-NELZ; sometimes spelled *fontanelles*):

- The *anterior fontanel* is the largest fontanel. It lies at the intersection of the frontal, sagittal, and coronal sutures in the anterior portion of the skull.
- The *occipital fontanel* is at the junction between the lambdoid and sagittal sutures.
- The *sphenoidal fontanels* are at the junctions between the squamous sutures and the coronal suture.
- The *mastoid fontanels* are at the junctions between the squamous sutures and the lambdoid suture.

The anterior fontanel is often referred to as the “soft spot” on newborns, and is often the only fontanel easily seen by new parents. Because it is composed of fibrous connective tissue and covers a major blood vessel, the anterior fontanel pulses as the heart beats. This fontanel is sometimes used to determine whether an infant is dehydrated, as the surface becomes indented when blood volume is low.

The occipital, sphenoidal, and mastoid fontanels disappear within a month or two after birth. The anterior fontanel generally persists until the child is nearly 2 years old. Even after the fontanels disappear, the bones of the skull remain separated by fibrous connections.

The skulls of infants and adults differ in terms of the shape and structure of cranial elements. This difference accounts for variations in proportions as well as in size. The most significant growth in the skull occurs before age 5, because at that time the brain stops growing and the cranial sutures develop. As a result, the cranium of a young child, compared with the skull as a whole, is relatively larger than that of an adult. The growth of the cranium is generally coordinated with the expansion of the brain. If one or more sutures form before the brain stops growing, the skull will be abnormal in shape, size, or both.

Clinical Note

Unusual distortions of the skull result from *craniostenosis* (kra¯-ne¯-¯o -sten-O¯-sis; *stenosis*, narrowing), the premature closure of one or more fontanels. As the brain continues to enlarge, the rest of the skull distorts to accommodate it. A long and narrow head is produced by early closure of the sagittal suture, whereas a very broad skull results if the coronal suture forms prematurely. Early closure of all cranial sutures restricts the development of the brain, and surgery must be performed to prevent brain damage. If brain enlargement stops due to genetic or developmental abnormalities, however, skull growth ceases as well. This condition, which results in an undersized head, is called *microcephaly* (m ¯ı -kr o¯-SEF-uh-le¯; *micro*-, small + *cephalon*, head).

The Vertebral Column

Objectives

- Identify and describe the curvatures of the spinal column and their functions.
- Identify the vertebral regions, and describe the distinctive structural and functional characteristics of each vertebral group.

The rest of the axial skeleton consists of the vertebral column, ribs, and sternum. The adult **vertebral column**, or *spine*, consists of 26 bones: the **vertebrae** (24), the **sacrum**, and the **coccyx** (KOK-siks), or tailbone. The vertebrae provide a column of support, bearing the weight of the head, neck, and trunk and ultimately transferring the weight to the appendicular skeleton of the lower limbs. The vertebrae also protect the spinal cord and help maintain an upright body position, as in sitting or standing.

The vertebral column is divided into cervical, thoracic, lumbar, sacral, and coccygeal regions (Figure 7–16•). Seven **cervical vertebrae** (C_1-C_7) constitute the neck and extend inferiorly to the trunk. Twelve **thoracic vertebrae** (T_1-T_{12}) form the superior

portion of the back; each articulates with one or more pairs of ribs. Five **lumbar vertebrae** (L_1-L_5) form the inferior portion of the back; the fifth articulates with the sacrum, which in turn articulates with the coccyx. The cervical, thoracic, and lumbar regions consist of individual vertebrae. During development, the sacrum originates as a group of five vertebrae, and the coccyx begins as three to five very small vertebrae. In general, the vertebrae of the sacrum are completely fused by age 25–30. Ossification of the distal coccygeal vertebrae is not complete before puberty, and thereafter fusion occurs at a variable pace. The total length of the vertebral column of an adult averages 71 cm (28 in.).

ATLAS: Embryology Summary 7: The Development of the Vertebral Column

Spinal Curvature

The vertebral column is not straight and rigid. A lateral view shows four **spinal curves** (see Figure 7–16•): the (1) **cervical curve**,

(2) **thoracic curve**, (3) **lumbar curve**, and (4) **sacral curve**.

You may have noticed that an infant’s body axis forms a loose comma or a C, with the back curving posteriorly. The C shape results from the thoracic and sacral curves. These are called **primary curves**, because they appear late in fetal development, or **accommodation curves**, because they accommodate the thoracic and abdominopelvic viscera. The primary curves are present in the vertebral column at birth. The lumbar and cervical curves, known as **secondary curves**, do not appear until several months after birth. These curves are also called **compensation curves**, because they help shift the weight to permit an upright posture. The cervical curve develops as the infant learns to balance the weight of the head on the vertebrae of the neck. The lumbar curve balances the weight of the trunk over the lower limbs; it develops with the ability to stand. Both compensations become accentuated as the toddler learns to walk and run. All four curves are fully developed by age 10. AM: Kyphosis, Lordosis, and Scoliosis

When you stand, the weight of your body must be transmitted through the vertebral column to the hips and ultimately to the lower limbs. Yet most of your body weight lies anterior to the vertebral column. The various curves bring that weight in line with the body axis. Consider what you do automatically when standing with a heavy object hugged to your chest. You avoid toppling forward by exaggerating the lumbar curve and by keeping the weight back toward the body axis. This posture can lead to discomfort at the base of the spinal column. For example, many women in the last three months of pregnancy develop chronic back pain from the changes in lumbar curvature that must adjust for the increasing weight of the fetus. In many parts of the world, people often balance heavy objects on their head. This practice increases the load on the vertebral column, but the spinal curves are not affected because the weight is aligned with the axis of the spine.

Vertebral Anatomy

Each vertebra consists of three basic parts: (1) a *vertebral body*, (2) a *vertebral arch*, and (3) *articular processes* (Figure 7–17a•).

The **vertebral body**, or *centrum* (plural, *centra*), is the part of a vertebra that transfers weight along the axis of the vertebral column (Figure 7–17a,b,e•). The bodies of adjacent vertebrae are interconnected by ligaments, but are separated by pads of fibrocartilage, the **intervertebral discs**.

The **vertebral arch** forms the posterior margin of each **vertebral foramen** (Figure 7–17a,c•). The vertebral arch has walls, called **pedicles** (PED-i-kulz), and a roof, formed by flat layers called **laminae** (LAM-i-ne¯; singular, *lamina*, a thin plate). The pedicles arise along the posterior and lateral margins of the body. The laminae on either side extend dorsally and medially to complete the roof. Together, the vertebral foramina of successive vertebrae form the **vertebral canal**, which encloses the spinal cord (Figure 7–17e•).

A **spinous process** projects posteriorly from the point where the vertebral laminae fuse to complete the vertebral arch. You can see—and feel—the spinous processes through the skin of the back when the spine is flexed. **Transverse processes** project laterally or dorsolaterally on both sides from the point where the laminae join the pedicles. These processes are sites of muscle attachment, and they may also articulate with the ribs. AM: Spina Bifida

Like the transverse processes, the **articular processes** arise at the junction between the pedicles and the laminae. A **superior** and an **inferior articular process** lie on each side of the vertebra. The superior articular processes articulate with the inferior articular processes of a more superior vertebra (or the occipital condyles, in the case of the first cervical vertebra). The inferior articular processes articulate with the superior articular processes of a more inferior vertebra (or the sacrum, in the case of the last lumbar vertebra).

The inferior articular processes of one vertebra articulate with the superior articular processes of the next vertebra. Each articular process has a smooth concave surface called an **articular facet**. The superior processes have articular facets on their dorsal surfaces, whereas the inferior processes articulate along their ventral surfaces.

Adjacent vertebral bodies are separated by intervertebral discs, and gaps separate the pedicles of successive vertebrae. These gaps, called **intervertebral foramina**, permit the passage of nerves running to or from the enclosed spinal cord.

Concept Check

Why does the vertebral column of an adult have fewer vertebrae than that of a newborn?

What is the importance of the secondary curves of the spine?

When you run your finger along a person’s spine, what part of the vertebrae are you feeling just beneath the skin?

Answers begin on p. A–1

Vertebral Regions

When referring to a specific vertebra, we use a capital letter to indicate the vertebral region: C, T, L, S, and Co indicate the cervical, thoracic, lumbar, sacral, and coccygeal regions, respectively. In addition, we use a subscript number to indicate the relative position of the vertebra within that region, with 1 indicating the vertebra closest to the skull. For example, C3 is the third cervical vertebra; C1 is in contact with the skull. Similarly, L4 is the fourth lumbar vertebra; L1 is in contact with T12 (see Figure 7–16•,
p. 224). We will use this shorthand throughout the text.

Although each vertebra bears characteristic markings and articulations, we will focus on the general characteristics of each region, and on how regional variations determine the vertebral group's function.

Cervical Vertebrae

Most mammals—whether giraffes, whales, mice, or humans— have seven cervical vertebrae (Figure 7–18•). The cervical vertebrae are the smallest in the vertebral column and extend from the occipital bone of the skull to the thorax. The body of a cervical vertebra is small compared with the size of the vertebral foramen (Figure 7–18b•). At this level, the spinal cord still contains most of the axons that connect the brain to the rest of the body. The diameter of the spinal cord decreases as you proceed caudally along the vertebral canal, and so does the diameter of the vertebral arch. However, cervical vertebrae support only the weight of the head, so the vertebral body can be relatively small and light. As you continue toward the sacrum, the loading increases and the vertebral bodies gradually enlarge.

In a typical cervical vertebra, the superior surface of the body is concave from side to side, and it slopes, with the anterior edge inferior to the posterior edge (Figure 7–18c•). Vertebra C_1 has no spinous process. The spinous processes of the other cervical vertebrae are relatively stumpy, generally shorter than the diameter of the vertebral foramen. In the case of vertebrae C2

the tip

¯I

of each spinous process bears a prominent notch (see Figure 7–18b•). A notched spinous process is said to be **bifid** (B -fid).

Laterally, the transverse processes are fused to the **costal processes**, which originate near the ventrolateral portion of the vertebral body. The costal and transverse processes encircle prominent, round **transverse foramina**. These passageways protect the *vertebral arteries* and *vertebral veins*, important blood vessels that service the brain.

The preceding description is adequate for identifying the cervical vertebrae C3

–

C6. The first two cervical vertebrae are unique,

and the seventh is modified; these vertebrae are described shortly. The interlocking bodies of articulated C3

–

C7

permit more flex

ibility than do those of other regions. Table 7–2 includes a summary of the features of these cervical vertebrae.

Compared with the cervical vertebrae, your head is relatively massive. It sits atop the cervical vertebrae like a soup bowl on the tip of a finger. With this arrangement, small muscles can produce significant effects by tipping the balance one way or another. But if you change position suddenly, as in a fall or during rapid acceleration (a jet takeoff) or deceleration (a car crash), the balancing muscles are not strong enough to stabilize the head. A dangerous partial or complete dislocation of the cervical vertebrae can result, with injury to muscles and ligaments and potential injury to the spinal cord. The term **whiplash** is used to describe such an injury, because the movement of the head resembles the cracking of a whip.

The Atlas (C_1) The **atlas**, cervical vertebra C1 (Figure 7–18d•), holds up the head, articulating with the occipital condyles of the skull. This vertebra is named after Atlas, who, according to Greek myth, holds the world on his shoulders. The articulation between the occipital condyles and the atlas is a joint that permits you to nod (such as when you indicate “yes”). The atlas can easily be distinguished from other vertebrae by (1) the lack of a body and spinous process and (2) the presence of a large, round vertebral foramen bounded by **anterior** and **posterior arches**.

The atlas articulates with the second cervical vertebra, the *axis*. This articulation permits rotation (as when you shake your head to indicate “no”).

The Axis (C_2) During development, the body of the atlas fuses to the body of the second cervical vertebra, called the **axis** (C2)

(see Figure 7–18d•). This fusion creates the prominent **dens** (DENZ; *dens*, tooth), or *odontoid* (

$\bar{o}$

-DON-toyd; *odontos*, tooth)

process, of the axis. A transverse ligament binds the dens to the inner surface of the atlas, forming a pivot for rotation of the atlas and skull. Important muscles controlling the position of the head and neck attach to the especially robust spinous process of the axis.

In children, the fusion between the dens and axis is incomplete. Impacts or even severe shaking can cause dislocation of the dens and severe damage to the spinal cord. In adults, a blow to the base of the skull can be equally dangerous, because a dislocation of the axis–atlas joint can force the dens into the base of the brain, with fatal results.

The Vertebra Prominens (C_7) The transition from one vertebral region to another is not abrupt, and the last vertebra of one region generally resembles the first vertebra of the next. The **vertebra prominens**, or seventh cervical vertebra (C7), has a long, slender spinous process (Figure 7–18a•) that ends in a broad tubercle that you can feel through the skin at the base of the neck. This vertebra is the interface between the cervical curve, which arches anteriorly, and the thoracic curve, which arches posteriorly (see Figure 7–16•). The transverse processes of C7 are large, providing additional surface area for muscle attachment. The **ligam entum nuchae** (lig-uh-MEN-tum NOO-k

;

‾e

nucha, nape), a stout elastic ligament, begins at the vertebra prominens and extends to an insertion along the occipital crest of the skull. Along the way, it attaches to the spinous processes of the other cervical vertebrae. When your head is upright, this ligament acts like the string on a bow, maintaining the cervical curvature without muscular effort. If you have bent your neck forward, the elasticity in the ligamentum nuchae helps return your head to an upright position.

Thoracic Vertebrae

There are 12 thoracic vertebrae (Figure 7–19•). A typical thoracic vertebra has a distinctive heart-shaped body that is more massive than that of a cervical vertebra. The vertebral foramen is relatively smaller, and the long, slender spinous process projects posteriorly and inferiorly. The spinous processes of T10, T11, and T12 increasingly resemble those of the lumbar region as the transition between the thoracic and lumbar curves approaches. Because the inferior thoracic and lumbar vertebrae carry so much weight, the transition between the thoracic and lumbar curves is difficult to stabilize. As a result, compression fractures or compression–dislocation fractures incurred after a hard fall tend to involve the last thoracic and first two lumbar vertebrae.

Each thoracic vertebra articulates with ribs along the dorsolateral surfaces of the body. The **costal facets** on the vertebral bodies articulate with the heads of the ribs. The location and structure of the articulations vary somewhat among thoracic vertebrae (Figure 7–19a•). Vertebrae T1

–

T8 each articulate with two pairs of ribs, so their vertebral bodies have two costal facets (*superior*
and *inferior*) on each side. Vertebrae T9
–

T11 have a single costal facet on each side, and each vertebra articulates with a single pair of ribs.
The transverse processes of vertebrae T1
–

T10 are relatively thick and contain **transverse costal facets** for rib articulation
(Figure 7–19b,c•). Thus, rib pairs 1 through 10 contact their vertebrae at two points: a costal facet and a transverse costal facet. Table 7–2, p. 228, summarizes the features of thoracic vertebrae.

Lumbar Vertebrae

The five lumbar vertebrae are the largest vertebrae. The body of a typical lumbar vertebra (Figure 7–20•) is thicker than that of a thoracic vertebra, and the superior and inferior surfaces are oval rather than heart shaped. Other noteworthy features are that
(1) lumbar vertebrae do not have costal facets; (2) the slender transverse processes, which lack transverse costal facets, project dorsolaterally; (3) the vertebral foramen is triangular; (4) the stumpy spinous processes project dorsally; (5) the superior articular processes face medially (“up and in”); and (6) the inferior articular processes face laterally (“down and out”).
The lumbar vertebrae bear the most weight. Their massive spinous processes provide surface area for the attachment of lower back muscles that reinforce or adjust the lumbar curve. Table 7–2, p. 228, summarizes the characteristics of lumbar vertebrae.

The Sacrum

The sacrum consists of the fused components of five sacral vertebrae. These vertebrae begin fusing shortly after puberty and, in general, are completely fused at age 25–30. The sacrum protects the reproductive, digestive, and urinary organs and, via paired articulations, attaches the axial skeleton to the pelvic girdle of the appendicular skeleton (see Figure 7–1b•, p. 207).

The broad posterior surface of the sacrum (Figure 7–21a•) provides an extensive area for the attachment of muscles, especially those that move the thigh. The superior articular processes of the first sacral vertebra articulate with the last lumbar vertebra. The **sacral canal** is a passageway that begins between these articular processes and extends the length of the sacrum. Nerves and membranes that line the vertebral canal in the spinal cord continue into the sacral canal.

The **median sacral crest** is a ridge formed by the fused spinous processes of the sacral vertebrae. The laminae of the fifth

sacral vertebra fail to contact one another at the midline; they form the **sacral cornua** (KOR-n

¯u

-uh; singular, *cornu*; *cornua*, horns).

¯A

These ridges form the margins of the **sacral hiatus** (h

–

ı is covered by connective tissues. Four pairs of **sacral foramina** open on either side of the median sacral crest. The intervertebral foramina of the fused sacral vertebrae open into these passageways. The **lateral sacral crest** on each side is a ridge that represents the fused transverse processes of the sacral vertebrae. The sacral crests provide surface area for the attachment of muscles.

The sacrum is curved, with a convex posterior surface (Figure 7–21b•). The degree of curvature is more pronounced in males than in females. The **auricular surface** is a thickened, flattened area lateral and anterior to the superior portion of the lateral sacral crest. The auricular surface is the site of articulation with the pelvic girdle (the *sacroiliac joint*). The **sacral tuberosity** is a roughened area between the lateral sacral crest and the auricular surface. It marks the attachment site of ligaments that stabilize the sacroiliac joint. The subdivisions of the sacrum are most clearly seen in anterior view (Figure 7–21c•). The narrow, inferior portion is the sacral **apex**, whereas the broad superior surface forms the **base**. The **sacral promontory**, a prominent bulge at the anterior tip of the base, is an important landmark in females during pelvic examinations and during labor and delivery. Prominent *transverse lines* mark the former boundaries of individual vertebrae that fuse during the formation of the sacrum. At the base of the sacrum, a broad sacral **ala**, or *wing*, extends on either side. The anterior and superior surfaces of each ala provide an extensive area for muscle attachment. At the apex, a flattened area marks the site of articulation with the coccyx.

The Coccyx

The small coccyx consists of three to five (typically, four) coccygeal vertebrae that have generally begun fusing by age 26 (see Figure 7–21•). The coccyx provides an attachment site for a number of ligaments and for a muscle that constricts the anal opening. The first two coccygeal vertebrae have transverse processes and unfused vertebral arches. The prominent laminae of the first coccygeal vertebrae are known as the **coccygeal cornua**. These laminae curve to meet the sacral cornua. The coccygeal vertebrae do not fuse completely until late in adulthood. In very old people, the coccyx may fuse with the sacrum.

Anatomy 360 | Review the anatomy of the vertebral column on the **Anatomy 360 CD-ROM: Skeletal System/ Axial Skele-ton/Vertebral Column.**

Concept Check

Joe suffered a hairline fracture at the base of the dens. Which bone is fractured, and where is it located?   Examining a human vertebra, you notice that, in addition to the large foramen for the spinal cord, two smaller foramina are on either side of the bone in the region of the transverse processes. From which region of the vertebral column is this vertebra? Why are the bodies of the lumbar vertebrae so large?

Answers begin on p. A–1

-tus), the opening at the inferior end of the sacral canal. This opening

-

The Thoracic Cage

Objective

- Explain the significance of the articulations between the thoracic vertebrae and the ribs, and between the ribs and sternum.

The skeleton of the chest, or **thoracic cage** (Figure 7–22•), provides bony support to the walls of the thoracic cavity. It consists of the thoracic vertebrae, the ribs, and the sternum (breastbone). The ribs and the sternum form the *rib cage*, whose movements are important in respiration. The thoracic cage as a whole serves two functions:

1. It protects the heart, lungs, thymus, and other structures in the thoracic cavity.

2. It serves as an attachment point for muscles involved in (1) respiration, (2) maintenance of the position of the vertebral column, and (3) movements of the pectoral girdle and upper limbs.

The Ribs

Ribs, or *costae*, are elongate, curved, flattened bones that originate on or between the thoracic vertebrae and end in the wall of the thoracic cavity. Each of us, regardless of sex, has 12 pairs of ribs (see Figure 7–22•). The first seven pairs are called **true ribs**, or *vertebrosternal ribs*. They reach the anterior body wall and are connected to the sternum by separate cartilaginous extensions, the **costal cartilages**. Beginning with the first rib, the vertebrosternal ribs gradually increase in length and in radius of curvature.

Ribs 8–12 are called **false ribs**, because they do not attach directly to the sternum. The costal cartilages of ribs 8–10, the *vertebrochondral ribs*, fuse together and merge with the cartilages of rib pair 7 before they reach the sternum (see Figure 7–22a•). The last two pairs of ribs (11 and 12) are called *floating ribs*, because they have no connection with the sternum, or *vertebral ribs*, because they are attached only to the vertebrae (see Figure 7–22b•) and muscles of the body wall.

Figure 7–23a• shows the superior surface of a typical rib. The *vertebral end* of the rib articulates with the vertebral column at the **head**, or *capitulum* (ka-PIT-ū-lum). A ridge divides the articular surface of the head into superior and inferior articular facets (Figure 7–23b•). From the head, a short **neck** leads to the **tubercle**, or *tuberculum* (too-BER-kū-lum), a small elevation that projects dorsally. The inferior portion of the tubercle contains an articular facet that contacts the transverse process of the thoracic vertebra. Ribs 1 and 10 originate at costal facets on vertebrae T1 and T10, respectively, and their tubercular facets articulate with the transverse costal facets on those vertebrae. The heads of ribs 2–9 articulate with costal facets on two adjacent vertebrae; their tubercular facets articulate with the transverse costal facets of the inferior member of the vertebral pair. Ribs 11 and 12, which originate at T11 and T12, do not have tubercular facets and do not contact the transverse processes of T11 or T12. The difference in rib orientation can be seen by comparing Figure 7–19a•, p. 229, with Figure 7–22b•.

The bend, or *angle*, of the rib is the site where the tubular **body**, or *shaft*, begins curving toward the sternum. The internal rib surface is concave, and a prominent *costal groove* along its inferior border marks the path of nerves and blood vessels. The superficial surface is convex and provides an attachment site for muscles of the pectoral girdle and trunk. The *intercostal muscles*, which move the ribs, are attached to the superior and inferior surfaces.

With their complex musculature, dual articulations at the vertebrae, and flexible connection to the sternum, the ribs are quite mobile. Note how the ribs curve away from the vertebral column to angle inferiorly (see Figure 7–22•). A typical rib acts as if it were the handle on a bucket, lying just below the horizontal plane. Pushing the handle down forces it inward; pulling it up swings it outward (Figure 7–23c•). In addition, because of the curvature of the ribs, the same movements change the position of the sternum. Depression of the ribs pulls the sternum inward, whereas elevation moves it outward. As a result, movements of the ribs affect both the width and the depth of the thoracic cage, increasing or decreasing its volume accordingly.

The ribs can bend and move to cushion shocks and absorb blows, but severe or sudden impacts can cause painful rib fractures. Because the ribs are tightly bound in connective tissues, a cracked rib can heal without a cast or splint. But compound fractures of the ribs can send bone splinters or fragments into the thoracic cavity, with potential damage to internal organs.

Surgery on the heart, lungs, or other organs in the thorax typically involves entering the thoracic cavity. The mobility of the ribs and the cartilaginous connections with the sternum allow the ribs to be temporarily moved out of the way. “Rib spreaders” are used to push the ribs apart in much the same way that a jack lifts a car off the ground for a tire change. If more extensive access is required, the cartilages of the sternum can be cut and the entire sternum folded out of the way. Once the sternum is replaced, scar tissue reunites the cartilages, and the ribs heal fairly rapidly.

The Sternum

The adult **sternum**, or breastbone, is a flat bone that forms in the anterior midline of the thoracic wall (see Figure 7–22a•). The sternum has three components:

¯e

1. The broad, triangular **manubrium** (ma-NOO-br -um) articulates with the *clavicles* (collarbones) and the cartilages of the first pair of ribs. The manubrium is the widest and most superior portion of the sternum. Only the first pair of ribs is attached by cartilage to this portion of the sternum. The **jugular notch**, located between the clavicular articulations, is a shallow indentation on the superior surface of the manubrium.

2. The tongue-shaped **body** attaches to the inferior surface of the manubrium and extends inferiorly along the midline. Individual costal cartilages from rib pairs 2–7 are attached to this porton of the sternum.

3. The **xiphoid** (Z -foyd) **process**, the smallest part of the sternum, is attached to the inferior surface of the body. The muscular

I¯

diaphragm and *rectus abdominis muscles* attach to the xiphoid process.

Ossification of the sternum begins at 6 to 10 ossification centers, and fusion is not complete until at least age 25. Before that age, the sternal body consists of four separate bones. In adults, their boundaries appear as a series of transverse lines crossing the sternum. The xiphoid process is generally the last sternal component to ossify and fuse. Its connection to the sternal body can be broken by impact or by strong pressure, creating a spear of bone that can severely damage the liver. Cardiopulmonary resuscitation (CPR) training strongly emphasizes proper hand positioning to reduce the chances of breaking ribs or the xiphoid process.

100 Keys | The axial skeleton protects the brain, spinal cord, and visceral organs of the chest. The vertebrae conduct the

body weight to the lower limbs; the inferior vertebrae are larger and stronger because they bear the most weight.

Anatomy 360 | Review the anatomy of the thoracic cage on the **Anatomy 360 CD-ROM: Skeletal System/ Axial Skele-ton/Thorax/Thoracic Cage.**

Concept Check

How could you distinguish between true ribs and false ribs?

Improper administration of cardiopulmonary resuscitation (CPR) can result in a fracture of which bone(s)?

What are the main differences between vertebrosternal and vertebrochondral ribs?

Answers begin on p. A–1

Chapter Review

Selected Clinical Terminology

craniostenosis: The premature closure of one or more fontanels, which can lead to unusual distortions of the skull and brain damage.

(p. 223) **deviated (nasal) septum:** A bent nasal septum that slows or prevents sinus drainage. [AM] **microcephaly:** An undersized head resulting from genetic or developmental abnormalities. (p. 223) **sinusitis:** Inflammation and congestion of the sinuses. [AM] **spina bifida:** A condition resulting from the failure of the vertebral laminae to unite during development; commonly associated with

developmental abnormalities of the brain and spinal cord. [AM] **TMJ syndrome:** A painful condition resulting from a misalignment of the mandible at the temporomandibular joint. (p. 220) **whiplash:** An injury caused by displacement of the cervical vertebrae during a sudden change in body position. (p. 227)

Study Outline

The Axial Division of the Skeletal System p. 206

1. The skeletal system consists of the axial skeleton and the appendicular skeleton. The **axial skeleton** can be divided into the **skull**, the **auditory ossicles** and **hyoid bone**, the **vertebral column**, and the **thoracic cage**. *(Figure 7–1)*

2. The **appendicular skeleton** includes the pectoral and pelvic girdles, which support the upper and lower limbs.

The Skull p. 206

1. The **skull** consists of the **cranium** and the bones of the face. The cranium, composed of **cranial bones**, encloses the **cranial cavity**, a division of the dorsal body cavity. The **facial bones** protect and support the entrances to the digestive and respiratory tracts.

(Figure 7–2)

2. Prominent superficial landmarks on the skull include the **lambdoid**, **coronal**, **sagittal**, and **squamous sutures**. *(Figure 7–3)*

FOCUS: The Individual Bones of the Skull p. 212

Cranial Bones p. 212

3. The cranial bones are the **occipital bone**, the two **parietal bones**, the **frontal bone**, the two **temporal bones**, the **sphenoid**, and the **ethmoid**. *(Figures 7–2 to 7–9)*

4. The occipital bone surrounds the **foramen magnum**. *(Figures 7–3 to 7–5)*

5. The frontal bone contains the **frontal sinuses**. *(Figures 7–4, 7–6)*

6. The **auditory ossicles** are located in a cavity within the temporal bone. *(Figure 7–7)*

Facial Bones p. 217

7. The bones of the face are the **maxillary bones**, the **palatine bones**, the **nasal bones**, the **vomer**, the **inferior nasal conchae**, the **zygomatic bones**, the **lacrimal bones**, and the **mandible**. *(Figures 7–2 to 7–4, 7–10 to 7–12)*

8. The left and right maxillary bones, or *maxillae*, are the largest facial bones; they form the upper jaw and most of the **hard palate**. *(Figures 7–3, 7–4, 7–10)*

9. The palatine bones are small L-shaped bones that form the posterior portions of the hard palate and contribute to the floor of the orbital cavities. *(Figures 7–3, 7–4, 7–10)*

10. The paired nasal bones extend to the superior border of the **external nares**. *(Figures 7–3, 7–4, 7–11)*

11. The vomer forms the inferior portion of the **nasal septum**. *(Figures 7–3, 7–4, 7–11)*

12. The **temporal process** of the zygomatic bone articulates with the **zygomatic process** of the temporal bone to form the **zygomatic arch**. *(Figures 7–3, 7–7, 7–11)*

13. The paired lacrimal bones, the smallest bones of the face, are situated medially in each **orbit**. *(Figures 7–3, 7–11)*

14. The mandible is the bone of the lower jaw. *(Figures 7–3, 7–4, 7–12)*

15. The **hyoid bone**, suspended by *stylohyoid ligaments*, supports the larynx. *(Figure 7–12)*

Summary: Foramina and Fissures of the Skull p. 220

16. Features of the adult skull are summarized in *Summary Table 7–1*.

The Orbital and Nasal Complexes p. 220

17. Seven bones form each **orbital complex**. *(Figure 7–13)*

18. The **nasal complex** includes the bones that enclose the nasal cavities and the **paranasal sinuses**, hollow airways that connect with the nasal passages. *(Figure 7–14)*

Anatomy 360 | Skeletal System/Axial Skeleton/Skull

The Skulls of Infants and Children p. 222

19. Fibrous connective-tissue **fontanels** permit the skulls of infants and children to continue growing. *(Figure 7–15)*

The Vertebral Column p. 224

1. The **vertebral column** consists of the vertebrae, sacrum, and coccyx. We have 7 **cervical vertebrae** (the first articulates with the skull), 12 **thoracic vertebrae** (which articulate with the ribs), and 5 **lumbar vertebrae** (the last articulates with the sacrum). The **sacrum** and **coccyx** consist of fused vertebrae. *(Figure 7–16)*

Spinal Curvature p. 224

2. The spinal column has four **spinal curves**. The **thoracic** and **sacral curves** are called **primary**, or **accommodation**, **curves**; the **lumbar** and **cervical curves** are known as **secondary**, or **compensation**, **curves**. *(Figure 7–16)*

Vertebral Anatomy p. 225

3. A typical vertebra has a **vertebral body** and a **vertebral arch**, and articulates with adjacent vertebrae at the **superior** and **inferior articular processes**. *(Figure 7–17)*

4. Adjacent vertebrae are separated by **intervertebral discs**. Spaces between successive **pedicles** form the **intervertebral foramina**.

(Figure 7–17)

Vertebral Regions p. 226

5. Cervical vertebrae are distinguished by the shape of the body, the relative size of the vertebral foramen, the presence of **costal processes** with **transverse foramina**, and notched **spinous processes**. These vertebrae include the **atlas**, **axis**, and **vertebra prominens**. *(Figure 7–18; Table 7–2)*

6. Thoracic vertebrae have a distinctive heart-shaped body; long, slender spinous processes; and articulations for the ribs. *(Figures 7–19, 7–22; Table 7–2)*

7. The lumbar vertebrae are the most massive and least mobile of the vertebrae; they are subjected to the greatest strains. *(Figure 7–20; Table 7–2)*

8. The sacrum protects reproductive, digestive, and urinary organs and articulates with the pelvic girdle and with the fused elements of the coccyx. *(Figure 7–21)*

Anatomy 360 | Skeletal System/Axial Skeleton/Vertebral Column

The Thoracic Cage p. 231

1. The skeleton of the **thoracic cage** consists of the thoracic vertebrae, the ribs, and the sternum. The **ribs** and **sternum** form the *rib cage*. *(Figure 7–22)*

The Ribs p. 233

2. Ribs 1–7 are **true**, or *vertebrosternal*, **ribs**. Ribs 8–12 are called **false ribs**; they include the *vertebrochondral ribs* (ribs 8–10) and two pairs of *floating (vertebral) ribs* (ribs 11–12). A typical rib has a **head**, or *capitulum*; a **neck**; a **tubercle**, or *tuberculum*; an *angle*; and a **body**, or *shaft*. A *costal groove* marks the path of nerves and blood vessels. *(Figures 7–22, 7–23)*

The Sternum p. 234

3. The sternum consists of the **manubrium**, **body**, and **xiphoid process**. *(Figure 7–22)*

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. Which list contains *only* facial bones?

(a) mandible, maxillary, nasal, zygomatic

(b) frontal, occipital, zygomatic, parietal

(c) occipital, sphenoid, temporal, lacrimal

(d) frontal, parietal, occipital, sphenoid

2. The unpaired facial bones include the

(a) lacrimal and nasal

(b) vomer and mandible

(c) maxillary and mandible

(d) zygomatic and palatine

3. The boundaries between skull bones are immovable joints called

(a) foramina **(b)** fontanels

(c) lacunae **(d)** sutures

4. The joint between the frontal and parietal bones is correctly called the **_____** suture.

(a) parietal **(b)** lambdoid

(c) squamous **(d)** coronal

5. Blood vessels that drain blood from the head pass through the

(a) jugular foramina **(b)** hypoglossal canals

(c) stylomastoid foramina **(d)** mental foramina

(e) lateral canals

6. Cervical vertebrae can usually be distinguished from other vertebrae by the presence of

(a) transverse processes

(b) transverse foramina

(c) demifacets on the centrum

(d) the vertebra prominens

(e) large spinous processes

7. The side walls of the vertebral foramen are formed by the

(a) centrum of the vertebra

(b) spinous process

(c) pedicles

(d) laminae

(e) transverse processes

8. The part(s) of the vertebra that transfer(s) weight along the axis of the vertebral column is (are) the

(a) vertebral arch **(b)** lamina

(c) pedicles **(d)** body

9. Which bones contain the paranasal sinuses?

10. Which five bones make up the facial complex?

11. What seven bones constitute the orbital complex?

12. What is the primary function of the vomer?

13. Which bones contain the paranasal sinuses?

LEVEL 2 Reviewing Concepts

14. What is the relationship between the temporal bone and the ear?

15. What is the relationship between the ethmoid and the nasal cavity?

16. Describe how ribs function in breathing.

17. Why is it important to keep your back straight when you lift a heavy object?

18. The atlas (C1) can be distinguished from the other vertebrae by

(a) the presence of anterior and posterior vertebral arches

(b) the lack of a body

(c) the presence of superior facets and inferior articular facets

(d) a, b, and c are correct

19. What purpose do the fontanels serve during birth?

20. The secondary spinal curves

(a) help position the body weight over the legs

(b) accommodate the thoracic and abdominopelvic viscera

(c) include the thoracic curvature

(d) all of the above

(e) a and c only

21. When you rotate your head to look to one side

(a) the atlas rotates on the occipital condyles

(b) C1 and C2 rotate on the other cervical vertebrae

(c) the atlas rotates on the dens of the axis

(d) the skull rotates the atlas

(e) all cervical vertebrae rotate

22. Improper administration of CPR (cardiopulmonary resuscitation) can force the _____ into the liver.

(a) floating ribs

(b) lumbar vertebrae

(c) manubrium of the sternum

(d) costal cartilage

(e) xiphoid process

LEVEL 3 Critical Thinking and Clinical Applications

23. Jane has an upper respiratory infection and begins to feel pain in her teeth. This is a good indication that the infection is located in the

(a) frontal sinuses **(b)** sphenoid bone

(c) temporal bone **(d)** maxillary sinuses

(e) zygomatic bones

24. While working at an excavation, an archaeologist finds several small skull bones. She examines the frontal, parietal, and occipital bones and concludes that the skulls are those of children not yet 1 year old. How can she tell their ages from an examination of their bones?

25. Mary is in her last month of pregnancy and is suffering from lower back pains. Since she is carrying excess weight in front of her, she wonders why her back hurts. What would you tell her?

- **FIGURE 7–4** The Sectional Anatomy of the Skull. **(a)** Medial view of a sagittal section through the skull. **(b)** Superior view of a horizontal section through the skull, showing the floor of the cranial cavity. Compare with part **(a)** and with *Figure 7–3e*. ATLAS: Plates 4c; 6; 7a,b

| SUMMARY TABLE 7–1 | A KEY TO THE FORAMINA AND FISSURES OF THE SKULL

Bone	**Foramen/Fissure**	**Major Structures Using Passageway**	
		Neural Tissue*	**Vessels and Other Structures**
OCCIPITAL BONE	Foramen magnum	Medulla oblongata (most caudal portion of brain) and accessory nerve (XI), which provides motor control over several neck and back muscles	Vertebral arteries to brain;
	Hypoglossal canal	Hypoglossal nerve (XII) provides motor control to muscles of the tongue	
With temporal bone	Jugular foramen	Glossopharyngeal nerve (IX), vagus nerve (X), accessory nerve (XI). Nerve IX provides taste sensation; X is important for visceral functions; XI innervates important muscles of the back and neck	Internal jugular vein; important vein returning blood from brain to heart

FRONTAL BONE Supraorbital foramen Supraorbital nerve, sensory branch of ophthalmic Supraorbital artery delivers blood (or notch) nerve, innervating the eyebrow, eyelid, to same region and frontal sinus

LACRIMAL BONE Lacrimal sulcus, Lacrimal sac and tear duct; drains nasolacrimal canal into nasal cavity (with maxillary bone)

TEMPORAL BONE Stylomastoid Facial nerve (VII) provides motor control foramen of facial muscles Carotid canal Internal carotid artery supplies blood to brain

External acoustic canal Air in canal conducts sound to eardrum

Internal acoustic canal Vestibulocochlear nerve (VIII) from sense Internal acoustic artery supplies organs for hearing and balance. Facial nerve blood to inner ear

(VII) enters here, exits at stylomastoid foramen

In the previous chapter, we discussed the 80 bones of the axial skeleton. Appended to these bones are the remaining 60 percent of the bones that make up the skeletal system. The **appendicular skeleton** includes the bones of the limbs and the supporting ele ments, or *girdles*, that connect them to the trunk (Figure 8–1•). To appreciate the role that the appendicular skeleton plays in your life, make a mental list of all the things you have done with your arms or legs in the past day. Standing, walking, writing, turning pages, eating, dressing, shaking hands, waving—the list quickly becomes unwieldy. Your axial skeleton protects and supports in ternal organs and participates in vital functions, such as respiration. But it is your appendicular skeleton that lets you manipulate objects and move from place to place.

The appendicular skeleton is dominated by the long bones that support the limbs. l**p. 180** Each long bone shares common features with other long bones. For example, one epiphysis is usually called the *head*, the diaphysis is called the *shaft*, and the head and shaft are normally separated by a *neck*. For simplicity, an illustration of a single bone will have labels that do not include the name of the bone. Thus, a photo of the humerus will have the label *head* rather than *head of the humerus* or *humeral head*. When more than one bone is shown, the label will use the complete name to avoid confusion. The descriptions in this chapter emphasize surface features that either have functional importance (such as the attachment sites for skeletal muscles and the paths of major nerves and blood vessels) or provide landmarks that define areas and locate structures of the body.

The Pectoral Girdle and Upper Limbs

Objectives

. • Identify the bones that form the pectoral girdle, their functions, and their superficial features.

. • Identify the bones of the upper limbs, their functions, and their superficial features.

Each arm articulates (that is, forms a joint) with the trunk at the **pectoral girdle**, or *shoulder girdle* (see Figure 8–1•). The pec
toral girdle consists of two S-shaped *clavicles* (KLAV-i-kulz; collarbones) and two broad, flat *scapulae* (SKAP-
¯u
-l
¯e
; singular, *scapula*,
SKAP-
¯u
-luh; shoulder blades). The medial, anterior end of each clavicle articulates with the manubrium of the sternum. l**p. 234**

These articulations are the *only* direct connections between the pectoral girdle and the axial skeleton. Skeletal muscles support and position the scapulae, which have no direct bony or ligamentous connections to the thoracic cage. As a result, the shoulders are extremely mobile, but not very strong.

The Pectoral Girdle

Movements of the clavicles and scapulae position the shoulder joints and provide a base for arm movement. The shoulder joints are positioned and stabilized by skeletal muscles that extend between the axial skeleton and the pectoral girdle. Once the joints are in position, other skeletal muscles, including several that originate on the pectoral girdle, move the upper limbs.

The surfaces of the scapulae and clavicles are extremely important as sites for muscle attachment. The attachment sites of major muscles are marked by bony ridges and flanges. Other bone markings, such as sulci or foramina, indicate the positions of nerves that control the muscles, or the passage of blood vessels that nourish the muscles and bones.

The Clavicles

The **clavicles** are S-shaped bones that originate at the superior, lateral border of the manubrium of the sternum, lateral to the jugular notch (Figure 8–2a•). From the roughly pyramidal **sternal end**, each clavicle curves laterally and posteriorly for roughly half

its length. It then forms a smooth posterior curve to articulate with a process of the scapula, the *acromion* (a-KR

¯O

-m

¯e

-on). The

flat, **acromial end** of the clavicle is broader than the sternal end (Figure 8–2b,c•).

The smooth, superior surface of the clavicle lies just beneath the skin. The acromial end has a rough inferior surface that bears prominent lines and tubercles (Figure 8–2c•). These surface features are attachment sites for muscles and ligaments of the shoulder. The combination of the direction of curvature and the differences between superior and inferior surfaces make it relatively easy to tell a left clavicle from a right clavicle.

You can explore the connection between the clavicles and sternum. With your fingers in your jugular notch, locate the clavicle on either side and find the *sternoclavicular joints* where the sternum articulates with the clavicles. These are the only articulations between the pectoral girdle and the axial skeleton. When you move your shoulders, you can feel the sternal ends of the clavicles change their positions.

The clavicles are relatively small and fragile, and therefore fractures of the clavicle are fairly common. For example, a simple fall can fracture a clavicle if you land on your hand with your arm outstretched. Fortunately, in view of the clavicle’s vulnerability, most clavicular fractures heal rapidly without a cast.

The Scapulae

The anterior surface of the **body** of each **scapula** forms a broad triangle (Figure 8–3a•). The three sides of the triangle are the **superior border**; the **medial border**, or *vertebral border*; and the **lateral border**, or *axillary border* (*axilla*, armpit). Muscles that position the scapula attach along these edges. The corners of the triangle are called the *superior angle*, the *inferior angle*, and the *lateral angle*. The lateral angle, or *head* of the scapula, forms a broad process that supports the cup-shaped **glenoid cavity** (Figure 8–3b•). At the glenoid cavity, the scapula articulates with the *humerus*, the proximal bone of the upper limb. This articulation is the shoulder joint, also known as the *glenohumeral joint*. The anterior surface of the body of the scapula is relatively smooth and concave. The depression in the anterior surface is called the **subscapular fossa**.

Two large scapular processes extend beyond the margin of the glenoid cavity (see Figure 8–3b•) superior to the head of the humerus. The smaller, anterior projection is the **coracoid** (KOR-uh-koyd) **process**. The **acromion** is the larger, posterior process. If you run your fingers along the superior surface of the shoulder joint, you will feel this process. The acromion articulates with the clavicle at the *acromioclavicular joint*. Both the coracoid process and the acromion are attached to ligaments and tendons associated with the shoulder joint.

The acromion is continuous with the **scapular spine** (Figure 8–3c•), a ridge that crosses the posterior surface of the scapular body before ending at the medial border. The scapular spine divides the convex posterior surface of the body into two regions. The area superior to this spine constitutes the **supraspinous fossa** (*supra*, above); the region inferior to the spine is the **infraspinous fossa** (*infra*, beneath). The entire posterior surface is marked by small ridges and lines where smaller muscles attach to the scapula.

Anatomy 360 | Review the anatomy of the pectoral girdle on the **Anatomy 360 CD-ROM: Skeletal System/Appendicular Skeleton/Pectoral Girdle.**

Concept Check

Why would a broken clavicle affect the mobility of the scapula?

Which bone articulates with the scapula at the glenoid cavity?

Answers begin on p. A–1

The Upper Limbs

The skeleton of the upper limbs consists of the bones of the arms, forearms, wrists, and hands. Notice that in anatomical descriptions, the term *arm* refers only to the proximal portion of the upper limb (from shoulder to elbow), not to the entire limb. We will examine the bones of the right upper limb. The arm, or *brachium*, contains one bone, the **humerus**, which extends from the scapula to the elbow.

The Humerus

At the proximal end of the humerus, the round **head** articulates with the scapula (Figure 8–4•). The prominent **greater tubercle** is a rounded projection on the lateral surface of the epiphysis, near the margin of the humeral head. The greater tubercle establishes the lateral contour of the shoulder. You can verify its position by feeling for a bump situated a few centimeters from the tip of the acromion. The **lesser tubercle** is a smaller projection that lies on the anterior, medial surface of the epiphysis, separated from the greater tubercle by the **intertubercular groove**, or *intertubercular sulcus*. Both tubercles are important sites for muscle attachment; a large tendon runs along the groove. Lying between the tubercles and the articular surface of the head, the **anatomical neck** marks the extent of the joint capsule. The narrower **surgical neck** corresponds to the metaphysis of the growing bone. The name reflects the fact that fractures typically occur at this site.

The proximal shaft of the humerus is round in section. The **deltoid tuberosity** is a large, rough elevation on the lateral surface of the shaft, approximately halfway along its length. It is named after the *deltoid muscle*, which attaches to it.

On the posterior surface, the deltoid tuberosity ends at the **radial groove** (Figure 8–4b•). This depression marks the path of the *radial nerve*, a large nerve that provides both sensory information from the posterior surface of the limb and motor control over the large muscles that straighten the elbow. Distal to the radial groove, the posterior surface of the humerus is relatively flat. Near the distal articulation with the bones of the forearm, the shaft expands to either side at the **medial** and **lateral epicondyles**. *Epicondyles* are processes that develop proximal to an articulation and provide additional surface area for muscle attachment. The *ulnar nerve* crosses the posterior surface of the medial epicondyle. A blow at the posteromedial surface of the elbow joint can strike this nerve and produce a temporary numbness and paralysis of muscles on the anterior surface of the forearm. Because of the odd sensation, this area is sometimes called the *funny bone*.

At the **condyle**, the humerus articulates with the *radius* and the *ulna*, the bones of the forearm (*antebrachium*). The condyle is divided into two articular regions: the trochlea and the capitulum (see Figure 8–4a•). The **trochlea** (*trochlea*, a pulley), the spool-shaped medial portion of the condyle, extends from the base of the **coronoid** (*corona,* crown) **fossa** on the anterior surface to the **olecranon** (o¯-LEK-ruh-non) **fossa** on the posterior surface (see Figure 8–4b•). These depressions accept projections from the ulnar surface as the elbow approaches the limits of its range of motion. The rounded **capitulum** forms the lateral surface of the condyle. A shallow **radial fossa** superior to the capitulum accommodates a portion of the radial head as the forearm approaches the humerus. The prominent lateral head and the differences between the lateral and medial condyles make it relatively easy to tell a left humerus from a right humerus.

The Ulna

The *ulna* and *radius* are parallel bones that support the forearm. In the anatomical position, the **ulna** lies medial to the radius. The **olecranon**, the superior end of the ulna, is the point of the elbow (Figure 8–5a•). On the anterior surface of the proximal epiphysis (Figure 8–5b•), the **trochlear notch** of the ulna articulates with the trochlea of the humerus at the elbow joint. (The fact that this notch forms a “U” in lateral view may help you to remember the name *ulna*.)

The olecranon forms the superior lip of the trochlear notch, and the **coronoid process** forms its inferior lip. At the limit of **extension**, with the forearm and arm forming a straight line, the olecranon swings into the olecranon fossa on the posterior surface of the humerus. At the limit of *flexion,* a movement that decreases the angle between the articulating bones, the arm and forearm form a tight V and the coronoid process projects into the coronoid fossa on the anterior humeral surface. Lateral to the coronoid process, a smooth **radial notch** accommodates the head of the radius at the *proximal radioulnar joint*.

Viewed in cross section, the shaft of the ulna is roughly triangular. The **interosseous membrane**, a fibrous sheet, connects the lateral margin of the ulna to the radius. Near the wrist, the shaft of the ulna narrows before ending at a disc-shaped **ulnar head**, or *head of the ulna*. The posterior, lateral surface of the ulnar head bears a short **styloid process** (*styloid*, long and pointed). A triangular *articular disc* attaches to the styloid process; this cartilage separates the ulnar head from the bones of the wrist. The lateral surface of the ulnar head articulates with the distal end of the radius to form the *distal radioulnar joint*.

The Radius

The **radius** is the lateral bone of the forearm (see Figure 8–5•). The disc-shaped **radial head**, or *head of the radius*, articulates with the capitulum of the humerus. During flexion, the radial head swings into the radial fossa of the humerus. A narrow neck extends from the radial head to the **radial tuberosity**, which marks the attachment site of the *biceps brachii muscle*, a large muscle on the anterior surface of the arm. The shaft of the radius curves along its length. It also enlarges, and the distal portion of the radius is considerably larger than the distal portion of the ulna. The **ulnar notch** on the medial surface of the distal end of the radius marks the site of articulation with the head of the ulna. The distal end of the radius articulates with the bones of the wrist. The **styloid process** on the lateral surface of the radius helps stabilize this joint. If you are looking at an isolated radius or ulna, you can quickly identify whether it is left or right by finding the radial notch (ulna) or ulnar notch (radius) and remembering that the radius lies lateral to the ulna.

The Carpal Bones

The *carpus*, or wrist, contains eight **carpal bones**. These bones form two rows, one with four **proximal carpal bones** and the other with four **distal carpal bones**.

The proximal carpal bones are the scaphoid bone, lunate bone, triquetrum, and pisiform bone (Figure 8–6a•).

. • The **scaphoid bone** is the proximal carpal bone on the lateral border of the wrist; it is the carpal bone closest to the styloid process of the radius.

. • The comma-shaped **lunate** (*luna*, moon) **bone** lies medial to the scaphoid bone and, like the scaphoid bone, articulates with the radius.

. • The **triquetrum** is a small pyramid-shaped bone medial to the lunate bone. The triquetrum articulates with the articular disc that separates the ulnar head from the wrist.

• The small, pea-shaped **pisiform** (PIS-i-form) **bone** sits anterior to the triquetrum.

The distal carpal bones are the trapezium, trapezoid bone, capitate bone, and hamate bone (Figure 8–6b•).

. • The **trapezium** is the lateral bone of the distal row; its proximal surface articulates with the scaphoid bone.

. • The wedge-shaped **trapezoid bone** lies medial to the trapezium. Like the trapezium, it has a proximal articulation with the scaphoid bone.

. • The **capitate bone**, the largest carpal bone, sits between the trapezoid bone and the hamate bone.

. • The **hamate** (*hamatum*, hooked) **bone** is the medial distal carpal bone.

It may help you to identify the eight carpal bones if you remember the sentence “Sam Likes To Push The Toy Car Hard.” In lateral-to-medial order, the first four words stand for the proximal carpal bones (scaphoid, lunate, triquetrum, pisiform) and the last four for the distal carpal bones (trapezium, trapezoid, capitate, hamate).

The carpal bones articulate with one another at joints that permit limited sliding and twisting. Ligaments interconnect the carpal bones and help stabilize the wrist joint. The tendons of muscles that flex the fingers pass across the anterior surface of the wrist, sandwiched between the intercarpal ligaments and a broad, superficial transverse ligament called the *flexor retinaculum*. Inflammation of the connective tissues between the flexor retinaculum and the carpal bones can compress the tendons and adjacent sensory and motor nerves, producing pain and a loss of wrist mobility. This condition is called *carpal tunnel syndrome*.

The Metacarpal Bones and Phalanges

Five **metacarpal** (met-uh-KAR-pul; *metacarpus*, hand) **bones** articulate with the distal carpal bones and support the hand (see Figure 8–6•). Roman numerals I–V are used to identify the metacarpal bones, beginning with the lateral metacarpal bone, which articulates with the trapezium. Hence, metacarpal I articulates with the proximal bone of the thumb.

Distally, the metacarpal bones articulate with the proximal finger bones. Each hand has 14 finger bones, or **phalanges** (fa-LAN-j z; singular, *phalanx*). The first finger, known as the **pollex** (POL-eks), or thumb, has two phalanges (*proximal* and *distal*).

e¯Each of the other fingers has three phalanges (*proximal*, *middle*, and *distal*).

Anatomy 360 | Review the anatomy of the upper limb on the **Anatomy 360 CD-ROM: Skeletal System/ Appendicular Skele-ton/Upper Limb.**

Concept Check

The rounded projections on either side of the elbow are parts of which bone?

Which bone of the forearm is lateral in the anatomical position?

Bill accidentally fractures his first distal phalanx with a hammer. Which finger is broken?

Answers begin on p. A–1

The Pelvic Girdle and Lower Limbs

Objectives

. • Identify the bones that form the pelvic girdle, their functions, and their superficial features.

. • Identify the bones of the lower limbs, their functions, and their superficial features.

. • Discuss structural and functional differences between the pelvis of females and that of males.

Because they must withstand the stresses involved in weight bearing and locomotion, the bones of the **pelvic girdle** are more massive than those of the pectoral girdle. For similar reasons, the bones of the lower limbs are more massive than those of the upper limbs. The pelvic girdle consists of the two hipbones. The *pelvis* is a composite structure that includes the hipbones of the appendicular skeleton and the sacrum and coccyx of the axial skeleton. l**pp. 230–231**

The Pelvic Girdle

The pelvic girdle consists of the paired hipbones, which are called the **ossa coxae**, or *innominate bones*. Each hipbone, or **os coxae**

¯e

(singular), forms by the fusion of three bones: an **ilium** (IL--um; plural, *ilia*), an **ischium** (IS-k -um; plural, *ischia*), and a **pubis** (P

¯e

¯U

-bis) (Figure 8–7•). The ilia have a sturdy articulation with the auricular surfaces of the sacrum, attaching the pelvic girdle to the axial skeleton. l**p. 231** Anteriorly, the medial surfaces of the hipbones are interconnected by a pad of fibrocartilage at a joint called the *pubic symphysis*. On the lateral surface of each hipbone, the **acetabulum** (as-e-TAB-

¯u

-lum; *acetabulum*, vinegar cup), a concave socket, articulates with the head of the femur (Figure 8–7a•). A ridge of bone forms the lateral and superior margins of the acetabulum, which has a diameter of about 5 cm (2 in.). The anterior and inferior portion of the ridge is incomplete; the gap is called the **acetabular notch**. The smooth, C-shaped articular surface of the acetabulum is the **lunate**

surface.

The ilium, ischium, and pubis meet inside the acetabulum, as though it were a pie sliced into three pieces. Superior to the acetabulum, the ilium forms a broad, curved surface that provides an extensive area for the attachment of muscles, tendons, and ligaments (Figure 8–7a•). Landmarks along the margin of the ilium include the *iliac spines*, which mark the attachment sites of im

–

portant muscles and ligaments; the *gluteal lines*, which mark the attachment of large hip muscles; and the **greater sciatic** (s -AT-ik)

ı **notch**, through which a major nerve (the *sciatic nerve*) reaches the lower limb.

The ischium forms the posterior, inferior portion of the acetabulum. Posterior to the acetabulum, the prominent **ischial spine** projects superior to the *lesser sciatic notch*, through which blood vessels, nerves, and a small muscle pass. The **ischial tuberosity**, a roughened projection, is located at the posterior and lateral edge of the ischium. When you are seated, the ischial tuberosities bear your body's weight.

The narrow **ischial ramus** (branch) continues until it meets the **inferior ramus** of the pubis. The inferior pubic ramus extends between the ischial ramus and the *pubic tubercle,* a small, elevated area anterior and lateral to the pubic symphysis. There the inferior pubic ramus meets the **superior ramus** of the pubis, which originates near the acetabulum. The anterior, superior surface of the superior ramus bears the *pectineal line*, a ridge that ends at the pubic tubercle. The pubic and ischial rami encircle the

obturator (OB-t

‾u

-r

‾a

-tor) **foramen**, a space that is closed by a sheet of collagen fibers whose inner and outer surfaces provide a

firm base for the attachment of muscles of the hip.

The broadest part of the ilium extends between the **arcuate line**, which is continuous with the pectineal line, and the **iliac crest** (Figure 8–7b•). These prominent ridges mark the attachments of ligaments and muscles. The area between the arcuate line and the iliac crest forms a shallow depression known as the **iliac fossa**. The concave surface of the iliac fossa helps support the abdominal organs and provides additional area for muscle attachment.

In medial view, the anterior and medial surface of the pubis contains a roughened area that marks the site of articulation with the pubis of the opposite side (see Figure 8–7b•). At this articulation—the pubic symphysis—the two pubic bones are attached to a median fibrocartilage pad. Posteriorly, the **auricular surface** of the ilium articulates with the auricular surface of the sacrum at

the *sacroiliac joint*. l**p. 231** Ligaments arising at the **iliac tuberosity**, a roughened area superior to the auricular surface, stabilize this joint.

The Pelvis

Figure 8–8• shows anterior and posterior views of the **pelvis**, which consists of the two ossa coxae, the sacrum, and the coccyx. An extensive network of ligaments connects the lateral borders of the sacrum with the iliac crest, the ischial tuberosity, the ischial spine, and the arcuate line. Other ligaments tie the ilia to the posterior lumbar vertebrae. These interconnections increase the stability of the pelvis.

The pelvis may be divided into the **true** (*lesser*) **pelvis** and the **false** (*greater*) **pelvis** (Figure 8–9a,b•). The true pelvis encloses the *pelvic cavity*, a subdivision of the abdominopelvic cavity. l**p. 21** The superior limit of the true pelvis is a line that extends from either side of the base of the sacrum, along the arcuate line and pectineal line to the pubic symphysis. The bony edge of the true pelvis is called the **pelvic brim**, or *linea terminalis*, and the enclosed space is the **pelvic inlet**. The false pelvis consists of the expanded, bladelike portions of each ilium superior to the pelvic brim.

The **pelvic outlet** is the opening bounded by the coccyx, the ischial tuberosities, and the inferior border of the pubic symphysis (Figure 8–9b,c•). The region bounded by the inferior edges of the pelvis is called the *perineum* (per-i-NE¯-um). Perineal muscles form the floor of the pelvic cavity and support the organs in the true pelvis.

The shape of the pelvis of a female is somewhat different from that of a male (Figure 8–

10•). Some of the differences are the result of variations in body size and muscle mass. For example, in females, the pelvis is generally smoother and lighter and has less-prominent markings. Females have other skeletal adaptations for childbearing, including:

- . • An enlarged pelvic outlet.
- . • A broader pubic angle (the inferior angle between the pubic bones), greater than 100°.
- . • Less curvature on the sacrum and coccyx, which, in males, arc into the pelvic outlet.
- . • A wider, more circular pelvic inlet.
- . • A relatively broad pelvis that does not extend as far superiorly (a “low pelvis”).
- . • Ilia that project farther laterally, but do not extend as far superior to the sacrum.

These adaptations are related to the support of the weight of the developing fetus and uterus, and the passage of the newborn through the pelvic outlet during delivery. In addition, the hormone *relaxin*, produced during pregnancy, loosens the pubic symphysis, allowing relative movement between the hipbones that can further increase the size of the pelvic inlet and outlet.

Concept Check

Which three bones make up the os coxae?

How is the pelvis of females adapted for childbearing?

When you are seated, which part of the pelvis bears your body’s weight?

Answers begin on p. A–1

The Lower Limbs

The skeleton of each lower limb consists of a *femur* (thigh), a *patella* (kneecap), a *tibia* and a *fibula* (leg), and the tarsal bones, metatarsal bones, and phalanges of the foot. Once again, anatomical terminology differs from common usage. In anatomical terms, *leg* refers only to the distal portion of the limb, not to the entire lower limb. Thus, we will use *thigh* and *leg*, rather than *upper leg* and *lower leg*.

The functional anatomy of the lower limbs differs from that of the upper limbs, primarily because the lower limbs transfer the body weight to the ground. We now examine the bones of the right lower limb.

The Femur

The **femur** is the longest and heaviest bone in the body (Figure 8–11•). It articulates with the os coxae at the hip joint and with the tibia of the leg at the knee joint. The rounded epiphysis, or **femoral head**, articulates with the pelvis at the acetabulum. A ligament attaches the acetabulum to the femur at the **fovea capitis**, a small pit in the center of the femoral head. The **neck** of the femur joins the **shaft** at an angle of about 125°. The **greater** and **lesser trochanters** are large, rough projections that originate at the junction of the neck and shaft. The greater trochanter projects laterally; the lesser trochanter projects posteriorly and medially. These trochanters develop where large tendons attach to the femur. On the anterior surface of the femur, the raised **intertrochanteric** (in-ter-tro¯-kan-TER-ik) **line** marks the edge of the articular capsule. This line continues around to the posterior surface as the **intertrochanteric crest**.

The **linea aspera** (*aspera*, rough), a prominent elevation, runs along the center of the posterior surface of the femur, marking the attachment site of powerful hip muscles (Figure 8–11b•). As it approaches the knee joint, the linea aspera divides into a pair of ridges that continue to the **medial** and **lateral epicondyles**. These smoothly rounded projections form superior to the **medial** and **lateral condyles**, which participate in the knee joint. The two condyles are separated by a deep **intercondylar fossa**.

The medial and lateral condyles extend across the inferior surface of the femur, but the intercondylar fossa does not reach the anterior surface (see Figure 8–11a•). The anterior and inferior surfaces of the two condyles are separated by the **patellar surface**, a smooth articular surface over which the patella glides.

The Patella

The **patella** is a large sesamoid bone that forms within the tendon of the *quadriceps femoris*, a group of muscles that extend (straighten) the knee. The patella has a rough, convex anterior surface and a broad **base** (Figure 8–12a•). The roughened surface reflects the attachment of the quadriceps tendon (anterior and superior surfaces) and the *patellar* *ligament* (anterior and inferior surfaces). The patellar ligament connects the **apex** of the patella to the tibia. The posterior patellar surface (Figure 8–12b•) presents two concave facets for articulation with the medial and lateral condyles of the femur. The patellae are cartilaginous at birth, but start to ossify after the individual begins walking, as thigh and leg movements become more powerful. Ossification usually begins at age 2 or 3 and ends at roughly the time of puberty.

Normally, the patella glides across the patellar surface of the femur. Its direction of movement is superior–inferior (up and down), not medial–lateral (side to side). *Runner's knee*, or *patellofemoral stress syndrome*, develops from improper tracking of the patella across the patellar surface. In this syndrome, the patella is forced outside its normal track, so that it shifts laterally; the movement is often associated with increased compression forces or with lateral muscles in the quadriceps group overpowering the medial muscles. Running on hard or slanted surfaces (such as the intertidal area of a beach or the shoulder of a road) and inadequate arch support are often responsible. The misalignment puts lateral pressure on the knee, resulting in swelling and tenderness after exercise.

The Tibia

The **tibia** (TIB--uh), or shinbone, is the large medial bone of the leg (Figure 8–13a•). The medial and lateral condyles of the femur articulate with the **medial** and **lateral tibial condyles** at the proximal end of the tibia. The **intercondylar eminence** is a ridge that separates the condyles (Figure 8–13b•). The anterior surface of the tibia near the condyles bears a prominent, rough **tibial tuberosity**, which you can feel through the skin. This tuberosity marks the attachment of the patellar ligament.

The **anterior margin** is a ridge that begins at the tibial tuberosity and extends distally along the anterior tibial surface. You can also easily feel the anterior margin of the tibia through the skin. As it approaches the ankle joint, the tibia broadens, and the medial border ends in the **medial malleolus** (ma-LE¯-o-lus; *malleolus*, hammer), a large process familiar to you as the medial projection at the ankle. The inferior surface of the tibia articulates with the proximal bone of the ankle; the medial malleolus provides medial support for this joint.

The Fibula

¯e

The slender **fibula** (FIB-
¯u
-luh) parallels the lateral border of the tibia (see Figure 8–13a,b•). The head of the fibula articulates
with the tibia. The articular facet is located on the anterior, inferior surface of the lateral tibial condyle. The medial border of the thin shaft is bound to the tibia by the **interosseous membrane**, which extends to the lateral margin of the tibia. This membrane helps stabilize the positions of the two bones and provides additional surface area for muscle attachment.

As its relatively small diameter suggests, the fibula does not help transfer weight to the ankle and foot. In fact, it does not even articulate with the femur. However, the fibula is important as a site for the attachment of muscles that move the foot and toes. In addition, the distal tip of the fibula extends lateral to the ankle joint. This fibular process, the **lateral malleolus**, provides lateral stability to the ankle. However, forceful movement of the foot outward and backward can dislocate the ankle, breaking both the
lateral malleolus of the fibula and the medial malleolus of the tibia. This injury is called a *Pott's fracture*. l**p. 200**

The Tarsal Bones

The ankle, or *tarsus*, consists of seven **tarsal bones** (Figure 8–14•). The large **talus** transmits the weight of the body from the tibia toward the toes. The articulation between the talus and the tibia occurs across the superior and medial surfaces of the **trochlea**, a pulley-shaped articular process. The lateral surface of the trochlea articulates with the lateral malleolus of the fibula.

The **calcaneus** (kal-KA¯
-n
¯e
-us), or heel bone, is the largest of the tarsal bones. When you stand normally, most of your weight
is transmitted from the tibia, to the talus, to the calcaneus and then to the ground. The

posterior portion of the calcaneus is a rough, knob-shaped projection. This is the attachment site for the *calcaneal tendon* (*Achilles tendon* or *calcanean tendon*), which arises at strong calf muscles. If you are standing, these muscles can lift the heel off the ground so that you stand on tiptoes. The superior and anterior surfaces of the calcaneus bear smooth facets for articulation with other tarsal bones.

The **cuboid bone** articulates with the anterior surface of the calcaneus. The **navicular bone** is anterior to the talus, on the medial side of the ankle. It articulates with the talus and with the three *cuneiform bones* (k
¯u
-N
¯E
-i-form). These are wedge-shaped bones arranged in a row, with articulations between them. They are named according to their position: **medial cuneiform**, **intermediate cuneiform**, and **lateral cuneiform**. Proximally, the cuneiform bones articulate with the anterior surface of the navicular bone. The lateral cuneiform bone also articulates with the medial surface of the cuboid bone. The distal surfaces of the cuboid bone and the cuneiform bones articulate with the metatarsal bones of the foot. To remember the names of the tarsal bones in the order presented, try the memory aid “Tom Can Control Not Much In Life.”

The Metarsal Bones and Phalanges

The **metatarsal bones** are five long bones that form the distal portion of the foot, or *metatarsus* (see Figure 8–14•). The metatarsal bones are identified by Roman numerals I–V, proceeding from medial to lateral across the sole. Proximally, metatarsal bones I–III articulate with the three cuneiform bones, and metatarsal bones IV and V articulate with the cuboid bone. Distally, each metatarsal bone articulates with a different proximal phalanx. The **phalanges**, or toe bones (see Figure 8–14•), have the same anatomical organization as the fingers. The toes contain 14 phalanges. The **hallux**, or great toe, has two phalanges (*proximal* and *distal*), and the other four toes have three phalanges apiece (*proximal*, *middle*, and *distal*).

Running, while beneficial to overall health, places the foot bones under more stress than does walking. *Stress fractures* are hairline fractures that develop in bones subjected to repeated shocks or impacts. Stress fractures of the foot usually involve one of the metatarsal bones. These fractures are caused either by improper placement of the foot while running or by poor arch support. In a fitness regime that includes street running, it is essential to provide proper support for the bones of the foot. An entire running-shoe market has arisen around the amateur runner's need for good arch support.

Arches of the Foot Weight transfer occurs along the **longitudinal arch** of the foot (see Figure 8–14b•). Ligaments and tendons maintain this arch by tying the calcaneus to the distal portions of the metatarsal bones. However, the lateral, or *calcaneal*, portion of the longitudinal arch has much less curvature than the medial, *talar* portion, in part because the talar portion has considerably more elasticity. As a result, the medial plantar surface of the foot remains elevated, so that the muscles, nerves, and blood vessels that supply the inferior surface are not squeezed between the metatarsal bones and the ground. In the condition known as *flatfeet*, normal arches are lost ("fall") or never form. Individuals with this condition cannot walk long distances without discomfort; hence, they are not allowed to enlist in the U.S. Army.

The elasticity of the talar portion of the longitudinal arch absorbs the shocks from sudden changes in weight loading. For example, the stresses that running or ballet dancing places on the toes are cushioned by the elasticity of this portion of the arch. The degree of curvature changes from the medial to the lateral borders of the foot, so a **transverse arch** also exists.

When you stand normally, your body weight is distributed evenly between the calcaneus and the distal ends of the metatarsal bones. The amount of weight transferred forward depends on the position of the foot and the placement of one's body weight. During *flexion* at the ankle, a movement also called *dorsiflexion*, all your body weight rests on the calcaneus—as when you "dig in your heels." During *extension* at the ankle, also known as *plantar flexion*, the talus and calcaneus transfer your weight to the metatarsal bones and phalanges through the more anterior tarsal bones; this occurs when you stand on tiptoe.

Clinical Note

The arches of the foot are usually present at birth. Sometimes, however, they fail to develop properly. In **congenital talipes equinovarus** (*clubfoot*), abnormal muscle development distorts growing bones and joints. One or both feet may be involved, and the condition can be mild, moderate, or severe. In most cases, the tibia, ankle, and foot are affected; the longitudinal arch is exaggerated, and the feet are turned medially and inverted. If both feet are involved, the soles face one another. This condition, which affects 2 in 1000 births, is roughly twice as common in boys as girls. Prompt treatment with casts or other supports in infancy helps alleviate the problem, and fewer than half the cases require surgery. Kristi Yamaguchi, an Olympic gold medalist in figure skating, was born with clubfeet. AM: Problems with the Ankle and Foot

100 Keys | The pectoral girdle is highly mobile and stabilized primarily by muscles; the pelvic girdle is more massive, stronger, and far less mobile.

Concept Check

The fibula neither participates in the knee joint nor bears weight. When it is fractured, however, walking becomes difficult. Why? While jumping off the back steps at his house, 10-year-old Joey lands on his right heel and breaks his foot. Which foot bone is most likely broken? Which foot bone transmits the weight of the body from the tibia toward the toes?

Answers begin on p. A–1

Individual Variation in the Skeletal System

Objectives

. • Explain how study of the skeleton can reveal significant information about an individual.

. • Summarize the skeletal differences between males and females.

. • Describe briefly how the aging process affects the skeletal system.

A comprehensive study of a human skeleton can reveal important information about the individual. We can estimate a person's muscular development and muscle mass from the appearance of various ridges and from the general bone mass. Details such as the condition of the teeth or the presence of healed fractures give an indication of the individual's medical history. Two important details, sex and age, can be determined or closely estimated on the basis of measurements indicated in Tables 8–1 and 8–2. In some cases, the skeleton may provide clues about the individual's nutritional state, handedness, and even occupation.

ATLAS: Embryology Summary 8: The Development of the Appendicular Skeleton

Table 8–1 identifies characteristic differences between the skeletons of males and females, but not every skeleton shows every feature in classic detail. Many differences, including markings on the skull, cranial capacity, and general skeletal features, reflect differences in average body size, muscle mass, and muscular strength. The general changes in the skeletal system that take place with age are summarized in Table 8–2. Note that these changes begin at age 3 months and continue throughout life. The epiphyseal cartilages, for example, begin to fuse at about age 3, and degenerative changes in the normal skeletal system, such as a reduction in mineral content in the bony matrix, typically do not begin until age 30–45. The timing of epiphyseal closure is a key factor determining adult body size. Young people whose long bones are still growing should avoid very heavy weight training, because they risk crushing the epiphyseal cartilages and thus shortening their stature.

Chapter Review

Selected Clinical Terminology

carpal tunnel syndrome: An inflammation of the tissues at the anterior wrist, causing compression of adjacent tendons and nerves. Symptoms are pain and a loss of wrist mobility. (p. 245) **congenital talipes equinovarus** *(clubfoot)***:** A congenital deformity affecting one or both feet. It develops secondary to abnormalities in muscular development. (p. 253) **flatfeet:** The loss or absence of a longitudinal arch. (p. 253)

Study Outline

1. The **appendicular skeleton** includes the bones of the upper and lower limbs and the pectoral and pelvic girdles, which connect the limbs to the trunk. *(Figure 8–1)*

The Pectoral Girdle and Upper Limbs p. 240

1. Each upper limb articulates with the trunk via the **pectoral girdle**, or *shoulder girdle*, which consists of two **scapulae** and two **clavicles**.

The Pectoral Girdle p. 240

1. **2.** On each side, a clavicle and scapula position the shoulder joint, help move the upper limb, and provide a base for muscle attachment. *(Figures 8–2, 8–3)*

2. **3.** Both the **coracoid process** and the **acromion** of the scapula are attached to ligaments and tendons associated with the shoulder joint.

(Figure 8–3)

Anatomy 360 | Skeletal System/Appendicular Skeleton/ Pectoral Girdle

The Upper Limbs p. 242

1. **4.** The scapula articulates with the **humerus** at the shoulder (*glenohumeral*) joint. The **greater** and **lesser tubercles** of the humerus are important sites of muscle attachment. *(Figure 8–4)*

2. **5.** The humerus articulates with the **radius** and **ulna**, the bones of the forearm, at the elbow joint. *(Figure 8–5)*

3. **6.** The **carpal bones** of the wrist, or *carpus*, form two rows. The distal row articulates with the five **metacarpal bones**. Four of the fingers contain three **phalanges**; the **pollex** (thumb) has only two phalanges. *(Figure 8–6)*

The Pelvic Girdle and Lower Limbs p. 245

1. The bones of the **pelvic girdle** are more massive than those of the pectoral girdle.

The Pelvic Girdle p. 245

2. The pelvic girdle consists of two **ossa coxae**. Each os coxae forms through the fusion of an **ilium**, an **ischium**, and a **pubis**.

(Figure 8–7)

1. **3.** The ilium is the largest hipbone. Inside the **acetabulum**, the ilium is fused to the ischium (posteriorly) and the pubis (anteriorly). The *pubic symphysis* limits movement between the pubic bones of the left and right hipbones. *(Figures 8–7, 8–8)*

2. **4.** The **pelvis** consists of the hipbones, the sacrum, and the coccyx. It is subdivided into the **false** (*greater*) **pelvis** and the **true** (*lesser*) **pelvis**. *(Figures 8–8 to 8–10)*

The Lower Limbs p. 249

1. **5.** The **femur** is the longest and heaviest bone in the body. It articulates with the **tibia** at the knee joint. *(Figures 8–11, 8–13)*

2. **6.** The **patella** is a large sesamoid bone. *(Figure 8–12)*

3. **7.** The **fibula** parallels the tibia laterally. *(Figure 8–13)*

4. **8.** The *tarsus*, or ankle, has seven **tarsal bones**. *(Figure 8–14)*

5. **9.** The basic organizational pattern of the **metatarsal bones** and **phalanges** of the foot resembles that of the hand. All the toes have three phalanges, except for the **hallux**, which has two. *(Figure 8–14)*

6. **10.** When a person stands normally, most of the body weight is transferred to the **calcaneus**, and the rest is passed on to the five metatarsal bones. Weight transfer occurs along the **longitudinal arch**; there is also a **transverse arch**. *(Figure 8–14)*

100 Keys | p. 253

Individual Variation in the Skeletal System p. 253

1. Studying a human skeleton can reveal important information, such as the person's weight, sex, body size, muscle mass, and age.

(Tables 8–1, 8–2)

2. Age-related changes and events take place in the skeletal system. These changes begin at about age 1 and continue throughout life.

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A-1.

LEVEL 1 Reviewing Facts and Terms

. **1.** Which of the following is primarily responsible for stabilizing, positioning, and bracing the pectoral girdle?

. **(a)** tendons **(b)** ligaments

. **(c)** the joint shape **(d)** muscles

. **(e)** the shape of the bones within the joint

. **2.** In anatomical position, the ulna lies

. **(a)** medial to the radius

. **(b)** lateral to the radius

. **(c)** inferior to the radius

. **(d)** superior to the radius

. **3.** The point of the elbow is actually the _____ of the ulna.

. **(a)** styloid process **(b)** olecranon

. **(c)** coronoid process **(d)** trochlear notch

. **4.** The bones of the hand articulate distally with the

. **(a)** carpal bones **(b)** ulna and radius

. **(c)** metacarpal bones **(d)** phalanges

. **5.** The epiphysis of the femur articulates with the pelvis at the

. **(a)** pubic symphysis **(b)** acetabulum

. **(c)** sciatic notch **(d)** obturator foramen

2. **6.** Which two movements are associated with the proximal radioulnar articulation?

3. **7.** Name the components of each os coxae.

4. **8.** Which seven bones make up the ankle (tarsus)?

LEVEL 2 Reviewing Concepts

. **9.** The presence of tubercles on bones indicates the positions of

. **(a)** tendons and ligaments

. **(b)** muscle attachment

. **(c)** ridges and flanges

. **(d)** a and b are correct

. **10.** At the glenoid cavity, the scapula articulates with the proximal end of the

. **(a)** humerus

. **(b)** radius

. **(c)** ulna

. **(d)** femur

. **11.** All of the following structural characteristics of the pelvic girdle adapt it to the role of bearing the weight of the body, *except*

. **(a)** heavy bones

. **(b)** strong and stable articulating surfaces

. **(c)** the arrangement of bursae around the joints

. **(d)** limited range of movement at some of the joints within the pelvic girdle

. **(e)** the arrangement of ligaments surrounding the joints

. **12.** The large foramen between the pubic and ischial rami is the

. **(a)** foramen magnum

. **(b)** suborbital foramen

. **(c)** acetabulum

. **(d)** obturator foramen

. **13.** Which of the following is an adaption for childbearing?

. **(a)** inferior angle of 100° or more between the pubic bones

. **(b)** a relatively broad, low pelvis

. **(c)** less curvature of the sacrum and coccyx

. **(d)** a, b, and c are correct

. **14.** The fibula

. **(a)** forms an important part of the knee joint

. **(b)** articulates with the femur

. **(c)** helps to bear the weight of the body

. **(d)** provides lateral stability to the ankle

. **(e)** both (a) and (c)

. **15.** The tarsal bone that accepts weight and distributes it to the heel or toes is the

. **(a)** cuneiform

. **(b)** calcaneus

. **(c)** talus

. **(d)** navicular

2. **16.** What is the difference in skeletal structure between the pelvic girdle and the pelvis?

. **17.** Jack injures himself playing hockey, and the physician who examines him informs him that he has dislocated his pollex. What part of Jack's body did he injure?

. **(a)** his arm **(b)** his leg

. **(c)** his hip **(d)** his thumb

. **(e)** his shoulder

3. **18.** Why would an instructor teaching self-defense advise a student to strike an assailant's clavicle in an attack?

. **19.** The pelvis

. **(a)** protects the upper abdominal organs

. **(b)** contains bones from both the axial and appendicular skeleton

. **(c)** is composed of the ossa coxae, sacrum, and coccyx

. **(d)** all of the above

. **(e)** (b) and (c) only

4. **20.** Why is the tibia, but not the fibula, involved in the transfer of weight to the ankle and foot?

. **21.** In determining the age of a skeleton, all of the following pieces of information would be helpful *except*

. **(a)** the number of cranial sutures

. **(b)** the size and roughness of the markings of the bones

. **(c)** the presence or absence of fontanels

. **(d)** the presence or absence of epiphyseal cartilages

. **(e)** the types of minerals deposited in the bones

LEVEL 3 Critical Thinking and Clinical Applications

1. **22.** Why would a person suffering from osteoporosis be more likely to suffer a broken hip than a broken shoulder?

2. **23.** While Fred, a fireman, is fighting a fire in a building, part of the ceiling collapses, and a beam strikes him on his left shoulder. He is rescued, but has a great deal of pain in his shoulder. He cannot move his arm properly, especially in the anterior direction. His clavicle is not broken, and his humerus is intact. What is the probable nature of Fred’s injury?

3. **24.** Archaeologists find the pelvis of a primitive human and are able to tell the sex, relative age, and some physical characteristics of the individual. How is this possible from only the pelvis?

TABLE 8–1 Sex Differences in the Human Skeleton

Region and Feature	**Male (compared with female)**	**Female (compared with male)**
SKULL		
General appearance	Heavier, rougher	Lighter, smoother
Forehead	More sloping	More vertical

Sinuses	Larger	Smaller
Cranium	About 10% larger (average)	About 10% smaller
Mandible	Larger, more robust	Smaller, lighter
Teeth	Larger	Smaller
PELVIS		
General appearance	Narrower, more robust, rougher	Broader, lighter, smoother
Pelvic inlet	Heart shaped	Oval to round
Iliac fossa	Deeper	Shallower
Ilium	More vertical; extends farther superior to sacroiliac joint	Less vertical; less extension superior to sacral articulation
Angle inferior to pubic symphysis	Under 90°	100° or more (*see Figure 8–10, p. 248*)
Acetabulum	Directed laterally	Faces slightly anteriorly as well as laterally
Obturator foramen	Oval	Triangular
Ischial spine	Points medially	Points posteriorly
Sacrum	Long, narrow triangle with pronounced sacral curvature	Broad, short triangle with less curvature
Coccyx	Points anteriorly	Points inferiorly
OTHER SKELETAL ELEMENTS		
Bone weight	Heavier	Lighter
Bone markings	More prominent	Less prominent

TABLE 8–2 Age-Related Changes in the Skeleton

Region and Feature	**Event(s)**	**Age (Years)**
GENERAL SKELETON		
Bony matrix	Reduction in mineral content;	Begins at age 30–45; values differ for males versus

	increased risk of osteoporosis	females between ages 45 and 65; similar reductions occur in both sexes after age 65
Markings	Reduction in size, roughness	Gradual reduction with increasing age and decreasing muscular strength and mass
SKULL		
Fontanels	Closure	Completed by age 2
Metopic suture	Fusion	2–8
Occipital bone	Fusion of ossification centers	1–4
Styloid process	Fusion with temporal bone	12–16
Hyoid bone	Complete ossification and fusion	25–30
Teeth	Loss of “baby teeth”; appearance of secondary dentition; eruption of permanent molars	
Mandible	Loss of teeth; reduction in bone mass; change in angle at mandibular notch	
VERTEBRAE		
Curvature	Development of major curves	3 months–10 years
Intervertebral discs	Reduction in size, percentage contribution to height	
LONG BONES		
Epiphyseal cartilages	Fusion	Begins about age 3; ranges vary, but general analysis permits determination of approximate age
PECTORAL AND PELVIC GIRDLES		
Epiphyses	Fusion	Relatively narrow ranges of ages (e.g., 14–16, 16–18, 22–25) increase accuracy of age estimates

Clinical Note

Bursitis 262

In the last two chapters, you have become familiar with the individual bones of the skeleton. These bones provide strength, support, and protection for softer tissues of the body. However, your daily life demands more of the skeleton—it must also facilitate and adapt to body movements. Think of your activities in a typical day: You breathe, talk, walk, sit, stand, and change positions innumerable times. In each case, your skeleton is directly involved. Because the bones of the skeleton are relatively inflexible, movements can occur only at **articulations**, or joints, where two bones interconnect. The characteristic structure of a joint determines the type and amount of movement that may occur. Each joint reflects a compromise between the need for strength and the need for mobility.

This chapter compares the relationships between articular form and function. We will use several examples that range from the relatively immobile but very strong (the intervertebral articulations) to the highly mobile but relatively weak (the shoulder).

The Classification of Joints

Objectives

. • Contrast the major categories of joints, and explain the relationship between structure and function for each category.

. • Describe the basic structure of a synovial joint, and describe common accessory structures and their functions.

Two classification methods are used to categorize joints. The first—the one we will use in this chapter—is based on the amount of movement possible, a property known as the *range of motion.* Each functional group is further subdivided primarily on the basis of the anatomical structure of the joint (Table 9–1):

1. An *immovable joint* is a **synarthrosis** (sin-ar-THR

¯O

-sis; *syn*, together + *arthros*, joint). A synarthrosis can be *fibrous* or *cartil*

aginous, depending on the nature of the connection. Over time, the two bones may fuse.

2. A *slightly movable joint* is an **amphiarthrosis** (am-f

¯e

-ar-THR
–

O

-sis; *amphi*, on both sides). An amphiarthrosis is either *fibrous*

or *cartilaginous*, depending on the nature of the connection between the opposing bones.

3. A *freely movable joint* is a **diarthrosis** (dı-ar-THR to the nature of the movement permitted.

The second classification scheme relies solely on the anatomical organization of the joint, without regard to the degree of move-

(Table 9–2).

synovial

, or

cartilaginous

,

,

bony

–

ment permitted. In this framework, joints are classified as

The two classifications are loosely correlated. Many anatomical patterns are seen among immovable or slightly movable joints, but there is only one type of freely movable joint—synovial joints—and all synovial joints are diarthroses. We will use the functional classification rather than the anatomical one because our primary interest is how joints work.

Synarthroses (Immovable Joints)

At a synarthrosis, the bony edges are quite close together and may even interlock. These extremely strong joints are located where movement between the bones must be prevented.

There are four major types of synarthrotic joints:

1. *Sutures.* A **suture** (*sutura*, a sewing together) is a synarthrotic joint located only between the bones of the skull. The edges of the bones are interlocked and bound together at the suture by dense fibrous connective tissue.

¯O

-sis; *dia*, through), or *synovial joint*. Diarthroses are subdivided according

2. *Gomphoses.* A **gomphosis** (gom-F

¯O

-sis; *gomphosis*, a bolting together) is a synarthrosis that binds the teeth to bony sockets in the maxillary bone and mandible. The fibrous connection between a tooth and its socket is a *periodontal* (per-

¯e

-

¯o

-DON-tal)

ligament (*peri*, around + *odontos*, tooth).

3. *Synchondroses.* A **synchondrosis** (sin-kon-DR

¯O

-sis; *syn*, together + *chondros*, cartilage) is a rigid, cartilaginous bridge between

two articulating bones. The cartilaginous connection between the ends of the first pair of vertebrosternal ribs and the sternum is a synchondrosis. Another example is the epiphyseal cartilage, which in a growing long bone connects the diaphysis to the epiphysis. l**p. 189**

4. *Synostoses.* A **synostosis** (sin-os-T

¯O

-sis) is a totally rigid, immovable joint created when two bones fuse and the boundary between them disappears. The *metopic suture* of the frontal bone and the epiphyseal lines of mature long bones are synostoses.

l**pp. 213, 190**

Amphiarthroses (Slightly Movable Joints)

An amphiarthrosis permits more movement than a synarthrosis, but is much stronger than a freely movable joint. The articulating bones are connected by collagen fibers or cartilage. There are two major types of amphiarthrotic joints:

1. At a **syndesmosis** (sin-dez-M

¯O

-sis; *desmos*, a band or ligament), bones are connected by a ligament. One example is the distal

articulation between the tibia and fibula (see Figure 8–13•). l**p. 251**

2. At a **symphysis**, or *symphyseal joint*, the articulating bones are separated by a wedge or pad of fibrocartilage. The articulation

between the bodies of vertebrae (at the *intervertebral disc*) and the connection between the two pubic bones (the *pubic symphysis*) are examples of symphyses.

Diarthroses (Freely Movable Joints)

–

Diarthroses, or **synovial** (si-NO-ve¯-ul) **joints**, permit a wider range of motion than do other types of joints. They are typically located at the ends of long bones, such as those of the upper and lower limbs. A synovial joint (Figure 9–1•) is surrounded by a fibrous **articular capsule**, and a *synovial membrane* lines the walls of the articular cavity. This membrane does not cover the articulating surfaces within the joint. Recall that a synovial membrane consists of areolar tissue covered by an incomplete epithelial

layer. The synovial fluid that fills the joint cavity originates in the areolar tissue of the synovial membrane. l**p. 131** We will now consider the major features of synovial joints.

Articular Cartilages

Under normal conditions, the bony surfaces at a synovial joint cannot contact one another, because the articulating surfaces are covered by special **articular cartilages**. Articular cartilages resemble hyaline cartilages elsewhere in the body. l**p. 126** However, articular cartilages have no perichondrium (the fibrous sheath described in Chapter 4), and the matrix contains more water than that of other cartilages.

The surfaces of the articular cartilages are slick and smooth. This feature alone can reduce friction during movement at the joint. However, even when pressure is applied across a joint, the smooth articular cartilages do not touch one another, because they are separated by a thin film of synovial fluid within the joint cavity (Figure 9–1a•). This fluid acts as a lubricant, minimizing friction.

Normal synovial joint function cannot continue if the articular cartilages are damaged. When such damage occurs, the matrix may begin to break down. The exposed surface will then change from a slick, smooth-gliding surface to a rough feltwork of bristly collagen fibers. This feltwork drastically increases friction at the joint.

Synovial Fluid

Synovial fluid resembles interstitial fluid, but contains a high concentration of proteoglycans secreted by fibroblasts of the synovial membrane. Even in a large joint such as the knee, the total quantity of synovial fluid in a joint is normally less than 3 ml. A clear, viscous solution with the consistency of heavy molasses, the synovial fluid within a joint has three primary functions:

1. **1.** *Lubrication.* The articular cartilages behave like sponges filled with synovial fluid. When part of an articular cartilage is compressed, some of the synovial fluid is squeezed out of the cartilage and into the space between the opposing surfaces. This thin layer of fluid markedly reduces friction between moving surfaces, just as a thin film of water reduces friction between a car’s tires and a highway. When the compression stops, synovial fluid is sucked back into the articular cartilages.

2. **2.** *Nutrient Distribution.* The synovial fluid in a joint must circulate continuously to provide nutrients and a waste-disposal route for the chondrocytes of the articular cartilages. It circulates whenever the joint moves, and the compression and reexpansion of the articular cartilages pump synovial fluid into and out of the cartilage matrix. As the synovial fluid flows through the areolar tissue of the synovial membrane, waste products are absorbed and additional nutrients are obtained by diffusion across capillary walls.

3. **3.** *Shock Absorption.* Synovial fluid cushions shocks in joints that are subjected to compression. For example, your hip, knee, and ankle joints are compressed as you walk and are more severely compressed when you jog or run. When the pressure across a joint suddenly increases, the synovial fluid lessens the shock by distributing it evenly across the articular surfaces and outward to the articular capsule.

Accessory Structures

Synovial joints may have a variety of accessory structures, including pads of cartilage or fat, ligaments, tendons, and bursae (Figure 9–1b•).

Cartilages and Fat Pads In several joints, including the knee (see Figure 9–1b•), menisci and fat pads may lie between the opposing articular surfaces. A **meniscus** (me-NIS-kus; a crescent; plural, *menisci*) is a pad of fibrocartilage situated between opposing bones within a synovial joint. Menisci, or *articular discs*, may subdivide a synovial cavity, channel the flow of synovial fluid, or allow for variations in the shapes of the articular surfaces.

Fat pads are localized masses of adipose tissue covered by a layer of synovial membrane. They are commonly superficial to the joint capsule (see Figure 9–1b•). Fat pads protect the articular cartilages and act as packing material for the joint. When the bones move, the fat pads fill in the spaces created as the joint cavity changes shape.

Ligaments The capsule that surrounds the entire joint is continuous with the periostea of the articulating bones. **Accessory ligaments** support, strengthen, and reinforce synovial joints. *Intrinsic ligaments*, or *capsular ligaments*, are localized thickenings of the joint capsule. *Extrinsic ligaments* are separate from the joint capsule. These ligaments may be located either inside or outside the joint capsule, and are called *intracapsular* or *extracapsular* ligaments, respectively.

Ligaments are very strong. In a **sprain**, a ligament is stretched to the point at which some of the collagen fibers are torn, but the ligament as a whole survives and the joint is not damaged. With excessive force, one of the attached bones usually breaks before the ligament tears. In general, a broken bone heals much more quickly and effectively than does a torn ligament.

Tendons Although not part of the articulation itself, tendons passing across or around a joint may limit the joint’s range of motion and provide mechanical support for it. For example, tendons associated with the muscles of the arm provide much of the bracing for the shoulder joint.

Bursae

Bursae (BUR-s ; singular, *bursa*, a pouch) are small, fluid-filled pockets in connective tissue. They contain synovial fluid and are lined by a synovial membrane. Bursae may be connected to the joint cavity or separate from it. They form where a tendon or ligament rubs against other tissues. Located around most synovial joints, including the shoulder joint, bursae reduce friction and act as shock absorbers. *Synovial tendon sheaths* are tubular bursae that surround tendons where they cross bony surfaces. Bursae may also appear deep to the skin, covering a bone or lying within other connective tissues exposed to friction or pres-

‾e

The pattern of stabilizing structures varies among joints. For example, the hip joint is stabilized by the shapes of the bones

sure. Bursae that develop in abnormal locations, or because of abnormal stresses, are called *adventitious bursae*.

Clinical Note

When bursae become inflamed, causing pain in the affected area whenever the tendon or ligament moves, the condition is called

bursitis. Inflammation can result from the friction due to repetitive motion, pressure over the joint, irritation by chemical stimuli, infection, or trauma. Bursitis associated with repetitive motion typically occurs at the shoulder; musicians, golfers, baseball pitchers, and tennis players may develop bursitis there. The most common pressure-related bursitis is a

bunion. Bunions form over the base of the great toe as a result of friction and distortion of the first metatarsophalangeal joint by tight shoes,
especially narrow shoes with pointed toes.

We have special names for bursitis at other locations, indicating the occupations most often associated with them. In “house-maid’s knee,” which accompanies prolonged kneeling, the affected bursa lies between the patella and the skin. The condition of “stu-dent’s elbow” is a form of bursitis that can result from propping your head up with your arm on a desk while you read your anatomy and physiology textbook.

Factors That Stabilize Joints

A joint cannot be both highly mobile and very strong. The greater the range of motion at a joint, the weaker it becomes. A synarthrosis, the strongest type of joint, permits no movement, whereas a diarthrosis, such as the shoulder, is far weaker but permits a broad range of movement. Any mobile diarthrosis will be damaged by movement beyond its normal range of motion. Several factors are responsible for limiting the range of motion, stabilizing the joint, and reducing the chance of injury:

. • The collagen fibers of the joint capsule and any accessory, extracapsular, or intracapsular ligaments.

. • The shapes of the articulating surfaces and menisci, which may prevent movement in specific directions.

. • The presence of other bones, skeletal muscles, or fat pads around the joint.

. • Tension in tendons attached to the articulating bones. When a skeletal muscle contracts and pulls on a tendon, movement in a specific direction may be either encouraged or opposed.

(the head of the femur projects into the acetabulum), a heavy capsule, intracapsular and extracapsular ligaments, tendons, and massive muscles. It is therefore very strong and stable. In contrast, the elbow, another stable joint, gains its stability primarily from the interlocking of the articulating bones; the capsule and associated ligaments provide additional support. In general, the more stable the joint, the more restricted is its range of motion. The shoulder joint, the most mobile synovial joint, relies only on the surrounding ligaments, muscles, and tendons for stability. It is thus fairly weak.

When reinforcing structures cannot protect a joint from extreme stresses, a **dislocation**, or **luxation** (luk-S
¯A

-shun), results.

In a dislocation, the articulating surfaces are forced out of position. The displacement can damage the articular cartilages, tear ligaments, or distort the joint capsule. Although the *inside* of a joint has no pain receptors, nerves that monitor the capsule, ligaments, and tendons are quite sensitive, so dislocations are very painful. The damage accompanying a partial dislocation, or **subluxation** (sub-luk-S
¯A

-shun), is less severe. People who are "double jointed" have joints that are weakly stabilized. Although their joints permit a greater range of motion than do those of other individuals, they are more likely to suffer partial or complete dislocations.

Concept Check

What common characteristics do typical synarthrotic and amphiarthrotic joints share?

In a newborn infant, the large bones of the skull are joined by fibrous connective tissue. Which type of joints are these? The bones later grow, interlock, and form immovable joints. Which type of joints are these? Why would improper circulation of synovial fluid lead to the degeneration of articular cartilages in the affected joint?

Answers begin on p. A–1

Form and Function of Synovial Joints

Objectives

. • Describe the dynamic movements of the skeleton.

. • List the types of synovial joints, and discuss how the characteristic motions of each type are related to its anatomical structure.

To understand human movement, you must be aware of the relationship between structure and function at each articulation. To *describe* human movement, you need a frame of reference that enables accurate and precise communication. We can classify the synovial joints according to their anatomical and functional properties. To demonstrate the basis for that classification, we will use a simple model to describe the movements that occur at a typical synovial joint.

Describing Dynamic Motion

Take a pencil (or a pen) as your model, and stand it upright on the surface of a desk or table (Figure 9–2a•). The pencil represents a bone, and the desktop represents an articular surface. A little imagination and a lot of twisting, pushing, and pulling will demonstrate that there are only three ways to move the model. Considering them one at a time will provide a frame of reference for us to analyze complex movements:

Possible Movement 1: The pencil point can move. If you hold the pencil upright, without securing the point, you can push the pencil point across the surface. This kind of motion, *gliding* (Figure 9–2b•), is an example of **linear motion**. You could slide the point forward or backward, from side to side, or diagonally. However you move the pencil, the motion can be described by using two lines of reference (axes). One line represents forward–backward motion, the other left–right movement. For example, a simple movement along one axis could be described as “forward 1 cm” or “left 2 cm.” A diagonal movement could be described with both axes, as in “backward 1 cm and to the right 2.5 cm.”

Possible Movement 2: The pencil shaft can change its angle with the surface. With the tip held in position, you can move the free (eraser) end of the pencil forward and backward, from side to side, or at some intermediate angle. These movements, which change the angle between the shaft and the desktop, are examples of **angular motion** (Figure 9–2c•). We can describe such motion by the angle the pencil shaft makes with the surface.

Any angular movement can be described with reference to the same two axes (forward–backward, left–right) and the angular change (in degrees). In one instance, however, a special term is used to describe a complex angular movement. Grasp the pencil eraser and move the pencil in any direction until it is no longer vertical. Now swing the eraser through a complete circle (Figure 9–2d•). This movement, which corresponds to the path of your arm when you draw a large circle on a chalkboard, is very difficult to describe. Anatomists avoid the problem by using a special term, **circumduction** (sir-kum-DUK-shun; *circum*, around), for this type of angular motion.

Possible Movement 3: The pencil shaft can rotate. If you keep the shaft vertical and the point at one location, you can still spin the pencil around its longitudinal axis. This movement is called **rotation** (Figure 9–2e•). Several articulations permit partial rotation, but none can rotate freely. Such a movement would hopelessly tangle the blood vessels, nerves, and muscles that cross the joint.

¯e

An articulation that permits movement along only one axis is called **monaxial** (mon-AKS--ul). In the pencil model, if an articulation permits only angular movement in the forward–backward plane or prevents any movement other than rotation around

¯e¯

its longitudinal axis, it is monaxial. If movement can occur along two axes, the articulation is **biaxial** (b -AKS--ul). If the pen-

ı cil could undergo angular motion in the forward– backward *and* left–right planes, but not rotation, it would be biaxial. The most

¯e

–

mobile joints permit a combination of angular movement and rotation. These joints are said to be **triaxial** (tr -AKS--ul).

ı Joints that permit gliding allow only small amounts of movement. These joints may be called *nonaxial*, because they permit only small sliding movements, or *multiaxial*, because sliding may occur in any direction.

Types of Movements at Synovial Joints

In descriptions of motion at synovial joints, phrases such as “bend the leg” or “raise the arm” are not sufficiently precise. Anatomists use descriptive terms that have specific meanings. We will consider these motions with reference to the basic categories of movement discussed previously: gliding, angular motion, and rotation.

Linear Motion (Gliding)

In **gliding**, two opposing surfaces slide past one another, as in possible movement 1. Gliding occurs between the surfaces of articulating carpal bones, between tarsal bones, and between the clavicles and the sternum. The movement can occur in almost any direction, but the amount of movement is slight, and rotation is generally prevented by the capsule and associated ligaments.

Angular Motion

Examples of angular motion include *flexion*, *extension*, *abduction*, *adduction*, and *circumduction* (Figure 9–3•). Descriptions of these movements are based on reference to an individual in the anatomical position. l**p. 16**

Flexion and Extension **Flexion** (FLEK-shun) is movement in the anterior–posterior plane that reduces the angle between the articulating elements. **Extension** occurs in the same plane, but it increases the angle between articulating elements (Figure 9–3a•).

These terms are usually applied to the movements of the long bones of the limbs, but they are also used to describe movements of the axial skeleton. For example, when you bring your head toward your chest, you flex the intervertebral joints of the neck. When you bend down to touch your toes, you flex the intervertebral joints of the spine. Extension reverses these movements, returning you to the anatomical position. When a person is in the anatomical position, all of the major joints of the axial and appendicular skeletons (except the ankle) are at full extension. (Special terms used to describe movements of the ankle joint are introduced shortly.)

Flexion of the shoulder joint or hip joint moves the limbs anteriorly, whereas extension moves them posteriorly. Flexion of the wrist joint moves the hand anteriorly, and extension moves it posteriorly. In each of these examples, extension can be continued past the anatomical position. Extension past the anatomical position is called **hyperextension** (see Figure 9–3a•). When you hyperextend your neck, you can gaze at the ceiling. Hyperextension of many joints, such as the elbow or the knee, is prevented by ligaments, bony processes, or soft tissues.

Abduction and Adduction **Abduction** (*ab*, from) is movement *away from the longitudinal axis of the body* in the frontal plane (Figure 9–3b•). For example, swinging the upper limb to the side is abduction of the limb. Moving it back to the anatomical position constitutes **adduction** (*ad*, to). Adduction of the wrist moves the heel of the hand and fingers *toward* the body, whereas abduction moves them farther away. Spreading the fingers or toes apart abducts them, because they move *away from* a central digit (Figure 9–3c•). Bringing them together constitutes adduction. (Fingers move toward or away from the middle finger; toes move toward or away from the second toe.) Abduction and adduction always refer to movements of the appendicular skeleton, not to those of the axial skeleton.

Circumduction We introduced a special type of angular motion, circumduction, in our model. Moving your arm in a loop is circumduction (Figure 9–3d•), as when you draw a large circle on a chalkboard. Your hand moves in a circle, but your arm does not rotate.

Rotation

Rotational movements are also described with reference to a figure in the anatomical position. Rotation of the head may involve **left rotation** or **right rotation** (Figure 9–4a•). Limb rotation may be described by reference to the longitudinal axis of the trunk. During **medial rotation**, also known as *internal rotation* or *inward rotation*, the anterior surface of a limb turns toward the long axis of the trunk (see Figure 9–4a•). The reverse movement is called **lateral rotation**, *external rotation*, or *outward rotation*.

The proximal articulation between the radius and the ulna permits rotation of the radial head. As the shaft of the radius ro

tates, the distal epiphysis of the radius rolls across the anterior surface of the ulna. This movement, called **pronation** (pr

¯o

-N

¯A

-

shun), turns the wrist and hand from palm facing front to palm facing back (Figure 9–4b•). The opposing movement, in which
the palm is turned anteriorly, is **supination** (soo-pi-N
¯A

-shun). The forearm is supinated in the anatomical position. This view
makes it easier to follow the path of the blood vessels, nerves, and tendons, which rotate with the radius during pronation.

Special Movements

Several special terms apply to specific articulations or unusual types of movement (Figure 9–5•):

- **Inversion** (*in*, into + *vertere,* to turn) is a twisting motion of the foot that turns the sole inward, elevating the medial edge of
the sole. The opposite movement is called **eversion** (
¯e
-VER-zhun; *e*, out).

. • **Dorsiflexion** is flexion at the ankle joint and elevation of the sole, as when you dig in your heel. **Plantar flexion** (*planta,* sole), the opposite movement, extends the ankle joint and elevates the heel, as when you stand on tiptoe. However, it is also acceptable (and simpler) to use “flexion and extension at the ankle,” rather than “dorsiflexion and plantar flexion.”

. • **Opposition** is movement of the thumb toward the surface of the palm or the pads of other fingers. Opposition enables you to grasp and hold objects between your thumb and palm. It involves movement at the first carpometacarpal and metacarpophalangeal joints. Flexion at the fifth metacarpophalangeal joint can assist this movement.

- **Protraction** entails moving a part of the body anteriorly in the horizontal plane. **Retraction** is the reverse movement. You protract your jaw when you grasp your upper lip with your lower teeth, and you protract your clavicles when you cross your arms.
- **Elevation** and **depression** occur when a structure moves in a superior or an inferior direction, respectively. You depress your mandible when you open your mouth; you elevate your mandible as you close your mouth. Another familiar elevation occurs when you shrug your shoulders.
- **Lateral flexion** occurs when your vertebral column bends to the side. This movement is most pronounced in the cervical and thoracic regions.

A Structural Classification of Synovial Joints

Synovial joints are described as *gliding, hinge, pivot, ellipsoidal, saddle,* or *ball-and-socket joints* on the basis of the shapes of the articulating surfaces. Each type of joint permits a different type and range of motion. Figure 9–6• lists the structural categories and the types of movement each permits.

- **Gliding joints**, also called *planar joints*, have flattened or slightly curved faces. The relatively flat articular surfaces slide across one another, but the amount of movement is very slight. Although rotation is theoretically possible at such a joint, ligaments usually prevent or restrict such movement.
- **Hinge joints** permit angular motion in a single plane, like the opening and closing of a door.
- **Pivot joints** also are monaxial, but they permit only rotation.
- In an **ellipsoidal joint**, or *condyloid joint*, an oval articular face nestles within a depression in the opposing surface. With such an arrangement, angular motion occurs in two planes: along or across the length of the oval.
- **Saddle joints**, or *sellaris joints*, fit together like a rider in a saddle. Each articular face is concave along one axis and convex along the other. This arrangement permits angular motion, including circumduction, but prevents rotation.

. • In a **ball-and-socket joint**, the round head of one bone rests within a cup-shaped depression in another. All combinations of angular and rotational movements, including circumduction, can be performed at ball-and-socket joints.

100 Keys | A joint cannot be both highly mobile and very strong. The greater the mobility, the weaker the joint, because
mobile joints rely on muscular and ligamentous support rather than solid bone-to-bone connections.

Concept Check

When you do jumping jacks, which lower limb movements are necessary?

Which movements are associated with hinge joints?

Answers begin on p. A–1

Representative Articulations

Objectives

. • Describe the articulations between the vertebrae of the vertebral column.

. • Describe the structure and function of the shoulder, elbow, hip, and knee joints.

. • Explain the relationship between joint strength and mobility, using specific examples.

In this section, we consider representative articulations that demonstrate important functional principles.

Intervertebral Articulations

The articulations between the superior and inferior articular processes of adjacent vertebrae are gliding joints that permit small movements associated with flexion and rotation of the vertebral column (Figure 9–7•). Little gliding occurs between adjacent vertebral bodies. From axis to sacrum, the vertebrae are separated and cushioned by pads of fibrocartilage called **intervertebral discs**. Thus, the bodies of vertebrae form symphyseal joints. Intervertebral discs and symphyseal joints are found neither in the sacrum or coccyx, where vertebrae have fused, nor between the first and second cervical vertebrae. The first cervical vertebra has no vertebral body and no intervertebral disc; the only articulation between the first two cervical vertebrae is a pivot joint that permits much more rotation than do the symphyseal joints between other cervical vertebrae.

The Intervertebral Discs

¯O

Each intervertebral disc has a tough outer layer of fibrocartilage, the **anulus fibrosus** (AN

–

-lus f -BR

ı of this layer attach the disc to the bodies of adjacent vertebrae. The anulus fibrosus surrounds the **nucleus pulposus** (pul-P

¯u

-sus). The collagen fibers

¯O

-

sus), a soft, elastic, gelatinous core (see Figure 9–7•). The nucleus pulposus gives the disc resiliency and enables it to absorb shocks.

Movement of the vertebral column compresses the nucleus pulposus and displaces it in the opposite direction. This displacement permits smooth gliding movements between vertebrae while maintaining their alignment. The discs make a significant contribution to an individual’s height: They account for roughly one-quarter the length of the vertebral column superior to the sacrum. As we grow older, the water content of the nucleus pulposus in each disc decreases. The discs gradually become less effective as cushions, and the chances of vertebral injury increase. Water loss from the discs also causes shortening of the vertebral column, accounting for the characteristic decrease in height with advancing age.

Intervertebral Ligaments

Numerous ligaments are attached to the bodies and processes of all vertebrae, binding them together and stabilizing the vertebral column (see Figure 9–7•). Ligaments interconnecting adjacent vertebrae include the following:

- The *anterior longitudinal ligament*, which connects the anterior surfaces of adjacent vertebral bodies.
- The *posterior longitudinal ligament*, which parallels the anterior longitudinal ligament and connects the posterior surfaces of adjacent vertebral bodies.
- The *ligamentum flavum* (plural, *ligamenta flava*), which connects the laminae of adjacent vertebrae.
- The *interspinous ligament*, which connects the spinous processes of adjacent vertebrae.
- The *supraspinous ligament*, which interconnects the tips of the spinous processes from C7 to the sacrum. The *ligamentum nuchae*, which extends from vertebra C7 to the base of the skull, is continuous with the supraspinous ligament. l**p. 228**

If the posterior longitudinal ligaments are weakened, as often occurs with advancing age, the compressed nucleus pulposus may distort the anulus fibrosus, forcing it partway into the vertebral canal. This condition is called a **slipped disc** (Figure 9–8a•), although the disc does not actually slip. If the nucleus pulposus breaks through the anulus fibrosus, it too may protrude into the vertebral canal. This condition is called a **herniated disc** (Figure 9–8b•). When a disc herniates, sensory nerves are distorted, and the protruding mass can also compress the nerves passing through the adjacent intervertebral foramen. AM: Diagnosing and Treating Intervertebral Disc Problems

Vertebral Movements

The following movements can occur across the intervertebral joints of the vertebral column: (1) flexion, or bending anteriorly;

(2) extension, or bending posteriorly; (3) lateral flexion, or bending laterally; and (4) rotation. Table 9–3 summarizes information about intervertebral and other articulations of the axial skeleton.

Concept Check

Which regions of the vertebral column do not contain intervertebral discs? Why is the absence of discs significant?

Which vertebral movements are involved in (a) bending forward, (b) bending to the side, and (c) moving the head to signify “no”?

Answers begin on p. A–1

The Shoulder Joint

The shoulder joint, or *glenohumeral joint*, permits the greatest range of motion of any joint. Because it is also the most frequently dislocated joint, it provides an excellent demonstration of the principle that stability must be sacrificed to obtain mobility.

This joint is a ball-and-socket diarthrosis formed by the articulation of the head of the humerus with the glenoid cavity of the scapula (Figure 9–9a•). The extent of the glenoid cavity is increased by a fibrocartilaginous **glenoid labrum** (*labrum*, lip or edge), which continues beyond the bony rim and deepens the socket (Figure 9–9b•). The relatively loose articular capsule extends from the scapula, proximal to the glenoid labrum, to the anatomical neck of the humerus. Somewhat oversized, the articular capsule permits an extensive range of motion. The bones of the pectoral girdle provide some stability to the superior surface, because the acromion and coracoid process project laterally superior to the head of the humerus. However, most of the stability at this joint is provided by the surrounding skeletal muscles, with help from their associated tendons and various ligaments. Bursae reduce friction between the tendons and other tissues at the joint.

The major ligaments that help stabilize the shoulder joint are the *glenohumeral*, *coracohumeral*, *coracoacromial*, *coracoclavicular*, and *acromioclavicular ligaments*. The acromioclavicular ligament reinforces the capsule of the acromioclavicular joint and supports the superior surface of the shoulder. A **shoulder separation** is a relatively common injury involving partial or complete dislocation of the acromioclavicular joint. This injury can result from a blow to the superior surface of the shoulder. The acromion is forcibly depressed while the clavicle is held back by strong muscles.

The muscles that move the humerus do more to stabilize the shoulder joint than do all the ligaments and capsular fibers combined. Muscles originating on the trunk, pectoral girdle, and humerus cover the anterior, superior, and posterior surfaces of the capsule. The tendons of the *supraspinatus, infraspinatus, subscapularis*, and *teres minor muscles* reinforce the joint capsule and limit range of movement. These muscles, known as the muscles of the *rotator cuff*, are the primary mechanism for supporting the shoulder joint and limiting its range of movement. Damage to the rotator cuff typically occurs when individuals are engaged in sports that place severe strains on the shoulder. White-water kayakers, baseball pitchers, and quarterbacks are all at high risk for rotator cuff injuries.

The anterior, superior, and posterior surfaces of the shoulder joint are reinforced by ligaments, muscles, and tendons, but the inferior capsule is poorly reinforced. As a result, a dislocation caused by an impact or a violent muscle contraction is most likely to occur at this site. Such a dislocation can tear the inferior capsular wall and the glenoid labrum. The healing process typically leaves a weakness that increases the chances for future dislocations.

As at other joints, bursae at the shoulder reduce friction where large muscles and tendons pass across the joint capsule. The shoulder has a relatively large number of important bursae, such as the *subacromial bursa*, the *subdeltoid bursa*, the *subcoracoid bursa*, and the *subscapular bursa* (see Figure 9–9a,b•). A tendon of the biceps brachii muscle runs through the shoulder joint.

l**p. 242** As it passes through the articular capsule, it is surrounded by a tubular bursa that is continuous with the joint cavity. Inflammation of any of these extracapsular bursae can restrict motion and produce the painful symptoms of bursitis (p. 262).

Anatomy 360 | Review the anatomy and function of the shoulder joint on the **Anatomy 360 CD-ROM: Skeletal System/Syn-ovial Joints/Shoulder.**

The Elbow Joint

The elbow joint is a complex hinge joint that involves the humerus, radius, and ulna (Figure 9–10•). The largest and strongest articulation at the elbow is the *humeroulnar joint*, where the trochlea of the humerus articulates with the trochlear notch of the ulna. This joint works like a door hinge, with physical limitations imposed on the range of motion. In the case of the elbow, the shape of the trochlear notch of the ulna determines the plane of movement, and the combination of the notch and the olecranon limits

the degree of extension permitted. l**p. 243** At the smaller *humeroradial joint*, the capitulum of the humerus articulates with the head of the radius.

Muscles that extend the elbow attach to the rough surface of the olecranon. These muscles are primarily under the control of the *radial nerve*, which passes along the radial groove of the humerus. l**p. 242** The large *biceps brachii muscle* covers the anterior surface of the arm. Its tendon is attached to the radius at the radial tuberosity. Contraction of this muscle produces supination of the forearm and flexion at the elbow.

The elbow joint is extremely stable because (1) the bony surfaces of the humerus and ulna interlock, (2) a single, thick articular capsule surrounds both the humeroulnar and proximal radioulnar joints, and (3) the articular capsule is reinforced by strong ligaments. The *radial collateral ligament* stabilizes the lateral surface of the elbow joint (Figure 9–10b•). It extends between the lateral epicondyle of the humerus and the *annular ligament*, which binds the head of the radius to the ulna. The medial surface of the elbow joint is stabilized by the *ulnar collateral ligament*, which extends from the medial epicondyle of the humerus anteriorly to the coronoid process of the ulna and posteriorly to the olecranon (Figure 9–10a•).

Despite the strength of the capsule and ligaments, the elbow can be damaged by severe impacts or unusual stresses. For example, if you fall on your hand with a partially flexed elbow, contractions of muscles that extend the elbow may break the ulna at the center of the trochlear notch. Less violent stresses can produce dislocations or other injuries to the elbow, especially if epiphyseal growth has not been completed. For example, parents in a rush may drag a toddler along behind them exerting an upward, twisting pull on the elbow joint that can result in a partial dislocation known as *nursemaid's elbow*.

Anatomy 360 | Review the anatomy and function of the elbow joint on the **Anatomy 360 CD-ROM: Skeletal System/Syn-ovial Joints/Elbow.**

Concept Check

Which tissues or structures provide most of the stability for the shoulder joint?

Would a tennis player or a jogger be more likely to develop inflammation of the subscapular bursa? Why?

A football player received a blow to the upper surface of his shoulder, causing a shoulder separation. What does this mean?

Terry suffers an injury to his forearm and elbow. After the injury, he notices an unusually large degree of motion between the

radius and the ulna at the elbow. Which ligament did Terry most likely damage?

Answers begin on p. A–1

The Hip Joint

Table 9–4 summarizes information about the articulations of the appendicular skeleton.

The hip joint, or *coxal joint*, is a sturdy ball-and-socket diarthrosis that permits flexion and extension, adduction and abduction, circumduction, and rotation. Figure 9–11• introduces the structure of the hip joint. The acetabulum, a deep fossa, accommodates the head of the femur. l**p. 249** Within the acetabulum, a fibrocartilage pad extends like a horseshoe to either side of the acetabular notch (Figure 9–11a•). The *acetabular labrum*, a projecting rim of fibrocartilage, increases the depth of the joint cavity.

The articular capsule of the hip joint is extremely dense and strong. It extends from the lateral and inferior surfaces of the pelvic girdle to the intertrochanteric line and intertrochanteric crest of the femur, enclosing both the head and neck of the femur. l**p. 249** This arrangement helps keep the femoral head from moving too far from the acetabulum.

Four broad ligaments reinforce the articular capsule (see Figure 9–11•). Three of them—the *iliofemoral*, *pubofemoral*, and *ischiofemoral ligaments*—are regional thickenings of the capsule. The *transverse acetabular ligament* crosses the acetabular notch, filling in the gap in the inferior border of the acetabulum. A fifth ligament, the *ligament of the femoral head*, or *ligamentum teres* (*teres*, long and round), originates along the transverse acetabular ligament (see Figure 9–11a•) and attaches to the fovea capitis, a small pit at the center of the femoral head. l**p. 249** This ligament tenses only when the hip is flexed and the thigh is undergoing lateral rotation. Much more important stabilization is provided by the bulk of the surrounding muscles, aided by ligaments and capsular fibers.

The combination of an almost complete bony socket, a strong articular capsule, supporting ligaments, and muscular padding makes the hip joint an extremely stable joint. The head of the femur is well supported, but the ball-and-socket joint is not directly aligned with the weight distribution along the shaft. Stress must be transferred at an angle from the joint, along the relatively thin

femoral neck to the length of the femur. l**p. 187** Fractures of the femoral neck or between the greater and lesser trochanters of the femur are more common than hip dislocations. As we noted in Chapter 6, however, hip fractures are relatively common in elderly individuals with severe osteoporosis. l**p. 201**

The Knee Joint

The hip joint passes weight to the femur, and the knee joint transfers the weight from the femur to the tibia. The shoulder is mobile; the hip, stable; and the knee. . .? If you had to choose one word, it would probably be “complicated.” Although the knee joint functions as a hinge, the articulation is far more complex than the elbow or even the ankle. The rounded condyles of the femur roll across the superior surface of the tibia, so the points of contact are constantly changing. The joint permits flexion, extension, and very limited rotation.

The knee joint contains three separate articulations: two between the femur and tibia (medial condyle to medial condyle, and lateral condyle to lateral condyle) and one between the patella and the patellar surface of the femur (Figure 9–12•).

The Articular Capsule and Joint Cavity

The articular capsule at the knee joint is thin and in some areas incomplete, but it is strengthened by various ligaments and the tendons of associated muscles. A pair of fibrocartilage pads, the **medial** and **lateral menisci**, lie between the femoral and tibial surfaces (Figures 9–1b•, p. 261, and 9–12c,d•). The menisci (1) act as cushions, (2) conform to the shape of the articulating surfaces as the femur changes position, and (3) provide lateral stability to the joint. Prominent fat pads cushion the margins of the joint and assist the many bursae in reducing friction between the patella and other tissues. AM: Knee Injuries

Supporting Ligaments

A complete dislocation of the knee is very rare, largely because seven major ligaments stabilize the knee joint:

1. The tendon from the muscles responsible for extending the knee passes over the anterior surface of the joint (Figure 9–12a•). The patella is embedded in this tendon, and the *patellar ligament* continues to its attachment on the anterior surface of the tibia. The patellar ligament and two ligamentous bands known as the *patellar retinaculae* support the anterior surface of the knee joint.

2, 3. Two *popliteal ligaments* extend between the femur and the heads of the tibia and fibula (Figure 9–12b•). These ligaments reinforce the knee joint’s posterior surface.

4, 5. Inside the joint capsule, the *anterior cruciate ligament* (ACL) and *posterior cruciate ligament* (PCL) attach the intercondylar area of the tibia to the condyles of the femur (see Figure 9–12c,d•). *Anterior* and *posterior* refer to the sites of origin of these ligaments on the tibia. They cross one another as they proceed to their destinations on the femur. (The term *cruciate* is derived from the Latin word *crucialis*, meaning a cross.) The ACL and the PCL limit the anterior and posterior movement of the femur and maintain the alignment of the femoral and tibial condyles.

6, 7. The *tibial collateral ligament* reinforces the medial surface of the knee joint, and the *fibular collateral ligament* reinforces the lateral surface (see Figure 9–12•). These ligaments tighten only at full extension, the position in which they stabilize the joint.

At full extension, a slight lateral rotation of the tibia tightens the anterior cruciate ligament and jams the lateral meniscus between the tibia and femur. The knee joint is essentially locked in the extended position. With the joint locked, a person can stand for prolonged periods without using (and tiring) the muscles that extend the knee. Unlocking the knee joint requires muscular contractions that medially rotate the tibia or laterally rotate the femur. If the locked knee is struck from the side, the lateral meniscus can tear and the supporting ligaments can be seriously damaged.

The knee joint is structurally complex and is subjected to severe stresses in the course of normal activities. Painful knee injuries are all too familiar to both amateur and professional athletes. Treatment is often costly and prolonged, and repairs seldom make the joint “good as new.” AM: Arthroscopy and Joint Injuries

Anatomy 360 | Review the anatomy and function of the knee joint on the **Anatomy 360 CD-ROM: Skeletal System/Syn-ovial Joints/Knee.**

Concept Check

Where would you find the following ligaments: iliofemoral ligament, pubofemoral ligament, and ischiofemoral ligament?

What symptoms would you expect to see in an individual who has damaged the menisci of the knee joint?

Why is “clergyman’s knee” (a type of bursitis) common among carpet layers and roofers?

Answers begin on p. A–1

Aging and Articulations

Objective

- Describe the effects of aging on articulations, and discuss the most common clinical problems that develop as a result.

Joints are subjected to heavy wear and tear throughout our lifetimes, and problems with joint function are relatively common, especially in older individuals. **Rheumatism** (ROO-muh-tizum) is a general term that indicates pain and stiffness affecting the skeletal system, the muscular system, or both. Several major forms of rheumatism exist. **Arthritis** (ar-THR -tis) encompasses all the rheumatic diseases that affect synovial joints. Arthritis always involves damage to the articular cartilages, but the specific cause can vary. For example, arthritis can result from bacterial or viral infection, injury to the joint, metabolic problems, or severe physical stresses.

¯I

Osteoarthritis (os-t

¯e

-

¯o

-ar-THR -tis), also known as *degenerative arthritis* or *degenerative joint disease* (*DJD*), generally affects

I¯

individuals age 60 or older. Osteoarthritis can result from cumulative wear and tear at the joint surfaces or from genetic factors affecting collagen formation. In the U.S. population, 25 percent of women and 15 percent of men over age 60 show signs of this disease.

Rheumatoid arthritis is an inflammatory condition that affects roughly 2.5 percent of the adult population. At least some cases occur when the immune response mistakenly attacks the joint tissues. Such a condition, in which the body attacks its own tissues, is called an *autoimmune disease*. Allergies, bacteria, viruses, and genetic factors have all been proposed as contributing to or triggering the destructive inflammation.

In *gouty arthritis*, crystals of uric acid form within the synovial fluid of joints. The accumulation of crystals of uric acid over time eventually interferes with normal movement. This form of arthritis is named after the metabolic disorder known as *gout*, discussed further in Chapter 25. In gout, the crystals are derived from uric acid (a metabolic waste product), and the joint most often affected is the metatarsal–phalangeal joint of the great toe. Gout is relatively rare, but other forms of gouty arthritis are much more common—some degree of calcium salt deposition occurs in the joints in 30–60 percent of those over age 85. The cause is unknown, but the condition appears to be linked to age-related changes in the articular cartilages.

Regular exercise, physical therapy, and drugs that reduce inflammation (such as aspirin) can often slow the progress of osteoarthritis. Surgical procedures can realign or redesign the affected joint. In extreme cases involving the hip, knee, elbow, or shoulder, the defective joint can be replaced by an artificial one. AM: Rheumatism, Arthritis, and Synovial Function

Degenerative changes comparable to those seen in arthritis may result from joint immobilization. When motion ceases, so does the circulation of synovial fluid, and the cartilages begin to degenerate. **Continuous passive motion (CPM)** of any injured joint appears to encourage the repair process by improving the circulation of synovial fluid. The movement is often performed by a physical therapist or a machine during the recovery process.

With age, bone mass decreases and bones become weaker, so the risk of fractures increases. l**p. 201** If osteoporosis develops, the bones may weaken to the point at which fractures occur in response to stresses that could easily be tolerated by normal bones. Hip fractures are among the most dangerous fractures seen in elderly people, with or without osteoporosis. These fractures, most often involving individuals over age 60, may be accompanied by hip dislocation or by pelvic fractures.

Although severe hip fractures are most common among those over age 60, in recent years the frequency of hip fractures has increased dramatically among young, healthy professional athletes. AM: Hip Fractures, Aging, and Arthritis

Integration with Other Systems

Although the bones you study in the lab may seem to be rigid and unchanging structures, the living skeleton is dynamic and undergoes continuous remodeling. The balance between osteoblast and osteoclast activity is delicate and subject to change at a mo-ment’s notice. When osteoblast activity predominates, bones thicken and strengthen; when osteoclast activity predominates, bones get thinner and weaker. The balance between bone formation and bone recycling varies with (1) the age of the individual, (2) the physical stresses applied to the bone, (3) circulating hormone levels, (4) rates of calcium and phosphorus absorption and excretion, and (5) genetic or environmental factors. Most of these variables involve some interaction between the skeletal system and other systems.

In fact, the skeletal system is intimately associated with other systems. For instance, the bones of the skeleton are attached to the muscular system, extensively connected to the cardiovascular and lymphatic systems, and largely under the physiological control of the endocrine system. The digestive and urinary systems also play important roles in providing the calcium and phosphate minerals needed for bone growth. In return, the skeleton represents a reserve of calcium, phosphate, and other minerals that can compensate for reductions in the dietary supply of those ions. Figure 9–13• reviews the components and functions of the skeletal system, and diagrams the major functional relationships between that system and other systems.

Clinical Patterns

Because the skeletal system is dependent on other systems, skeletal system disorders can reflect problems originating within the

skeletal system itself (such as bone tumors or inherited conditions affecting bone formation), or secondary problems that reflect changes in other systems. *Rickets*, a condition characterized by inadequate bone mineralization l**p. 161**, is an example of a skeletal problem that develops when other systems—especially the integumentary system and the digestive system—fail to function normally.

The *Applications Manual* considers the diagnosis and treatment of major conditions affecting the skeletal system.

Chapter Review Selected Clinical Terminology

arthritis: A group of rheumatic diseases that affect synovial joints. Arthritis always involves damage to the articular cartilages, but the specific cause can vary. The diseases of arthritis are usually classified as either *degenerative* or *inflammatory*. (p. 278 and [AM])

bunion: The most common pressure-related bursitis, involving a tender nodule formed around bursae over the base of the great toe.

(p. 262) **bursitis:** An inflammation of a bursa, causing pain whenever the associated tendon or ligament moves. (p. 262) **continuous passive motion (CPM):** A therapeutic procedure involving the passive movement of an injured joint to stimulate the cir

culation of synovial fluid. The goal is to prevent degeneration of the articular cartilages. (p. 278 and [AM])

herniated disc: A condition caused by intervertebral compression severe enough to rupture the anulus fibrosus and release the nucleus pulposus, which may protrude beyond the intervertebral space. (p. 270)

luxation: A dislocation; a condition in which the articulating surfaces are forced out of position. (p. 262)

osteoarthritis *(degenerative arthritis* or *degenerative joint disease, DJD)***:** An arthritic condition resulting from either cumulative wear and tear on joint surfaces or a genetic predisposition. In the U.S. population, 25 percent of women and 15 percent of men over age 60 show signs of this disease. (p. 278 and [AM])

rheumatism: A general term that indicates pain and stiffness affecting the skeletal system, the muscular system, or both. (p. 278 and [AM])

rheumatoid arthritis: An inflammatory arthritis that affects roughly 2.5 percent of the adult U.S. population. The cause is uncertain, although allergies, bacteria, viruses, and genetic factors have all been proposed. The primary symptom is *synovitis*—swelling and inflammation of the synovial membrane. (p. 278 and [AM])

shoulder separation: The partial or complete dislocation of the acromioclavicular joint. (p. 272) **slipped disc:** A common name for a condition caused by the distortion of an intervertebral disc. The distortion applies pressure to spinal nerves, causing pain and limiting range of motion. (p. 270) **sprain:** A condition in which a ligament is stretched to the point at which some of the collagen fibers are torn. The ligament remains functional, and the structure of the joint is not affected. (p. 262) **subluxation:** A partial dislocation; the displacement of articulating surfaces sufficient to cause discomfort, but resulting in less physical damage to the joint than occurs during a dislocation. (p. 262)

Study Outline

The Classification of Joints p. 259

1. 1. **Articulations** (joints) exist wherever two bones interconnect.

2. 2. *Immovable joints* are **synarthroses**; *slightly movable joints* are **amphiarthroses**; and joints that are *freely movable* are called **diarthroses** or **synovial joints**. *(Table 9–1)*

3. 3. Alternatively, joints are classified structurally, as *bony*, *fibrous, cartilaginous*, or *synovial*. *(Table 9–2)*

Synarthroses (Immovable Joints) p. 260

4. The four major types of synarthroses are a **suture** (skull bones bound together by dense connective tissue), a **gomphosis** (teeth bound to bony sockets by *periodontal ligaments*), a **synchondrosis** (two bones joined by a rigid cartilaginous bridge), and a **synostosis** (two bones completely fused).

Amphiarthroses (Slightly Movable Joints) p. 260

5. The two major types of amphiarthroses are a **syndesmosis** (bones connected by a ligament) and a **symphysis** (bones separated by fibrocartilage).

Diarthroses (Freely Movable Joints) p. 260

1. **6.** The bony surfaces at diarthroses are enclosed within an **articular capsule**, covered by **articular cartilages**, and lubricated by **synovial fluid**.

2. **7.** Other synovial structures include **menisci**, or *articular discs*; **fat pads**; **accessory ligaments**; and **bursae**. *(Figure 9–1)*

3. **8.** A **dislocation** occurs when articulating surfaces are forced out of position.

Form and Function of Synovial Joints p. 263 Describing Dynamic Motion p. 263

1. **1.** The possible types of articular movements are **linear motion (gliding)**, **angular motion**, and **rotation**. *(Figure 9–2)*

2. **2.** Joints are called **monaxial**, **biaxial**, or **triaxial**, depending on the planes of movement they allow.

Types of Movements at Synovial Joints p. 264

1. **3.** In **gliding**, two opposing surfaces slide past one another.

2. **4.** Important terms that describe angular motion are **flexion**, **extension**, **hyperextension**, **abduction**, **adduction**, and **circumduction**.

(Figure 9–3)

1. **5.** Rotational movement can be **left** or **right**, **medial** (*internal*) or **lateral** (*external*), or, in the bones of the forearm, **pronation** or **supination**. *(Figure 9–4)*

2. **6.** Movements of the foot include **inversion** and **eversion**. The ankle undergoes flexion and extension, also known as **dorsiflexion** and **plantar flexion**, respectively. *(Figure 9–5)*

3. **7.** **Opposition** is the thumb movement that enables us to grasp objects. *(Figure 9–5)*

4. **8.** **Protraction** involves moving something anteriorly; **retraction** involves moving it posteriorly. **Depression** and **elevation** occur when we move a structure inferiorly and superiorly, respectively. **Lateral flexion** occurs when the vertebral column bends to one side.

(Figure 9–5)

A Structural Classification of Synovial Joints p. 267

1. **9.** **Gliding joints** permit limited movement, generally in a single plane. *(Figure 9–6)*

2. **10. Hinge joints** are monaxial joints that permit only angular movement in one plane. *(Figure 9–6)*

3. **11. Pivot joints** are monaxial joints that permit only rotation. *(Figure 9–6)*

4. **12. Ellipsoidal joints** are biaxial joints with an oval articular face that nestles within a depression in the opposing articular surface.

(Figure 9–6)

1. **13. Saddle joints** are biaxial joints with articular faces that are concave on one axis and convex on the other. *(Figure 9–6)*

2. **14. Ball-and-socket joints** are triaxial joints that permit rotation as well as other movements. *(Figure 9–6)*

100 Keys | p. 267

Representative Articulations p. 269 Intervertebral Articulations p. 269

1. The articular processes of vertebrae form gliding joints with those of adjacent vertebrae. The bodies form symphyseal joints that are separated and cushioned by

intervertebral discs, which contain an outer **anulus fibrosus** and an inner **nucleus pulposus**. Several ligaments stabilize the vertebral column. *(Figures 9–7, 9–8; Summary Table 9–3)*

The Shoulder Joint p. 272

2. The shoulder joint, or *glenohumeral joint*, is formed by the glenoid cavity and the head of the humerus. This articulation permits the greatest range of motion of any joint. It is a ball-and-socket diarthrosis with various stabilizing ligaments. Strength and stability are sacrificed in favor of mobility. *(Figure 9–9; Summary Table 9–4)*

Anatomy 360 | Skeletal System/Synovial Joints/Shoulder

The Elbow Joint p. 273

3. The elbow joint permits only flexion–extension. It is a hinge diarthrosis whose capsule is reinforced by strong ligaments. *(Figure 9–10; Summary Table 9–4)*

Anatomy 360 | Skeletal System/Synovial Joints/Elbow

The Hip Joint p. 274

4. The hip joint is a ball-and-socket diarthrosis formed by the union of the acetabulum with the head of the femur. The joint permits flexion–extension, adduction–abduction, circumduction, and rotation; it is stabilized by numerous ligaments. *(Figure 9–11; Summary Table 9–4)*

The Knee Joint p. 276

5. The knee joint is a hinge joint formed by the union of the condyles of the femur with the superior condylar surfaces of the tibia. The joint permits flexion–extension and limited rotation, and it has various supporting ligaments. *(Figure 9–12; Summary Table 9–4)*

Anatomy 360 | Skeletal System/Synovial Joints/Knee

Aging and Articulations p. 278

1. Problems with joint function are relatively common, especially in older individuals. **Rheumatism** is a general term for pain and stiffness affecting the skeletal system, the muscular system, or both; several major forms exist. **Arthritis** encompasses all the rheumatic diseases that affect synovial joints. Both conditions become increasingly common with age.

Integration with Other Systems p. 278

1. The skeletal system interacts extensively with the muscular, cardiovascular, lymphatic, digestive, urinary, and endocrine systems.

(Figure 9–13)

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. A synarthrosis located between the bones of the skull is a

. **(a)** symphysis **(b)** syndesmosis

. **(c)** synchondrosis **(d)** suture

2. The articulation between adjacent vertebral bodies is a

. **(a)** syndesmosis **(b)** symphysis

. **(c)** synchondrosis **(d)** synostosis

3. The anterior articulation between the two pubic bones is a

. **(a)** synchondrosis **(b)** synostosis

. **(c)** symphysis **(d)** synarthrosis

4. Joints typically located between the ends of adjacent long bones are

. **(a)** synarthroses **(b)** amphiarthroses

. **(c)** diarthroses **(d)** symphyses

5. The function of the articular cartilage is

. **(a)** to reduce friction

. **(b)** to prevent bony surfaces from contacting one another

. **(c)** to provide lubrication

. **(d)** a and b are correct

6. Which of the following is *not* a function of synovial fluid?

. **(a)** shock absorption

. **(b)** nutrient distribution

. **(c)** maintenance of ionic balance

. **(d)** lubrication of the articular surfaces

. **(e)** waste disposal

7. The structures that limit the range of motion of a joint and provide mechanical support across or around the joint are

. **(a)** bursae **(b)** tendons

. **(c)** menisci **(d)** a, b, and c are correct

8. A partial dislocation of an articulating surface is a

. **(a)** circumduction **(b)** hyperextension

. **(c)** subluxation **(d)** supination

9. Abduction and adduction always refer to movements of the

. **(a)** axial skeleton **(b)** appendicular skeleton

. **(c)** skull **(d)** vertebral column

10. Rotation of the forearm that makes the palm face posteriorly is

. **(a)** supination **(b)** pronation

. **(c)** proliferation **(d)** projection

11. A saddle joint permits _____ movement but prevents _____ movement.

. **(a)** rotational, gliding **(b)** angular, linear

. **(c)** linear, rotational **(d)** angular, rotational

12. Standing on tiptoe is an example of _____ at the ankle.

. **(a)** elevation **(b)** flexion

. **(c)** extension **(d)** retraction

13. Examples of monaxial joints, which permit angular movement in a single plane, are the

. **(a)** intercarpal and intertarsal joints

. **(b)** shoulder and hip joints

. **(c)** elbow and knee joints

. **(d)** a, b, and c are correct

14. Decreasing the angle between bones is termed

. **(a)** flexion **(b)** extension

. **(c)** abduction **(d)** adduction

. **(e)** hyperextension

15. Movements that occur at the shoulder and the hip represent the actions that occur at a _____ joint.

. **(a)** hinge **(b)** ball-and-socket

. **(c)** pivot **(d)** gliding

16. The anulus fibrosus and nucleus pulposus are structures associated with the

. **(a)** intervertebral discs **(b)** knee and elbow

. **(c)** shoulder and hip **(d)** carpal and tarsal bones

17. Subacromial, subcoracoid, and subscapular bursae reduce friction in the _____ joint.

. **(a)** hip **(b)** knee

. **(c)** elbow **(d)** shoulder

18. Although the knee joint is only one joint, it resembles _____ separate joints

(a) 2 **(b)** 3 **(c)** 4 **(d)** 5 **(e)** 6

LEVEL 2 Reviewing Concepts

19. The hip is an extremely stable joint because it has

. **(a)** a complete bony socket

. **(b)** a strong articular capsule

. **(c)** supporting ligaments

. **(d)** a, b, and c are correct

20. Dislocations involving synovial joints are usually prevented by all of the following *except*

. **(a)** structures such as a ligaments that stabilize
and support the joint

. **(b)** the position of bursae that limits the degree
of movement

. **(c)** the presence of other bones that prevent certain movements

. **(d)** the position of muscles and fat pads that limit the degree of movement

. **(e)** the shape of the articular surface

1. **21.** How does a meniscus (articular disc) function in a joint?

2. **22.** Partial or complete dislocation of the acromioclavicular joint is called a(n) _____.

3. **23.** How do articular cartilages differ from other cartilages in the body?

4. **24.** Differentiate between a slipped disc and a herniated disc.

5. **25.** How would you explain to your grandmother the characteristic decrease in height with advancing age?

6. **26.** The abnormal fusion of bones in a joint as the result of disease or damage is termed _____.

7. **27.** List the six different types of diarthroses and give an example of each.

LEVEL 3 Critical Thinking and Clinical Applications

1. **28.** While playing tennis, Dave “overturns” his ankle. He experiences swelling and pain. After being examined, he is told that he has no torn ligaments and that the structure of the ankle is not affected. On the basis of the symptoms and the examination results, what happened to Dave’s ankle?

2. **29.** Joe injures his knee during a football practice such that the synovial fluid in the knee joint no longer circulates. The physician who examines him tells him that they have to reestablish circulation of the synovial fluid before the articular cartilages become damaged. Why?

3. **30.** When playing a contact sport, which injury would you expect to occur more frequently, a dislocated shoulder or a dislocated hip? Why?

TABLE 9–1 A Functional Classification of Articulations

Functional Category	**Structural Category and Type**		
Synarthrosis	*Fibrous*		
(no movement)	**Suture**	Fibrous connections plus interlocking projections	Between the bones of the skull
	Gomphosis	Fibrous connections plus insertion in alveolar process	Between the teeth and jaws
	Cartilaginous		
	Synchondrosis	Interposition of cartilage plate	Epiphyseal cartilages

Bony fusion

Synostosis Conversion of other articular Portions of the skull, epiphyseal lines

form to a solid mass of bone

Amphiarthrosis *Fibrous* (little movement) **Syndesmosis** Ligamentous connection Between the tibia and fibula

Cartilaginous

Symphysis Connection by a fibrocartilage pad Between right and left pubic bones of pelvis; between adjacent vertebral bodies along vertebral column

Diarthrosis Synovial Complex joint bounded by joint Numerous; subdivided by range (free movement) capsule and containing of movement (*see Figure 9–6*)

synovial fluid **Monaxial** Permits movement in one plane Elbow, ankle **Biaxial** Permits movement in two planes Ribs, wrist **Triaxial** Permits movement in all three planes Shoulder, hip

Skeletal Muscle Tissue and the Muscular System

Objective

- Specify the functions of skeletal muscle tissue.

Muscle tissue, one of the four primary types of tissue, consists chiefly of muscle cells that are highly specialized for contraction. Three types of muscle tissue exist: (1) *skeletal muscle*, (2) *cardiac muscle*, and (3) *smooth muscle*. l**p. 132** Without these muscle tissues, nothing in the body would move, and no body movement could occur. Skeletal muscle tissue moves the body by pulling on bones of the skeleton, making it possible for us to walk, dance, bite an apple, or play the ukulele. Cardiac muscle tissue pushes blood through the circulatory system. Smooth muscle tissue pushes fluids and solids along the digestive tract and regulates the diameters of small arteries, among other functions.

This chapter primarily describes the structure and function of skeletal muscle tissue, in preparation for our discussion of the muscular system (Chapter 11). This chapter also provides an overview of the differences among skeletal, cardiac, and smooth muscle tissues.

Skeletal muscles are organs composed primarily of skeletal muscle tissue, but they also contain connective tissues, nerves, and blood vessels. Each cell in skeletal muscle tissue is a single muscle *fiber*. Skeletal muscles are directly or indirectly attached to the bones of the skeleton. Our skeletal muscles perform the following six functions:

1. *Produce Skeletal Movement.* Skeletal muscle contractions pull on tendons and move the bones of the skeleton. The effects range from simple motions such as extending the arm or breathing, to the highly coordinated movements of swimming, skiing, or typing.

2. *Maintain Posture and Body Position.* Tension in our skeletal muscles maintains body posture—for example, holding your head still when you read a book or balancing your body weight above your feet when you walk. Without constant muscular activity, we could neither sit upright nor stand.

3. *Support Soft Tissues.* The abdominal wall and the floor of the pelvic cavity consist of layers of skeletal muscle. These muscles support the weight of visceral organs and shield internal tissues from injury.

4. *Guard Entrances and Exits.* The openings of the digestive and urinary tracts are encircled by skeletal muscles. These muscles provide voluntary control over swallowing, defecation, and urination.

5. *Maintain Body Temperature.* Muscle contractions require energy; whenever energy is used in the body, some of it is converted to heat. The heat released by working muscles keeps body temperature in the range required for normal functioning.

6. *Store Nutrient Reserves.* When the diet contains inadequate proteins or calories, the contractile proteins in skeletal muscles are broken down, and the amino acids released into the circulation. Some of these amino acids can be used by the liver to synthesize glucose; others can be broken down to provide energy.

We will begin our discussion with the functional anatomy of a typical skeletal muscle, with particular emphasis on the microscopic structural features that make contractions possible.

Functional Anatomy of Skeletal Muscle

Objectives

- Describe the organization of muscle at the tissue level.
- Explain the unique characteristics of skeletal muscle fibers.
- Identify the structural components of a sarcomere.

Figure 10–1• illustrates the organization of a representative skeletal muscle. As we noted, in addition to skeletal muscle tissue, a skeletal muscle contains connective tissues, blood vessels, and nerves.

Organization of Connective Tissues

Three layers of connective tissue are part of each muscle: (1) an epimysium, (2) a perimysium, and (3) an endomysium. These layers and the relationships among them are diagrammed in Figure 10–1•.

¯I

The entire muscle is surrounded by the **epimysium** (ep-i-M Z-The epimysium separates the muscle from surrounding tissues and organs. It is connected to the deep fascia, a dense connective tissue layer (see Figure 4–18•). l**p. 133**

¯e

-um; *epi*-, on + *mys*, muscle), a dense layer of collagen fibers.

The connective tissue fibers of the **perimysium** (per-i-M Z

I¯

‾e

-um; *peri*-, around) divide the skeletal muscle into a series of

compartments, each containing a bundle of muscle fibers called a **fascicle** (FAS-i-kl; *fasciculus*, a bundle). In addition to possessing collagen and elastic fibers, the perimysium contains blood vessels and nerves that maintain blood flow and innervate the muscle fibers within the fascicles. Each fascicle receives branches of these blood vessels and nerves.

‾I

-M Z-vidual skeletal muscle cells, or *muscle fibers*, and loosely interconnects adjacent muscle fibers. This flexible, elastic connective tissue layer contains (1) capillary networks that supply blood to the muscle fibers; (2) **satellite cells**, embryonic stem cells that func-

Within a fascicle, the delicate connective tissue of the **endomysium** (en-d

‾o‾e

-um; *endo*-, inside) surrounds the indi

tion in the repair of damaged muscle tissue; and (3) nerve fibers that control the muscle. All these structures are in direct contact with the individual muscle fibers. l**p. 132** AM: Disruption of Normal Muscle Organization

The collagen fibers of the perimysium and endomysium are interwoven and blend into one another. At each end of the muscle, the collagen fibers of the epimysium, perimysium, and endomysium come together to form either a bundle known as a **tendon**, or a broad sheet called an **aponeurosis**. Tendons and aponeuroses usually attach skeletal muscles to bones. Where they contact the bone, the collagen fibers extend into the bone matrix, providing a firm attachment. As a result, any contraction of the muscle will exert a pull on the attached bone (or bones).

Blood Vessels and Nerves

The connective tissues of the epimysium and perimysium contain the blood vessels and nerves that supply the muscle fibers. Muscle contraction requires tremendous quantities of energy. An extensive vascular network delivers the necessary oxygen and nutrients and carries away the metabolic wastes generated by active skeletal muscles. The blood vessels and the nerve supply generally enter the muscle together and follow the same branching course through the perimysium. Within the endomysium, arterioles supply blood to a capillary network that services the individual muscle fiber.

Skeletal muscles contract only under stimulation from the central nervous system. Axons, or *nerve fibers*, penetrate the epimysium, branch through the perimysium, and enter the endomysium to innervate individual muscle fibers. Skeletal muscles are often called voluntary muscles, because we have voluntary control over their contractions. Many skeletal muscles may also be controlled at a subconscious level. For example, skeletal muscles involved with breathing, such as the *diaphragm*, usually work outside our conscious awareness.

Next, we will examine the microscopic structure of a typical skeletal muscle fiber and relate that microstructure to the physiology of the contraction process.

Skeletal Muscle Fibers

Skeletal muscle fibers are quite different from the “typical” cells we described in Chapter 3. One obvious difference is size: Skeletal muscle fibers are enormous. A muscle fiber from a thigh muscle could have a diameter of 100 mm and a length equal to the distance between the tendons at either end (up to 30 cm, or 12 in.). A second obvious difference is that skeletal muscle fibers are *multinucleate*: Each contains hundreds of nuclei just internal to the cell membrane. The genes in these nuclei control the production of enzymes and structural proteins required for normal muscle contraction, and the more copies of these genes, the faster these proteins can be produced.

The distinctive features of size and multiple nuclei are related. During development, groups of embryonic cells called **myoblasts** (*myo*-, muscle + *blastos,* formative cell or germ) fuse, forming individual multinucleate skeletal muscle fibers (Figure 10–2•). Each nucleus in a skeletal muscle fiber reflects the contribution of a single myoblast. Some myoblasts, however, do not fuse with developing muscle fibers. These unfused cells remain in adult skeletal muscle tissue as the satellite cells seen in Figures 10–1 and Figure 10–2a•. After an injury, satellite cells may enlarge, divide, and fuse with damaged muscle fibers, thereby assisting in the repair of the tissue.

The Sarcolemma and Transverse Tubules

The **sarcolemma** (sar-kō-LEM-uh; *sarkos*, flesh + *lemma*, husk), or cell membrane of a muscle fiber, surrounds the **sarcoplasm** (SAR-kō-plazm), or cytoplasm of the muscle fiber (Figure 10–3•). Like other cell membranes, the sarcolemma has a characteristic transmembrane potential due to the unequal distribution of positive and negative charges across the membrane. l**p. 94** In a skeletal muscle fiber, a sudden change in the transmembrane potential is the first step that leads to a contraction.

Even though a skeletal muscle fiber is very large, all regions of the cell must contract simultaneously. Thus, the signal to contract must be distributed quickly throughout the interior of the cell. This signal is conducted through the transverse tubules. **Transverse tubules**, or **T tubules**, are narrow tubes that are continuous with the sarcolemma and extend into the sarcoplasm at right angles to the cell surface (see Figure 10–3•). Filled with extracellular fluid, T tubules form passageways through the muscle fiber, like a network of tunnels through a mountain. The T tubules have the same general properties as the sarcolemma, so electrical impulses conducted by the sarcolemma travel along the T tubules into the cell interior. These impulses, or *action potentials*, are the triggers for muscle fiber contraction.

Myofibrils

Inside the muscle fiber, branches of the transverse tubules encircle cylindrical structures called **myofibrils** (see Figure 10–3•). A myofibril is 1–2 mm in diameter and as long as the entire cell. Each skeletal muscle fiber contains hundreds to thousands of myofibrils.

Myofibrils consist of bundles of protein filaments called **myofilaments**. Two types of myofilaments were introduced in Chapter 3: **Thin filaments** are composed primarily of actin, whereas **thick filaments** are composed primarily of myosin. l**pp. 69, 70** In addition, myofibrils contain *titin*, elastic myofilaments associated with the thick filaments. (We will consider the role of titin later in the chapter.)

Myofibrils, which can actively shorten, are responsible for skeletal muscle fiber contraction. At each end of the skeletal muscle fiber, the myofibrils are anchored to the inner surface of the sarcolemma. In turn, the outer surface of the sarcolemma is attached to collagen fibers of the tendon or aponeurosis of the skeletal muscle. As a result, when the myofibrils contract, the entire cell shortens and pulls on the tendon. Scattered among and around the myofibrils are mitochondria and granules of glycogen, the storage form of glucose. Glucose breakdown through glycolysis and mitochondrial activity provides the ATP required by short-duration, maximum intensity muscular contractions. l**p. 76**

The Sarcoplasmic Reticulum

Wherever a transverse tubule encircles a myofibril, the tubule is tightly bound to the membranes of the sarcoplasmic reticulum. The **sarcoplasmic reticulum (SR)** is a membrane complex similar to the smooth endoplasmic reticulum of other cells. In skeletal muscle fibers, the SR forms a tubular network around each individual myofibril (see Figure 10–3•). On either side of a T tubule, the tubules of the SR enlarge, fuse, and form expanded chambers called **terminal cisternae** (sis-TUR-ne). The combination of a pair of terminal cisternae plus a transverse tubule is known as a **triad**. Although the membranes of the triad are tightly bound together, their fluid contents are separate and distinct.

In Chapter 3, we noted the existence of special ion pumps that keep the intracellular concentration of calcium ions (Ca^{2+}) very low. l**p. 90** Most cells pump the calcium ions across their cell membranes and into the extracellular fluid. Although skeletal muscle fibers do pump Ca^{2+} out of the cell in this way, they also remove calcium ions from the sarcoplasm by actively transporting them into the terminal cisternae of the sarcoplasmic reticulum. The sarcoplasm of a resting skeletal muscle fiber contains very low concentrations of Ca^{2+} around 10^{-7} mmol> L. The free Ca^{2+} concentration levels inside the terminal cisternae may be as much as 1000 times higher. In addition, cisternae contain the protein *calsequestrin*, which reversibly binds Ca^{2+}. Including both the free calcium and the bound calcium, the total concentration of Ca^{2+} inside cisternae can be 40,000 times that of the surrounding sarcoplasm.

A muscle contraction begins when stored calcium ions are released into the sarcoplasm. These ions then diffuse into individual contractile units called *sarcomeres*.

Sarcomeres

As we have seen, myofibrils are bundles of thin and thick filaments. These myofilaments are organized into repeating functional units called **sarcomeres** (SAR-kō-mērz; *sarkos*, flesh + *meros*, part).

A myofibril consists of approximately 10,000 sarcomeres, end to end. Each sarcomere has a resting length of about 2 mm. Sarcomeres are the smallest functional units of the muscle fiber. Interactions between the thick and thin filaments of sarcomeres are responsible for muscle contraction. A sarcomere contains (1) thick filaments, (2) thin filaments, (3) proteins that stabilize the positions of the thick and thin filaments, and (4) proteins that regulate the interactions between thick and thin filaments.

Differences in the size, density, and distribution of thick filaments and thin filaments account for the banded appearance of each myofibril. Each sarcomere has dark bands (**A**

bands) and light bands (**I bands**) (Figure 10–4•). The names of these bands are derived from *anisotropic* and *isotropic*, which refer to their appearance when viewed under polarized light. You may find it helpful to remember that in a typical light micrograph, A bands are d**A**rk and I bands are l**I**ght.

The A Band The thick filaments are located at the center of a sarcomere, in the A band. The length of the A band is equal to the length of a typical thick filament. The A band, which also includes portions of thin filaments, contains the following three subdivisions (see Figure 10–4•):

1. *The M Line.* The central portion of each thick filament is connected to its neighbors by proteins of the **M line**. These dark-staining proteins help stabilize the positions of the thick filaments.

2. *The H Zone.* In a resting sarcomere, the **H zone**, or *H band*, is a lighter region on either side of the M line. The H zone contains thick filaments, but no thin filaments.

3. *The Zone of Overlap.* In the **zone of overlap**, thin filaments are situated between the thick filaments. In this region, each thin filament is surrounded by three thick filaments, and each thick filament is surrounded by six thin filaments.

The cross sectional views in Figure 10–5• should help you visualize these features of the three-dimensional structure of the sarcomere.

The I Band Each I band, which contains thin filaments, but not thick filaments, extends from the A band of one sarcomere to the A band of the next sarcomere (see Figure 10–4•. **Z lines** mark the boundary between adjacent sarcomeres. The Z lines consist of proteins called *actinins,* which interconnect thin filaments of adjacent sarcomeres. From the Z lines at either end of the sarcomere, thin filaments extend toward the M line and into the zone of overlap. Strands of the elastic protein **titin** extend from the tips of the thick filaments to attachment sites at the Z line (see Figure 10–4a and 10–5•). Titin helps keep the thick and thin filaments in proper alignment; it also helps the muscle fiber resist extreme stretching that would otherwise disrupt the contraction mechanism.

Two transverse tubules encircle each sarcomere, and triads are located in the zones of overlap, at the edges of the A band (see Figure 10–3•). As a result, calcium ions released by the SR enter the regions where thick and thin filaments can interact.

Each Z line is surrounded by a meshwork of intermediate filaments that interconnect adjacent myofibrils. The myofibrils closest to the sarcolemma are bound to attachment sites on the inside of the membrane. Because the Z lines of all the myofibrils are aligned in this way, the muscle fiber as a whole has a banded appearance (see Figure 10–2b•). These bands, or *striations*, are visi

ble with the light microscope, so skeletal muscle tissue is also known as striated muscle. l**p. 132** Figure 10–6• reviews the levels of organization we have discussed so far. We now consider the molecular structure of the myofilaments responsible for muscle contraction.

Thin Filaments A typical thin filament is 5–6 nm in diameter and 1 mm in length (Figure 10–7a•). A single thin filament contains four proteins: F actin, nebulin, tropomyosin, and troponin (Figure 10–7b•).

F actin is a twisted strand composed of two rows of 300–400 individual globular molecules of **G actin** (Figure 10–7b•). A long strand of **nebulin** extends along the F actin strand in the cleft between the rows of G actin molecules. Nebulin holds the F actin strand together; as thin filaments develop, the length of the nebulin molecule probably determines the length of the F actin strand. Each G actin molecule contains an **active site** that can bind to myosin much as a substrate molecule binds to the active

site of an enzyme. l**p. 36** Under resting conditions, myosin binding is prevented by the *troponin–tropomyosin complex*.

Strands of **tropomyosin** (tr

¯o

-p

¯o

-M

¯I

-

–o

-sin; *trope,* turning) cover the active sites on G actin and prevent actin–myosin inter

action. A tropomyosin molecule is a double-stranded protein that covers seven active sites. It is bound to one molecule of troponin

–

midway along its length. A **troponin** (TRO

-p

–o

-nin) molecule consists of three globular subunits. One subunit binds to

tropomyosin, locking them together as a troponin– tropomyosin complex; a second subunit binds to one G actin, holding the tro-ponin–tropomyosin complex in position; the third subunit has a receptor that binds a calcium ion. In a resting muscle, intracellular Ca^{2+} concentrations are very low, and that binding site is empty.

A contraction cannot occur unless the position of the troponin–tropomyosin complex changes, exposing the active sites on F actin. The necessary change in position occurs when calcium ions bind to receptors on the troponin molecules.

At either end of the sarcomere, the thin filaments are attached to the Z line (see Figure 10–7a•). Although it is called a “line” because it looks like a dark line on the surface of the myofibril, the Z line in sectional view is more like a disc with an open meshwork (see Figure 10–5a•). For this reason, the Z line is often called the *Z disc*.

Thick Filaments Thick filaments are 10–12 nm in diameter and 1.6 mm long (Figure 10–7c•). A thick filament contains roughly 300 myosin molecules, each made up of a pair of myosin subunits twisted around one another (Figure 10–7d•). The long **tail** is bound to other myosin molecules in the thick filament. The free **head**, which projects outward toward the nearest thin filament, has two globular protein subunits. When the myosin heads interact with thin filaments during a contraction, they are known as **cross-bridges**. The connection between the head and the tail functions as a hinge that lets the head pivot at its base. When pivoting occurs, the head swings toward or away from the M line. As we will see in a later section, this pivoting is the key step in muscle contraction.

All the myosin molecules are arranged with their tails pointing toward the M line (see Figure 10–7c•). The H zone includes a central region where there are no myosin heads. Elsewhere, the myosin heads are arranged in a spiral, each facing one of the surrounding thin filaments.

Each thick filament has a core of titin. On either side of the M line, a strand of titin extends the length of the thick filament and then continues across the I band to the Z line on that side. The portion of the titin strand exposed within the I band is elastic and will recoil after stretching. In the normal resting sarcomere, the titin strands are completely relaxed; they become tense only when some external force stretches the sarcomere. AM: The Muscular Dystrophies

Sliding Filaments and Muscle Contraction

When a skeletal muscle fiber contracts, (1) the H zones and I bands get smaller, (2) the zones of overlap get larger, (3) the Z lines move closer together, and (4) the width of the A band remains constant (Figure 10–8a•). These observations make sense only if the thin filaments are sliding toward the center of each sarcomere, alongside the thick filaments; this explanation is known as the **sliding filament theory**. The contraction weakens with the disappearance of the I bands, at which point the Z lines are in contact with the ends of the thick filaments.

During a contraction, sliding occurs in every sarcomere along the myofibril. As a result, the myofibril gets shorter. Because myofibrils are attached to the sarcolemma at each Z line and at either end of the muscle fiber, when myofibrils get shorter, so does the muscle fiber.

You now know *how* the myofilaments in a sarcomere change position during a contraction, but not *why* these changes occur. To understand this process in detail, we must take a closer look at the contraction process and its regulation.

Concept Check

How would severing the tendon attached to a muscle affect the muscle’s ability to move a body part?

Why do skeletal muscle fibers appear striated when viewed through a microscope?

Where would you expect the greatest concentration of Ca^{2+} in resting skeletal muscle to be?

Answers begin on p. A–1

Review the sliding filament theory on the **IP CD-ROM: Muscular System/Sliding Filament Theory**.

The Contraction of Skeletal Muscle

Objectives

- Identify the components of the neuromuscular junction, and summarize the events involved in the neural control of skeletal muscles.
- Explain the key steps involved in the contraction of a skeletal muscle fiber.

Most of the rest of this chapter describes how muscles contract and how those contractions are harnessed to do what you want them to do. First, you have to understand some basic physical principles that apply to muscle cells. When muscle cells contract, they pull on the attached tendon fibers the way a line of people might pull on a rope. The pull, called *tension*, is an active force: Energy must be expended to produce it. Tension is applied *to* some object, whether a rope, a rubber band, or a book on a tabletop.

Tension applied to an object tends to pull the object toward the source of the tension. However, before movement can occur, the applied tension must overcome the object’s *resistance*, a passive force that opposes movement. The amount of resistance can depend on the weight of the object, its shape, friction, and other factors. When the applied tension exceeds the resistance, the object moves. In contrast, *compression*, or a push applied to an object, tends to force the object away from the source of the compression. Again, no movement can occur until the applied compression exceeds the resistance of the object. Muscle cells can use energy to shorten and generate tension, through interactions between thick and thin filaments, but not to lengthen and generate compression. In other words, muscle cells can pull, but they cannot push.

With that background, we can investigate the mechanics of muscle contraction in some detail. Figure 10–9• provides an overview of the “big picture” we will be examining.

- Normal skeletal muscle is under neural control: Contraction occurs only when skeletal muscle fibers are activated by neurons whose cell bodies are in the central nervous system (brain and spinal cord). A neuron can activate a muscle fiber through stimulation of its sarcolemma. What follows is called *excitation–contraction coupling*.
- The first step in excitation–contraction coupling is the release of calcium ions from the cisternae of the sarcoplasmic reticulum.
- The calcium ions then trigger interactions between thick filaments and thin filaments, resulting in muscle fiber contraction and the consumption of energy in the form of ATP.
- These filament interactions produce active tension.

The Control of Skeletal Muscle Activity

Skeletal muscle fibers contract only under the control of the nervous system. Communication between the nervous system and a skeletal muscle fiber occurs at a specialized intercellular connection known as a **neuromuscular junction (NMJ)**, or *myoneural junction* (Figure 10–10a•).

Each skeletal muscle fiber is controlled by a neuron at a single neuromuscular junction midway along the fiber’s length. A single axon branches within the perimysium to form a number of fine branches. Each branch ends at an expanded **synaptic terminal** (Figure 10–

10b•). The cytoplasm of the synaptic terminal contains mitochondria and vesicles filled with molecules of **acetylcholine** (as-ē-til-KŌ-lēn), or **ACh**. Acetylcholine is a *neurotransmitter*, a chemical released by a neuron to change the permeability or other properties of another cell membrane. In this case, the release of ACh from the synaptic terminal can alter the permeability of the sarcolemma and trigger the contraction of the muscle fiber.

The **synaptic cleft**, a narrow space, separates the synaptic terminal of the neuron from the opposing sarcolemmal surface. This surface, which contains membrane receptors that bind ACh, is known as the **motor end plate**. The motor end plate has deep creases called *junctional folds*, which increase its surface area and thus the number of available ACh receptors. The synaptic cleft and the sarcolemma also contain molecules of the enzyme **acetylcholinesterase** (**AChE**, or *cholinesterase*), which breaks down ACh.

A neuron stimulates a muscle fiber through a series of steps (Figure 10–10c•):

Step 1 The Arrival of an Action Potential. The stimulus for ACh release is the arrival of an electrical impulse, or **action potential**, at the synaptic terminal. An action potential is a sudden change in the transmembrane potential that travels along the length of the axon.

Step 2 The Release of ACh. When the action potential reaches the synaptic terminal, permeability changes in the membrane trigger the exocytosis of ACh into the synaptic cleft. This is accomplished when vesicles in the synaptic terminal fuse with the cell membrane of the neuron.

Step 3 ACh Binding at the Motor End Plate. ACh molecules diffuse across the synaptic cleft and bind to ACh receptors on the surface of the sarcolemma at the motor end plate. ACh binding changes the permeability of the motor end plate to sodium ions. Recall from Chapter 3 that the extracellular fluid contains a high concentration of sodium ions, whereas sodium ion concentrations inside the cell are very low. l**p. 90** When the membrane permeability to sodium increases, sodium ions rush into the sarcoplasm. This influx continues until AChE removes the ACh from the receptors.

Step 4 Appearance of an Action Potential in the Sarcolemma. The sudden inrush of sodium ions results in the generation of an action potential in the sarcolemma. This electrical impulse originates at the edges of the motor end plate, sweeps across the entire membrane surface, and travels inward along each T tubule. The arrival of an action potential at the synaptic terminal thus leads to the appearance of an action potential in the sarcolemma.

Step 5 Return to Initial State. Even before the action potential has spread across the entire sarcolemma, the ACh has been broken down by AChE. Some of the breakdown products will be absorbed by the synaptic terminal and used to resynthesize ACh for subsequent release. This sequence of events can now be repeated should another action potential arrive at the synaptic terminal.

Review neural control of muscle on the **IP CD-ROM: Muscular System/The Neuromuscular Junction.**

Excitation–Contraction Coupling

The link between the generation of an action potential in the sarcolemma and the start of a muscle contraction is called **excitation–contraction coupling**. This coupling occurs at the triads. On reaching a triad, an action potential triggers the release of Ca^{2+} from the cisternae of the sarcoplasmic reticulum. The change in the permeability of the SR to Ca^{2+} is temporary, lasting only about 0.03 second. Yet within a millisecond, the Ca^{2+} concentration in and around the sarcomere reaches 100 times resting levels. Because the terminal cisternae are situated at the zones of overlap, where the thick and thin filaments interact, the effect of calcium release on the sarcomere is almost instantaneous.

Troponin is the lock that keeps the active sites inaccessible. Calcium is the key to that lock. Recall from Figure 10–7• that troponin binds to actin and to tropomyosin, and that the tropomyosin molecules cover the active sites and prevent interactions between thick filaments and thin filaments. Each troponin molecule also has a binding site for calcium; this site is empty when the muscle fiber is at rest. Calcium binding changes the shape of the troponin molecule and weakens the bond between tropinin and actin. The troponin molecule then changes position, rolling the tropomyosin strand away from the active sites (Figure 10–11•). At this point, the **contraction cycle** begins.

The Contraction Cycle

Figure 10–12• details the molecular events that occur during the contraction cycle. In the resting sarcomere, each myosin head is

already "energized"—charged with the energy that will be used to power a contraction. The myosin head functions as ATPase, an enzyme that can break down ATP. l**p. 56** At the start of the contraction cycle, each myosin head has already split a molecule of ATP and stored the energy released in the process. The breakdown products, ADP and phosphate (often represented as P), remain bound to the myosin head.

The contraction cycle involves five interlocking steps (see Figure 10–12•):

Step 1 Exposure of Active Sites. The calcium ions entering the sarcoplasm bind to troponin. This binding weakens the bond between the troponin–tropomyosin complex and actin. The troponin molecule then changes position, pulling the tropomyosin molecule away from the active sites on actin and allowing interaction with the energized myosin heads.

Step 2 Formation of Cross-Bridges. When the active sites are exposed, the energized myosin heads bind to them, forming cross-bridges.

Step 3 Pivoting of Myosin Heads. In the resting sarcomere, each myosin head points away from the M line. In this position, the myosin head is "cocked" like the spring in a mousetrap. Cocking the myosin head requires energy, which is obtained by breaking down ATP into ADP and a phosphate group. In the cocked position, both the ADP and the phosphate are still bound to the myosin head. After cross-bridge formation, the stored energy is released as the myosin head pivots toward the M line. This action is called the *power stroke*; when it occurs, the ADP and phosphate group are released.

Step 4 Detachment of Cross-Bridges. When another ATP binds to the myosin head, the link between the active site on the actin molecule and the myosin head is broken. The active site is now exposed and able to form another cross-bridge.

Step 5 Reactivation of Myosin. Myosin reactivation occurs when the free myosin head splits the ATP into ADP and a phosphate group. The energy released in this process is used to recock the myosin head. The entire cycle will now be repeated, several times each second, as long as calcium ion concentrations remain elevated and ATP reserves are sufficient. Each power stroke shortens the sarcomere by about 1 percent, because all the sarcomeres contract together, the entire muscle shortens at the same rate. The speed at which shortening occurs depends on the cycling rate (the number of power strokes per second): The higher the resistance, the slower the cycling rate.

To better understand how tension is produced in a muscle fiber, imagine that you are on a tug-of-war team. You reach forward, grab the rope with both hands, and pull it in. This action corresponds to cross-bridge attachment and pivoting. You then release the rope, reach forward and grab it, and pull once again. Your actions are not coordinated with the rest of your team; if everyone let go at the same time, your opponents would pull the rope away. So at any given time, some people are reaching and grabbing, some are pulling, and others are letting go. The amount of tension produced is thus a function of how many people are pulling at any given moment. The situation is comparable in a muscle fiber; the myosin heads along a thick filament work together in a similar way to pull a thin filament toward the center of the sarcomere.

Each myofibril consists of a string of sarcomeres, and in a contraction all of the thin filaments are pulled toward the centers of the sarcomeres. If neither end of the myofibril is held in position, both ends move toward the middle, as illustrated in Figure 10–13a•. This kind of contraction seldom occurs in an intact skeletal muscle, because one end of the muscle (the *origin*) is usually fixed in position during a contraction, while the other end (the *insertion*) moves. In that case, the free end moves toward the fixed end (see Figure 10–13b•). If neither end of the myofibril can move, thick and thin filament interactions consume energy and generate tension, but sliding cannot occur. This kind of contraction, called *isometric*, will be the topic of a later section.

AM: Problems with the Control of Muscle Activity

Relaxation

The duration of a contraction depends on (1) the duration of stimulation at the neuromuscular junction, (2) the presence of free calcium ions in the sarcoplasm, and (3) the availability of ATP. A single stimulus has only a brief effect on a muscle fiber because the ACh released after a single action potential arrives at the synaptic terminal does not remain intact for long. Whether it is bound to the sarcolemma or free in the synaptic cleft, the released ACh is rapidly broken down and inactivated by AChE. Inside the muscle fiber, the permeability changes in the SR are also very brief. Thus, a contraction will continue only if additional action potentials arrive at the synaptic terminal in rapid succession. When they do, the continual release of ACh into the synaptic cleft produces a series of action potentials in the sarcolemma that keeps Ca^{2+} levels elevated in the sarcoplasm. Under these conditions, the contraction cycle will be repeated over and over.

If just one action potential arrives at the neuromuscular junction, Ca^{2+} concentrations in the sarcoplasm will quickly return to normal resting levels. Two mechanisms are involved in this process: (1) active Ca^{2+} transport across the cell membrane into the extracellular fluid and (2) active Ca^{2+} transport into the SR. Of the two, transport into the SR is far more important. Virtually as soon as the calcium ions have been released, the SR returns to its normal permeability and begins actively absorbing Ca^{2+} from the surrounding sarcoplasm. As Ca^{2+} concentrations in the sarcoplasm fall, (1) calcium ions detach from troponin, (2) troponin returns to its original position, and (3) the active sites are re-covered by tropomyosin. The contraction has ended.

Once the contraction has ended, the sarcomere does not automatically return to its original length. Sarcomeres shorten actively, but there is no active mechanism for reversing the process. External forces must act on the contracted muscle fiber to stretch the myofibrils and sarcomeres to their original dimensions. We will describe those forces in a later section.

When death occurs, circulation ceases and the skeletal muscles are deprived of nutrients and oxygen. Within a few hours, the skeletal muscle fibers have run out of ATP and the sarcoplasmic reticulum becomes unable to pump Ca^{2+} out of the sarcoplasm. Calcium ions diffusing into the sarcoplasm from the extracellular fluid or leaking out of the sarcoplasmic reticulum then trigger a sustained contraction. Without ATP, the cross-bridges cannot detach from the active sites, so skeletal muscles throughout the body become locked in the contracted position. Because all the skeletal muscles are involved, the individual becomes “stiff as a board.” This physical state—**rigor mortis**—lasts until the lysosomal enzymes released by autolysis break down the Z lines and titin filaments 15–25 hours later. The timing is dependent on environmental factors, such as temperature. Forensic pathologists can estimate the time of death on the basis of the degree of rigor mortis and environmental conditions.

Before you proceed, review the entire sequence of events from neural activation through excitation– contraction coupling to the completion of a contraction. Table 10–1 provides a review of the contraction process, from ACh release to the end of the contraction.

100 Keys | Skeletal muscle fibers shorten as thin filaments interact with thick filaments and sliding occurs. The trigger for contraction is the appearance of free calcium ions in the sarcoplasm; the calcium ions are released by the sarcoplasmic reticulum when the muscle fiber is stimulated by the associated motor neuron. Contraction is an active process; the return to resting length is entirely passive.

Concept Check

How would a drug that interferes with cross-bridge formation affect muscle contraction?

What would happen to a resting skeletal muscle if the sarcolemma suddenly became very permeable to Ca^{2+}?

Predict what would happen to a muscle if the motor end plate failed to produce acetylcholinesterase.

Answers begin on p. A–1

Tension Production

Objectives

- Describe the mechanism responsible for tension production in a muscle fiber, and discuss the factors that determine the peak tension developed during a contraction.
- Discuss the factors that affect peak tension production during the contraction of an entire skeletal muscle, and explain the significance of the motor unit in this process.
- Compare the different types of muscle contractions.

When sarcomeres shorten in a contraction, they shorten the muscle fiber. This shortening exerts tension on the connective tissue fibers attached to the muscle fiber. The tension produced by an individual muscle fiber can vary, and in the next section we will consider the specific factors involved. In a subsequent section, we will see that the tension produced by an entire skeletal *muscle* can vary even more widely, because not only can tension production vary among the individual muscle fibers, but the number of stimulated muscle fibers can change from moment to moment.

Tension Production by Muscle Fibers

The amount of tension produced by an individual muscle fiber ultimately depends on the number of pivoting cross-bridges. There is no mechanism to regulate the amount of tension produced in that contraction by changing the number of contracting sarcomeres. When calcium ions are released, they are released from all triads in the muscle fiber. Thus, a muscle fiber is either “on” (producing tension) or “off” (relaxed). Tension production at the level of the individual muscle fiber *does* vary, depending on (1) the fiber's resting length at the time of stimulation, which determines the degree of overlap between thick and thin filaments, and

(2) the frequency of stimulation, which affects the internal concentration of calcium ions and thus the amount bound to troponins.

Length–Tension Relationships

When many people pull on a rope, the amount of tension produced is proportional to the number of people pulling. Similarly, in a skeletal muscle fiber, the amount of tension generated during a contraction depends on the number of pivoting cross-bridges in all the sarcomeres along all the myofibrils. The number of cross-bridges that can form, in turn, depends on the degree of overlap between thick filaments and thin filaments within these sarcomeres. When the muscle fiber is stimulated to contract, only myosin heads in the zones of overlap can bind to active sites and produce tension. The tension produced by the entire muscle fiber can thus be related to the structure of individual sarcomeres.

A sarcomere works most efficiently within an optimal range of lengths (Figure 10–14a•). When the resting sarcomere length is within this range, the maximum number of cross-bridges can form, and the tension produced is highest. If the resting sarcomere length falls outside the range—if the sarcomere is compressed and shortened, or stretched and lengthened—it cannot produce as much tension when stimulated. This is because the amount of tension produced is largely determined by the number of cross-bridges that form. An increase in sarcomere length reduces the tension produced by reducing the size of the zone of overlap and the number of potential cross-bridge interactions (Figure 10–14b•). When the zone of overlap is reduced to zero, thin and thick filaments cannot interact at all. Under these conditions, the muscle fiber cannot produce any active tension, and a contraction cannot occur. Such extreme stretching of a muscle fiber is normally opposed by the titin filaments in the muscle fiber, which tie the thick filaments to the Z lines, and by the surrounding connective tissues, which limit the degree of muscle stretch.

A decrease in the resting sarcomere length reduces efficiency because the stimulated sarcomere cannot shorten very much before the thin filaments extend across the center of the sarcomere and collide with or overlap the thin filaments of the opposite side (Figure 10–14c•). This disrupts the precise three-dimensional relationship between thick and thin filaments (see Figure 10–5•) and interferes with the binding of myosin heads to active sites and the propagation of the action potential along the transverse tubules. Because the number of cross-bridges is reduced, tension declines in the stimulated muscle fiber. Tension production falls to zero when the resting sarcomere is as short as it can be (Figure 10–14d•). At this point, the thick filaments are jammed against the Z lines and the sarcomere cannot shorten further. Although cross-bridge binding can still occur, the myosin heads cannot pivot and generate tension, because the thin filaments cannot move.

In summary, skeletal muscle fibers contract most forcefully when stimulated over a narrow range of resting lengths. The normal range of resting sarcomere lengths in the body is 75 to 130 percent of the optimal length (see Figure 10–14•). The arrangement of skeletal muscles, connective tissues, and bones normally prevents extreme compression or excessive stretching. For example, straightening your elbow stretches your *biceps brachii muscle*, but the bones and ligaments of the elbow stop this movement before the muscle fibers stretch too far. During an activity such as walking, in which muscles contract and relax cyclically, muscle fibers are stretched to a length very close to “ideal” before they are stimulated to contract. When muscles must contract over a larger range of resting lengths, they often “team up” to improve efficiency. (We will discuss the mechanical principles involved in Chapter 11.)

The Frequency of Stimulation

A single stimulation produces a single contraction, or *twitch*, that may last 7–100 milliseconds, depending on the muscle stimulated. Although muscle twitches can be produced by electrical stimulation in a laboratory and can generate heat when you are shivering, they are too brief to be part of any normal activity. The duration of a contraction can be extended by repeated stimulation, and a muscle fiber undergoing such a sustained contraction produces more tension than it does in a single twitch. To understand why, we need to take a closer look at tension production during a twitch and then follow the changes that occur as the rate of stimulation increases. This is a subject with real importance, as all consciously and subconsciously directed muscular activities—stand-ing, walking, running, reaching, and so forth—involve sustained muscular contractions rather than twitches.

Twitches A **twitch** is a single stimulus–contraction–relaxation sequence in a muscle fiber. Twitches vary in duration, depending on the type of muscle, its location, internal and external environmental conditions, and other factors. Twitches in an eye muscle fiber can be as brief as 7.5 msec, but a twitch in a muscle fiber from the *soleus*, a small calf muscle, lasts about 100 msec. Figure 10–15a• is a **myogram**, or graph of twitch tension development in muscle fibers from various skeletal muscles.

Figure 10–15b• details the phases of a 40-msec twitch in a muscle fiber from the *gastrocnemius muscle*, a prominent calf muscle. A single twitch can be divided into a *latent period*, a *contraction phase*, and a *relaxation phase*:

1. The **latent period** begins at stimulation and typically lasts about 2 msec. During this period, the action potential sweeps across the sarcolemma, and the sarcoplasmic reticulum releases calcium ions. The muscle fiber does not produce tension during the latent period, because the contraction cycle has yet to begin.

2. In the **contraction phase**, tension rises to a peak. As the tension rises, calcium ions are binding to troponin, active sites on thin filaments are being exposed, and cross-bridge interactions are occurring. For this muscle fiber, the contraction phase ends roughly 15 msec after stimulation.

3. The **relaxation phase** lasts about 25 msec. During this period, calcium levels are falling, active sites are being covered by tropomyosin, and the number of active cross-bridges is declining. As a result, tension falls to resting levels.

Treppe If a skeletal muscle is stimulated a second time immediately after the relaxation phase has ended, the resulting contraction will develop a slightly higher maximum tension than did the contraction after the first stimulus. The increase in peak tension indicated in Figure 10–16a• will continue over the first 30–50 stimulations. Thereafter, the amount of tension produced will remain constant. Because the tension rises in stages, like the steps in a staircase, this phenomenon is called **treppe** (TREP-eh), a German word meaning “stairs.” The rise is thought to result from a gradual increase in the concentration of calcium ions in the sarcoplasm, in part because the ion pumps in the sarcoplasmic reticulum have too little time to recapture the ions between stimulations.

Wave Summation and Incomplete Tetanus If a second stimulus arrives before the relaxation phase has ended, a second, more powerful contraction occurs. The addition of one twitch to another in this way constitutes the **summation of twitches**, or **wave summation** (Figure 10–16b•). The duration of a single twitch determines the maximum time available to produce wave summation. For example, if a twitch lasts 20 msec (1 > 50 sec), subsequent stimuli must be separated by less than 20 msec—a stimulation rate of more than 50 stimuli per second. This rate is usually expressed in terms of *stimulus frequency*, which is the number of stimuli per unit time. In this instance, a stimulus frequency of greater than 50 per second produces wave summation, whereas a stimulus frequency of less than 50 per second will produce individual twitches and treppe.

If the stimulation continues and the muscle is never allowed to relax completely, tension will rise until it reaches a peak value roughly four times the maximum produced by treppe (Figure 10–16c•). A muscle producing almost peak tension during rapid cycles of contraction and relaxation is in **incomplete tetanus** (*tetanos*, convulsive tension).

Complete Tetanus Complete tetanus occurs when a higher stimulation frequency eliminates the relaxation phase (Figure 10–16d•). During complete tetanus, action potentials arrive so rapidly that the sarcoplasmic reticulum does not have time to reclaim the calcium ions. The high Ca^{2+} concentration in the cytoplasm prolongs the contraction, making it continuous.

Tension Production by Skeletal Muscles

Now that you are familiar with the basic mechanisms of muscle contraction at the level of the individual muscle fiber, we can begin to examine the performance of skeletal muscles—the organs of the muscular system. In this section, we will consider the coordinated contractions of an entire population of skeletal muscle fibers. The amount of tension produced in the skeletal muscle *as a whole* is determined by (1) the tension produced by the stimulated muscle fibers and (2) the total number of muscle fibers stimulated.

As muscle fibers actively shorten, they pull on the attached tendons which become streched. The tension is transferred in turn to bones which are moved against an external load. (We will look at the interactions between the muscular and skeletal systems in Chapter 11.)

A myogram performed in the laboratory generally measures the tension in a tendon. A single twitch is so brief in duration that there isn't enough time to activate a significant percentage of the available cross-bridges. Twitches are therefore ineffective in terms of performing useful work.

However, if a second twitch occurs before the tension returns to zero, tension will peak at a higher level, because additional cross-bridges will form. Think of pushing a child on a swing: You push gently to start the swing moving; if you push harder the second time, the child swings higher because the energy of the second push is added to the energy remaining from the first. Each successive contraction begins before the tension has fallen to resting levels, so the tension continues to rise until it peaks. During a tetanic contraction, there is enough time for essentially all of the potential cross-bridges to form, and tension peaks. Muscle are rarely used this way in the body, but they can be made to contract tetanically in the laboratory.

Motor Units and Tension Production

The amount of tension produced by the muscle as a whole is the sum of the tensions generated by the individual muscle fibers, since they are all pulling together. Thus, you can control the amount of tension produced by a skeletal muscle by controlling the number of stimulated muscle fibers.

A typical skeletal muscle contains thousands of muscle fibers. Although some motor neurons control a few muscle fibers, most control hundreds of them. All the muscle fibers controlled by a single motor neuron constitute a **motor unit**. The size of a motor unit is an indication of how fine the control of movement can be. In the muscles of the eye, where precise control is extremely important, a motor neuron may control 4–6 muscle fibers. We have much less precise control over our leg muscles, where a single motor neuron may control 1000–2000 muscle fibers. The muscle fibers of each motor unit are intermingled with those of other motor units (Figure 10–17a•). Because of this intermingling, the direction of pull exerted on the tendon does not change when the number of activated motor units changes.

When you decide to perform a specific arm movement, specific groups of motor neurons in the spinal cord are stimulated. The contraction begins with the activation of the smallest motor units in the stimulated muscle. These motor units generally contain muscle fibers that contract relatively slowly. As the movement continues, larger motor units containing faster and more powerful muscle fibers are activated, and tension production rises steeply. The smooth, but steady, increase in muscular tension produced by increasing the number of active motor units is called **recruitment**.

Peak tension production occurs when all motor units in the muscle contract in a state of complete tetanus. Such powerful contractions do not last long, however, because the individual muscle fibers soon use up their available energy reserves. During a sustained contraction, motor units are activated on a rotating basis, so some of them are resting and recovering while others are actively contracting. In this "relay team" approach, called *asynchronous motor unit summation*, each motor unit can recover somewhat before it is stimulated again (Figure 10–17b•). As a result, when your muscles contract for sustained periods, they produce slightly less than maximal tension.

100 Keys | All voluntary muscle contractions and intentional movements involve the sustained contractions of skeletal

muscle fibers. The force exerted can be increased by increasing the frequency of motor neuron action potentials or the number of stimulated motor units (recruitment).

Muscle Tone

In any skeletal muscle, some motor units are always active, even when the entire muscle is not contracting. Their contractions do not produce enough tension to cause movement, but they do tense and firm the muscle. This resting tension in a skeletal muscle is called **muscle tone**. A muscle with little muscle tone appears limp and flaccid, whereas one with moderate muscle tone is firm and solid. The identity of the stimulated motor units changes constantly, so individual muscle fibers can relax while a constant tension is maintained in the attached tendon.

Resting muscle tone stabilizes the positions of bones and joints. For example, in muscles involved with balance and posture, enough motor units are stimulated to produce the tension needed to maintain body position. Muscle tone also helps prevent sudden, uncontrolled changes in the positions of bones and joints. In addition to bracing the skeleton, the elastic nature of muscles and tendons lets skeletal muscles act as shock absorbers that cushion the impact of a sudden bump or shock. Heightened muscle tone accelerates the recruitment process during a voluntary contraction, because some of the motor units are already stimulated. Strong muscle tone also makes skeletal muscles appear firm and well defined, even at rest.

Activated muscle fibers use energy, so the greater the muscle tone, the higher the “resting” rate of metabolism. Increasing this rate is one of the significant effects of exercise in a weight-loss program. In such a program, you lose weight when your daily energy use exceeds your daily energy intake in food. Although exercise consumes energy very quickly, the period of activity is usually quite brief. In contrast, elevated muscle tone increases resting energy consumption by a small amount, but the effects are cumulative, and they continue 24 hours per day.

Review motor units and muscle tone on the **IP CD-ROM: Muscular System/Contraction of Motor Units.**

Isotonic and Isometric Contractions

We can classify muscle contractions as *isotonic* or *isometric* on the basis of their pattern of tension production.

Isotonic Contractions In an **isotonic contraction** (*iso*-, equal + *tonos,* tension), tension rises and the skeletal muscle's length changes. Lifting an object off a desk, walking, and running involve isotonic contractions.

Two types of isotonic contractions exist: concentric and eccentric. In a **concentric contraction**, the muscle tension *exceeds* the resistance and the muscle *shortens*. Consider a skeletal muscle that is 1 cm^2 in cross-sectional area and can produce roughly 4 kg of tension in complete tetanus. If we hang a 2-kg weight from that muscle and stimulate it, the muscle will shorten (Figure 10–18a•). Before the muscle can shorten, the cross-bridges must produce enough tension to overcome the resistance—in this case, the 2-kg weight. During this initial period, tension in the muscle fibers rises until the tension in the tendon exceeds the amount of resistance. As the muscle shortens, the tension in the skeletal muscle remains constant at a value that just exceeds the load (Figure 10–18b•). The term *isotonic* originated from this type of experiment.

In the body, however, the situation is more complicated. Muscles are not always positioned directly above the resistance, and they are attached to bones rather than to static weights. Changes in the relative positions of the muscle and the articulating bones, the effects of gravity, and other mechanical and physical factors interact to increase or decrease the amount of resistance the muscle must overcome as a movement proceeds. Nevertheless, during a concentric contraction, the peak tension produced exceeds that resistance.

The speed of shortening varies with the difference between the amount of tension produced and the amount of resistance. If all the motor units are stimulated and the resistance is relatively small, the muscle will shorten very quickly. In contrast, if the muscle barely produces enough tension to overcome the resistance, it will shorten very slowly.

In an **eccentric contraction**, the peak tension developed is *less than* the load, and the muscle *elongates* owing to the contraction of another muscle or the pull of gravity. Think of a tug-of-war team trying to stop a moving car. Although everyone pulls as hard as they can, the rope slips through their fingers. The speed of elongation depends on the difference between the amount of tension developed by the active muscle fibers and the amount of resistance. In our analogy, the team might slow down a small car, but would have little effect on a large truck.

Eccentric contractions are very common, and they are an important part of a variety of movements. In these movements, you exert precise control over the amount of tension produced. By varying the tension in an eccentric contraction, you can control the rate of elongation, just as you can vary the tension in a concentric contraction. During physical training, people commonly perform cycles of concentric and eccentric contractions, as when you hold a weight in your hand and slowly perform flexion and extension at the elbow. The flexion involves concentric contractions that exceed the resistance posed by the weight. During extension, the same muscles are active, but the contractions are eccentric. The tension produced isn't sufficient to overcome the force of gravity, but it is enough to control the speed of movement.

Isometric Contractions In an **isometric contraction** (*metric*, measure), the muscle as a whole does not change length, and the tension produced never exceeds the resistance. Figure 10–18c• shows what happens if we attach a weight heavier than 4 kg to the experimental muscle and then stimulate the muscle. Although cross-bridges form and tension rises to peak values, the muscle cannot overcome the resistance of the weight and so cannot shorten (Figure 10–18d•). Examples of isometric contractions include carrying a bag of groceries, holding a baby, and holding our heads up. Many of the reflexive muscle contractions that keep your body upright when you stand or sit involve isometric contractions of muscles that oppose the force of gravity.

Notice that when you perform an isometric contraction, the contracting muscle bulges, but not as much as it does during an isotonic contraction. In an isometric contraction, although the muscle *as a whole* does not shorten, the individual muscle fibers shorten as connective tissues stretch. The muscle fibers cannot shorten further, because the tension does not exceed the resistance.

Normal daily activities therefore involve a combination of isotonic and isometric muscular contractions. As you sit and read this text, isometric contractions of postural muscles stabilize your vertebrae and maintain your upright position. When you turn a page, the movements of your arm, forearm, hand, and fingers are produced by a combination of concentric and eccentric isotonic contractions.

Resistance and Speed of Contraction

You can lift a light object more rapidly than you can lift a heavy one because resistance and the speed of contraction are inversely related. If the resistance is less than the tension produced, a concentric isotonic contraction will occur; the muscle will shorten. The heavier the resistance, the longer it takes for the movement to begin, because muscle tension (which increases gradually) must exceed the resistance before shortening can occur (Figure 10–19•). The contraction itself proceeds more slowly. At the molecular level, the speed of cross-bridge pivoting is reduced as the load increases.

For each muscle, an optimal combination of tension and speed exists for any given resistance. If you have ever ridden a 10speed bicycle, you are probably already aware of this fact. When you are cruising along comfortably, your thigh and leg muscles are working at an optimal combination of speed and tension. When you start up a hill, the resistance increases. Your muscles must now develop more tension, and they move more slowly; they are no longer working at optimal efficiency. If you then shift to a lower gear, the load on your muscles decreases and their speed increases, and the muscles are once again working efficiently.

Muscle Relaxation and the Return to Resting Length

As we noted earlier, there is no active mechanism for muscle fiber elongation. The sarcomeres in a muscle fiber can shorten and develop tension, but the power stroke cannot be reversed to push the Z lines farther apart. After a contraction, a muscle fiber returns to its original length through a combination of elastic forces, opposing muscle contractions, and gravity.

Elastic Forces When the contraction ends, some of the energy initially “spent” in stretching the tendons and distorting intracellular organelles is recovered as they recoil or rebound to their original dimensions. This elasticity gradually helps return the muscle fiber to its original resting length.

Opposing Muscle Contractions The contraction of opposing muscles can return a muscle to its resting length more quickly than elastic forces can. Consider the muscles of the arm that flex or extend the elbow. Contraction of the *biceps brachii muscle* on the anterior part of the arm flexes the elbow; contraction of the *triceps brachii muscle* on the posterior part of the arm extends the elbow. When the biceps brachii muscle contracts, the triceps brachii muscle is stretched. When the biceps brachii muscle relaxes, contraction of the triceps brachii muscle extends the elbow and stretches the muscle fibers of the biceps brachii muscle to their original length.

Gravity Gravity may assist opposing muscle groups in quickly returning a muscle to its resting length after a contraction. For example, imagine the biceps brachii muscle fully contracted with the elbow pointed at the ground. When the muscle relaxes, gravity will pull the forearm down and stretch the muscle. Although gravity can provide assistance in stretching muscles, some active muscle tension is needed to control the rate of movement and to prevent damage to the joint. In the previous example, eccentric contraction of the biceps brachii muscle can control the movement.

Concept Check

Why is it difficult to contract a muscle that has been overstretched?

During treppe, why does tension in a muscle gradually increase even though the strength and frequency of the stimulus are constant?

Can a skeletal muscle contract without shortening? Explain.

Answers begin on p. A–1

Review tension production by skeletal muscle fibers and whole skeletal muscles on the **IP CD-ROM: Muscular System/Contraction of Whole Muscle.**

Energy Use and Muscular Activity

Objectives

- Describe the mechanisms by which muscle fibers obtain the energy to power contractions.
- Describe the factors that contribute to muscle fatigue, and discuss the stages and mechanisms involved in the muscle's subsequent recovery.

A single muscle fiber may contain 15 billion thick filaments. When that muscle fiber is actively contracting, each thick filament breaks down roughly 2500 ATP molecules per second. Because even a small skeletal muscle contains thousands of muscle fibers, the ATP demands of a contracting skeletal muscle are enormous. In practical terms, the demand for ATP in a contracting muscle fiber is so high that it would be impossible to have all the necessary energy available as ATP before the contraction begins. Instead, a resting muscle fiber contains only enough ATP and other high-energy compounds to sustain a contraction until additional ATP can be generated. Throughout the rest of the contraction, the muscle fiber will generate ATP at roughly the same rate as it is used.

ATP and CP Reserves

The primary function of ATP is the transfer of energy from one location to another rather than the long-term storage of energy. At rest, a skeletal muscle fiber produces more ATP than it needs. Under these conditions, ATP transfers energy to creatine. *Creatine* (KRE¯-uh-te¯n) is a small molecule that muscle cells assemble from fragments of amino acids. The energy transfer creates another high-energy compound, **creatine phosphate (CP)**, or *phosphorylcreatine*:

ATP + creatine ¡ ADP + creatine phosphate

During a contraction, each myosin head breaks down ATP, producing ADP and a phosphate group. The energy stored in creatine phosphate is then used to "recharge" ADP, converting it back to ATP through the reverse reaction:

ADP + creatine phosphate ¡ ATP + creatine

The enzyme that facilitates this reaction is **creatine phosphokinase** (**CPK** or **CK**). When muscle cells are damaged, CPK leaks across the cell membranes and into the bloodstream. Thus, a high blood concentration of CPK usually indicates serious muscle damage.

The energy reserves of a representative muscle fiber are indicated in Table 10–2. A resting skeletal muscle fiber contains about six times as much creatine phosphate as ATP, but when a muscle fiber is undergoing a sustained contraction, these energy reserves are exhausted in only about 15 seconds. The muscle fiber must then rely on other mechanisms to generate ATP from ADP.

ATP Generation

As we saw in Chapter 3, most cells in the body generate ATP through (1) aerobic metabolism in mitochondria and (2) glycolysis in the cytoplasm. l**p. 76**

Aerobic Metabolism

Aerobic metabolism normally provides 95 percent of the ATP demands of a resting cell. In this process, mitochondria absorb oxygen, ADP, phosphate ions, and organic substrates (such as pyruvic acid) from the surrounding cytoplasm. The substrates then enter the *TCA* (*tricarboxylic acid*) *cycle* (also known as the *citric acid cycle* or the *Krebs cycle*), an enzymatic pathway that breaks down organic molecules. The carbon atoms are released as carbon dioxide. The hydrogen atoms are shuttled to respiratory enzymes in the inner mitochondrial membrane, where their electrons are removed. After a series of intermediate steps, the protons and electrons are combined with oxygen to form water. Along the way, large amounts of energy are released and used to make ATP. The entire process is very efficient: For each molecule of pyruvic acid “fed” into the TCA cycle, the cell gains 17 ATP molecules.

Resting skeletal muscle fibers rely almost exclusively on the aerobic metabolism of fatty acids to generate ATP. These fatty acids are absorbed from the circulation. When the muscle starts contracting, the mitochondria begin breaking down molecules of pyruvic acid instead of fatty acids. The pyruvic acid is provided by the enzymatic pathway of glycolysis, which breaks down glucose in the cytoplasm. The glucose can come either from the surrounding interstitial fluid or through the breakdown of glycogen reserves within the sarcoplasm. Because a typical skeletal muscle fiber contains large amounts of glycogen, the shift from fatty acid metabolism to glucose metabolism makes it possible for the cell to continue contracting for an extended period, even without an external source of nutrients.

Glycolysis

Glycolysis is the breakdown of glucose to pyruvic acid in the cytoplasm of a cell. It is an **anaerobic process**, because it does not require oxygen. Glycolysis provides a net gain of 2 ATP molecules and generates 2 pyruvic acid molecules from each glucose molecule. The ATP produced by glycolysis is therefore only a small fraction of that produced by aerobic metabolism, in which the breakdown of the 2 pyruvic acid molecules in mitochondria would generate 34 ATP molecules. Thus, when energy demands are relatively low and oxygen is readily available, glycolysis is important only because it provides the substrates for aerobic metabolism. Yet, because it can proceed in the absence of oxygen, glycolysis becomes an important source of energy when energy demands are at a maximum and the availability of oxygen limits the rate of mitochondrial ATP production.

The glucose broken down under these conditions is obtained primarily from the reserves of glycogen in the sarcoplasm. Glycogen is a polysaccharide chain of glucose molecules. l**p. 44** Typical skeletal muscle fibers contain large glycogen reserves, which may account for 1.5 percent of the total muscle weight. When the muscle fiber begins to run short of ATP and CP, enzymes split the glycogen molecules, releasing glucose, which can be used to generate more ATP. When energy demands are low and oxygen is abundant, glycolysis provides substrates for anaerobic metabolism, and aerobic metabolism provides the ATP needed for contraction. However, during peak periods of muscular activity, energy demands are extremely high and oxygen supplies are very limited. Under these conditions, glycolysis provides most of the ATP needed to sustain muscular contraction.

Energy Use and the Level of Muscular Activity

As the level of muscular activity increases, the pattern of energy production and use changes:

- In a resting skeletal muscle (Figure 10–20a•), the demand for ATP is low. More than enough oxygen is available for the mitochondria to meet that demand, and they produce a surplus of ATP. The extra ATP is used to build up reserves of CP and glycogen. Resting muscle fibers absorb fatty acids and glucose delivered by the bloodstream. The fatty acids are broken down in the mitochondria, and the ATP that is generated is used to convert creatine to creatine phosphate and glucose to glycogen.
- At moderate levels of activity (Figure 10–20b•), the demand for ATP increases. This demand is met by the mitochondria. As the rate of mitochondrial ATP production rises, so does the rate of oxygen consumption. Oxygen availability is not a limiting factor, because oxygen can diffuse into the muscle fiber fast enough to meet mitochondrial needs. But all the ATP produced is needed by the muscle fiber, and no surplus is available. The skeletal muscle now relies primarily on the aerobic metabolism of pyruvic acid to generate ATP. The pyruvic acid is provided by glycolysis, which breaks down glucose molecules obtained from glycogen in the muscle fiber. If glycogen reserves are low, the muscle fiber can also break down other substrates, such as lipids or amino acids. As long as the demand for ATP can be met by mitochondrial activity, the ATP provided by glycolysis makes a relatively minor contribution to the total energy budget of the muscle fiber.
- At peak levels of activity (Figure 10–20c•), ATP demands are enormous and mitochondrial ATP production rises to a maximum. This maximum rate is determined by the availability of oxygen, and oxygen cannot diffuse into the muscle fiber fast enough to enable the mitochondria to produce the required ATP. At peak levels of exertion, mitochondrial activity can provide only about one-third of the ATP needed. The remainder is produced through glycolysis. When glycolysis produces pyruvic acid faster than it can be utilized by the mitochondria, pyruvic acid levels rise in the sarcoplasm. Under these conditions, pyruvic acid is converted to **lactic acid**, a related three-carbon molecule.

The anaerobic process of glycolysis enables the cell to generate additional ATP when the mitochondria are unable to meet the current energy demands. However, anaerobic energy production has drawbacks. First, the lactic acid produced is an organic acid that dissociates in body fluids into a hydrogen ion and a negatively charged *lactate ion*. Thus, production of lactic acid can lower the intracellular pH. Buffers in the sarcoplasm can resist pH shifts, but these mechanisms are limited. Eventually, changes in pH will alter the functional characteristics of key enzymes so that the muscle fiber cannot continue to contract. Moveover, glycolysis is a relatively inefficient way to generate ATP. Under anaerobic conditions, each glucose molecule generates 2 pyruvic acid molecules, which are converted to lactic acid. In return, the cell gains 2 ATP molecules through glycolysis. Had those 2 pyruvic acid molecules been catabolized aerobically in a mitochondrion, the cell would have produced 34 additional ATP.

Muscle Fatigue

An active skeletal muscle is said to be **fatigued** when it can no longer continue to perform at the required level of activity. Many factors are involved in promoting muscle fatigue. For example, muscle fatigue has been correlated with (1) depletion of metabolic reserves within the muscle fibers, (2) damage to the sarcolemma and sarcoplasmic reticulum, (3) a decline in pH within the muscle fibers and the muscle as a whole, decreasing calcium ion binding to troponin and altering enzyme activities, and (4) a sense of weariness and a reduction in the desire to continue the activity, due to the effects of low blood pH and pain on the brain. Muscle fatigue is cumulative—the effects become more pronounced as more neurons and muscle fibers are affected. The result is a gradual reduction in the capabilities and performance of the entire skeletal muscle.

If a muscle fiber is contracting at moderate levels and ATP demands can be met through aerobic metabolism, fatigue will not occur until glycogen, lipid, and amino acid reserves are depleted. This type of fatigue affects the muscles of endurance athletes, such as marathon runners, after hours of exertion.

When a muscle produces a sudden, intense burst of activity at peak levels, most of the ATP is provided by glycolysis. After just seconds to minutes, the rising lactic acid levels lower the tissue pH, and the muscle can no longer function normally. Sprinters get this type of muscle fatigue. We will return to the topics of fatigue, athletic training, and metabolic activity later in the chapter.

Normal muscle function requires (1) substantial intracellular energy reserves, (2) a normal circulatory supply, (3) normal blood oxygen levels, and (4) blood pH within normal limits. Anything that interferes with any of these factors will promote premature muscle fatigue. For example, reduced blood flow from tight clothing, heart problems, or blood loss slows the delivery of oxygen and nutrients, accelerates the buildup of lactic acid, and promotes muscle fatigue.

The Recovery Period

When a muscle fiber contracts, conditions in the sarcoplasm change. Energy reserves are consumed, heat is released, and, if the contraction was at peak levels, lactic acid is generated. In the **recovery period**, the conditions in muscle fibers are returned to normal, preexertion levels. After a period of moderate activity, it may take several hours for muscle fibers to recover. After sustained activity at higher levels, complete recovery can take a week.

Lactic Acid Removal and Recycling

Glycolysis enables a skeletal muscle to continue contracting even when mitochondrial activity is limited by the availability of oxygen. As we have seen, however, lactic acid production is not an ideal way to generate ATP. It squanders the glucose reserves of the muscle fibers, and it is potentially dangerous because lactic acid can alter the pH of the blood and tissues.

During the recovery period, when oxygen is available in abundance, lactic acid can be recycled by conversion back to pyruvic acid. The pyruvic acid can then be used either by mitochondria to generate ATP or as a substrate for enzyme pathways that synthesize glucose and rebuild glycogen reserves.

During exertion, lactic acid diffuses out of muscle fibers and into the bloodstream. The process continues after the exertion has ended, because intracellular lactic acid concentrations are still relatively high. The liver absorbs the lactic acid and converts it to pyruvic acid. Roughly 30 percent of these pyruvic acid molecules are broken down in the TCA cycle, providing the ATP needed to convert the other pyruvic acid molecules to glucose. (We will cover these processes more fully in Chapter 25.) The glucose molecules are then released into the circulation, where they are absorbed by skeletal muscle fibers and used to rebuild their glycogen reserves. This shuffling of lactic acid to the liver and glucose back to muscle cells is called the **Cori cycle**.

The Oxygen Debt

During the recovery period, the body's oxygen demand remains elevated above normal resting levels. The more ATP required, the more oxygen will be needed. The amount of oxygen required to restore normal, preexertion conditions is called the **oxygen debt**, or *excess postexercise oxygen consumption (EPOC).*

Most of the additional oxygen consumption occurs in skeletal muscle fibers, which must restore ATP, creatine phosphate, and glycogen concentrations to their former levels, and in liver cells, which generate the ATP needed to convert excess lactic acid to glucose. However, several other tissues also increase their rate of oxygen consumption and ATP generation during the recovery period. For example, sweat glands increase their secretory activity until normal body temperature is restored. While the oxygen debt is being repaid, breathing rate and depth are increased. As a result, you continue to breathe heavily long after you stop exercising.

100 Keys | Skeletal muscles at rest metabolize fatty acids and store glycogen. During light activity, muscles can generate

ATP through the aerobic breakdown of carbohydrates, lipids, or amino acids. At peak levels of activity, most of the energy

is provided by anaerobic reactions that generate lactic acid as a byproduct.

Heat Production and Loss

Muscular activity generates substantial amounts of heat. During a catabolic process, such as the breakdown of glycogen or the reactions of glycolysis, a muscle fiber captures only a portion of the released energy. l**p. 35** The rest is released as heat. A resting muscle fiber relying on aerobic metabolism captures about 42 percent of the energy released in catabolism. The other 58 percent warms the sarcoplasm, interstitial fluid, and circulating blood. Active skeletal muscles release roughly 85 percent of the heat needed to maintain normal body temperature.

When muscles become active, their energy consumption skyrockets. As anaerobic energy production becomes the primary method of ATP generation, muscle fibers become less efficient at capturing energy. At peak levels of exertion, only about 30 percent of the released energy is captured as ATP; the remaining 70 percent warms the muscle and surrounding tissues. Body temperature soon climbs, and heat loss at the skin accelerates through mechanisms introduced in Chapters 1 and 5. l**pp. 12, 169**

Hormones and Muscle Metabolism

Metabolic activities in skeletal muscle fibers are adjusted by hormones of the endocrine system. *Growth hormone* from the pituitary gland and *testosterone* (the primary sex hormone in males) stimulate the synthesis of contractile proteins and the enlargement of skeletal muscles. *Thyroid hormones* elevate the rate of energy consumption in resting and active skeletal muscles. During a sudden crisis, hormones of the adrenal gland, notably *epinephrine* (adrenaline), stimulate muscle metabolism and increase both the duration of stimulation and the force of contraction. (We will further examine the effects of hormones on muscle and other tissues in Chapter 18.)

Muscle Performance

Objectives

- Relate the types of muscle fibers to muscle performance.
- Distinguish between aerobic and anaerobic endurance, and explain their implications for muscular performance.

Muscle performance can be considered in terms of **force**, the maximum amount of tension produced by a particular muscle or muscle group, and **endurance**, the amount of time during which the individual can perform a particular activity. Two major factors determine the performance capabilities of any skeletal muscle: (1) the types of muscle fibers in the muscle and (2) physical conditioning or training.

Types of Skeletal Muscle Fibers

The human body has three major types of skeletal muscle fibers: *fast fibers*, *slow fibers*, and *intermediate fibers* (Table 10–3).

Fast Fibers

Most of the skeletal muscle fibers in the body are called **fast fibers**, because they can contract in 0.01 sec or less after stimulation. Fast fibers are large in diameter and contain densely packed myofibrils, large glycogen reserves, and relatively few mitochondria. The tension produced by a muscle fiber is directly proportional to the number of myofibrils, so muscles dominated by fast fibers produce powerful contractions. However, fast fibers fatigue rapidly because their contractions use ATP in massive amounts, and there are relatively few mitochondria to generate ATP. As a result, prolonged activity is supported primarily by anaerobic metabolism. Other names used to refer to these muscle fibers include *white muscle fibers, fast-twitch glycolytic fibers,* and *Type II-B fibers*.

Slow Fibers

Slow fibers have only about half the diameter of fast fibers and take three times as long to reach peak tension after stimulation. These fibers are specialized to enable them to continue contracting for extended periods, long after a fast fiber would have become fatigued. The most important specializations improve mitochondrial performance.

One of the main characteristics of slow muscle fibers is that they are surrounded by a more extensive network of capillaries than is typical of fast muscle tissue; thus, they have a dramatically higher oxygen supply to support mitochondrial activity. Slow
fibers also contain the red pigment **myoglobin** (MI¯
-

¯o
-gl
¯o
-bin). This globular protein is structurally related to hemoglobin, the
red oxygen-carrying pigment in blood. Both myoglobin and hemoglobin reversibly bind oxygen molecules. Although other muscle fiber types contain small amounts of myoglobin, it is most abundant in slow fibers. As a result, resting slow fibers contain substantial oxygen reserves that can be mobilized during a contraction. Because slow fibers have both an extensive capillary supply and a high concentration of myoglobin, skeletal muscles dominated by slow fibers are dark red. Slow fibers are also known as *red muscle fibers, slow-twitch oxidative fibers*, and *Type I fibers*.

With oxygen reserves and a more efficient blood supply, the mitochondria of slow fibers can contribute more ATP during contraction. In addition, the cross-bridges in slow fibers cycle more slowly than those of fast fibers, and this reduces demand for ATP. Thus, slow fibers are less dependent on anaerobic metabolism than are fast fibers. Some of the mitochondrial energy production involves the breakdown of stored lipids rather than glycogen, so glycogen reserves of slow fibers are smaller than those of fast fibers. Slow fibers also contain more mitochondria than do fast fibers. Figure 10–21• compares the appearance of fast and slow fibers.

Intermediate Fibers

Most properties of **intermediate fibers** are intermediate between those of fast fibers and slow fibers. In appearance, intermediate fibers most closely resemble fast fibers, for they contain little myoglobin and are relatively pale. They have a more extensive capillary network around them, however, and are more resistant to fatigue than are fast fibers. Intermediate fibers are also known as *fast-twitch oxidative fibers* and *Type II-A fibers*.

Muscle Performance and the Distribution of Muscle Fibers

The percentages of fast, intermediate, and slow fibers in a skeletal muscle can be quite variable. In muscles that contain a mixture of fast and intermediate fibers, the proportion can change with physical conditioning. For example, if a muscle is used repeatedly for endurance events, some of the fast fibers will develop the appearance and functional capabilities of intermediate fibers. The muscle as a whole will thus become more resistant to fatigue.

Muscles dominated by fast fibers appear pale and are often called **white muscles**. Chicken breasts contain “white meat” because chickens use their wings only for brief intervals, as when fleeing from a predator, and the power for flight comes from the anaerobic process of glycolysis in the fast fibers of their breast muscles. As we saw earlier, the extensive blood vessels and myoglobin in slow fibers give these fibers a reddish color; muscles dominated by slow fibers are therefore known as **red muscles**. Chickens walk around all day, and these movements are powered by aerobic metabolism in the slow fibers of the “dark meat” of their legs.

Most human muscles contain a mixture of fiber types and so appear pink. However, there are no slow fibers in muscles of the eye or hand, where swift, but brief, contractions are required. Many back and calf muscles are dominated by slow fibers; these muscles contract almost continuously to maintain an upright posture. The percentage of fast versus slow fibers in each muscle is genetically determined. As noted earlier, the ratio of intermediate fibers to fast fibers can increase as a result of athletic training.

Muscle Hypertrophy and Atrophy

As a result of repeated, exhaustive stimulation, muscle fibers develop more mitochondria, a higher concentration of glycolytic enzymes, and larger glycogen reserves. Such muscle fibers have more myofibrils than do fibers that are less used, and each myofibril contains more thick and thin filaments. The net effect is **hypertrophy**, or an enlargement of the stimulated muscle. The number of muscle fibers does not change significantly, but the muscle as a whole enlarges because each muscle fiber increases in diameter.

Hypertrophy occurs in muscles that have been repeatedly stimulated to produce near-maximal tension. The intracellular changes that occur increase the amount of tension produced when these muscles contract. The muscles of a bodybuilder are excellent examples of muscular hypertrophy.

Clinical Note

A skeletal muscle that is not regularly stimulated by a motor neuron loses muscle tone and mass. The muscle becomes flaccid, and the muscle fibers become smaller and weaker. This reduction in muscle size, tone, and power is called atrophy. Individuals paralyzed by spinal injuries or other damage to the nervous system will gradually lose muscle tone and size in the areas affected. Even a temporary reduction in muscle use can lead to muscular atrophy; you can easily observe this effect by comparing “before and after” limb muscles in someone who has worn a cast. Muscle atrophy is initially reversible, but dying muscle fibers are not replaced. In extreme atrophy, the functional losses are permanent. That is why physical therapy is crucial for people who are temporarily unable to move normally. Electrical stimulation by an external device can substitute for nerve stimulation and prevent or reduce muscle atrophy.

Because skeletal muscles depend on motor neurons for stimulation, disorders that affect the nervous system can indirectly affect the muscular system. In *polio*, a virus attacks motor neurons in the spinal cord and brain, causing muscular paralysis and atrophy.

AM: Problems with the Control of Muscle Activity

Physical Conditioning

Physical conditioning and training schedules enable athletes to improve both power and endurance. In practice, the training schedule varies, depending on whether the activity is supported primarily by aerobic or anaerobic energy production.

Anaerobic endurance is the length of time muscular contraction can continue to be supported by glycolysis and by the existing energy reserves of ATP and CP. Anaerobic endurance is limited by (1) the amount of ATP and CP available, (2) the amount of glycogen available for breakdown, and (3) the ability of the muscle to tolerate the lactic acid generated during the anaerobic period. Typically, the onset of muscle fatigue occurs within 2 minutes of the start of maximal activity.

Activities that require above-average levels of anaerobic endurance include a 50-meter dash or swim, pole vaulting, and competitive weight lifting. These activities involve the contractions of fast fibers. The energy for the first 10–20 seconds of activity comes from the ATP and CP reserves of the cytoplasm. As these reserves dwindle, glycogen breakdown and glycolysis provide additional energy. Athletes training to improve anaerobic endurance perform frequent, brief, intensive workouts that stimulate muscle hypertrophy. AM: Delayed Onset Muscle Soreness

Aerobic endurance is the length of time a muscle can continue to contract while supported by mitochondrial activities. Aerobic endurance is determined primarily by the availability of substrates for aerobic respiration, which muscle fibers can obtain by breaking down carbohydrates, lipids, or amino acids. Initially, many of the nutrients catabolized by muscle fibers are obtained from reserves in the sarcoplasm. Prolonged aerobic activity, however, must be supported by nutrients provided by the circulating blood.

During exercise, blood vessels in the skeletal muscles dilate, increasing blood flow and thus bringing more oxygen and nutrients to the active muscle tissue. Warm-up periods are therefore important not only in that they take advantage of treppe, the increase in tension production noted on p. 303, but also because they stimulate circulation in the muscles before the serious workout begins. Because glucose is a preferred energy source, endurance athletes such as marathon runners typically “load” or “bulk up” on carbohydrates for the three days before an event. They may also consume glucose-rich “sports drinks” during a competition. (We will consider the risks and benefits of these practices in Chapter 25.)

Training to improve aerobic endurance generally involves sustained low levels of muscular activity. Examples include jogging, distance swimming, and other exercises that do not require peak tension production. Improvements in aerobic endurance result from two factors:

1. *Alterations in the Characteristics of Muscle Fibers.* The composition of fast and slow fibers in each muscle is genetically determined, and individual differences are significant. These variations affect aerobic endurance, because a person with more slow fibers in a particular muscle will be better able to perform under aerobic conditions than will a person with fewer. However, skeletal muscle cells respond to changes in the pattern of neural stimulation. Fast fibers trained for aerobic competition develop the characteristics of intermediate fibers, and this change improves aerobic endurance.

2. *Improvements in Cardiovascular Performance.* Cardiovascular activity affects muscular performance by delivering oxygen and nutrients to active muscles. Physical training alters cardiovascular function by accelerating blood flow, thus improving oxygen and nutrient availability. Another important benefit of endurance training is increased capillarity, providing better blood flow at the cellular level. (We will examine factors involved in improving cardiovascular performance in Chapter 21.)

Aerobic activities do not promote muscle hypertrophy. Many athletes train using a combination of aerobic and anaerobic exercises so that their muscles will enlarge and both anaerobic and aerobic endurance will improve. These athletes alternate an aerobic activity, such as swimming, with sprinting or weight lifting. The combination is known as *interval training* or *cross-training*. Interval training is particularly useful for people engaged in racquet sports, such as tennis or squash, which are dominated by aerobic activities but are punctuated by brief periods of anaerobic effort. AM: Power, Endurance, and Energy Reserves

100 Keys | What you don’t use, you lose. Muscle tone is an indication of the chronic background level of activity in the motor units in skeletal muscles. When inactive for days or weeks, muscles become flaccid, and the muscle fibers break down their contractile proteins and grow smaller and weaker. If inactive for long periods, muscle fibers may be replaced by fibrous tissue.

Concept Check

Why would a sprinter experience muscle fatigue before a marathon runner would?

Which activity would be more likely to create an oxygen debt: swimming laps or lifting weights?

Which type of muscle fibers would you expect to predominate in the large leg muscles of someone who excels at endurance activities, such as cycling or long-distance running?

Answers begin on p. A–1

Review muscle metabolism, muscle fatigue, and types of skeletal muscle fibers on the **IP CD-ROM: Muscular System/Muscle Metabolism.**

Cardiac Muscle Tissue

Objective

- Identify the structural and functional differences between skeletal muscle fibers and cardiac muscle cells.

We introduced **cardiac muscle tissue** in Chapter 4 and briefly compared its properties with those of other types of muscle. **Cardiac muscle cells**, also called *cardiocytes* or *cardiac myocytes*, are found only in the heart.

Like skeletal muscle fibers, cardiac muscle cells contain organized myofibrils, and the presence of many aligned sarcomeres gives the cells a striated appearance. However, significant structural and functional differences exist between skeletal muscle fibers and cardiac muscle cells.

Structural Characteristics of Cardiac Muscle Tissue

Important structural differences between skeletal muscle fibers and cardiac muscle cells include the following:

- Cardiac muscle cells are relatively small, averaging 10–20 mm in diameter and 50–100 mm in length.
- A typical cardiac muscle cell (Figure 10–22a,b•) has a single, centrally placed nucleus, although a few may have two or more nuclei.
- The T tubules in a cardiac muscle cell are short and broad, and there are no triads (Figure 10–22c•). The T tubules encircle the sarcomeres at the Z lines rather than at the zones of overlap.
- The SR of a cardiac muscle cell lacks terminal cisternae, and its tubules contact the cell membrane as well as the T tubules (see

Figure 10–22c•). As in skeletal muscle fibers, the appearance of an action potential triggers the release of calcium from the SR and the contraction of sarcomeres; it also increases the permeability of the sarcolemma to extracellular calcium ions.

- Cardiac muscle cells are almost totally dependent on aerobic metabolism to obtain the energy they need to continue contracting. Energy reserves are maintained in the form of glycogen and lipid inclusions. The sarcoplasm of a cardiac muscle cell contains large numbers of mitochondria and abundant reserves of myoglobin that store the oxygen needed to break down those energy reserves during times of peak activity.
- Each cardiac muscle cell contacts several others at specialized sites known as **intercalated** (in-TER-ka-l -ted) **discs**. l**p. 134**

¯a

Intercalated discs play a vital role in the function of cardiac muscle, as we will see next.

Intercalated Discs

At an intercalated disc (see Figure 10–22a,b•), the cell membranes of two adjacent cardiac muscle cells are extensively intertwined

¯e

and bound together by gap junctions and desmosomes. l**p. 110** These connections help stabilize the relative positions of adjacent cells and maintain the three-dimensional structure of the tissue. The gap junctions allow ions and small molecules to move from one cell to another. This arrangement creates a direct electrical connection between the two muscle cells. An action potential can travel across an intercalated disc, moving quickly from one cardiac muscle cell to another.

Myofibrils in the two interlocking muscle cells are firmly anchored to the membrane at the intercalated disc. Because their myofibrils are essentially locked together, the two muscle cells can "pull together" with maximum efficiency. Because the cardiac muscle cells are mechanically, chemically, and electrically connected to one another, the entire tissue resembles a single, enormous muscle cell. For this reason, cardiac muscle has been called a *functional syncytium* (sin-SISH--um; a fused mass of cells).

Functional Characteristics of Cardiac Muscle Tissue

In Chapter 20, we will examine cardiac muscle physiology in detail; here, we will briefly summarize four major functional specialties of cardiac muscle:

1. Cardiac muscle tissue contracts without neural stimulation. This property is called **automaticity**. The timing of contractions is normally determined by specialized cardiac muscle cells called **pacemaker cells**.

2. Innervation by the nervous system can alter the pace established by the pacemaker cells and adjust the amount of tension produced during a contraction.

3. Cardiac muscle cell contractions last roughly 10 times as long as do those of skeletal muscle fibers. They also have longer refractory periods and do not readily fatique.

4. The properties of cardiac muscle cell membranes differ from those of skeletal muscle fiber membranes. As a result, individual twitches cannot undergo wave summation, and cardiac muscle tissue cannot produce tetanic contractions. This difference is important, because a heart in a sustained tetanic contraction could not pump blood.

Smooth Muscle Tissue

Objectives

• Identify the structural and functional differences between skeletal muscle fibers and smooth muscle cells.

• Discuss the role that smooth muscle tissue plays in systems throughout the body.

Smooth muscle tissue forms sheets, bundles, or sheaths around other tissues in almost every organ. Smooth muscles around blood vessels regulate blood flow through vital organs. In the digestive and urinary systems, rings of smooth muscle, called *sphincters*, regulate the movement of materials along internal passageways. Smooth muscles play a variety of other roles in various body systems:

- **Integumentary System:** Smooth muscles around blood vessels regulate the flow of blood to the superficial dermis; smooth muscles of the arrector pili elevate hairs. l**p. 164**
- **Cardiovascular System:** Smooth muscles encircling blood vessels control the distribution of blood and help regulate the blood pressure.
- **Respiratory System:** Smooth muscle contraction or relaxation alters the diameters of the respiratory passageways and changes the resistance to airflow.
- **Digestive System:** Extensive layers of smooth muscle in the walls of the digestive tract play an essential role in moving materials along the tract. Smooth muscle in the walls of the gallbladder contract to eject bile into the digestive tract.
- **Urinary System:** Smooth muscle tissue in the walls of small blood vessels alters the rate of filtration in the kidneys. Layers of smooth muscle in the walls of the ureters transport urine to the urinary bladder; the contraction of the smooth muscle in the wall of the urinary bladder forces urine out of the body.
- **Reproductive System:** Layers of smooth muscle help move sperm along the reproductive tract in males and cause the ejection

of glandular secretions from the accessory glands into the reproductive tract. In females, layers of smooth muscle help move oocytes (and perhaps sperm) along the reproductive tract, and contraction of the smooth muscle in the walls of the uterus expels the fetus at delivery.

Figure 10–23a• shows typical smooth muscle tissue as seen by light microscopy. Smooth muscle tissue differs from both skeletal and cardiac muscle tissues in structure and function (Table 10–4).

Structural Characteristics of Smooth Muscle Tissue

Actin and myosin are present in all three types of muscle tissue. In skeletal and cardiac muscle cells, these proteins are organized in sarcomeres, with thin and thick filaments. The internal organization of a smooth muscle cell is very different:

- Smooth muscle cells are relatively long and slender, ranging from 5 to 10 mm in diameter and from 30 to 200 mm in length.
- Each cell is spindle shaped and has a single, centrally located nucleus.
- A smooth muscle fiber has no T tubules, and the sarcoplasmic reticulum forms a loose network throughout the sarcoplasm. Smooth muscle cells also lack myofibrils and sarcomeres. As a result, this tissue also has no striations and is called **nonstriated** muscle.
- Thick filaments are scattered throughout the sarcoplasm of a smooth muscle cell. The myosin proteins are organized differently than in skeletal or cardiac muscle cells, and smooth muscle cells have more myosin heads per thick filament.
- The thin filaments in a smooth muscle cell are attached to **dense bodies**, structures distributed throughout the sarcoplasm in a network of intermediate filaments composed of the protein *desmin* (Figure 10–23b•). Some of the dense bodies are firmly attached to the sarcolemma. The dense bodies and intermediate filaments anchor the thin filaments such that, when sliding occurs between thin and thick filaments, the cell shortens. Dense bodies are not arranged in straight lines, so when a contraction occurs, the muscle cell twists like a corkscrew.

- Adjacent smooth muscle cells are bound together at dense bodies, transmitting the contractile forces from cell to cell throughout the tissue.
- Although smooth muscle cells are surrounded by connective tissue, the collagen fibers never unite to form tendons or aponeuroses, as they do in skeletal muscles.

Functional Characteristics of Smooth Muscle Tissue

Smooth muscle tissue differs from other muscle tissue in (1) excitation–contraction coupling, (2) length–tension relationships,
(3) control of contractions, and (4) smooth muscle tone.

Excitation–Contraction Coupling

The trigger for smooth muscle contraction is the appearance of free calcium ions in the cytoplasm. On stimulation, a blast of calcium ions enters the cell from the extracellular fluid, and additional calcium ions are released by the sarcoplasmic reticulum. The net result is a rise in calcium ion concentrations throughout the cell. Once in the sarcoplasm, the calcium ions interact with **calmodulin**, a calcium-binding protein. Calmodulin then activates the enzyme **myosin light chain kinase**, which in turn enables the attachment of myosin heads to actin. This mechanism is quite different from that in skeletal and cardiac muscles, in which the trigger for contraction is the binding of calcium ions to troponin.

Length–Tension Relationships

Because the thick and thin filaments are scattered and are not organized into sarcomeres in smooth muscle, tension development and resting length are not directly related. A stretched smooth muscle soon adapts to its new length and retains the ability to contract on demand. This ability to function over a wide range of lengths is called **plasticity**. Smooth muscle can contract over a range of lengths four times greater than that of skeletal muscle. Plasticity is especially important in digestive organs that undergo great changes in volume, such as the stomach. Despite the lack of sarcomere organization, smooth muscle contractions can be just as powerful as those of skeletal muscles. Like skeletal muscle fibers, smooth muscle cells can undergo sustained contractions.

Control of Contractions

Many smooth muscle cells are not innervated by motor neurons, and the neurons that do innervate smooth muscles are not under voluntary control. Smooth muscle cells are categorized as either multiunit or visceral. **Multiunit smooth muscle cells** are innervated in motor units comparable to those of skeletal muscles, but each smooth muscle cell may be connected to more than a single motor neuron. In contrast, many **visceral smooth muscle cells** lack a direct contact with any motor neuron.

Multiunit smooth muscle cells resemble skeletal muscle fibers and cardiac muscle cells in that neural activity produces an action potential that is propagated over the sarcolemma. However, the contractions of these smooth muscle cells occur more slowly than those of skeletal or cardiac muscle cells. Multiunit smooth muscle cells are located in the iris of the eye, where they regulate the diameter of the pupil; along portions of the male reproductive tract; within the walls of large arteries; and in the arrector pili muscles of the skin. Multiunit smooth muscle cells do not typically occur in the digestive tract.

Visceral smooth muscle cells are arranged in sheets or layers. Within each layer, adjacent muscle cells are connected by gap junctions. As a result, whenever one muscle cell contracts, the electrical impulse that triggered the contraction can travel to adjacent smooth muscle cells. The contraction therefore spreads in a wave that soon involves every smooth muscle cell in the layer. The initial stimulus may be the activation of a motor neuron that contacts one of the muscle cells in the region. But smooth muscle cells also contract or relax in response to chemicals, hormones, local concentrations of oxygen or carbon dioxide, or physical factors such as extreme stretching or irritation.

Many visceral smooth muscle networks show rhythmic cycles of activity in the absence of neural stimulation. These cycles are characteristic of the smooth muscle cells in the wall of the digestive tract, where **pacesetter cells** undergo spontaneous depolarization and trigger the contraction of entire muscular sheets. Visceral smooth muscle cells are located in the walls of the digestive tract, the gallbladder, the urinary bladder, and many other internal organs.

Smooth Muscle Tone

Both multiunit and visceral smooth muscle tissues have a normal background level of activity, or smooth muscle tone. The regulatory mechanisms just detailed stimulate contraction and increase muscle tone. Neural, hormonal, or chemical factors can also stimulate smooth muscle relaxation, producing a decrease in muscle tone. For example, smooth muscle cells at the entrances to capillaries regulate the amount of blood flow into each vessel. If the tissue becomes starved for oxygen, the smooth muscle cells relax, whereupon blood flow increases, delivering additional oxygen. As conditions return to normal, the smooth muscle regains its normal muscle tone.

Concept Check

What feature of cardiac muscle tissue allows the heart to act as a functional syncytium?

Why are cardiac and smooth muscle contractions more affected by changes in extracellular Ca^{2+} than are skeletal muscle contractions?

Smooth muscle can contract over a wider range of resting lengths than skeletal muscle can. Why?

Answers begin on p. A–1

Review the anatomy of cardiac and smooth muscle on the **IP CD-ROM: Muscular System/Anatomy Review: Skeletal Muscle Tissue.**

Chapter Review

Selected Clinical Terminology

botulism: A severe, potentially fatal paralysis of skeletal muscles, resulting from the consumption of a bacterial toxin. [AM] **Duchenne's muscular dystrophy (DMD):** One of the most common and best understood of the muscular dystrophies. [AM] **muscular dystrophies:** A varied collection of inherited diseases that produce progressive muscle weakness and deterioration. [AM] **myasthenia gravis:** A general muscular weakness resulting from a reduction in the number of ACh receptors on the motor end plate.

[AM] **polio:** A disease resulting from the destruction of motor neurons by a certain virus and characterized by the paralysis and atrophy of

motor units. (p. 315 and [AM]) **rigor mortis:** A state following death during which muscles are locked in the contracted position, making the body extremely stiff.

(p. 298) **tetanus:** A disease in which sustained, powerful contractions of skeletal muscles are stimulated by the action of a bacterial toxin. (p. 304)

Study Outline

Skeletal Muscle Tissue and the Muscular System 284

1. The three types of muscle tissue are *skeletal muscle*, *cardiac muscle*, and *smooth muscle*.

2. **Skeletal muscles** attach to bones directly or indirectly. Their functions are to (1) produce skeletal movement, (2) maintain posture and body position, (3) support soft tissues, (4) guard entrances and exits, and (5) maintain body temperature.

Functional Anatomy of Skeletal Muscle p. 284

Organization of Connective Tissues p. 284

1. Each muscle cell or fiber is surrounded by an **endomysium**. Bundles of muscle fibers are sheathed by a **perimysium**, and the entire muscle is covered by an **epimysium**. At the ends of the muscle are **tendons** or **aponeuroses** that attach the muscle to bones. *(Figure 10–1)*

Blood Vessels and Nerves p. 285

2. The epimysium and perimysium contain the blood vessels and nerves that supply the muscle fibers.

Skeletal Muscle Fibers p. 286

3. A skeletal muscle fiber has a **sarcolemma**, or cell membrane; **sarcoplasm** (cytoplasm); and **sarcoplasmic reticulum (SR)**, similar to the smooth endoplasmic reticulum of other cells. **Transverse (T) tubules** and **myofibrils** aid in contraction. Filaments in a myofibril are organized into repeating functional units called **sarcomeres**. *(Figures 10–2 to 10–6)*

4. **Myofilaments** called **thin filaments** and **thick filaments** form myofibrils. *(Figures 10–2 to 10–6)*

5. Thin filaments consist of **F actin**, **nebulin**, **tropomyosin**, and **troponin**. Tropomyosin molecules cover **active sites** on the **G actin** subunits that form the F actin strand. Troponin binds to G actin and tropomyosin and holds the tropomyosin in position. *(Figure 10–7)*

6. Thick filaments consist of a bundle of myosin molecules around a **titin** core. Each myosin molecule has an elongated **tail** and a globular **head**, which forms **cross-bridges** during contraction. In a resting muscle cell, the attachment of myosin heads to active sites on G actin is prevented by tropomyosin. *(Figure 10–7)*

Sliding Filaments and Muscle Contraction p. 291

7. The relationship between thick and thin filaments changes as a muscle fiber contracts. *(Figure 10–8)*

Muscular System/Sliding Filament Theory

The Contraction of Skeletal Muscle p. 292

1. When muscle cells contract, they create *tension* and pull on the attached tendons. *(Figure 10–9)*

The Control of Skeletal Muscle Activity p. 293

2. The activity of a muscle fiber is controlled by a neuron at a **neuromuscular** *(myoneural)* **junction (NMJ)**. *(Figure 10–10)*

3. When an **action potential** arrives at the **synaptic terminal**, **acetylcholine (ACh)** is released into the **synaptic cleft**. The binding of ACh to receptors on the opposing *junctional folds* leads to the generation of an action potential in the sarcolemma. *(Figure 10–10)*

Muscular System/The Neuromuscular Junction

Excitation–Contraction Coupling p. 295

4. **Excitation–contraction coupling** occurs as the passage of an action potential along a T tubule triggers the release of Ca^{2+} from the cisternae of the SR at triads. *(Figure 10–11)*

5. Release of Ca^{2+} initiates a **contraction cycle** of attachment, pivoting, detachment, and return. The calcium ions bind to troponin, which changes position and moves tropomyosin away from the active sites of actin. Cross-bridges of myosin heads then bind to actin. Next, each myosin head pivots at its base, pulling the actin filament toward the center of the sarcomere. *(Figure 10–12/10–13)*

6. Acetylcholinesterase (AChE) breaks down ACh and limits the duration of muscle stimulation. *(Summary Table 10–1)*

Relaxation p. 298

100 Keys | p. 300

Tension Production p. 300

Tension Production by Muscle Fibers p. 300

1. The amount of tension produced by a muscle fiber depends on the number of cross-bridges formed.

2. Skeletal muscle fibers can contract most forcefully when stimulated over a narrow range of resting lengths. *(Figure 10–14)*

3. A **twitch** is a cycle of contraction and relaxation produced by a single stimulus. *(Figure 10–15)*

4. Repeated stimulation at slow rate produces **treppe**, a progressive increase in twitch tension. *(Figure 10–16)*

5. Repeated stimulation before the relaxation phase ends may produce **summation of twitches (wave summation)**, in which one twitch is added to another; **incomplete tetanus**, in which tension peaks because the muscle is never allowed to relax completely; or **complete tetanus**, in which the relaxation phase is eliminated. *(Figure 10–16)*

Tension Production by Skeletal Muscles p. 304

6. The number and size of a muscle's **motor units** determine how precisely controlled its movements are. *(Figure 10–17)*

100 Keys | p. 305

7. Resting **muscle tone** stabilizes bones and joints.

Muscular System/Contraction of Motor Units

8. Normal activities generally include both **isotonic contractions** (in which the tension in a muscle rises and the length of the muscle changes) and **isometric contractions** (in which tension rises, but the length of the muscle remains constant). *(Figure 10–18)*

9. Resistance (load) and speed of contraction are inversely related. *(Figure 10–19)*

10. The return to resting length after a contraction may involve elastic forces, the contraction of opposing muscle groups, and gravity.

Muscular System/Contraction of Whole Muscles

Energy Use and Muscular Activity p. 308

1. Muscle contractions require large amounts of energy. *(Table 10–2)*

ATP and CP Reserves p. 309

2. **Creatine phosphate (CP)** can release stored energy to convert ADP to ATP. *(Table 10–2)*

ATP Generation p. 309

3. At rest or at moderate levels of activity, **aerobic metabolism** can provide most of the ATP needed to support muscle contractions.

4. At peak levels of activity, the cell relies heavily on the **anaerobic process** of **glycolysis** to generate ATP, because the mitochondria cannot obtain enough oxygen to meet the existing ATP demands.

Energy Use and the Level of Muscular Activity p. 310

5. As muscular activity changes, the pattern of energy production and use changes. *(Figure 10–20)*

Muscle Fatigue p. 310

6. A fatigued muscle can no longer contract, because of changes in pH due to the buildup of **lactic acid**, the exhaustion of energy resources, or other factors.

The Recovery Period p. 312

7. The **recovery period** begins immediately after a period of muscle activity and continues until conditions inside the muscle have returned to preexertion levels. The **oxygen debt**, or *excess postexercise oxygen consumption (EPOC)*, created during exercise is the amount of oxygen required during the recovery period to restore the muscle to its normal condition.

100 Keys | p. 312

Hormones and Muscle Metabolism p. 312

8. Circulating hormones may alter metabolic activities in skeletal muscle fibers.

Muscle Performance p. 313 Types of Skeletal Muscle Fibers p. 313

1. The three types of skeletal muscle fibers are **fast fibers**, **slow fibers**, and **intermediate fibers**. *(Table 10–3; Figure 10–21)*

2. Fast fibers, which are large in diameter, contain densely packed myofibrils, large glycogen reserves, and relatively few mitochondria. They produce rapid and powerful contractions of relatively brief duration. *(Figure 10–21)*

3. Slow fibers are about half the diameter of fast fibers and take three times as long to contract after stimulation. Specializations such as abundant mitochondria, an extensive capillary supply, and high concentrations of **myoglobin** enable slow fibers to continue contracting for extended periods. *(Figure 10–21)*

4. Intermediate fibers are very similar to fast fibers, but have a greater resistance to fatigue.

Muscle Performance and the Distribution of Muscle Fibers p. 314

5. Muscles dominated by fast fibers appear pale and are called **white muscles**.

6. Muscles dominated by slow fibers are rich in myoglobin and appear as **red muscles**.

Muscle Hypertrophy and Atrophy p. 315

7. Training to develop anaerobic endurance can lead to **hypertrophy** (enlargement) of the stimulated muscles.

Physical Conditioning p. 315

8. **Anaerobic endurance** is the time over which muscular contractions can be sustained by glycolysis and reserves of ATP and CP.

9. **Aerobic endurance** is the time over which a muscle can continue to contract while supported by mitochondrial activities.

100 Keys | p. 316

Muscular System/Muscle Metabolism

Cardiac Muscle Tissue p. 316 Structural Characteristics of Cardiac Muscle Tissue p. 316

1. **Cardiac muscle tissue** is located only in the heart. **Cardiac muscle cells** are small; have one centrally located nucleus; have short, broad T tubules; and are dependent on aerobic metabolism. **Intercalated discs** are found where cell membranes connect. *(Figure 10–22; Table 10–4)*

Functional Characteristics of Cardiac Muscle Tissue p. 317

2. Cardiac muscle cells contract without neural stimulation (**automaticity**), and their contractions last longer than those of skeletal muscle.

3. Because cardiac muscle twitches do not exhibit wave summation, cardiac muscle tissue cannot produce tetanic contractions.

Smooth Muscle Tissue p. 318 Structural Characteristics of Smooth Muscle Tissue p. 319

1. **Smooth muscle tissue** is nonstriated, involuntary muscle tissue.

2. Smooth muscle cells lack sarcomeres and the resulting striations. The thin filaments are anchored to **dense bodies.** *(Figure 10–23; Table 10–4)*

Functional Characteristics of Smooth Muscle Tissue p. 319

3. Smooth muscle contracts when calcium ions interact with **calmodulin**, which activates **myosin light chain kinase**.

4. Smooth muscle functions over a wide range of lengths (**plasticity**).

5. In **multiunit smooth muscle cells** each smooth muscle cell acts relatively independently of other smooth muscle cells in the organ. **Visceral smooth muscle cells** are not always innervated by motor neurons. Neurons that innervate smooth muscle cells are not under voluntary control.

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you’ll find learning activities, case studies, quizzes, Interactive Physiology exercises and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The connective tissue coverings of a skeletal muscle, listed from superficial to deep, are

(a) endomysium, perimysium, and epimysium

(b) endomysium, epimysium, and perimysium

(c) epimysium, endomysium, and perimysium

(d) epimysium, perimysium, and endomysium

2. The command to contract is distributed deep into a muscle fiber by the

(a) sarcolemma

(b) sarcomere

(c) transverse tubules

(d) myotubules

(e) myofibrils

3. The detachment of the myosin cross-bridges is directly triggered by

(a) the repolarization of T tubules

(b) the attachment of ATP to myosin heads

(c) the hydrolysis of ATP

(d) calcium ions

4. A muscle producing peak tension during rapid cycles of contraction and relaxation is said to be in

(a) incomplete tetanus

(b) treppe

(c) complete tetanus

(d) a twitch

5. The type of contraction in which the tension rises, but the resistance does not move, is

(a) a wave summation

(b) a twitch

(c) an isotonic contraction

(d) an isometric contraction

6. Which of the following statements about myofibrils is *not* correct?

(a) Each skeletal muscle fiber contains hundreds to thousands of myofibrils.

(b) Myofibrils contain repeating units called sarcomeres.

(c) Myofibrils extend the length of a skeletal muscle fiber.

(d) Filaments consist of bundles of myofibrils.

(e) Myofibrils are attached to the cell membrane at both ends of a muscle fiber.

7. An action potential can travel quickly from one cardiac muscle cell to another because of the presence of

(a) gap junctions

(b) tight junctions

(c) intercalated discs

(d) a and c are correct

8. List the three types of muscle tissue in the body.

9. What three layers of connective tissue are part of each muscle? What functional role does each layer play?

10. The ___ contains vesicles filled with acetylcholine.

(a) synaptic terminal

(b) motor end plate

(c) neuromuscular junction

(d) synaptic cleft

(e) transverse tubule

11. What structural feature of a skeletal muscle fiber is responsible for conducting action potentials into the interior of the cell?

12. What five interlocking steps are involved in the contraction process?

13. What two factors affect the amount of tension produced when a skeletal muscle contracts?

14. What forms of energy reserves do resting skeletal muscle fibers contain?

15. What two mechanisms are used to generate ATP from glucose in muscle cells?

16. What is the calcium-binding protein in smooth muscle tissue?

LEVEL 2 Reviewing Concepts

17. An activity that would require anaerobic endurance is

(a) a 50-meter dash

(b) a pole vault

(c) a weight-lifting competition

(d) a, b, and c are correct

18. Areas of the body where you would not expect to find slow fibers include the

(a) back and calf muscles **(b)** eye and hand

(c) chest and abdomen **(d)** a, b, and c are correct

19. During relaxation, muscles return to their original length because of all of the following *except*

(a) actin and myosin actively pushing away from one another

(b) the contraction of opposing muscles

(c) the pull of gravity

(d) the elastic nature of the sarcolemma

(e) elastic forces

20. According to the length–tension relationship

(a) longer muscles can generate more tension than shorter muscles

(b) the greater the zone of overlap in the sarcomere the greater the tension the muscle can develop

(c) the greatest tension is achieved in sarcomeres where the actin and myosin initially do not overlap

(d) there is an optimum range of actin and myosin overlap that will produce the greatest amount of tension

(e) both (b) and (d)

21. Describe the graphic events seen on a myogram as tension is developed in a stimulated calf muscle fiber during a twitch.

22. What three processes are involved in repaying the oxygen debt during a muscle's recovery period?

23. How does cardiac muscle tissue contract without neural stimulation?

24. Atracurium is a drug that blocks the binding of ACh to receptors. Give an example of a site where such binding normally occurs, and predict the physiological effect of this drug.

25. The time of a murder victim's death may be estimated by the flexibility of the body. Explain why.

26. Which of the following activities would employ isometric contractions?

(a) flexing the forearm

(b) chewing food

(c) maintaining an upright posture

(d) running

(e) writing

LEVEL 3 Critical Thinking and Clinical Applications

27. Many potent insecticides contain toxins, called organophosphates, that interfere with the action of the enzyme acetylcholinesterase. Ivan is using an insecticide containing organophosphates and is very careless. He does not use gloves or a dust mask and absorbs some of the chemical through his skin. He inhales a large amount as well. What symptoms would you expect to observe in Ivan as a result of the organophosphate poisoning?

28. Linda's father suffers an apparent heart attack and is rushed to the emergency room of the local hospital. The doctor on call tells her that he has ordered some blood work and that he will be able to tell if her father actually had an attack by looking at the levels of CPK, LDH, and cardiac troponin the blood. Why would the level of these enzymes help to indicate if a person suffered a heart attack?

29. Bill broke his leg in a football game, and after 6 weeks in a cast, the cast is finally removed. As he steps down from the table after the cast is removed, he loses his balance and falls. Why?

| SUMMARY TABLE 10–1 | STEPS INVOLVED IN SKELETAL MUSCLE CONTRACTION

STEPS THAT INITIATE A CONTRACTION:

1. At the neuromuscular junction (NMJ), ACh released by the synaptic terminal binds to receptors on the sarcolemma.
2. The resulting change in the transmembrane potential of the muscle fiber leads to the production of an action potential that spreads across the entire surface of the muscle fiber and along the T tubules.
3. The sarcoplasmic reticulum (SR) releases stored calcium ions, increasing the calcium concentration of the sarcoplasm in and around the sarcomeres.
4. Calcium ions bind to troponin, producing a change in the orientation of the troponin–tropomyosin complex that exposes active sites on the thin (actin) filaments. Cross-bridges form when myosin heads bind to active sites on F actin.
5. The contraction begins as repeated cycles of cross-bridge binding, pivoting, and detachment occur, powered by the hydrolysis of ATP. These events produce filament sliding, and the muscle fiber shortens.

STEPS THAT END A CONTRACTION:

6. Action potential generation ceases as ACh is broken down by acetylcholinesterase (AChE).
7. The SR reabsorbs calcium ions, and the concentration of calcium ions in the sarcoplasm declines.

8. When calcium ion concentrations approach normal resting levels, the troponin–tropomyosin complex returns to its normal position. This change re-covers the active sites and prevents further cross-bridge interaction.

9. Without cross-bridge interactions, further sliding cannot take place, and the contraction ends.

10. Muscle relaxation occurs, and the muscle returns passively to its resting length.

TABLE 10–2 Sources of Energy Stored in a Typical Muscle Fiber

Number of Twitches Duration of Isometric Tetanic

Energy Supported by Each Contraction Supported by Each

Stored as Utilized through Initial Quantity Energy Source Alone Energy Source Alone

- **FIGURE 10–5** Sarcomere Structure, Part II. **(a)** A superficial view of a sarcomere. **(b)** Cross-sectional views of different portions of a sarcomere. Dashed lines show the relationships between thick and thin filaments in the zone of overlap.
- **FIGURE 10–6** Levels of Functional Organization in a Skeletal Muscle
- **FIGURE 10–7** Thick and Thin Filaments. **(a)** The gross structure of a thin filament, showing the attachment at the Z line. **(b)** The organization of G actin subunits in an F actin strand, and the position of the troponin–tropomyosin complex. **(c)** The structure of thick filaments, showing the orientation of the myosin molecules. **(d)** The structure of a myosin molecule.
- **FIGURE 10–8** Changes in the Appearance of a Sarcomere during the Contraction of a Skeletal Muscle Fiber. **(a)** During a contraction, the A band stays the same width, but the Z

lines move closer together and the I band gets smaller. **(b)** When the ends of a myofibril are free to move, the sarcomeres shorten simultaneously and the ends of the myofibril are pulled toward its center.

•**FIGURE 10–9** An Overview of Skeletal Muscle Contraction. The major factors are indicated here as a series of interrelated steps and processes. Each factor will be described further in a related section of the text. A simplified version of this figure will appear in later figures as a Navigator icon; its presence indicates that we are taking another step in the discussion.

• **FIGURE 10–10** Skeletal Muscle Innervation. The Navigator in the shadow box highlights your location in the discussion. **(a)** A diagrammatic view of a neuromuscular junction. **(b)** Details of the neuromuscular junction. **(c)** Changes at the motor end plate that trigger an action potential in the sarcolemma.

• **FIGURE 10–11** The Exposure of Active Sites. **(a)** In a resting sarcomere, the tropomyosin strands cover the active sites on the thin filaments, preventing cross-bridge formation. **(b)** When calcium ions enter the sarcomere, they bind to troponin, which rotates and swings the tropomyosin away from the active sites. **(c)** Cross-bridge formation then occurs, and the contraction cycle begins.

• **FIGURE 10–12** The Contraction Cycle

• **FIGURE 10–13** Shortening During a Contraction. **(a)** When both ends are free to move, the ends of a contracting muscle fiber move toward the center of the muscle fiber. **(b)** When one end of a myofibril is fixed in position, and the other end free to move, the free end is pulled toward the fixed end.

• **FIGURE 10–14** The Effect of Sarcomere Length on Active Tension. **(a)** Maximum tension is produced when the zone of overlap is large but the thin filaments do not extend across the sarcomere’s center. **(b)** If the sarcomeres are stretched too far, the zone of overlap is reduced or disappears, and cross-bridge interactions are reduced or cannot occur. **(c)** At short resting lengths, thin filaments extending across the center of the sarcomere interfere with the normal orientation of thick and thin filaments, reducing tension production. **(d)** When the thick filaments contact the Z lines, the sarcomere cannot shorten—the myosin heads cannot pivot and tension cannot be produced. The width of the light purple area represents the normal range of resting sarcomere lengths.

- **FIGURE 10–15** The Development of Tension in a Twitch. **(a)** A myogram showing differences in tension over time for a twitch in different skeletal muscles. **(b)** The details of tension over time for a single twitch in the gastrocnemius muscle. Notice the presence of a latent period, which corresponds to the time needed for the conduction of an action potential and the subsequent release of calcium ions by the sarcoplasmic reticulum.
- **FIGURE 10–16** Effects of Repeated Stimulations. **(a)** Treppe is an increase in peak tension with each successive stimulus delivered shortly after the completion of the relaxation phase of the preceding twitch. **(b)** Wave summation occurs when successive stimuli arrive before the relaxation phase has been completed. **(c)** Incomplete tetanus occurs if the stimulus frequency increases further. Tension production rises to a peak, and the periods of relaxation are very brief. **(d)** During complete tetanus, the stimulus frequency is so high that the relaxation phase is eliminated; tension plateaus at maximal levels.
- **FIGURE 10–17** The Arrangement and Activity of Motor Units in a Skeletal Muscle. **(a)** Muscle fibers of different motor units are intermingled, so the forces applied to the tendon remain roughly balanced regardless of which motor units are stimulated. **(b)** The tension applied to the tendon remains relatively constant, even though individual motor units cycle between contraction and relaxation.
- **FIGURE 10–18** Isotonic and Isometric Contractions. **(a, b)** This muscle is attached to a weight less than its peak tension capabilities. On stimulation, it develops enough tension to lift the weight. Tension remains constant for the duration of the contraction, although the length of the muscle changes. This is an example of isotonic contraction. **(c, d)** The same muscle is attached to a weight that exceeds its peak tension capabilities. On stimulation, tension will rise to a peak, but the muscle as a whole cannot shorten. This is an isometric contraction.

- **FIGURE 10–19** Resistance and Speed of Contraction. The heavier the resistance on a muscle, the longer it will take for the muscle to begin to shorten and the less the muscle will shorten.
- **FIGURE 10–20** Muscle Metabolism. **(a)** A resting muscle breaks down fatty acids by aerobic metabolism to make ATP. Surplus ATP is used to build reserves of creatine phosphate (CP) and glycogen. **(b)** At moderate activity levels, mitochondria can meet ATP demands through the aerobic metabolism of fatty acids and glucose. **(c)** At peak activity levels, mitochondria cannot get enough oxygen to meet ATP demands. Most of the ATP is provided by glycolysis, leading to the production of lactic acid.
- **FIGURE 10–21** Fast versus Slow Fibers. **(a)** A longitudinal section, showing more mitochondria (M) and a more extensive capillary supply (cap) in a slow fiber (R, for red) than in a fast fiber (W, for white). **(b)** Cross sections of both types of fibers. Note the larger diameter of fast fibers.
- **FIGURE 10–22** Cardiac Muscle Tissue. **(a)** A light micrograph of cardiac muscle tissue. Notice the striations and the intercalated discs. **(b, c)** The structure of a cardiac muscle cell; compare with *Figure 10–3*.
- **FIGURE 10–23** Smooth Muscle Tissue. **(a)** Many visceral organs contain several layers of smooth muscle tissue oriented in different directions. Here, a single sectional view shows smooth muscle cells in both longitudinal (L) and transverse (T) sections. **(b)** A single relaxed smooth muscle cell is spindle shaped and has no striations. Note the changes in cell shape as contraction occurs.

Muscle Organization and Function

Objectives

- Describe the arrangement of fascicles in the various types of muscles and explain the resulting functional differences.
- Describe the classes of levers and how they make muscles more efficient.

Although most skeletal muscle fibers contract at similar rates and shorten to the same degree, variations in microscopic and macroscopic organization can dramatically affect the power, range, and speed of movement produced when muscles contract.

Organization of Skeletal Muscle Fibers

Muscle fibers in a skeletal muscle form bundles called *fascicles*. l**p. 248** The muscle fibers in a single fascicle are parallel, but the organization of fascicles in skeletal muscles can vary, as can the relationship between the fascicles and the associated tendon. Based on the patterns of fascicle organization, skeletal muscles can be classified as *parallel muscles, convergent muscles, pennate muscles,* and *circular muscles* (Figure 11–1•).

Parallel Muscles

In a **parallel muscle**, the fascicles are parallel to the long axis of the muscle. Most of the skeletal muscles in the body are parallel muscles. Some are flat bands with broad attachments (*aponeuroses*) at each end; others are plump and cylindrical, with tendons at one or both ends. In the latter case, the muscle is spindle-shaped (Figure 11–1a•), with a central **body**, also known as the *belly*, or *gaster* (GAS-ter; stomach). The *biceps brachii muscle* of the arm is a parallel muscle with a central body. When a parallel muscle contracts, it shortens and gets larger in diameter. You can see the bulge of the contracting biceps brachii muscle on the anterior surface of your arm when you flex your elbow.

A skeletal muscle fiber can contract until it has shortened by roughly 30 percent. Because the muscle fibers in a parallel muscle are parallel to the long axis of the muscle, when those fibers contract together the entire muscle shortens by about 30 percent. Thus, if the muscle is 10 cm long and one end is held in place, the other end will move 3 cm when the muscle contracts. The ten sion developed during this contraction depends on the total number of myofibrils the muscle contains. l**p. 305** Because the myofibrils are distributed evenly through the sarcoplasm of each cell, we can use the cross-sectional area of the resting muscle to estimate the tension. For each 6.45 cm^2 (1 $in.^2$) in cross-sectional area, a parallel muscle can develop approximately 23 kg (50 lb) of isometric tension.

Convergent Muscles

In a **convergent muscle**, muscle fascicles extending over a broad area converge on a common attachment site (Figure 11–1b•). The muscle may pull on a tendon, an aponeurosis, or a slender band of collagen fibers known as a **raphe** (RA-fe; seam). The muscle fibers typically spread out, like a fan or a broad triangle, with a tendon at the apex. Examples include the prominent *pectoralis muscles* of the chest. A convergent muscle is versatile, because the stimulation of different portions of the muscle can change the direction of pull. However, when the entire muscle contracts, the muscle fibers do not pull as hard on the attachment site as would a parallel muscle of the same size. This is because convergent muscle fibers pull in different directions, rather than all pulling in the same direction.

Pennate Muscles

In a **pennate muscle** (*penna*, feather), the fascicles form a common angle with the tendon. Because the muscle fibers pull at an angle, contracting pennate muscles do not move their tendons as far as parallel muscles do. But a pennate muscle contains more muscle fibers—and thus more myofibrils—than does a parallel muscle of the same size, and so produces more tension.

If all the muscle fibers are on the same side of the tendon, the pennate muscle is *unipennate*. The *extensor digitorum muscle*, a forearm muscle that extends the finger joints, is unipennate (Figure 11–1c•). More commonly, a pennate muscle has fibers on both sides of the tendon. Such a muscle is called *bipennate*. The *rectus femoris muscle*, a prominent muscle that extends the knee, is bipennate (Figure 11–1d•). If the tendon branches within a pennate muscle, the muscle is said to be *multipennate*. The triangular *deltoid muscle* of the shoulder is multipennate (Figure 11–1e•).

Circular Muscles

In a **circular muscle**, or **sphincter** (SFINK-ter), the fascicles are concentrically arranged around an opening or a recess. When the muscle contracts, the diameter of the opening decreases. Circular muscles guard entrances and exits of internal passageways such as the digestive and urinary tracts. An example is the *orbicularis oris muscle* of the mouth (Figure 11–1f•).

Levers

Skeletal muscles do not work in isolation. For muscles attached to the skeleton, the nature and site of the connection determine the force, speed, and range of the movement produced. These characteristics are interdependent, and the relationships can explain a great deal about the general organization of the muscular and skeletal systems.

The force, speed, or direction of movement produced by contraction of a muscle can be modified by attaching the muscle to a lever. A **lever** is a rigid structure—such as a board, a crowbar, or a bone—that moves on a fixed point called the **fulcrum**. A lever moves when an applied force (AF) is sufficient to overcome any resistance (R) that would otherwise oppose or prevent such movement. In the body, each bone is a lever and each joint is a fulcrum, and muscles provide the applied force. The resistance can vary from the weight of an object held in the hand to the weight of a limb or the weight of the entire body, depending on the situation. The important thing about levers is that they can change (1) the direction of an applied force, (2) the distance and speed of movement produced by an applied force, and (3) the effective strength of an applied force.

Classes of Levers

There are three classes of levers, and examples of each are found in the human body (Figure 11–2•). The seesaw or teeter-totter is an example of a **first-class lever**. In such a lever, the fulcrum (F) lies between the applied force (AF) and the resistance (R). The body has few first-class levers. One, involved with extension of the neck, is shown in Figure 11–2a•.

In a **second-class lever** (Figure 11–2b•), the resistance is located between the applied force and the fulcrum. A familiar example is a loaded wheelbarrow. The weight of the load is the resistance, and the upward lift on the handle is the applied force. Because in this arrangement the force is always farther from the fulcrum than the resistance is, a small force can move a larger weight. That is, the effective force is increased. Notice, however, that when a force moves the handle, the load moves more slowly and covers a shorter distance. Thus the effective force is increased at the expense of speed and distance. The body has few second-class levers. Ankle extension (plantar flexion) by the calf muscles involves a second-class lever (Figure 11–2b•).

Third-class levers are the most common levers in the body. In this lever system, a force is applied between the resistance and the fulcrum (Figure 11–2c•). The effect is the reverse of that for a second-class lever: Speed and distance traveled are increased at the expense of effective force. In the example shown (the biceps brachii muscle, which flexes the elbow), the resistance is six times farther from the fulcrum than is the applied force. The effective force is reduced to the same degree. The muscle must generate 180 kg of tension at its attachment to the forearm to support 30 kg held in the hand. However, the distance traveled and the speed of movement are increased by that same 6 : 1 ratio: The load will travel 45 cm when the point of attachment moves 7.5 cm.

Although not every muscle operates as part of a lever system, the presence of levers provides speed and versatility far in excess of what we would predict on the basis of muscle physiology alone. Skeletal muscle fibers resemble one another closely, and their abilities to contract and generate tension are quite similar. Consider a skeletal muscle that can shorten 1 cm while it exerts a 10-kg pull. Without using a lever, this muscle would be performing efficiently only when moving a 10-kg weight a distance of 1 cm. By using a lever, however, the same muscle operating at the same efficiency could move 20 kg a distance of 0.5 cm, 5 kg a distance of 2 cm, or 1 kg a distance of 10 cm.

100 Keys | Most skeletal muscles can shorten to roughly 70 percent of their “ideal” resting length. The versatility in terms of power, speed, and range of body movements results from differences in the positions of muscle attachments relative to the joints involved.

Concept Check

Why does a pennate muscle generate more tension than does a parallel muscle of the same size? Which type of fascicle arrangement would you expect in a muscle guarding the opening between the stomach and the small intestine? The joint between the occipital bone of the skull and the first cervical vertebra (atlas) is part of which type of lever system?

Answers begin on p. A–1

Muscle Terminology

Objectives

- Predict the actions of a muscle on the basis of the relative positions of its origin and insertion.
- Explain how muscles interact to produce or oppose movements.
- Explain how the name of a muscle can help identify its location, appearance, or function.

This chapter focuses on the functional anatomy of skeletal muscles and muscle groups. You must learn a number of new terms, and this section attempts to help you understand them. It may also help you to create a vocabulary list from the terms introduced. Once you are familiar with the basic terminology, the names and actions of skeletal muscles are easily understood.

Origins and Insertions

In Chapter 10 we noted that when both ends of a myofibril are free to move, the ends move toward the center during a contraction. l**p. 298** In the body, however, the ends of a skeletal muscle are always attached to other structures that limit their movement. In most cases one end is fixed in position, and during a contraction the other end moves toward the fixed end. The place

where the fixed end attaches to a bone, cartilage, or connective tissue is called the **origin** of the muscle. The site where the movable end attaches to another structure is called the **insertion** of the muscle. The origin is typically proximal to the insertion. When a muscle contracts, it produces a specific **action**, or movement. Actions are described using the terms introduced in Chapter 9 (flexion, extension, adduction, and so forth).

As an example, consider the *gastrocnemius muscle*, a calf muscle that extends from the distal portion of the femur to the calcaneus. As Figure 11–2b• shows, when the gastrocnemius muscle contracts, it pulls the calcaneus toward the knee. As a result, we say that the gastrocnemius muscle has its origin at the femur and its insertion at the calcaneus; its action can be described as “extension at the ankle” or “plantar flexion.”

The decision as to which end is the origin and which is the insertion is usually based on movement from the anatomical position. Part of the fun of studying the muscular system is that you can actually do the movements and think about the muscles involved. As a result, laboratory discussions of the muscular system tend to resemble disorganized aerobics classes.

When the origins and insertions cannot be determined easily on the basis of movement from the anatomical position, other rules are used. If a muscle extends between a broad aponeurosis and a narrow tendon, the aponeurosis is the origin and the tendon is the insertion. If several tendons are at one end and just one is at the other, the muscle has multiple origins and a single insertion. These simple rules cannot cover every situation. Knowing which end is the origin and which is the insertion is ultimately less important than knowing where the two ends attach and what the muscle accomplishes when it contracts.

Most muscles originate at a bone, but some originate at a connective-tissue sheath or band. Examples of these sheaths or bands include *intermuscular septa* (components of the deep fascia that may separate adjacent skeletal muscles), *tendinous inscriptions* that join muscle fibers to form long muscles such as the *rectus abdominis*, the interosseous membranes of the forearm or leg, and the fibrous sheet that spans the obturator foramen of the pelvis.

Actions

Almost all skeletal muscles either originate or insert on the skeleton. When a muscle moves a portion of the skeleton, that movement may involve flexion, extension, adduction, abduction, protraction, retraction, elevation, depression, rotation, circumduction, pronation, supination, inversion, eversion, lateral flexion, or opposition. (Before proceeding, you may want to review the discussions of planes of motion and Figures 9–2 to 9–5•.) l**pp. 263–267**

Actions can be described in one of two ways. The first, used by most undergraduate textbooks and references such as *Gray's Anatomy*, describes actions in terms of the bone or region affected. Thus, a muscle such as the biceps brachii muscle is said to perform "flexion of the forearm." The second way, of increasing use among specialists such as kinesiologists and physical therapists, identifies the joint(s) involved. In this approach, the action of the biceps brachii muscle would be "flexion at (or of) the elbow." Both approaches are valid, and each has its advantages. In general, we will use the latter approach.

When complex movements occur, muscles commonly work in groups rather than individually. Their cooperation improves the efficiency of a particular movement. For example, large muscles of the limbs produce flexion or extension over an extended range of motion. Although these muscles cannot produce powerful movements at full extension due to the relative positions of the articulating bones, they are generally paired with one or more smaller muscles that provide assistance until the larger muscle can perform at maximum efficiency. At the start of the movement, the smaller muscle is producing maximum tension, while the larger muscle is producing minimum tension. The importance of this smaller "assistant" decreases as the movement proceeds and the effectiveness of the primary muscle increases.

Based on their functions, muscles are described as follows:

- An **agonist**, or **prime mover**, is a muscle whose contraction is chiefly responsible for producing a particular movement. The biceps brachii muscle is an agonist that produces flexion at the elbow.
- An **antagonist** is a muscle whose action opposes that of a particular agonist. The *triceps brachii muscle* is an agonist that extends the elbow. It is therefore an antagonist of the biceps brachii muscle, and the biceps brachii is an antagonist of the triceps brachii. Agonists and antagonists are functional opposites; if one produces flexion, the other will produce extension. When an agonist contracts to produce a particular movement, the corresponding antagonist will be stretched, but it will usually not relax completely. Instead, it will contract eccentrically, with just enough tension to control the speed of the movement and ensure its

smoothness. l**p. 306** You may find it easiest to learn about muscles in agonist–antagonist pairs (flexors–extensors, abductors–adductors) that act at a specific joint. This method highlights the functions of the muscles involved, and it can help organize the information into a logical framework. The tables in this chapter are arranged to facilitate such an approach.

- When a **synergist** (*syn-*, together + *ergon*, work) contracts, it helps a larger agonist work efficiently. Synergists may provide additional pull near the insertion or may stabilize the point of origin. Their importance in assisting a particular movement may change as the movement progresses. In many cases, they are most useful at the start, when the agonist is stretched and unable to develop maximum tension. For example, the *latissimus dorsi muscle* is a large trunk muscle that extends, adducts, and medially rotates the arm at the shoulder joint. A much smaller muscle, the *teres* (TER-z) *major muscle*, assists in starting such

e movements when the shoulder joint is at full flexion. Synergists may also assist an agonist by preventing movement at another joint and thereby stabilizing the origin of the agonist. Such synergists are called **fixators**.

Names of Skeletal Muscles

Except for the *platysma* and the *diaphragm*, the complete names of all skeletal muscles include the term *muscle*. Although the full name, such as the biceps brachii muscle, will usually appear in the text, for simplicity only the descriptive name (biceps brachii) will be used in figures and tables.

You need not learn every one of the approximately 700 muscles in the human body, but you will have to become familiar with the most important ones. Fortunately, the names anatomists assigned to the muscles include descriptive terms that can help you remember the names and identify the muscles. When faced with a new muscle name, it is helpful to first identify the descriptive portions of the name. The name of a muscle may include descriptive information about its location in the body, origin and insertion, fascicle organization, relative position, structural characteristics, and action.

Location in the Body

Table 11–1 includes a useful summary of muscle terminology, including terms that designate specific regions of the body. Regional terms are most common as modifiers that help identify individual muscles. In a few cases, a muscle is such a prominent feature of a body region that a name referring to the region alone will identify it. Examples include the *temporalis muscle* of the head and the *brachialis* (bra-ke-A-lis) *muscle* of the arm.

Origin and Insertion

Many muscle names include terms for body locales that tell you the specific origin and insertion of each muscle. In such cases, the first part of the name indicates the origin, the second part the insertion. The *genioglossus muscle*, for example, originates at the chin (*geneion*) and inserts in the tongue (*glossus*). The names may be long and difficult to pronounce, but Table 11–1 and the

anatomical terms introduced in Chapter 1 can help you identify and remember them. l**pp. 16–23**

Fascicle Organization

A muscle name may refer to the orientation of the muscle fascicles within a particular skeletal muscle. **Rectus** means “straight,” and rectus muscles are parallel muscles whose fibers generally run along the long axis of the body. Because we have several rectus muscles, the name typically includes a second term that refers to a precise region of the body. For example, the *rectus abdominis muscle* is located on the abdomen, and the *rectus femoris muscle* on the thigh. Other common directional indicators include **transversus** and **oblique**, for muscles whose fibers run across or at an oblique angle to the longitudinal axis of the body, respectively.

Relative Position

Muscles visible at the body surface are often called **externus** or **superficialis**, whereas deeper muscles are termed **internus** or **profundus**. Superficial muscles that position or stabilize an organ are called **extrinsic**; muscles located entirely within an organ are **intrinsic**.

Structural Characteristics

Some muscles are named after distinctive structural features. The biceps brachii muscle, for example, has two tendons of origin (*bi-*, two + *caput*, head); the triceps brachii muscle has three; and the *quadriceps group*, four. Shape is sometimes an important clue to the name of a muscle. For example, the *trapezius* (tra-PE-ze-us), *deltoid*, *rhomboid* (ROM-boyd), and *orbicularis* (or-bik-u -LA-ris) muscles look like a trapezoid, a triangle, a rhomboid, and a circle, respectively. Many terms refer to muscle size. Long muscles are called **longus** (long) or **longissimus** (longest), and **teres** muscles are both long and round. Short muscles are called **brevis**. Large ones are called **magnus** (big), **major** (bigger), or **maximus** (biggest); small ones are called **minor** (smaller) or **mini-mus** (smallest).

Action

Many muscles are named *flexor*, *extensor*, *pronator*, *abductor*, and so on. These are such common actions that the names almost always include other clues as to the appearance or location of the muscle. For example, the *extensor carpi radialis longus muscle* is a long muscle along the radial (lateral) border of the forearm. When it contracts, its primary function is extension at the carpus (wrist).

A few muscles are named after the specific movements associated with special occupations or habits. The *sartorius* (sar-TOR-e -us) *muscle* is active when you cross your legs. Before sewing machines were invented, a tailor would sit on the floor cross-legged, and the name of this muscle was derived from *sartor*, the Latin word for "tailor." The *buccinator* (BUK-si-n -tor) *muscle* on the

a face compresses the cheeks— when, for example, you purse your lips and blow forcefully. *Buccinator* translates as "trumpet player." Another facial muscle, the *risorius* (ri-SOR--us) *muscle*, was supposedly named after the mood expressed. However, the Latin

e word *risor* means "laughter"; a more appropriate description for the effect would be "grimace."

Axial and Appendicular Muscles

The separation of the skeletal system into axial and appendicular divisions provides a useful guideline for subdividing the muscular system as well:

1. The **axial muscles** arise on the axial skeleton. They position the head and spinal column and also move the rib cage, assisting

in the movements that make breathing possible. They do not play a role in movement or support of either the pectoral or pelvic girdle or the limbs. This category encompasses roughly 60 percent of the skeletal muscles in the body.

2. The **appendicular muscles** stabilize or move components of the appendicular skeleton and include the remaining 40 percent of all skeletal muscles.

Figure 11–3• provides an overview of the major axial and appendicular muscles of the human body. These are superficial muscles, which tend to be relatively large. The superficial muscles cover deeper, smaller muscles that cannot be seen unless the overlying muscles are either removed or *reflected*—that is, cut and pulled out of the way. Later figures that show deep muscles in specific regions will indicate for the sake of clarity whether superficial muscles have been removed or reflected.

Paying attention to patterns of origin, insertion, and action, we will now examine representatives of both muscular divisions. The discussion assumes that you already understand skeletal anatomy. As you examine the figures in this chapter, you will find that some bony and cartilaginous landmarks are labeled to provide orientation. These labels are shown in italics, to differentiate these landmarks from the muscles and tendons that are the primary focus of each figure. Should you need further review of skeletal anatomy, figure captions in this chapter indicate the relevant figures in Chapters 7, 8, and 9.

The tables that follow also contain information about the innervation of the individual muscles. **Innervation** is the distribution of nerves to a region or organ; the tables indicate the nerves that control each muscle. Many of the muscles of the head and neck are innervated by cranial nerves, which originate at the brain and pass through the foramina of the skull. Alternatively, spinal nerves are connected to the spinal cord and pass through the intervertebral foramina. For example, spinal nerve L1 passes between vertebrae L1 and L2. Spinal nerves may form a complex network after exiting the spinal cord; one branch of this network may contain axons from several spinal nerves. Thus, many tables identify the spinal nerves involved as well as the names of the peripheral nerves.

Concept Check

The *gracilis muscle* is attached to the anterior surface of the tibia at one end, and to the pubis and ischium of the pelvis at the other. When the muscle contracts, flexion occurs at the hip. Which attachment point is the muscle's origin?

Muscle A abducts the humerus, and muscle B adducts the humerus. What is the relationship between these two muscles?

What does the name *flexor carpi radialis longus* tell you about this muscle?

Answers begin on p. A–1

The Axial Muscles

Objective

- Identify the principal axial muscles of the body and indicate their origins, insertions, actions, and innervation.

The axial muscles fall into logical groups on the basis of location, function, or both. The groups do not always have distinct anatomical boundaries. For example, a function such as extension of the vertebral column involves muscles along its entire length and movement at each of the intervertebral joints. We will discuss the axial muscles in four groups:

1. *The Muscles of the Head and Neck.* This group includes muscles that move the face, tongue, and larynx. They are therefore responsible for verbal and nonverbal communication—laughing, talking, frowning, smiling, whistling, and so on. You also use these muscles while eating—especially in sucking and chewing—and even while looking for food, as some of them control your eye movements. The group does not include muscles of the neck that are involved with movements of the vertebral column.

2. *The Muscles of the Vertebral Column.* This group includes numerous flexors, extensors, and rotators of the vertebral column.

3. *The Oblique and Rectus Muscles.* This group forms the muscular walls of the thoracic and abdominopelvic cavities between the first thoracic vertebra and the pelvis. In the thoracic area these muscles are partitioned by the ribs, but over the abdominal surface they form broad muscular sheets. The neck also has oblique and rectus muscles. Although they do not form a complete muscular wall, they share a common developmental origin with the oblique and rectus muscles of the trunk. ATLAS: Embryology Summary 9: The Development of the Muscular System

4. *The Muscles of the Pelvic Floor.* These muscles extend between the sacrum and pelvic girdle. The group forms the *perineum,* a muscular sheet that closes the pelvic outlet.

Muscles of the Head and Neck

We can divide the muscles of the head and neck into several functional groups. The *muscles of facial expression*, the *muscles of mastication* (chewing), the *muscles of the tongue*, and the *muscles of the pharynx* originate on the skull or hyoid bone. Muscles involved with sight and hearing also are based on the skull. Here, we will consider the *extrinsic eye muscles*—those associated with movements of the eye. We will discuss the intrinsic eye muscles, which control the diameter of the pupil and the shape of the lens, and the tiny skeletal muscles associated with the auditory ossicles, in Chapter 17. In the neck, the *extrinsic muscles of the larynx* adjust the position of the hyoid bone and larynx. We will examine the intrinsic laryngeal muscles, including those of the vocal cords, in Chapter 23.

Muscles of Facial Expression

The muscles of facial expression originate on the surface of the skull (Figure 11–4• and Table 11–2, p. 338). At their insertions, the fibers of the epimysium are woven into those of the superficial fascia and the dermis of the skin: Thus, when they contract, the skin moves.

The largest group of facial muscles is associated with the mouth. The **orbicularis oris** muscle constricts the opening, and other muscles move the lips or the corners of the mouth. The **buccinator** muscle has two functions related to eating (in addition to its importance to musicians). During chewing, it cooperates with the masticatory muscles by moving food back across the teeth from the *vestibule*, the space inside the cheeks. In infants, the buccinator provides suction for suckling at the breast.

Smaller groups of muscles control movements of the eyebrows and eyelids, the scalp, the nose, and the external ear. The **epicranium** (ep-i-KRA-ne-um; *epi-*, on + *kranion*, skull), or scalp, contains the **temporoparietalis** muscle and the **occipitofrontalis** muscle, which has a *frontal belly* and an *occipital belly*. The two bellies are separated by the **epicranial aponeurosis**, a thick, collagenous sheet. The **platysma** (pla-TIZ-muh; *platy*, flat) covers the anterior surface of the neck, extending from the base of the neck to the periosteum of the mandible and the fascia at the corner of the mouth. One of the effects of aging is the loss of muscle tone in the platysma, resulting in a looseness of the skin of the anterior throat.

Extrinsic Eye Muscles

Six extrinsic eye muscles, also known as the **extra-ocular muscles** or *oculomotor muscles*, originate on the surface of the orbit and control the position of each eye. These muscles, shown in Figure 11–5• and detailed in Table 11–3, are the **inferior rectus**, **medial rectus**, **superior rectus**, **lateral rectus**, **inferior oblique**, and **superior oblique** muscles.

Muscles of Mastication

The muscles of mastication (Figure 11–6• and Table 11–4) move the mandible at the temporomandibular joint. The large **masseter** muscle is the strongest jaw muscle. The **temporalis** muscle assists in elevation of the mandible. You can feel these muscles in action by gritting your teeth while resting your hand on the side of your face below and then above the zygomatic arch. The **pterygoid** muscles, used in various combinations, can elevate, depress, or protract the mandible or slide it from side to side, a movement called *lateral excursion*. These movements are important in making efficient use of your teeth while you chew foods of various consistencies.

Muscles of the Tongue

The muscles of the tongue have names ending in *glossus*, the Greek word for “tongue.” The **palatoglossus** muscle originates at the palate, the **styloglossus** muscle at the styloid process of the temporal bone, the **genioglossus** muscle at the chin, and the **hyoglossus** muscle at the hyoid bone (Figure 11–7•). These muscles, used in various combinations, move the tongue in the delicate and complex patterns necessary for speech, and manipulate food within the mouth in preparation for swallowing (Table 11–5).

Muscles of the Pharynx

The muscles of the pharynx (Figure 11–8• and Table 11–6) are responsible for initiating the swallowing process. The **pharyngeal constrictor** muscles (*superior*, *middle*, and *inferior*) move materials into the esophagus by constricting the pharyngeal walls. The **laryngeal elevator** muscles elevate the larynx. The two **palatal muscles**—the *tensor veli palatini* and the *levator veli palatini*— elevate the soft palate and adjacent portions of the pharyngeal wall and also pull open the entrance to the auditory tube. As a result, swallowing repeatedly can open the entrance to the auditory tube and help you adjust to pressure changes when you fly or dive.

Anterior Muscles of the Neck

The anterior muscles of the neck include (1) five muscles that control the position of the larynx, (2) muscles that depress the mandible and tense the floor of the mouth, and (3) muscles that provide a stable foundation for muscles of the tongue and pharynx (Figure 11–9• and Table 11–7). The **digastric** (d -GAS-trik) muscle has two bellies, as the name implies (*di-*, two + *gaster*,

ı stomach). One belly extends from the chin to the hyoid bone; the other continues from the hyoid bone to the mastoid portion of the temporal bone. Depending on which belly contracts and whether fixator muscles are stabilizing the position of the hyoid bone, the digastric muscle can open the mouth by depressing the mandible, or it can elevate the larynx by raising the hyoid bone. The digastric muscle overlies the broad, flat **mylohyoid** muscle, which provides a muscular floor to the mouth, aided by the deeper **geniohyoid** muscles that extend between the hyoid bone and the chin. The **stylohyoid** muscle forms a muscular connection between the hyoid bone and the styloid process of the skull. The **sternocleidomastoid** (ster-no-kl -do-MAS-toyd) muscle extends

ı from the clavicle and the sternum to the mastoid region of the skull (see Figures 11–4, p. 337, and 11–9•). The **omohyoid** (-mo

o -H -oyd) muscle attaches to the scapula, the clavicle and first rib, and the hyoid bone. The other members of this group are strap-

I like muscles that extend between the sternum and larynx (*sternothyroid*) or hyoid bone (*sternohyoid*), and between the larynx and hyoid bone (*thyrohyoid*).

Answers begin on p. A–1

Muscles of the Vertebral Column

The muscles of the vertebral column are covered by more superficial back muscles, such as the trapezius and latissimus dorsi muscles (see Figure 11–3b•, p. 335). The **erector spinae** muscles, or *spinal extensors*, include superficial and deep layers. The superficial layer can be divided into **spinalis**, **longissimus**, and **iliocostalis** groups (Figure 11–10• and Table 11–8). In the inferior lumbar and sacral regions, the boundary between the longissimus and iliocostalis muscles is indistinct. When contracting together, the erector spinae extend the vertebral column. When the muscles on only one side contract, the result is lateral flexion of the vertebral column.

Deep to the spinalis muscles, smaller muscles interconnect and stabilize the vertebrae. These muscles include the **semispinalis** group; the **multifidus** muscle; and the **interspinales**, **intertransversarii**, and **rotatores** muscles (Figure 11–10c•). In various combinations, they produce slight extension or rotation of the vertebral column. They are also important in making delicate adjustments in the positions of individual vertebrae, and they stabilize adjacent vertebrae. If injured, these muscles can start a cycle of pain : muscle stimulation : contraction

: pain. Pressure on adjacent spinal nerves results, leading to sensory losses and limiting mobility. Many of the warm-up and stretching exercises recommended before athletic activity are intended to prepare these small but very important muscles for their supporting role.

The muscles of the vertebral column include many dorsal extensors, but few ventral flexors. The vertebral column does not need a massive series of flexor muscles, because (1) many of the large trunk muscles flex the vertebral column when they contract, and (2) most of the body weight lies anterior to the vertebral column, so gravity tends to flex the spine. However, a few spinal flexors are associated with the anterior surface of the vertebral column. In the neck, the **longus capitis** and the **longus colli** muscles rotate or flex the neck, depending on whether the muscles of one or both sides are contracting (Figure 11–10b•). In the lumbar region, the large **quadratus lumborum** muscles flex the vertebral column and depress the ribs (see Figure 11–10a•).

Oblique and Rectus Muscles

The oblique and rectus muscles lie within the body wall, between the spinous processes of vertebrae and the ventral midline (see Figures 11–3, pp. 334–335, and 11–11• and Table 11–9, p. 347). The oblique muscles compress underlying structures or rotate the vertebral column, depending on whether one or both sides contract. The rectus muscles are important flexors of the vertebral column, acting in opposition to the erector spinae. The oblique and rectus muscles share embryological origins; we can divide these groups into cervical, thoracic, and abdominal regions.

The oblique group includes the **scalene** muscles of the neck (see Figure 11–10b•) and the **intercostal** and **transversus** muscles of the thorax (see Figure 11–11a,b•). The scalene muscles (*anterior*, *middle*, and *posterior*) elevate the first two ribs and assist in flexion of the neck. In the thorax, the oblique muscles extend between the ribs, with the **external intercostal** muscles covering the **internal intercostal** muscles. Both groups of intercostal muscles aid in respiratory movements of the ribs. A small **transversus thoracis** muscle crosses the inner surface of the rib cage and is separated from the pleural cavity by the parietal pleura, a

serous membrane. l**p. 129** The sternum occupies the place where we might otherwise expect thoracic rectus muscles to be.

The same basic pattern of musculature extends unbroken across the abdominopelvic surface (see Figure 11–11a,c•). Here, the muscles are called the **external oblique**, **internal oblique**, **transversus abdominis**, and **rectus abdominis** muscles. The rectus abdominis muscle inserts at the xiphoid process and originates near the pubic symphysis. This muscle is longitudinally divided by the **linea alba** (white line), a median collagenous partition (see Figure 11–3a,• p. 334). The rectus abdominis muscle is separated into segments by transverse bands of collagen fibers called **tendinous inscriptions**. Each segment contains muscle fibers that extend longitudinally, originating and inserting on the tendinous inscriptions. Due to the bulging of enlarged muscle fibers between the tendinous inscriptions, bodybuilders often refer to the rectus abdominis as the "six-pack."

The Diaphragm

The term *diaphragm* refers to any muscular sheet that forms a wall. When used without a modifier, however, **diaphragm**, or *diaphragmatic muscle*, specifies the muscular partition that separates the abdominopelvic and thoracic cavities (see Figure 11–11b•). We include this muscle here because it develops in association with the other muscles of the chest wall. The diaphragm is a major respiratory muscle.

Muscles of the Pelvic Floor

The muscles of the pelvic floor (Figure 11–12• and Table 11–10) extend from the sacrum and coccyx to the ischium and pubis. These muscles (1) support the organs of the pelvic cavity, (2) flex the sacrum and coccyx, and (3) control the movement of materials through the urethra and anus.

The boundaries of the **perineum**, the muscular sheet that forms the pelvic floor, are established by the inferior margins of the pelvis. A line drawn between the ischial tuberosities divides the perineum into two triangles: an anterior **urogenital triangle** and a posterior **anal triangle** (Figure 11–12b•). The superficial muscles of the urogenital triangle are the muscles of the external genitalia. They cover deeper muscles that strengthen the pelvic floor and encircle the urethra. These muscles constitute the **urogenital diaphragm** (Figure 11–12a•), a deep muscular layer that extends between the pubic bones.

An even more extensive muscular sheet, the **pelvic diaphragm**, forms the muscular foundation of the anal triangle (see Figure 11–12b•). This layer, covered by the urogenital diaphragm, extends as far as the pubic symphysis.

The urogenital and pelvic diaphragms do not completely close the pelvic outlet, for the urethra, vagina, and anus pass through them to open on the external surface. Muscular sphincters surround the passageways and the external sphincters permit voluntary control of urination and defecation. Muscles, nerves, and blood vessels also pass through the pelvic outlet as they travel to or from the lower limbs.

Anatomy 360 | Review the axial muscles on the **Anatomy 360 CD-ROM: Muscular System/Axial Musculature.**

The Appendicular Muscles

Objectives

- Identify the principal appendicular muscles of the body and indicate their origins, insertions, actions, and innervation.
- Compare the major muscle groups of the upper and lower limbs and relate their differences to their functional roles.

The appendicular musculature positions and stabilizes the pectoral and pelvic girdles and moves the upper and lower limbs. There are two major groups of appendicular muscles: (1)

the muscles of the shoulders and upper limbs and (2) *the muscles of the pelvis and lower limbs*. The functions and required ranges of motion are very different between these groups. In addition to increasing the mobility of the arms, the muscular connections between the pectoral girdle and the axial skeleton must act as shock absorbers. For example, while you jog, you can still perform delicate hand movements, because the muscular connections between the axial and appendicular components of the skeleton smooth out the bounces in your stride. In contrast, the pelvic girdle has evolved to transfer weight from the axial to the appendicular skeleton. Rigid, bony articulations are essential, because the emphasis is on strength rather than versatility, and a muscular connection would reduce the efficiency of the transfer. Figure 11–13• provides an introduction to the organization of the appendicular muscles of the trunk. The larger appendicular muscles are often used as sites for drug injection and vaccination delivery. AM: Intramuscular Injections

Muscles of the Shoulders and Upper Limbs

Muscles associated with the shoulders and upper limbs can be divided into four groups: (1) *muscles that position the pectoral girdle*, (2) *muscles that move the arm*, (3) *muscles that move the forearm and hand*, and (4) *muscles that move the hand and fingers*.

Muscles That Position the Pectoral Girdle

The large, superficial **trapezius** muscles cover the back and portions of the neck, reaching to the base of the skull. These muscles originate along the midline of the neck and back and insert on the clavicles and the scapular spines (Figures 11–13 and 11–14a•). The trapezius muscles are innervated by more than one nerve (Table 11–11), and specific regions can be made to contract independently. As a result, their actions are quite varied.

Removing the trapezius muscle reveals the **rhomboid** and **levator scapulae** muscles (see Figure 11–14a•). These muscles are attached to the dorsal surfaces of the cervical and thoracic vertebrae. They insert along the vertebral border of each scapula, between the superior and inferior angles. Contraction of a rhomboid muscle adducts (retracts) the scapula on that side. The levator scapulae muscle, as its name implies, elevates the scapula.

On the chest, the **serratus anterior** muscle originates along the anterior surfaces of several ribs (see Figures 11–3•, pp. 334–335, and 11–14a,b•). This fan-shaped muscle inserts along the anterior margin of the vertebral border of the scapula. When the serratus anterior muscle contracts, it abducts (protracts) the scapula and swings the shoulder anteriorly.

Two other deep chest muscles arise along the ventral surfaces of the ribs on either side. The **subclavius** (sub-KLA-ve-us; *sub-*, below + *clavius*, clavicle) muscle inserts on the inferior border of the clavicle (see Figure 11–14b•). When it contracts, it depresses and protracts the scapular end of the clavicle. Because ligaments connect this end to the shoulder joint and scapula, those structures move as well. The **pectoralis** (pek-to-RA-lis) **minor** muscle attaches to the coracoid process of the scapula. The contraction of this muscle generally complements that of the subclavius muscle.

Muscles That Move the Arm

The muscles that move the arm (Figures 11–13 to 11–15•) are easiest to remember when they are grouped by their actions at the shoulder joint (Table 11–12). The **deltoid** muscle is the major abductor, but the **supraspinatus** (soo-pra-sp -NA-tus) muscle as-

ı sists at the start of this movement. The **subscapularis** and **teres major** muscles produce medial rotation at the shoulder, whereas the **infraspinatus** and the **teres minor** muscles produce lateral rotation. All these muscles originate on the scapula. The small **coracobrachialis** (KOR-uh-ko-bra-ke-A-lis) muscle is the only muscle attached to the scapula that produces flexion and adduction at the shoulder (see Figure 11–15a•).

The **pectoralis major** muscle extends between the anterior portion of the chest and the crest of the greater tubercle of the humerus. The **latissimus dorsi** (la-TIS-i-mus DOR-s) muscle extends between the thoracic vertebrae at the posterior midline

e and the intertubercular groove of the humerus (see Figure 11–15b•). The pectoralis major muscle produces flexion at the shoulder joint, and the latissimus dorsi muscle produces extension. These two muscles can also work together to produce adduction and medial rotation of the humerus at the shoulder.

Collectively, the supraspinatus, infraspinatus, subscapularis, and teres minor muscles and their associated tendons form the **rotator cuff**. The acronym SITS assists in remembering these four muscles. Sports that involve throwing a ball, such as baseball or football, place considerable strain on the rotator cuff, and rotator cuff injuries are relatively common. AM: Sports Injuries

Muscles That Move the Forearm and Hand

Although most of the muscles that insert on the forearm and hand originate on the humerus, the biceps brachii and triceps brachii muscles are noteworthy exceptions. The **biceps brachii** muscle and the *long head* of the **triceps brachii** muscle originate on the scapula and insert on the bones of the forearm (Figure 11–16•). The triceps brachii muscle inserts on the olecranon. Contraction of the triceps brachii muscle extends the elbow, as when you do push-ups. The biceps brachii muscle inserts on the radial tuberosity, a roughened area on the anterior surface of the radius. l**p. 244** Contraction of the biceps brachii muscle flexes the elbow and supinates the forearm. With the forearm pronated (palm facing back), the biceps brachii muscle cannot function effectively. As a result, you are strongest when you flex your elbow with a supinated forearm; the biceps brachii muscle then makes a prominent bulge.

The biceps brachii muscle plays an important role in the stabilization of the shoulder joint. The short head originates on the coracoid process and provides support to the posterior surface of the capsule. The long head originates at the supraglenoid tubercle, inside the shoulder joint. l**p. 241** After crossing the head of the humerus, it passes along the intertubercular groove. In this position, the tendon helps to hold the head of the humerus within the glenoid cavity while arm movements are under way.

More muscles are shown in Figure 11–16• and listed in Table 11–13. As you study these muscles, notice that, in general, the extensor muscles lie along the posterior and lateral surfaces of the arm, whereas the flexors are on the anterior and medial surfaces. Connective tissue partitions separate major muscle groups, dividing the muscles into *compartments* that are discussed further on p. 372.

The **brachialis** and **brachioradialis** (BRA-ke-o-ra-de-A-lis) muscles flex the elbow and are opposed by the **anconeus** muscle and the triceps brachii muscle, respectively.

The **flexor carpi ulnaris**, **flexor carpi radialis**, and **palmaris longus** muscles are superficial muscles that work together to produce flexion of the wrist. The flexor carpi radialis muscle flexes and *ab*ducts, and the flexor carpi ulnaris muscle flexes and *ad*ducts. *Pitcher's arm* is an inflammation at the origins of the flexor carpi muscles at the medial epicondyle of the humerus. This condition results from forcibly flexing the wrist just before releasing a baseball.

The **extensor carpi radialis** muscles and the **extensor carpi ulnaris** muscle have a similar relationship to that between the flexor carpi muscles. That is, the extensor carpi radialis muscles produce extension and *ab*duction, whereas the extensor carpi ulnaris muscle produces extension and *ad*duction.

The **pronator teres** and **supinator** muscles originate on both the humerus and ulna. These muscles rotate the radius without either flexing or extending the elbow. The **pronator quadratus** muscle originates on the ulna and assists the pronator teres muscle in opposing the actions of the supinator or biceps brachii muscles. The muscles involved in pronation and supination are shown in Figure 11–17•. During pronation, the tendon of the biceps brachii muscle rotates with the radius. As a result, this muscle cannot assist in flexion of the elbow when the forearm is pronated.

Muscles That Move the Hand and Fingers

Several superficial and deep muscles of the forearm flex and extend the finger joints (see Figure 11–17• and Table 11–14). These relatively large muscles end before reaching the wrist, and only their tendons cross the articulation, ensuring maximum mobility at both the wrist and hand. The tendons that cross the dorsal and ventral surfaces of the wrist pass through **synovial tendon sheaths**, elongated bursae that reduce friction. l**p. 262**

The muscles of the forearm provide strength and crude control of the hand and fingers. These muscles are known as the *extrinsic muscles of the hand*. Fine control of the hand involves small *intrinsic muscles*, which originate on the carpal and metacarpal bones. No muscles originate on the phalanges, and only tendons extend across the distal joints of the fingers. The intrinsic muscles of the hand are detailed in Figure 11–18• and Table 11–15.

The fascia of the forearm thickens on the posterior surface of the wrist, forming the **extensor retinaculum** (ret-i-NAK-û-lum), a wide band of connective tissue. The extensor retinaculum holds the tendons of the extensor muscles in place. On the anterior surface, the fascia also thickens to form another wide band of connective tissue, the **flexor retinaculum**, which stabilizes the tendons of the flexor muscles. Inflammation of the retinacula and synovial tendon sheaths can restrict movement and irritate the distal portions of the *median nerve*, a mixed (sensory and motor) nerve that innervates the hand. This condition, known as *carpal tunnel syndrome*, causes chronic pain.

Concept Check

Which muscle are you using when you shrug your shoulders?

Baseball pitchers sometimes suffer from rotator cuff injuries. Which muscles are involved in this type of injury?

Which two movements would injury to the flexor carpi ulnaris muscle impair?

Answers begin on p. A–1

Muscles of the Pelvis and Lower Limbs

The pelvic girdle is tightly bound to the axial skeleton, permitting little relative movement. In our discussion of the axial musculature, we therefore encountered few muscles that can influence the position of the pelvis. The muscles that position the lower limbs can be divided into three functional groups: (1) *muscles that move the thigh*, (2) *muscles that move the leg,* and (3) *muscles that move the foot and toes*.

Muscles That Move the Thigh

Table 11–16 lists the muscles that move the thigh. **Gluteal muscles** cover the lateral surfaces of the ilia (see Figures 11–13a, p. 351, and Figure 11–19a,b,c•). The **gluteus maximus** muscle is the largest and most posterior of the gluteal muscles. Its origin includes parts of the ilium; the sacrum, coccyx, and associated ligaments; and the lumbodorsal fascia (see Figure 11–13•). Acting alone, this massive muscle produces extension and lateral rotation at the hip joint. The gluteus maximus shares an insertion with the **tensor fasciae latae** (FASH-e-e LA-ta) muscle, which originates on the iliac crest and the anterior superior iliac spine. Together, these muscles pull on the **iliotibial** (il-e-o-TIB-e-ul) **tract**, a band of collagen fibers that extends along the lateral surface of the thigh and inserts on the tibia. This tract provides a lateral brace for the knee that becomes particularly important when you balance on one foot.

The **gluteus medius** and **gluteus minimus** muscles (see Figure 11–19b,c•) originate anterior to the origin of the gluteus maximus muscle and insert on the greater trochanter of the femur. The anterior gluteal line on the lateral surface of the ilium marks the boundary between these muscles.

The **lateral rotators** originate at or inferior to the horizontal axis of the acetabulum. There are six lateral rotator muscles in all, of which the **piriformis** (pir-i-FOR-mis) muscle and the **obturator** muscles are dominant (Figure 11–19c,d•).

The **adductors** (see Figure 11–19c,d•) originate inferior to the horizontal axis of the acetabulum. This muscle group includes the **adductor magnus**, **adductor brevis**, **adductor longus**, **pectineus** (pek-TI-n -us), and **gracilis** (GRAS-i-lis) muscles. All but

e the adductor magnus originate both anterior and inferior to the joint, so they perform hip flexion as well as adduction. The adductor magnus muscle can produce either adduction and flexion or adduction and extension, depending on the region stimulated. The adductor magnus muscle can also produce medial or lateral rotation at the hip. The other muscles, which insert on low ridges along the posterior surface of the femur, produce medial rotation. When an athlete suffers a *pulled groin,* the problem is a *strain*— a muscle tear or break—in one of these adductor muscles.

The internal surface of the pelvis is dominated by a pair of muscles. The large **psoas** (SO-us) **major** muscle originates alongside the inferior thoracic and lumbar vertebrae, and its insertion lies on the lesser trochanter of the femur. Before reaching this insertion, its tendon merges with that of the **iliacus** (il-E-ah-kus) muscle, which nestles within the iliac fossa. These two powerful hip flexors are often referred to collectively as the **iliopsoas** (il-e-o-SO-us) muscle.

Muscles That Move the Leg

As in the upper limb, muscle distribution in the lower limb exhibits a pattern: Extensor muscles are located along the anterior and lateral surfaces of the leg, and flexors lie along the posterior and medial surfaces (Figure 11–20• and Table 11–17). As in the upper limb, sturdy connective tissue partitions divide the lower limb into separate muscular compartments (see p. 372). Although the flexors and adductors originate on the pelvic girdle, most extensors originate on the femoral surface.

The *flexors of the knee* include the **biceps femoris, semimembranosus** (sem-e-mem-bra-NO-sus), **semitendinosus** (sem-e
-ten-di-NO-sus), and **sartorius** muscles (Figure 11–20•). These muscles originate along the edges of the pelvis and insert on the tibia and fibula. The sartorius muscle is the only knee flexor that originates superior to the acetabulum, and its insertion lies along the medial surface of the tibia. When the sartorius contracts, it produces flexion at the knee and lateral rotation at the hip—for example, when you cross your legs.

Because the biceps femoris, semimembranosus, and semitendinosus muscles originate on the pelvic surface inferior and posterior to the acetabulum, their contractions produce not only flexion at the knee, but also extension at the hip. These three muscles are often called the **hamstrings**. A *pulled hamstring* is a relatively common sports injury caused by a strain affecting one of the hamstring muscles.

The knee joint can be locked at full extension by a slight lateral rotation of the tibia. l**p. 276** The small **popliteus** (pop-LI-te -us) muscle originates on the femur near the lateral condyle and inserts on the posterior tibial shaft (see Figure 11–21a•). When flexion is initiated, this muscle contracts to produce a slight medial rotation of the tibia that unlocks the knee joint.

Collectively, four *knee extensors*—the three **vastus muscles**, which originate along the shaft of the femur, and the **rectus femoris muscle—**make up the **quadriceps femoris** (the "quads"). Together, the vastus muscles cradle the rectus femoris muscle the way a bun surrounds a hot dog (Figure 11–20c•). All four muscles insert on the patella via the quadriceps tendon. The force of their contraction is relayed to the tibial tuberosity by way of the patellar ligament. The rectus femoris muscle originates on the anterior inferior iliac spine and the superior acetabular rim—so in addition to extending the knee, it assists in flexion of the hip.

Muscles That Move the Foot and Toes

The extrinsic muscles that move the foot and toes are shown in Figure 11–21• and listed in Table 11–18. Most of the muscles that move the ankle produce the plantar flexion involved with walking and running movements. The **gastrocnemius** (gas-trok-NE-me-us; *gaster*, stomach + *kneme*, knee) muscle of the calf is an important plantar flexor, but the slow muscle fibers of the underlying **soleus** (SO-le-us) muscle are better suited for making continuous postural adjustments. These muscles are best seen in posterior and lateral views (Figure 11–21a,b•). The gastrocnemius muscle arises from two heads located on the medial and lateral epicondyles of the femur just proximal to the knee. The *fabella*, a sesamoid bone, is occasionally present within the lateral head of the gastrocnemius muscle. The gastrocnemius and soleus muscles share a common tendon, the **calcaneal tendon**, commonly known as the *Achilles tendon* or *calcanean tendon*.

The term "Achilles tendon" comes from Greek mythology. Achilles was a warrior who was invincible but for one vulnerable spot: the calcaneal tendon. His mother had dipped him in the River Styx as an infant to make him invulnerable, but she held him by the ankle and forgot to dip the heel of his foot. This oversight proved fatal for Achilles, who was killed in battle by an arrow through the tendon that now bears his name. Outside mythology, damage to the calcaneal tendon isn't a fatal problem. But although it is among the largest, strongest tendons in the body, its rupture is relatively common. The applied forces increase markedly during rapid acceleration or deceleration; sprinters can rupture the calcaneal tendon pushing off from the starting blocks, and the elderly often snap this tendon during a stumble or fall. Surgery may be necessary to reposition and reconnect the broken ends of the tendon to promote healing.

Deep to the gastrocnemius and soleus muscles lie a pair of **fibularis** muscles, or *peroneus* muscles (Figure 11–21b,c•). The fibularis muscles produce eversion and extension (plantar flexion) at the ankle. Inversion is caused by the contraction of the **tibialis** (tib--A-lis) muscles. The large **tibialis anterior** muscle (Figure 11–21b,d•) flexes the ankle and opposes the gastrocnemius

e muscle.

Important digital muscles originate on the surface of the tibia, the fibula, or both (see Figure 11–21b,c,d•). Large synovial tendon sheaths surround the tendons of the tibialis anterior, **extensor digitorum longus**, and **extensor hallucis longus** muscles, where they cross the ankle joint. The positions of these sheaths are stabilized by superior and inferior **extensor retinacula** (see Figure 11–21b,d•).

Intrinsic muscles of the foot originate on the tarsal and metatarsal bones (Figure 11–22• and Table 11–19). Their contractions move the toes and contribute to the maintenance of the longitudinal arch of the foot. l**p. 253**

Concept Check

Which leg movement would be impaired by injury to the obturator muscle?

You often hear of athletes who suffer a pulled hamstring. To what does this phrase refer?

How would a torn calcaneal tendon affect movement of the foot? What muscles are the antagonists of the muscles that pull on the calcaneal tendon?

Answers begin on p. A–1

Anatomy 360 | Review the anatomy of the appendicular muscles on the **Anatomy 360 CD-ROM: Muscular System/Appen-dicular Musculature.**

Aging and the Muscular System

As the body ages, the size and power of all muscle tissues decrease. The effects on the muscular system can be summarized as follows:

- **Skeletal Muscle Fibers Become Smaller in Diameter.** This reduction in size reflects primarily a decrease in the number of myofibrils. In addition, the muscle fibers contain smaller ATP, CP, and glycogen reserves and less myoglobin. The overall effect is a reduction in skeletal muscle size, strength, and endurance, combined with a tendency to fatigue rapidly. Because cardiovascular performance also decreases with age, blood flow to active muscles does not increase with exercise as rapidly as it does in younger people. These factors interact to produce decreases of 30–50 percent in anaerobic and aerobic performance by age 65.
- **Skeletal Muscles Become Less Elastic.** Aging skeletal muscles develop increasing amounts of fibrous connective tissue, a process called **fibrosis**. Fibrosis makes the muscle less flexible, and the collagen fibers can restrict movement and circulation.
- **Tolerance for Exercise Decreases.** A lower tolerance for exercise results in part from the tendency toward rapid fatigue and in part from the reduction in thermoregulatory ability described in Chapter 5. l**p. 169** Individuals over age 65 cannot eliminate the heat their muscles generate during contraction as effectively as younger people can and thus are subject to overheating.
- **The Ability to Recover from Muscular Injuries Decreases.** The number of satellite cells steadily decreases with age, and the amount of fibrous tissue increases. As a result, when an injury occurs, repair capabilities are limited. Scar tissue formation is the usual result.

To be in good shape late in life, you must be in *very* good shape early in life. Regular exercise helps control body weight, strengthens bones, and generally improves the quality of life at all ages. Extremely demanding exercise is not as important as regular exercise. In fact, extreme exercise in the elderly can damage tendons, bones, and joints.

Integration with Other Systems

To operate at maximum efficiency, the muscular system must be supported by many other systems. The changes that occur during exercise provide a good example of such interaction. As noted earlier, active muscles consume oxygen and generate carbon dioxide and heat. Exercise produces various responses in other body systems:

- **Cardiovascular System:** Blood vessels in active muscles and the skin dilate, and heart rate increases. These adjustments accelerate oxygen and nutrient delivery to and carbon dioxide removal from the muscle, and bring heat to the skin for radiation into the environment.
- **Respiratory System:** Respiratory rate and depth of respiration increase. Air moves into and out of the lungs more quickly, keeping pace with the increased rate of blood flow through the lungs.
- **Integumentary System:** Blood vessels dilate, and sweat gland secretion increases. This combination promotes evaporation at the skin surface and removes the excess heat generated by muscular activity.
- **Nervous and Endocrine Systems:** The above responses of other systems are directed and coordinated through neural and hormonal adjustments in heart rate, respiratory rate, sweat gland activity, and mobilization of stored nutrient reserves.

Even when the body is at rest, the muscular system has extensive interactions with other systems. Figure 11–24• summarizes the range of interactions between the muscular system and other vital systems.

Chapter Review

Selected Clinical Terminology

carpal tunnel syndrome: An inflammation of the sheath surrounding the flexor tendons of the palm that leads to nerve compression, pain, and weakness. (p. 360) **compartment syndrome:** Ischemia resulting from accumulated blood and fluid trapped within a musculoskeletal compartment. (p. 372) **diaphragmatic hernia** *(hiatal hernia):* A hernia that occurs when abdominal organs are forced into the thoracic cavity. (p. 348) **fibrosis:** The formation of fibrous connective tissue; in muscles, the replacement of muscle tissue by fibrous connective tissue makes muscles weaker and less flexible. (p. 371) **hernia:** A condition wherein an organ or a body part protrudes through an abnormal opening. (p. 348) **inguinal hernia:** A condition in which the inguinal canal enlarges and abdominal contents are forced into it. (p. 348) **intramuscular (IM) injection:** The administration of a drug by injecting it into the mass of a large skeletal muscle. [AM] **ischemia:** Insufficient blood supply ("blood starvation") resulting from the compression of regional blood vessels. (p. 372) **rotator cuff:** The muscles that surround the shoulder joint; a common site of sports injuries. (p. 355)

Study Outline

Muscle Organization and Function p. 327

1. Structural variations among skeletal muscles affect their power, range, and speed of movement.

Organization of Skeletal Muscle Fibers p. 327

2. A muscle can be classified as a **parallel muscle**, **convergent muscle**, **pennate muscle**, or **circular muscle (sphincter)** according to the arrangement of fibers and fascicles in it. A pennate muscle may be *unipennate, bipennate,* or *multipennate. (Figure 11–1)*

Levers p. 328

3. A **lever** is a rigid structure that moves around a fixed point called the **fulcrum**. Levers can change the direction and effective strength of an applied force, and the distance and speed of the movement such a force produces.

4. Levers are classified as **first-class**, **second-class**, or **third-class levers**. Third-class levers are the most common levers in the body.

(Figure 11–2)

100 Keys | p. 330

Muscle Terminology p. 330 Origins and Insertions p. 330

1. Each muscle can be identified by its *origin*, *insertion*, and *action*.

2. The site of attachment of the fixed end of a muscle is called the **origin**; the site where the movable end of the muscle attaches to another structure is called the **insertion**.

Actions p. 330

3. The movement produced when a muscle contracts is its **action**.

4. According to the function of its action, a muscle can be classified as an **agonist**, or **prime mover**; an **antagonist**; a **synergist**; or a **fixator**.

Names of Skeletal Muscles p. 331

5. The names of muscles commonly provide clues to their body region, origin and insertion, fascicle organization, relative position, structural characteristics, and action. *(Table 11–1)*

Axial and Appendicular Muscles p. 333

6. The **axial musculature** arises on the axial skeleton; it positions the head and spinal column and moves the rib cage. The **appendicular musculature** stabilizes or moves components of the appendicular skeleton. *(Figure 11–3)*

7. **Innervation** refers to the distribution of nerves that control a region or organ, including a muscle.

The Axial Muscles p. 336

1. The axial muscles fall into logical groups on the basis of location, function, or both.

Muscles of the Head and Neck p. 336

2. The principal muscles of facial expression are the **orbicularis oris**, **buccinator**, and **occipitofrontalis** muscles and the **platysma**.

(Figure 11–4; Table 11–2)

3. Six extrinsic eye muscles (**extra-ocular muscles** or *oculomotor muscles*) control eye movements: the **inferior** and **superior rectus** muscles, the **lateral** and **medial rectus** muscles, and the **inferior** and **superior oblique** muscles. *(Figure 11–5; Table 11–3)*

4. The muscles of mastication (chewing) are the **masseter**, **temporalis**, and **pterygoid** muscles. *(Figure 11–6; Table 11–4)*

5. The muscles of the tongue are necessary for speech and swallowing and assist in mastication. They are the **palatoglossus**, **styloglossus**, **genioglossus**, and **hyoglossus** muscles. *(Figure 11–7; Table 11–5)*

6. The muscles of the pharynx constrict the pharyngeal walls **(pharyngeal constrictors)**, elevate the larynx **(laryngeal elevators)**, or raise the soft palate **(palatal muscles)**. *(Figure 11–8; Table 11–6)*

7. The anterior muscles of the neck control the position of the larynx, depress the mandible, and provide a foundation for the muscles of the tongue and pharynx. The neck muscles include the **digastric** and **sternocleidomastoid** muscles and seven muscles that originate or insert on the hyoid bone. *(Figure 11–9; Table 11–7)*

Muscles of the Vertebral Column p. 344

8. The superficial muscles of the spine can be classified into the **spinalis**, **longissimus**, and **iliocostalis** groups. *(Figure 11–10; Table 11–8)*

9. Other muscles of the spine include the **longus capitis** and **longus colli** muscles of the neck, the small invertebral muscles of the deep layer, and the **quadratus lumborum** muscle of the lumbar region. *(Figure 11–10; Table 11–8)*

Oblique and Rectus Muscles p. 346

10. The oblique muscles include the **scalene** muscles and the **intercostal** and **transversus** muscles. The **external** and **internal intercostal** muscles are important in respiratory movements of the ribs. Also important to respiration is the **diaphragm**. *(Figures 11–10, 11–11; Table 11–9)*

Muscles of the Pelvic Floor p. 348

11. The **perineum** can be divided into an anterior **urogenital triangle** and a posterior **anal triangle**. The pelvic floor consists of the **urogenital diaphragm** and the **pelvic diaphragm**. *(Figure 11–12; Table 11–10)*

Anatomy 360 | Muscular System/Axial Musculature

The Appendicular Muscles p. 350 Muscles of the Shoulders and Upper Limbs p. 351

1. The **trapezius** muscle affects the positions of the shoulder girdle, head, and neck. Other muscles inserting on the scapula include the **rhomboid**, **levator scapulae**, **serratus anterior**, **subclavius**, and **pectoralis minor** muscles. *(Figures 11–13, 11–14; Table 11–11)*

2. The **deltoid** and the **supraspinatus** muscles are important abductors. The **subscapularis** and **teres major** muscles produce medial rotation at the shoulder; the **infraspinatus** and **teres minor** muscles produce lateral rotation; and the **coracobrachialis** muscle produces flexion and adduction at the shoulder. *(Figures 11–13 to 11–15; Table 11–12)*

3. The **pectoralis major** muscle flexes the shoulder joint, and the **latissimus dorsi** muscle extends it. *(Figures 11–13 to 11–15; Table 11–12)*

4. The actions of the **biceps brachii** muscle and the **triceps brachii** muscle (long head) affect the elbow joint. The **brachialis** and **brachioradialis** muscles flex the elbow, opposed by the **anconeus** muscle. The **flexor carpi ulnaris**, **flexor carpi radialis**, and **palmaris longus** muscles cooperate to flex the wrist. They are opposed by the **extensor carpi radialis** muscles and the **extensor carpi ulnaris** muscle. The **pronator teres** and **pronator quadratus** muscles pronate the forearm and are opposed by the **supinator** muscle.

(Figures 11–15 to 11–18; Tables 11–13 to 11–15)

Muscles of the Pelvis and Lower Limbs p. 363

5. **Gluteal muscles** cover the lateral surfaces of the ilia. The largest is the **gluteus maximus** muscle, which shares an insertion with the **tensor fasciae latae**. Together, these muscles pull on the **iliotibial tract**. *(Figures 11–13, 11–19; Table 11–16)*

6. The **piriformis** muscle and the **obturator** muscles are the most important **lateral rotators**. The **adductors** can produce a variety of movements. *(Figure 11–19; Table 11–16)*

7. The **psoas major** and **iliacus** muscles merge to form the **iliopsoas** muscle, a powerful flexor of the hip. *(Figures 11–19, 11–20; Table 11–16)*

8. The flexors of the knee include the **biceps femoris**, **semimembranosus**, and **semitendinosus** muscles (the three **hamstrings**) and the **sartorius** muscle. The **popliteus** muscle unlocks the knee joint. *(Figures 11–20, 11–21; Table 11–17)*

9. Collectively, the knee extensors are known as the **quadriceps femoris**. This group consists of the three **vastus** muscles and the **rectus femoris** muscle. *(Figure 11–20; Table 11–17)*

10. The **gastrocnemius** and **soleus** muscles produce plantar flexion (ankle extension). A pair of **fibularis** muscles produces eversion as well as extension (plantar flexion) at the ankle. *(Figure 11–21; Table 11–18)*

11. Smaller muscles of the calf and shin position the foot and move the toes. Precise control of the phalanges is provided by muscles originating at the tarsal and metatarsal bones. *(Figure 11–22; Table 11–19)*

Anatomy 360 | Muscular System/Appendicular Musculature

Aging and the Muscular System p. 371

1. With aging, the size and power of all muscle tissues decrease. Skeletal muscles undergo **fibrosis**, the tolerance for exercise decreases, and repair of injuries slows.

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you’ll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A-1.

LEVEL 1 Reviewing Facts and Terms

1. What are the bundles of muscle fibers within a skeletal muscle called?

(a) muscles **(b)** fascicles

(c) fibers **(d)** myofilaments

(e) groups

2. Levers make muscle action more versatile by all of the following, *except*

(a) changing the location of the muscle's insertion

(b) changing the speed of movement produced by an applied force

(c) changing the distance of movement produced by an applied force

(d) changing the strength of an applied force

(e) changing the direction of an applied force

3. The more moveable end of a muscle is the

(a) insertion **(b)** belly

(c) origin **(d)** proximal end

(e) distal end

4. The muscles of facial expression are innervated by cranial nerve

(a) VII **(b)** V **(c)** IV **(d)** VI

5. The strongest masticatory muscle is the _____ muscle.

(a) pterygoid **(b)** masseter

(c) temporalis **(d)** mandible

6. The muscle that rotates the eye medially is the _____ muscle.

(a) superior oblique **(b)** inferior rectus

(c) medial rectus **(d)** lateral rectus

7. Important flexors of the vertebral column that act in opposition to the erector spinae are the _____ muscles.

(a) rectus **(b)** longus capitis

(c) longus colli **(d)** scalene

8. The major extensor of the elbow is the _____ muscle.

(a) triceps brachii **(b)** biceps brachii

(c) deltoid **(d)** subscapularis

9. The muscles that rotate the radius without producing either flexion or extension of the elbow are the _____ muscles.

(a) brachialis and brachioradialis

(b) pronator teres and supinator

(c) biceps brachii and triceps brachii

(d) a, b, and c are correct

10. The powerful flexors of the hip are the _____ muscles.

(a) piriformis **(b)** obturators

(c) pectineus **(d)** iliopsoas

11. Knee extensors known as the quadriceps consist of the _________.

(a) three vastus muscles and the rectus femoris muscle

(b) biceps femoris, gracilis, and sartorius muscles

(c) popliteus, iliopsoas, and gracilis muscles

(d) gastrocnemius, tibialis, and peroneus muscles

12. List the four fascicle organizations that produce the different patterns of skeletal muscles.

13. What is an aponeurosis? Give two examples.

14. Which four muscle groups make up the axial musculature?

15. What three functions are accomplished by the muscles of the pelvic floor?

16. Which four muscles are associated with the rotator cuff?

17. What three functional groups make up the muscles of the lower limbs?

LEVEL 2 Reviewing Concepts

18. Of the following examples, the one that illustrates the action of a second-class lever is

(a) knee extension

(b) ankle extension (plantar flexion)

(c) flexion at the elbow

(d) a, b, and c are correct

19. Compartment syndrome can result from all of the following except:

(a) compressing a nerve in the wrist

(b) compartments swelling with blood due to an injury involving blood vessels

(c) torn ligaments in a given compartment

(d) pulled tendons in the muscles of a given compartment

(e) torn muscles in a particular compartment

20. A(n) ____________ develops when an organ protrudes through an abnormal opening.

21. Elongate bursae that reduce friction and surround the tendons that cross the dorsal and ventral surfaces of the wrist form ____________.

22. The muscles of the vertebral column include many dorsal extensors but few ventral flexors. Why?

23. Why does a convergent muscle exhibit more versatility when contracting than does a parallel muscle?

24. Why can a pennate muscle generate more tension than can a parallel muscle of the same size?

25. Why is it difficult to lift a heavy object when the elbow is at full extension?

26. Which types of movements are affected when the hamstrings are injured?

LEVEL 3 Critical Thinking and Clinical Applications

27. Mary sees Jill coming toward her and immediately contracts her frontalis and procerus muscles. She also contracts her levator labii muscles. Is Mary glad to see Jill? How can you tell?

28. Mary's newborn is having trouble suckling. The doctor suggests that it may be a problem with a particular muscle. What muscle is the doctor probably referring to?

(a) orbicularis oris **(b)** buccinator
(c) masseter **(d)** risorius
(e) zygomaticus

29. While unloading her car trunk, Amy pulls a muscle and as a result has difficulty moving her arm. The doctor in the emergency room tells her that she pulled her pectoralis major. Amy tells you that she thought the pectoralis major was a chest muscle and doesn't understand what that has to do with her arm. What would you tell her?

TABLE 11–1 Muscle Terminology

Terms Indicating Terms Indicating
Specific Regions Position, Direction, or
of the Body* Fascicle Organization

Terms Indicating Structural Characteristics Terms Indicating of the Muscle Actions
Abdominis (abdomen) Anterior (front)
Anconeus (elbow) Externus (superficial)
Auricularis (auricle of ear) Extrinsic (outside)
Brachialis (brachium) Inferioris (inferior)
Capitis (head) Internus (deep, internal)
Carpi (wrist) Intrinsic (inside)

Cervicis (neck) Lateralis (lateral)
Cleido-/-clavius (clavicle) Medialis/medius (medial, middle)
Coccygeus (coccyx) Oblique
Costalis (ribs) Posterior (back)
Cutaneous (skin) Profundus (deep)
Femoris (femur) Rectus (straight, parallel)
Genio- (chin) Superficialis (superficial)

Glosso-/-glossal (tongue) Superioris (superior)
Hallucis (great toe) Transversus (transverse)
Ilio- (ilium)
Inguinal (groin)
Lumborum (lumbar region)
Nasalis (nose)

Nuchal (back of neck)
Oculo- (eye)
Oris (mouth)
Palpebrae (eyelid)
Pollicis (thumb)
Popliteus (posterior to knee)
Psoas (loin)
Radialis (radius)
Scapularis (scapula)
Temporalis (temples)
Thoracis (thoracic region)
Tibialis (tibia)
Ulnaris (ulna)
Uro- (urinary)

Nature of Origin General Biceps (two heads) Abductor Triceps (three heads) Adductor Quadriceps (four heads) Depressor

Extensor **Shape** Flexor Deltoid (triangle) Levator Orbicularis (circle) Pronator Pectinate (comblike) Rotator Piriformis (pear-shaped) Supinator Platy- (flat) Tensor Pyramidal (pyramid) Rhomboid **Specific**

Serratus (serrated) Buccinator (trumpeter)

Splenius (bandage) Risorius (laugher)

Teres (long and round) Sartorius (like a tailor)

Trapezius (trapezoid)

Other Striking Features

Alba (white)

Brevis (short)

Gracilis (slender)

Lata (wide)

Latissimus (widest)

Longissimus (longest)

Longus (long)

Magnus (large)

Major (larger)

Maximus (largest)

Minimus (smallest)

Minor (smaller)

-tendinosus (tendinous)

Vastus (great)

* For other regional terms, refer to Figure 1–6, p. 16, which deals with anatomical landmarks.

TABLE 11–2 Muscles of Facial Expression (Figure 11–4)

Region/Muscle **Origin** **Insertion**

Action **Innervation**

MOUTH

Buccinator Alveolar processes of maxillary Blends into fibers

Compresses cheeks Facial nerve (VII)

bone and mandible of orbicularis oris

Depressor labii inferioris Mandible between the Skin of lower lip Depresses lower lip As above anterior midline and the mental foramen

Levator labii superioris Inferior margin of orbit, superior Orbicularis oris Elevates upper lip As above to the infraorbital foramen

Mentalis Incisive fossa of mandible Skin of chin Elevates and protrudes As above lower lip

Orbicularis oris Maxillary bone and mandible Lips Compresses, purses lips As above

Risorius Fascia surrounding Angle of mouth Draws corner of mouth As above parotid salivary gland to the side

Depressor anguli oris Anterolateral surface of Skin at angle Depresses corner As above mandibular body of mouth of mouth mandibular ramus and closes the jaws mandibular branch

Zygomaticus major Zygomatic bone near Angle

of mouth Retracts and elevates As above

zygomaticomaxillary suture corner

of mouth

Zygomaticus minor Zygomatic bone posterior Upper

lip Retracts and elevates As above

to zygomaticotemporal suture upper

lip

EYE

Corrugator supercilii Orbital rim of frontal Eyebrow Pulls

skin inferiorly and As above

bone near nasal suture

anteriorly; wrinkles brow

Levator palpebrae Tendinous band around Upper eyelid

Elevates upper eyelid Oculomotor nerve (III)*

superioris (*see Figure 11–5*) optic foramen

Orbicularis oculi Medial margin of orbit Skin around eyelids Closes eye

NOSE

Procerus Nasal bones and lateral Aponeurosis at bridge Moves

nose, changes As above

nasal cartilages of nose and skin position and shape

of forehead of nostrils

Nasalis Maxillary bone and alar Bridge of nose Compresses bridge,

cartilage of nose depresses tip of nose;

elevates corners

of nostrils

EAR

Temporoparietalis Fascia around external Epicranial aponeurosis Tenses

scalp, moves As above

ear auricle of ear

SCALP (EPICRANIUM)

Occipitofrontalis Skin of eyebrow and Raises

eyebrows, As above

Frontal belly Epicranial aponeurosis bridge of nose wrinkles forehead

Occipital belly Superior nuchal line Epicranial aponeurosis Tenses

and retracts scalp As above

NECK

Platysma Superior thorax between Mandible and skin Tenses

skin of neck; As above

cartilage of 2nd rib and of cheek depresses mandible

acromion of scapula

* This muscle originates in association with the extrinsic eye muscles, so its innervation is unusual.

TABLE 11–3

Extrinsic Eye Muscles (Figure 11–5)

Muscle **Origin** **Insertion** **Action**

Innervation

Inferior rectus Sphenoid around Inferior, medial surface

optic canal of eyeball

Medial rectus As above Medial surface Eye

looks medially As above

of eyeball

Superior rectus As above Superior surface Eye

looks up As above

of eyeball

Lateral rectus As above Lateral surface Eye

looks laterally Abducens nerve (VI)

of eyeball

Inferior oblique Maxillary bone at Inferior, lateral surface

anterior portion of orbit of eyeball and laterally

Superior oblique Sphenoid around Superior, lateral surface

optic canal of eyeball and laterally

TABLE 11–4 Muscles of Mastication (Figure 11–6)

Muscle **Origin** **Insertion** **Action**

Innervation

Masseter Zygomatic arch Lateral surface of Elevates mandible
Trigeminal nerve (V),

Temporalis Along temporal lines Coronoid process of Elevates mandible As above of skull mandible

Pterygoids (medial Lateral pterygoid plate Medial surface of *Medial*: Elevates the mandible and As above **and lateral)** mandibular ramus closes the jaws, or performs lateral excursion *Lateral*: Opens jaws, protrudes mandible, As above or performs lateral excursion

TABLE 11–5 Muscles of the Tongue (Figure 11–7)

Muscle Origin Insertion Action Innervation

Genioglossus Medial surface of mandible Body of tongue, hyoid Depresses and protracts Hypoglossal nerve (XII) around chin bone tongue

Hyoglossus Body and greater horn of Side of tongue Depresses and retracts As above hyoid bone tongue

Palatoglossus Anterior surface of soft As above Elevates tongue, depresses Internal branch of accessory palate soft palate nerve (XI)

Styloglossus Styloid process of temporal Along the side to tip and Retracts tongue, elevates Hypoglossal nerve (XII) bone base of tongue side

TABLE 11–6 Muscles of the Pharynx (Figure 11–8)

Muscle Origin Insertion Action Innervation

PHARYNGEAL CONSTRICTORS

Superior constrictor Pterygoid process of sphenoid, Median raphe attached Constricts pharynx to Branches of pharyngeal medial surfaces of mandible to occipital bone propel bolus into plexus (X) esophagus

Middle constrictor Horns of hyoid bone Median raphe As above As above

Inferior constrictor Cricoid and thyroid cartilages As above As above As above of larynx

LARYNGEAL ELEVATORS* Ranges from soft palate, to cartilage Thyroid cartilage Elevate larynx Branches of pharyngeal around inferior portion of auditory plexus (IX and X) tube, to styloid process of temporal bone

PALATAL MUSCLES

Levator veli palatini Petrous part of temporal bone; Soft palate Elevates soft palate Branches of pharyngeal tissues around the auditory tube plexus (X)

Tensor veli palatini Sphenoidal spine; tissues As above As above V around the auditory tube

* Refers to the palatopharyngeus, salpingopharyngeus, and stylopharyngeus, assisted by the thyrohyoid, geniohyoid, stylohyoid, and hyoglossus muscles, discussed in Tables 11–5 and 11–7.

TABLE 11–7 Anterior Muscles of the Neck (Figure 11–9)

Muscle Origin Insertion Action Innervation

Digastric Two bellies: *anterior* from inferior surface of mandible at chin; *posterior* from mastoid region of temporal bone

Hyoid bone Depresses mandible or *Anterior belly*: Trigeminal elevates larynx nerve (V), mandibular branch *Posterior belly*: Facial nerve (VII)

Geniohyoid Medial surface of Hyoid bone As above and pulls hyoid Cervical nerve C_1 via mandible at chin bone anteriorly hypoglossal nerve (XII)

Mylohyoid	Mylohyoid line of mandible mandibular branch	Median connective tissue band (raphe) that runs to hyoid bone	Elevates floor of mouth and hyoid bone or depresses mandible

Omohyoid Superior border of scapula Hyoid bone Depresses hyoid bone Cervical spinal nerves C_2–C_3 (superior and near scapular notch and larynx inferior bellies united at central tendon anchored to clavicle and first rib)

Sternohyoid Clavicle and manubrium Hyoid bone As above Cervical spinal nerves C_1–C_3

Sternothyroid Dorsal surface of Thyroid cartilage of As above As above manubrium and first larynx costal cartilage

Stylohyoid Styloid process of Hyoid bone Elevates larynx Facial nerve (VII) temporal bone

Thyrohyoid Thyroid cartilage of larynx Hyoid bone Elevates thyroid, Cervical spinal nerves C_1–C_2 depresses hyoid bone via hypoglossal nerve (XII)

Sternocleido- Two bellies: *clavicular head*
mastoid attaches to sternal end
of clavicle; *sternal head*
attaches to manubrium

Mastoid region of skull Together, they flex the neck; Accessory nerve (XI) and and lateral portion of alone, one side bends head cervical spinal nerves (C_2–C_3) superior nuchal line toward shoulder and turns of cervical plexus face to opposite side

TABLE 11–8 Muscles of the Vertebral Column (Figure 11–10)

Group and Muscle(s) Origin Insertion Action Innervation

SUPERFICIAL LAYER Splenius Spinous processes and ligaments Mastoid process, occipital Together, the two sides extend Cervical spinal **(Splenius capitis,** connecting inferior cervical bone of skull, and superior neck; alone, each rotates and nerves **splenius cervicis)** and superior thoracic vertebrae cervical vertebrae laterally flexes neck to that side

Erector spinae

Spinalis group

Spinalis cervicis Inferior portion of ligamentum Spinous process of axis
nuchae and spinous process of C_7

Spinalis thoracis Spinous processes of inferior Spinous processes of
thoracic and superior superior thoracic

lumbar vertebrae vertebrae

Extends neck As above

Extends vertebral column Thoracic and lumbar spinal nerves

Longissimus group

Longissimus capitis Transverse processes of Mastoid process of Together, the two sides Cervical and

inferior cervical and superior temporal bone extend head; alone, each thoracic

thoracic vertebrae rotates and laterally spinal nerves

flexes neck to that side

Longissimus cervicis Transverse processes of superior Transverse processes of As above As above

thoracic vertebrae middle and superior

cervical vertebrae

Longissimus thoracis Broad aponeurosis and Transverse processes of Extends vertebral column; Thoracic and

transverse processes of inferior superior vertebrae and alone, each produces lateral lumbar

thoracic and superior lumbar inferior surfaces of ribs flexion to that side spinal nerves

vertebrae; joins iliocostalis

Iliocostalis group

Iliocostalis cervicis Superior borders of Transverse processes of Extends or laterally flexes Cervical and vertebrosternal ribs near middle and inferior neck, elevates ribs superior thoracic the angles cervical vertebrae spinal nerves

Iliocostalis thoracis Superior borders of inferior Upper ribs and transverse Stabilizes thoracic vertebrae Thoracic

seven ribs medial to the angles process of last cervical in extension spinal nerves

vertebra

Iliocostalis lumborum Iliac crest, sacral crests, and Inferior surfaces of inferior Extends vertebral column, Inferior thoracic spinous processes seven ribs near their angles depresses ribs and lumbar

spinal nerves

DEEP LAYER (TRANSVERSOSPINALIS)

Semispinalis group

Semispinalis capitis

Semispinalis cervicis

Semispinalis thoracis

Multifidus

Rotatores

Interspinales

Intertransversarii

SPINAL FLEXORS Longus capitis

Longus colli

Quadratus lumborum

Articular processes of inferior

cervical and transverse processes

of superior thoracic vertebrae Transverse processes of T_1–T_5

or T_6

Transverse processes of T_6–T_{10}

Sacrum and transverse processes of each vertebra

Transverse processes of each vertebra

Spinous processes of each vertebra

Transverse processes of each vertebra

Transverse processes of cervical vertebrae

Anterior surfaces of cervical and superior thoracic vertebrae

Iliac crest and iliolumbar ligament

Occipital bone, between nuchal lines

Spinous processes of C_2–C_5

Spinous processes of C_5–T_4

Spinous processes of the third or fourth more superior vertebrae

Spinous processes of adjacent, more superior vertebra

Spinous processes of more superior vertebra

Transverse process of more superior vertebra

Base of the occipital bone

Transverse processes of superior cervical vertebrae

Last rib and transverse

Together, the two sides extend head; alone, each extends and laterally flexes neck

Extends vertebral column and rotates toward opposite side

As above

As above

As above

Extends vertebral column

Laterally flexes the vertebral column

Together, the two sides flex the neck; alone, each rotates head to that side

Flexes or rotates neck; limits hyperextension

Together, they depress ribs;

Cervical spinal nerves

As above

Thoracic spinal nerves

Cervical, thoracic, and lumbar spinal nerves

As above

As above

As above

Cervical spinal nerves

As above

Thoracic and lumbar spinal nerves processes of lumbar vertebrae

alone, each side laterally flexes vertebral column

TABLE 11–9 Oblique and Rectus Muscles (Figure 11–11)

Group and Muscle(s)		**Origin**
OBLIQUE GROUP		
Cervical region		
Scalenes	Transverse and costal	
(anterior, middle,		processes of cervical
and posterior)	vertebrae	
Thoracic region		
External intercostals		Inferior border of each rib
Internal intercostals		Superior border of each rib
Transversus thoracis		Posterior surface of sternum
Serratus posterior		
superior	Spinous processes of C7–T3	
(*see Figure 11–13a*)		and ligamentum nuchae
inferior	Aponeurosis from spinous	
	processes of T10–L3	
Abdominal region		
External oblique	External and inferior borders	

Insertion

Superior surfaces of first two ribs

Superior border of more inferior rib

Inferior border of the preceding rib

Cartilages of ribs

Superior borders of ribs 2–5 near angles Inferior borders of ribs 8–12

Linea alba and iliac crest

Action

Elevate ribs or flex neck

Elevate ribs

Depress ribs

As above

Elevates ribs, enlarges thoracic cavity

Pulls ribs inferiorly; also pulls outward, opposing diaphragm

Compresses abdomen,

Innervation*

Cervical spinal nerves

Intercostal nerves (branches of thoracic spinal nerves)

As above

As above

Thoracic nerves (T_1–T_4)

Thoracic nerves (T_9–T_{12})

Intercostal, iliohypogastric,

of ribs 5–12

Internal oblique	Lumbodorsal fascia and iliac crest
Transversus abdominis	Cartilages of ribs 6–12, iliac crest, and lumbodorsal fascia

RECTUS GROUP

Cervical region	*See muscles in Table 11–6*	
Thoracic region		
Diaphragm	Xiphoid process, cartilages of ribs 4–10, and anterior surfaces of lumbar vertebrae	
Abdominal region		
Rectus abdominis	around symphysis	Superior surface of pubis

Inferior ribs, xiphoid process, and linea alba

Linea alba and pubis

Central tendinous sheet

Inferior surfaces of costal cartilages (ribs 5–7) and xiphoid process

* Where appropriate, spinal nerves involved are given in parentheses.

TABLE 11–10 Muscles of the Pelvic Floor (Figure 11–12)

Group and Muscle(s)	Origin	Insertion
UROGENITAL TRIANGLE		
Superficial muscles		
Bulbospongiosus:		
Males	Collagen sheath at base of penis; fibers cross over urethra	Median raphe and central tendon of perineum
Females	Collagen sheath at base of clitoris; fibers run on either side of urethral and vaginal opening	Central tendon of perineum

Ischiocavernosus	Ischial ramus and tuberosity	Pubic symphysis anterior to base of penis or clitoris	
Superficial transverse perineal		Ischial ramus perineum	Central tendon of
Deep muscles			
Urogenital diaphragm			
Deep transverse perineal		Ischial ramus urogenital diaphragm	Median raphe of
External urethral sphincter:			
Males	Ischial and pubic rami	of penis; inner fibers encircle urethra	To median raphe at base
Females	Ischial and pubic rami	fibers encircle urethra	To median raphe; inner
ANAL TRIANGLE			
Pelvic diaphragm			
Coccygeus	Ischial spine	Lateral, inferior borders of sacrum and coccyx	
Levator ani	Ischial spine, pubis		Coccyx and median raphe
Iliococcygeus			
Pubococcygeus	Inner margins of pubis		As above

depresses ribs, flexes or and ilioinguinal nerves
bends spine
As above As above
Compresses abdomen As above

Contraction expands Phrenic nerves (C3–C5)
thoracic cavity,

compresses abdominopelvic cavity	
Depresses ribs, flexes vertebral column, compresses abdomen	Intercostal nerves (T7–T12)

Action	**Innervation***
Compresses base and stiffens penis; ejects urine or semen	Pudendal nerve, perineal branch (S2–S4)
Compresses and stiffens clitoris; narrows vaginal opening	As above
Compresses and stiffens penis or clitoris	As above
Stabilizes central tendon of perineum	As above
As above	As above
Closes urethra; compresses prostate and bulbourethral glands	As above
Closes urethra; compresses vagina and greater vestibular glands	As above
Flexes coccygeal joints; tenses and supports pelvic floor	Inferior sacral nerves (S4–S5)
Tenses floor of pelvis; flexes coccygeal joints; elevates and retracts anus	Pudendal nerve (S2–S4)

As above As above

External anal sphincter Via tendon from coccyx Encircles anal opening Closes anal opening Pudendal nerve, hemorrhoidal branch (S_2–S_4)

* Where appropriate, spinal nerves involved are given in parentheses.

TABLE 11–11 Muscles That Position the Pectoral Girdle (Figures 11–13, 11–14)

Muscle **Origin** **Insertion** **Action**
Innervation*

Levator Transverse processes of first Vertebral border of scapula
scapulae four cervical vertebrae near superior angle dorsal scapular nerve (C5)

Pectoralis Anterior-superior Coracoid process Depresses and protracts shoulder; Medial pectoral nerve (C8, T1)
minor surfaces of ribs 3–5 of scapula rotates scapula so glenoid cavity
moves inferiorly (downward rotation);
elevates ribs if scapula is stationary

Rhomboid Spinous processes of Vertebral border Adducts scapula and performs Dorsal scapular **major** superior thoracic of scapula from spine downward rotation nerve (C5) vertebrae to inferior angle

Rhomboid Spinous processes of Vertebral border As above As above **minor** vertebrae C_7–T_1 of scapula near spine

Serratus Anterior and superior Anterior surface of **anterior** margins of ribs 1–8 vertebral border or 1–9 of scapula

Protracts shoulder; rotates scapula Long thoracic nerve (C5 –C7) so glenoid cavity moves superiorly (upward rotation)

Subclavius First rib Clavicle (inferior border) Depresses and protracts shoulder Nerve to subclavius (C_5–C_6)

Trapezius Occipital bone, Clavicle and scapula ligamentum nuchae, (acromion and and spinous processes scapular spine)

of thoracic vertebrae

Depends on active region and state of Accessory nerve (XI) other muscles; may (1) elevate, retract, and cervical spinal depress, or rotate scapula upward, (2) nerves (C_3–C_4)

elevate clavicle, or (3) extend neck

* Where appropriate, spinal nerves involved are given in parentheses.

TABLE 11–12 Muscles That Move the Arm (Figures 11–13 to 11–15)

Muscle Origin Insertion Action Innervation*

Deltoid Clavicle and scapula Deltoid tuberosity of *Whole muscle*: abduction at Axillary nerve (C_5–C_6) (acromion and adjacent humerus shoulder; *anterior part*: scapular spine) flexion and medial rotation; *posterior part*: extension and lateral rotation

Supraspinatus Supraspinous fossa of Greater tubercle of humerus Abduction at the shoulder Suprascapular nerve (C_5) scapula

Subscapularis Subscapular fossa of Lesser tubercle of humerus Medial rotation at shoulder Subscapular nerves (C_5–C_6) scapula

Teres major Inferior angle of scapula Passes medially to reach the Extension, adduction, and Lower subscapular medial lip of intertubercular medial rotation at shoulder nerve (C_5–C_6) groove of humerus

Infraspinatus Infraspinous fossa of Greater tubercle of humerus Lateral rotation at shoulder Suprascapular nerve scapula (C_5–C_6)

Teres minor Lateral border of scapula Passes laterally to reach the Lateral rotation at shoulder Axillary nerve (C_5) greater tubercle of humerus

Coracobrachialis Coracoid process Medial margin of shaft Adduction and flexion Musculocutaneous of humerus at shoulder nerve (C_5–C_7)

Pectoralis major Cartilages of ribs 2–6, body Crest of greater tubercle and Flexion, adduction, and Pectoral nerves (C_5–T_1) of sternum, and inferior, lateral lip of intertubercular medial rotation at shoulder medial portion of clavicle groove of humerus

Latissimus dorsi Spinous processes of inferior Floor of intertubercular Extension, adduction, and Thoracodorsal nerve (C_6–C_8) thoracic and all lumbar groove of the humerus medial rotation at shoulder vertebrae, ribs 8–12, and lumbodorsal fascia

Triceps brachii *See Table 11–13*

(long head)

* Where appropriate, spinal nerves involved are given in parentheses.

TABLE 11–13 Muscles That Move the Forearm and Hand (Figure 11–16)

Muscle Origin Insertion Action Innervation ACTION AT THE ELBOW

Flexors

Biceps brachii *Short head* from the coracoid Tuberosity of radius Flexion at elbow and Musculocutaneous

process; *long head* from the shoulder; supination nerve (C_5–C_6)

supraglenoid tubercle

(both on the scapula)

Brachialis Anterior, distal surface of Tuberosity of ulna Flexion at elbow As above and radial humerus nerve (C_7–C_8) **Brachioradialis** Ridge superior to the lateral Lateral aspect of styloid As above Radial nerve (C_5–C_6) epicondyle of humerus process of radius

Extensors

Anconeus Posterior, inferior surface of Lateral margin of olecranon Extension at elbow Radial nerve (C_7–C_8) lateral epicondyle of humerus on ulna

Triceps brachii

lateral head Superior, lateral margin of Olecranon of ulna As above Radial nerve (C_6–C_8)

humerus

long head Infraglenoid tubercle of As above As above, plus extension As above
scapula and adduction at
the shoulder
medial head Posterior surface of humerus As above Extension at elbow As above
inferior to radial groove

PRONATORS/SUPINATORS **Pronator quadratus** Anterior and medial surfaces Anterolateral surface of Pronation Median nerve (C_8–T_1) of distal portion of ulna distal portion of radius **Pronator teres** Medial epicondyle of Midlateral surface As above Median nerve (C_6–C_7) humerus and coronoid of radius process of ulna **Supinator** Lateral epicondyle of humerus, Anterolateral surface Supination Deep radial nerve (C_6–C_8) annular ligament, and ridge of radius distal to near radial notch of ulna the radial tuberosity

ACTION AT THE HAND

Flexors

Flexor carpi radialis Medial epicondyle of humerus Bases of second and third Flexion and Median nerve (C_6–C_7) metacarpal bones abduction at wrist **Flexor carpi ulnaris** Medial epicondyle of humerus; Pisiform bone, hamate Flexion and Ulnar nerve (C_8–T_1) adjacent medial surface of bone, and base of fifth adduction at wrist olecranon and anteromedial metacarpal bone portion of ulna **Palmaris longus** Medial epicondyle of humerus Palmar aponeurosis and Flexion at wrist Median nerve (C_6–C_7) flexor retinaculum

Extensors

Extensor carpi	Lateral supracondylar ridge		Base of second
metacarpal	Extension and	Radial nerve (C6–C7)	
radialis longus	of humerus	bone	abduction at wrist
Extensor carpi	Lateral epicondyle of humerus		Base of third

Digital extensors

Extensor digitorum longus Lateral condyle of tibia, Superior surfaces of Extension at joints of Deep fibular nerve

anterior surface of fibula phalanges, toes 2–5 toes 2–5 (L_4–S_1)

Extensor hallucis longus Anterior surface of fibula Superior surface, distal Extension at joints of great toe As above

phalanx of great toe

TABLE 11–19 Intrinsic Muscles of the Foot (Figure 11–22)

Muscle Origin Insertion Action Innervation

Extensor digitorum Calcaneus (superior Dorsal surfaces Extension at metatarsophalangeal Deep fibular

brevis and lateral surfaces) of toes 1–4 joints of toes 1–4 nerve (L_5–S_1)

Abductor hallucis Calcaneus (tuberosity Medial side of proximal Abduction at metatarsophalangeal Medial plantar

on inferior surface) phalanx of great toe joint of great toe nerve (L_4–L_5)

Flexor digitorum As above Sides of middle Flexion at proximal interphalangeal As above

brevis phalanges, toes 2–5 joints of toes 2–5

Abductor digiti As above Lateral side of proximal Abduction at metatarsophalangeal Lateral plantar
minimi phalanx, toe 5 joint of toe 5 nerve (L_4–L_5)

Quadratus Calcaneus (medial, Tendon of flexor Flexion at joints As above
plantae inferior surfaces) digitorum longus of toes 2–5

Lumbrical (4) Tendons of flexor Insertions of extensor Flexion at metatarsophalangeal Medial plantar
digitorum longus digitorum longus joints; extension at proximal nerve (1),
interphalangeal joints of lateral plantar
toes 2–5 nerve (2–4)
Flexor hallucis Cuboid and lateral Proximal phalanx Flexion at metatarsophalangeal Medial plantar
brevis cuneiform bones of great toe joint of great toe nerve (L_4–L_5)

Adductor hallucis Bases of metatarsal As above Adduction at metatarsophalangeal Lateral plantar
bones II–IV and joint of great toe nerve (S_1–S_2)
plantar ligaments

Flexor digiti Base of metatarsal Lateral side of proximal Flexion at metatarsophalangeal As above
minimi brevis bone V phalanx of toe 5 joint of toe 5

Dorsal interosseus (4) Sides of metatarsal Medial and lateral sides Abduction at metatarsophalangeal As above
bones of toe 2; lateral sides joints of toes 3 and 4

of toes 3 and 4

Plantar interosseus (3) Bases and medial sides Medial sides of toes 3–5 Adduction at metatarsophalangeal As above
of metatarsal bones joints of toes 3–5

Clinical Note

Compartment Syndrome

In the limbs, the interconnections among the superficial fascia, the deep fascia of the muscles, and the periostea of the appendicular skeleton are quite substantial. The muscles within a limb are in effect isolated in **compartments** formed by dense collagenous sheets (Figure 11–23•). Blood vessels and nerves traveling to specific muscles within the limb enter and branch within the appropriate compartments.

When a crushing injury, severe contusion, or muscle strain occurs, the blood vessels in one or more compartments may be damaged. The compartments become swollen with blood and fluid leaked from damaged vessels. The connective-tissue partitions are very strong; the accumulated fluid cannot escape, so pressure rises within the affected compartments. Eventually, the pressure can become so high that it compresses regional blood vessels, eliminating the circulatory supply to the muscles and nerves of the compartment. This compression produces **ischemia** (is-K E -m ē-uh), or "blood starvation," known in this case as **compartment syndrome**.

–

Emergency measures for relieving the pressure include slicing into the compartment along its longitudinal axis and inserting a drain. If such steps are not taken, the contents of the compartment will suffer severe damage. Nerves in the affected compartment will be destroyed after 2–4 hours of ischemia, although they can regenerate to some degree if the circulation is restored. After 6 hours or more, the muscle tissue will also be destroyed, and no regeneration can occur. The muscles will be replaced by scar tissue, and shortening of the connective tissue fibers may result in *contracture*, a permanent contraction of an entire muscle following the atrophy of individual muscle fibers.

- **FIGURE 11–23** Musculoskeletal Compartments. A section through the leg, with the muscles partially removed. A section through the thigh or arm would show a comparable arrangement of dense connective-tissue partitions. The anterior and lateral compartments of the leg contain muscles that flex (dorsiflex) the ankle and extend the toes, and the posterior compartments contain the muscles that extend (plantar flex) the ankle and flex the toes.

3

Control and Regulation

Chapter 12, Neural Tissue, considers the structure of neural tissue and introduces the basic principles of neurophysiology.

Chapter 13, The Spinal Cord, Spinal Nerves, and Spinal Reflexes, discusses the functional anatomy and organization of the spinal cord and spinal nerves, and diagrams simple spinal reflexes.

Chapter 14, The Brain and Cranial Nerves, introduces the functional organization of the brain and cranial nerves, and describes simple cranial reflexes.

Chapter 15, Neural Integration I: Sensory Pathways and the Somatic Nervous System, and **Chapter 16, Neural Integration II: The Autonomic Nervous System and Higher Order Functions,** examine how the nervous system works as an integrated unit and briefly consider aspects of higher function such as consciousness, learning, and intelligence.

Chapter 17, The Special Senses, explores smell, taste, balance, hearing, and vision.

Chapter 18, The Endocrine System, completes the unit by comparing the structural and functional organization of the endocrine and nervous systems, and describing the mechanisms involved in the hormonal modification of metabolic operations.

The End of Chapter questions within this unit include critical thinking questions about both normal and abnormal functions. For comprehensive exercises covering material in the unit as a whole, see the Clinical Problems at the end of the corresponding unit in the *Applications Manual* [AM].

An Overview of the Nervous System

Objective

- Describe the anatomical and functional divisions of the nervous system.

The nervous system includes all the neural tissue in the body. l**p. 134** The basic functional units of the nervous system are in-

¯O

¯E

dividual cells called **neurons**. Supporting cells, or **neuroglia** (noo-R

¯ o

¯ e

-uh or noo-r tect the neurons, provide a supportive framework for neural tissue, act as phagocytes, and help regulate the composition of the interstitial fluid. Neuroglia, also called *glial cells*, far outnumber neurons.

Neural tissue, with supporting blood vessels and connective tissues, forms the organs of the nervous system: the brain; the spinal cord; the receptors in complex sense organs, such as the eye and ear; and the *nerves* that link the nervous system with other systems. In the *Systems Overview* section (pp. 142–149), we introduced the two major anatomical divisions of the nervous system: the central nervous system and the peripheral nervous system.

The Anatomical Divisions of the Nervous System

The **central nervous system (CNS)** consists of the spinal cord and brain. These are complex organs that include not only neural tissue, but also blood vessels and the various connective tissues that provide physical protection and support. The CNS is responsible for integrating, processing, and coordinating sensory data and motor commands. Sensory data convey information about conditions inside or outside the body. Motor commands control or adjust the activities of peripheral organs, such as skeletal muscles. When you stumble, for example, the CNS integrates information regarding your balance and the position of your limbs and then coordinates your recovery by sending motor commands to appropriate skeletal muscles—all in a split second and without conscious effort. The CNS—specifically, the brain—is also the seat of higher functions, such as intelligence, memory, learning, and emotion.

The **peripheral nervous system (PNS)** includes all the neural tissue outside the CNS. The PNS delivers sensory information to the CNS and carries motor commands to peripheral tissues and systems. Bundles of axons, or *nerve fibers*, carry sensory information and motor commands in the PNS. Such bundles, with associated blood vessels and connective tissues, are called *peripheral nerves*, or simply **nerves**. Nerves connected to the brain are called **cranial nerves**; those attached to the spinal cord are called **spinal nerves**.

The Functional Divisions of the Nervous System

The PNS is divided into afferent and efferent divisions. The **afferent division** (*ad*, to + *ferre*, to carry) of the PNS brings sensory information to the CNS from receptors in peripheral tissues and organs. **Receptors** are sensory structures that either detect changes in the internal environment or respond to the presence of specific stimuli. There are complex receptor organs, such as the eye or ear; at the cellular level, receptors range from the dendrites (slender cytoplasmic extensions) of single cells to complex organs. Re

ceptors may be neurons or specialized cells of other tissues. l**p. 163**

The **efferent division** (*effero*, to bring out) of the PNS carries motor commands from the CNS to muscles and glands. These target organs, which respond by *doing* something, are called **effectors**. The efferent division has both somatic and autonomic components.

- The **somatic nervous system (SNS)** controls skeletal muscle contractions. *Voluntary* contractions are under conscious control. For example, you exert conscious control over your arm as you raise a full glass of water to your lips. *Involuntary* contractions may be simple, automatic responses or complex movements, but they are controlled at the subconscious level, outside your conscious awareness. For instance, if you accidentally place your hand on a hot stove, you will withdraw it immediately, usually before you even notice any pain. This type of automatic response is called a **reflex**.
- The **autonomic nervous system (ANS)**, or *visceral motor system*, provides automatic regulation of smooth muscle, cardiac muscle, and glandular secretions at the subconscious level. The ANS includes a *sympathetic division* and a *parasympathetic division*, which commonly have antagonistic effects. For example, activity of the sympathetic division accelerates the heart rate, whereas

G-l

-GL

-uh; *glia*, glue), separate and pro

parasympathetic activity slows the heart rate. AM: The Neurological Examination

Now that we have completed a brief orientation on the nervous system as a whole, we can examine the structure of neural tissue and the functional principles that govern neural activities. We begin by considering neurons, the basic functional units of the nervous system.

Neurons

Objectives

- Sketch and label the structure of a typical neuron and describe the functions of each component.
- Classify neurons on the basis of their structure and function.

In this section, we will examine the structure of a representative neuron before considering the structural and functional classifications of neurons.

The Structure of Neurons

Figure 12–1• shows the structure of a representative neuron. Neurons have a variety of shapes. The one shown is a *multipolar neuron*, the most common type of neuron in the central nervous system. Each multipolar neuron has a large *cell body* that is connected to a single, elongate *axon* and several short, branched *dendrites*.

The Cell Body

The **cell body**, or *soma* (plural, *somata*), contains a relatively large, round nucleus with a prominent nucleolus (see Figure 12–1•).

The cytoplasm surrounding the nucleus constitutes the **perikaryon** (per-i-KAR-ē-on; *peri,* around+*karyon*, nucleus). The cytoskeleton of the perikaryon contains **neurofilaments** and **neurotubules**, which are similar to the microfilaments and microtubules of other types of cells. Bundles of neurofilaments, called **neurofibrils**, extend into the dendrites and axon, providing internal support for these slender processes.

The perikaryon contains organelles that provide energy and synthesize organic materials, especially the chemical neurotransmitters that are important in cell-to-cell communication. l**p. 293** The numerous mitochondria, free and fixed ribosomes, and membranes of the rough endoplasmic reticulum (RER) give the perikaryon a coarse, grainy appearance.

Mitochondria generate ATP to meet the high energy demands of an active neuron. The ribosomes and RER synthesize proteins. Some areas of the perikaryon contain clusters of RER and free ribosomes. These regions, which stain darkly, are called *Nissl bodies*, because they were first described by the German microscopist Franz Nissl. Nissl bodies account for the gray color of areas containing neuron cell bodies—the *gray matter* seen in gross dissection.

Most neurons lack centrioles, important organelles involved in the organization of the cytoskeleton and the movement of chromosomes during mitosis. l**p. 97** As a result, typical CNS neurons cannot divide; thus, they cannot be replaced if lost to injury or disease. Although neural stem cells persist in the adult nervous system, they are typically inactive except in the nose, where the regeneration of olfactory (smell) receptors maintains our sense of smell, and in the *hippocampus*, a portion of the brain involved with memory storage. The control mechanisms that trigger neural stem cell activity are now being investigated, with the goal of preventing or reversing neuron loss due to trauma, disease, or aging.

Dendrites and Axons

A variable number of slender, sensitive processes known as **dendrites** extend out from the cell body (see Figure 12–1•). Typical dendrites are highly branched, and each branch bears fine processes called *dendritic spines*. In the CNS, a neuron receives information from other neurons primarily at the dendritic spines, which represent 80–90 percent of the neuron’s total surface area.

An **axon** is a long cytoplasmic process capable of propagating an electrical impulse known as an *action potential*. l**p. 295**

The **axoplasm** (AK-s

¯o

-plazm), or cytoplasm of the axon, contains neurofibrils, neurotubules, small vesicles, lysosomes, mito chondria, and various enzymes. The axoplasm is surrounded by the **axolemma** (*lemma*, husk), a specialized portion of the cell membrane. In the CNS, the axolemma may be exposed to the interstitial fluid or covered by the processes of neuroglia. The base, or **initial segment**, of the axon in a multipolar neuron is attached to the cell body at a thickened region known as the **axon hillock** (see Figure 12–1•).

An axon may branch along its length, producing side branches collectively known as **collaterals**. Collaterals enable a single neuron to communicate with several other cells. The main axon trunk and any collaterals end in a series of fine extensions, or **telodendria** (tel-ō-DEN-drē-uh; *telo*-, end + *dendron*, tree) (see Figure 12–1•). The telodendria of an axon end at **synaptic terminals**.

The Synapse

Each synaptic terminal is part of a **synapse**, a specialized site where the neuron communicates with another cell (Figure 12–2•). Every synapse involves two cells: (1) the *presynaptic cell*, which includes the synaptic terminal and sends a message, and (2) the *postsynaptic cell*, which receives the message. The communication between cells at a synapse most commonly involves the release of chemicals called **neurotransmitters** by the synaptic terminal. These chemicals, released by the presynaptic cell, affect the activity of the postsynaptic cell. As we saw in Chapter 10, this release is triggered by electrical events, such as the arrival of an action potential. Neurotransmitters are typically packaged in *synaptic vesicles*.

The presynaptic cell is usually a neuron. (Specialized receptor cells may form synaptic connections with the dendrites of neurons, a process that will be described in Chapter 15.) The postsynaptic cell can be either a neuron or another type of cell. When one neuron communicates with another, the synapse may occur on a dendrite, on the cell body, or along the length of the axon of

the receiving cell. A synapse between a neuron and a muscle cell is called a **neuromuscular junction**. l**p. 293** At a **neuroglandular junction**, a neuron controls or regulates the activity of a secretory (gland) cell. Neurons also innervate a variety of other cell types, such as adipocytes (fat cells). We will consider the nature of that innervation in later chapters.

The structure of the synaptic terminal varies with the type of postsynaptic cell. A relatively simple, round **synaptic knob** occurs where the postsynaptic cell is another neuron.1 At a synapse, a narrow *synaptic cleft* separates the **presynaptic membrane**, where neurotransmitters are released, from the **postsynaptic membrane**, which bears receptors for neurotransmitters (see Figure 12–2•). The synaptic terminal at a neuromuscular junction is much more complex. We will primarily consider the structure of synaptic knobs in this chapter, leaving the details of other types of synaptic terminals to later chapters.

Each synaptic knob contains mitochondria, portions of the endoplasmic reticulum, and thousands of vesicles filled with neurotransmitter molecules. Breakdown products of neurotransmitters released at the synapse are reabsorbed and reassembled at the synaptic knob, which also receives a continuous supply of neurotransmitters synthesized in the cell body, along with enzymes and lysosomes. These materials travel the length of the axon along neurotubules, pushed along by "molecular motors," called *kinesins*, that run on ATP. The movement of materials between the cell body and synaptic knobs is called **axoplasmic transport**. Some materials travel slowly, at rates of a few millimeters per day. This transport mechanism is known as the "slow stream." Vesicles containing neurotransmitters move much more rapidly, traveling in the "fast stream" at 5–10 mm per hour.

Axoplasmic transport occurs in both directions. The flow of materials from the cell body to the synaptic knob is *anterograde*

(AN-ter-

¯o

-gr

¯a

d; *antero*-, forward) *flow*. At the same time, other substances are being transported toward the cell body in *retrograde*

(RET-r

¯o

-gr

¯a

d) *flow* (*retro*, backward). If debris or unusual chemicals appear in the synaptic knob, retrograde flow soon delivers

them to the cell body. The arriving materials may then alter the activity of the cell by turning appropriate genes on or off.

Rabies is perhaps the most dramatic example of a clinical condition directly related to retrograde flow. A bite from a rabid animal injects the rabies virus into peripheral tissues, where virus particles quickly enter synaptic knobs and peripheral axons. Retrograde flow then carries the virus into the CNS, with fatal results. Many toxins, including heavy metals, some pathogenic bacteria, and other viruses, also bypass CNS defenses by exploiting axoplasmic transport. AM: Axoplasmic Transport and Disease

The Classification of Neurons

Neurons can be grouped by structure or by function.

Structural Classification of Neurons

Neurons are classified as anaxonic, bipolar, unipolar, or multipolar on the basis of the relationship of the dendrites to the cell body and the axon (Figure 12–3•):

- **Anaxonic** (an-ak-SON-ik) neurons are small and have no anatomical features that distinguish dendrites from axons; all the cell processes look alike. Anaxonic neurons are located in the brain and in special sense organs. Their functions are poorly understood.
- **Bipolar neurons** have two distinct processes—one dendritic process that branches extensively at its distal tip, and one axon— with the cell body between the two. Bipolar

neurons are rare, but occur in special sense organs, where they relay information about sight, smell, or hearing from receptor cells to other neurons. Bipolar neurons are small; the largest measure less than 30 mm from end to end.

- In a **unipolar neuron**, or *pseudounipolar neuron,* the dendrites and axon are continuous—basically, fused—and the cell body lies off to one side. In such a neuron, the initial segment lies where the dendrites converge. The rest of the process, which carries action potentials, is usually considered to be an axon. Most sensory neurons of the peripheral nervous system are unipolar. Their axons may extend a meter or more, ending at synapses in the central nervous system. The longest are those carrying sensations from the tips of the toes to the spinal cord.
- **Multipolar neurons** have two or more dendrites and a single axon. These are the most common neurons in the CNS. All the motor neurons that control skeletal muscles, for example, are multipolar neurons. The axons of multipolar neurons can be as long as those of unipolar neurons; the longest carry motor commands to small muscles that move the toes.

Functional Classification of Neurons

Alternatively, neurons are categorized by function as (1) sensory neurons, (2) motor neurons, and (3) interneurons.

Sensory Neurons **Sensory neurons**, or *afferent neurons*, form the afferent division of the PNS. They deliver information from sensory receptors to the CNS. The cell bodies of sensory neurons are located in peripheral *sensory ganglia*. (A *ganglion* is a collection of neuron cell bodies in the PNS.) Sensory neurons are unipolar neurons with processes, known as **afferent fibers**, that extend between a sensory receptor and the central nervous system (spinal cord or brain). The human body’s 10 million or so sensory neurons collect information concerning the external or internal environment. **Somatic sensory neurons** monitor the outside world and our position within it; **visceral sensory neurons** monitor internal conditions and the status of other organ systems.

Sensory receptors are either the processes of specialized sensory neurons or cells monitored by sensory neurons. Receptors are broadly categorized as follows:

- **Interoceptors** (*intero-*, inside) monitor the digestive, respiratory, cardiovascular, urinary, and reproductive systems and provide sensations of taste, deep pressure, and pain.
- **Exteroceptors** (*extero-*, outside) provide information about the external environment in the form of touch, temperature, or pressure sensations and the more complex senses of sight, smell, and hearing.

•

Proprioceptors (pr
¯o
-pr
¯e
-

¯o
-SEP-torz) monitor the position and movement of skeletal muscles and joints.

Motor Neurons **Motor neurons**, or *efferent neurons,* form the efferent division of the PNS. These neurons carry instructions from the CNS to peripheral effectors in a peripheral tissue, organ, or organ system. The human body has about half a million motor neurons. Axons traveling away from the CNS are called **efferent fibers**. As noted earlier, the two major efferent systems are the somatic nervous system (SNS) and the autonomic (visceral) nervous system (ANS).

The somatic nervous system includes all the **somatic motor neurons** that innervate skeletal muscles. You have conscious control over the activity of the SNS. The cell body of a somatic motor neuron lies in the CNS, and its axon extends into the periphery to innervate skeletal muscle fibers at neuromuscular junctions.

You do not have conscious control over the activities of the ANS. **Visceral motor neurons** innervate all peripheral effectors other than skeletal muscles—that is, smooth muscle, cardiac muscle, glands, and adipose tissue throughout the body. The axons of visceral motor neurons in the CNS innervate a second set of visceral motor neurons in peripheral *autonomic ganglia*. The neurons whose cell bodies are located in those ganglia innervate and control peripheral effectors.

To get from the CNS to a visceral effector such as a smooth muscle cell, the signal must travel along one axon, be relayed across a synapse, and then travel along a second axon to its final destination. The axons extending from the CNS to an autonomic ganglion are called *preganglionic fibers*; axons connecting the ganglion cells with the peripheral effectors are known as *postganglionic fibers*.

Interneurons The 20 billion or so **interneurons**, or *association neurons*, outnumber all other types of neurons combined. Although most are located within the brain and spinal cord, some are in autonomic ganglia. Interneurons are responsible for both the distribution of sensory information and the coordination of motor activity. One or more interneurons are situated between sensory neurons and motor neurons; the more complex the response to a given stimulus, the more interneurons are involved. Interneurons are also involved with all higher functions, such as memory, planning, and learning.

We next turn our attention to the neuroglia, cells that support and protect the neurons.

Neuroglia

Objective

- Describe the locations and functions of neuroglia.

Neuroglia are abundant and diverse, and they account for roughly half of the volume of the nervous system. The organization of neural tissue in the CNS differs significantly from that in the PNS, primarily because of the greater variety of neuroglial cell types in the CNS. Although histological descriptions have been available for the past century, the technical problems involved in isolating and manipulating individual glial cells have limited our understanding of their functions. We begin by examining the neuroglia in the CNS.

Neuroglia of the Central Nervous System

The central nervous system has four types of neuroglia: (1) *ependymal cells*, (2) *astrocytes*, (3) *oligodendrocytes*, and (4) *microglia* (Figure 12–4•).

Ependymal Cells

A fluid-filled central passageway extends along the longitudinal axis of the spinal cord and brain. This passageway is filled with **cerebrospinal fluid (CSF)**, which also surrounds the brain and spinal cord. This fluid, which circulates continuously, provides a protective cushion and transports dissolved gases, nutrients, wastes, and other materials. The diameter of the internal passageway varies from one region to another. The narrow passageway in the spinal cord is called the *central canal* (see Figure 12–4a,b•). In several regions of the brain, the passageway forms enlarged chambers called *ventricles*. The central canal and ventricles are lined by **ependymal cells**, which form an epithelium known as the **ependyma** (ep-EN-di-muh).

During embryonic development and early childhood, the free surfaces of ependymal cells are covered with cilia. The cilia persist in adults only within the ventricles of the brain, where they assist in the circulation of the CSF. In other areas, the ependymal cells typically have scattered microvilli. In a few parts of the brain, specialized ependymal cells participate in the secretion of the CSF. Other regions of the ependyma may have sensory functions, such as monitoring the composition of the CSF. It appears that the ependyma in adults contains stem cells that can divide to produce additional neurons. The specific regulatory mechanisms involved are now being investigated.

Unlike typical epithelial cells, ependymal cells have slender processes that branch extensively and make direct contact with neuroglia in the surrounding neural tissue. The functions of these connections are not known. During early embryonic development, stem cells line the central canal and ventricles; the divisions of these stem cells give rise to neurons and all CNS neuroglia other than microglia. ATLAS: Embryology Summary 10: An Introduction to the Development of the Nervous System

Astrocytes

Astrocytes (AS-tr

¯o

-s

ts; *astro*-, star +

cyte, cell), are the largest and most numerous neuroglia in the CNS (see Figure 12–4b•).

ı These cells have a variety of functions, many of them poorly understood:

- **Maintaining the Blood–Brain Barrier.** Compounds dissolved in the circulating blood do not have free access to the interstitial fluid of the CNS. Neural tissue must be physically and biochemically isolated from the general circulation, because hormones or other chemicals in the blood can alter neuron function. The endothelial cells lining CNS capillaries control the chemical exchange between the blood and interstitial fluid. These cells create a **blood–brain barrier** that isolates the CNS from the general circulation.

The slender cytoplasmic extensions of astrocytes end in expanded "feet," processes that wrap around capillaries. Astrocytic processes form a complete blanket around the capillaries, interrupted only where other neuroglia come in contact with the capillary walls. Chemicals secreted by astrocytes are somehow responsible for maintaining the special permeability characteristics of endothelial cells. (We will discuss the blood–brain barrier further in Chapter 14.)

- **Creating a Three-Dimensional Framework for the CNS.** Astrocytes are packed with microfilaments that extend across the breadth of the cell and its processes. This extensive cytoskeletal reinforcement assists astrocytes in providing a structural framework for the neurons of the brain and spinal cord.
- **Repairing Damaged Neural Tissue.** In the CNS, damaged neural tissue seldom regains normal function. However, astrocytes moving into an injury site can make structural repairs that stabilize the tissue and prevent further injury. We will consider neural damage and subsequent repair in a later section.
- **Guiding Neuron Development.** Astrocytes in the embryonic brain appear to be involved in directing both the growth and interconnection of developing neurons.

- **Controlling the Interstitial Environment.** Astrocytes appear to adjust the composition of interstitial fluid by several means:

(1) regulating the concentration of sodium ions, potassium ions, and carbon dioxide; (2) providing a “rapid-transit system” for the transport of nutrients, ions, and dissolved gases between capillaries and neurons; (3) controlling the volume of blood flow through the capillaries; (4) absorbing and recycling some neurotransmitters; and (5) releasing chemicals that enhance or suppress communication across synaptic terminals.

Oligodendrocytes

–

Like astrocytes, **oligodendrocytes** (ol-i-g

–

ı ies of oligodendrocytes are smaller, and have fewer processes, than astrocytes (see Figure 12–4b•). The processes of oligodendrocytes generally are in contact with the exposed surfaces of neurons; the functions of processes ending at the neuron cell body have yet to be determined. Much more is known about the processes that end on the surfaces of axons. Many axons in the CNS are completely sheathed in these processes, which insulate them from contact with the extracellular fluid.

Near the tip of each process, the axolemma expands to form an enormous membranous pad, and the cytoplasm there becomes very thin. This flattened “pancake” somehow gets wound around the axon, forming concentric layers of cell membrane (see Figure 12–4b•). The membranous wrapping of insulation, called **myelin** (M -e-lin), increases the speed at which an action potential trav-

I¯els along the axon (the mechanism will be described in a later section).

Many oligodendrocytes cooperate in the formation of a **myelin sheath** along the length of an axon. Such an axon is said to be **myelinated**. Each oligodendrocyte myelinates segments of several axons. The relatively large areas of the axon that are thus wrapped in myelin are called **internodes** (*inter*, between). Internodes are typically 1–2 mm in length. The small gaps of a few mi-

¯o

-DEN-dr

¯o

ts; *oligo*-, few) possess slender cytoplasmic extensions, but the cell bod--s

crometers that separate adjacent internodes are called **nodes**, or *nodes of Ranvier* (rahn-v

¯e

-

¯A

). When an axon branches, the

branches originate at nodes.

In dissection, myelinated axons appear glossy white, primarily because of the lipids within the myelin. As a result, regions dominated by myelinated axons constitute the **white matter** of the CNS. Not all axons in the CNS are myelinated, however. **Unmyelinated** axons may not be completely covered by the processes of neuroglia. Such axons are common where relatively short axons and collaterals form synapses with densely packed neuron cell bodies. Areas containing neuron cell bodies, dentrites, and unmyelinated axons have a dusky gray color, and they constitute the **gray matter** of the CNS.

In sum, oligodendrocytes play a role in structural organization by tying clusters of axons together, and these neuroglia also improve the functional performance of neurons by wrapping axons within a myelin sheath.

Microglia

¯O

–

The least numerous and smallest neuroglia in the CNS are **microglia** (m -KR ı have many fine branches (see Figure 12–4b•). These cells are capable of migrating through neural tissue. Microglia appear early in embryonic development, originating from mesodermal stem cells related to those stem cells that produce monocytes and

macrophages. l**pp. 119, 125** Microglia migrate into the CNS as the nervous system forms. Thereafter, they remain isolated in neural tissue, where in effect they act as a wandering police force and janitorial service by engulfing cellular debris, waste products, and pathogens.

G-l

‾e

-uh). Their slender cytoplasmic processes

Clinical Note

Tumors of the brain, spinal cord, and associated membranes result in approximately 90,000 deaths in the United States each year. Tu

mors that originate in the central nervous system are called *primary CNS tumors*, to distinguish them from *secondary CNS tumors*,

which arise from the metastasis (spread) of cancer cells that originate elsewhere. Roughly 75 percent of CNS tumors are primary tu

mors. In adults, primary CNS tumors result from the divisions of abnormal neuroglia rather than from the divisions of abnormal neurons,

because typical neurons in adults cannot divide. However, through the divisions of stem cells, neurons increase in number until children

reach age 4. As a result, primary CNS tumors involving abnormal neurons can occur in young children. Symptoms of CNS tumors vary

with the location affected. Treatment may involve surgery, radiation, chemotherapy, or a combination of these procedures.

Neuroglia of the Peripheral Nervous System

As previously noted, the cell bodies of neurons in the PNS are clustered in masses called **ganglia** (singular, *ganglion*). Neuronal cell bodies and most axons in the PNS are completely insulated from their surroundings by the processes of neuroglia. The two types of neuroglia in the PNS are called satellite cells and Schwann cells.

Satellite cells, or *amphicytes* (AM-fi-s ts), surround neuron cell bodies in ganglia; they regulate the environment around the

–

ı neurons, much as astrocytes do in the CNS. **Schwann cells**, or *neurilemmal cells* (*neurilemmocytes*), form a sheath around peripheral axons (Figure 12–5•). Wherever a Schwann cell covers an axon, the outer surface of the Schwann cell is called the **neurilemma** (noor-i-LEM-uh). Most axons in the PNS, whether myelinated or unmyelinated, are shielded from contact with interstitial fluids by Schwann cells.

Whereas an oligodendrocyte in the CNS may myelinate portions of several adjacent axons (see Figure 12–4b•), a Schwann cell can myelinate only one segment of a single axon (see Figure 12–5a•). However, a Schwann cell can *enclose* segments of several unmyelinated axons (see Figure 12–5b•). A series of Schwann cells is required to enclose an axon along its entire length.

Clinical Note

Demyelination is the progressive destruction of myelin sheaths, both in the CNS and in the PNS. The result is a loss of sensation and motor control that leaves affected regions numb and paralyzed. Many unrelated conditions that result in the destruction of myelin can cause symptoms of demyelination. Several important demyelinating disorders are *heavy-metal poisoning, diphtheria, multiple sclerosis (MS),*

and *Guillain–Barré syndrome*. AM: Demyelination Disorders

100 Keys | Neurons perform all of the communication, information processing, and control functions of the nervous system. Neuroglia outnumber neurons and have functions that are essential to the preservation of the physical and biochemical structure of neural tissue, and to the survival and functionality of neurons.

Neural Responses to Injuries

A neuron responds to injury in a very limited, stereotyped fashion. In the cell body, the Nissl bodies disperse and the nucleus moves away from its centralized location as the cell increases its rate of protein synthesis. If the neuron recovers its functional abilities, it will regain its normal appearance. The key to recovery appears to be events in the axon. If, for example, the pressure applied during a crushing injury produces a local decrease in blood flow and oxygen availability, the affected axonal membrane becomes unexcitable. If the pressure is alleviated after an hour or two, the neuron will recover within a few weeks, but more severe or prolonged pressure produces effects similar to those caused by cutting the axon.

In the PNS, Schwann cells participate in the repair of damaged nerves. In the process known as **Wallerian degeneration** (Figure 12–6•), the axon distal to the injury site degenerates, and macrophages migrate into the area to phagocytize the debris. The Schwann cells do not degenerate; instead, they proliferate and form a solid cellular cord that follows the path of the original axon. As the neuron recovers, its axon grows into the site of injury, and the Schwann cells wrap around the axon.

If the axon continues to grow into the periphery alongside the appropriate cord of Schwann cells, it may eventually reestablish its normal synaptic contacts. However, if it stops growing or wanders off in some new direction, normal function will not return. The growing axon is most likely to arrive at its appropriate destination if the cut edges of the original nerve bundle remain in contact.

Limited regeneration can occur in the CNS, but the situation is more complicated because (1) many more axons are likely to be involved, (2) astrocytes produce scar tissue that can prevent axon growth across the damaged area, and (3) astrocytes release chemicals that block the regrowth of axons.

Concept Check

What would be the effect of damage to the afferent division of the PNS?

Are unipolar neurons in a tissue sample more likely to be sensory neurons or motor neurons?

Which type of neuroglia would occur in larger-than-normal numbers in the brain tissue of a person with a CNS infection?

Answers begin on p. A–1

Ion Movements and Electrical Signals

Objectives

- Explain how the resting potential is created and maintained.
- Describe the events involved in the generation and propagation of an action potential.
- Discuss the factors that affect the speed with which action potentials are propagated.

In Chapter 3, we introduced the concepts of the *transmembrane potential* and the *resting potential*, two characteristic features of all cells. l**p. 94** In this section, we will focus on the membrane properties of neurons; many of the principles discussed also apply to other types of cells.

Figure 12–7• introduces the important membrane processes we will be examining.

- All living cells have a transmembrane potential that varies from moment to moment depending on the activities of the cell. The *resting potential* is the transmembrane potential of a resting cell. All neural activities begin with a change in the resting potential of a neuron.
- A typical stimulus produces a temporary, localized change in the resting potential. The effect, which decreases with distance from the stimulus, is called a *graded potential*.
- If the graded potential is sufficiently large, it produces an *action potential* in the membrane of the axon. An action potential is an electrical impulse that is propagated across the surface of an axon and does not diminish as it moves away from its source. This impulse travels along the axon to one or more synapses.

- *Synaptic activity* then produces graded potentials in the cell membrane of the postsynaptic cell. The process typically involves the release of neurotransmitters, such as ACh, by the presynaptic cell. These compounds bind to receptors on the postsynaptic cell membrane, changing its permeability. The mechanism is comparable to that of the neuromuscular junction, described in
Chapter 10. l**p. 293**
- The response of the postsynaptic cell ultimately depends on what the stimulated receptors do and what other stimuli are influencing the cell at the same time. The integration of stimuli at the level of the individual cell is the simplest form of *information processing* in the nervous system.

When you understand each of the foregoing processes, you will know how neurons process information and communicate with one another and with peripheral effectors.

The Transmembrane Potential

Chapter 3 introduced three important concepts regarding the transmembrane potential:

1. The intracellular fluid (cytosol) and extracellular fluid differ markedly in ionic composition. The extracellular fluid (ECF) contains high concentrations of sodium ions (Na^+) and chloride ions (Cl^-), whereas the cytosol contains high concentrations of potassium ions (K^+) and negatively charged proteins.

2. If the cell membrane were freely permeable, diffusion would continue until all the ions were evenly distributed across the membrane and a state of equilibrium existed. But an even distribution does not occur, because cells have selectively permeable membranes. l**p. 85** Ions cannot freely cross the lipid portions of the cell membrane; they can enter or leave the cell only through membrane channels. Many kinds of membrane channels exist, each with its own properties. At the resting potential, or transmembrane potential of an undisturbed cell, ion movement occurs through *leak channels*—membrane channels that are always open. l**pp. 66–67** Active transport mechanisms also move specific ions into or out of the cell.

3. The cell's passive and active transport mechanisms do not ensure an equal distribution of charges across its membrane, because

membrane permeability varies by ion. For example, negatively charged proteins inside the cell cannot cross the membrane, and it is easier for K^+ to diffuse out of the cell through a potassium channel than it is for Na^+ to enter the cell through a sodium channel. As a result, the inner surface has an excess of negative charges with respect to the outer surface.

Both passive and active forces act across the cell membrane to determine the transmembrane potential at any moment. Figure 12–8• provides a brief overview of the state of the membrane at the normal resting potential.

Passive Forces Acting across the Membrane

The passive forces acting across the membrane are both chemical and electrical in nature.

Chemical Gradients Because the intracellular concentration of potassium ions is relatively high, these ions tend to move out of the cell through open potassium channels. The movement is driven by a concentration gradient, or *chemical gradient*. Similarly, a chemical gradient for sodium ions tends to drive those ions into the cell.

Electrical Gradients Because the cell membrane is much more permeable to potassium than to sodium, potassium ions leave the cytoplasm more rapidly than sodium ions enter. As a result, the cytosol along the interior of the membrane exhibits a net loss of positive charges, leaving an excess of negatively charged proteins. At the same time, the extracellular fluid near the outer surface of the cell membrane displays a net gain of positive charges. The positive and negative charges are separated by the cell membrane, which restricts the free movement of ions. Whenever positive and negative ions are held apart, a *potential difference* arises.

The size of a potential difference is measured in volts (V) or millivolts (mV; thousandths of a volt). The resting potential varies widely, depending on the type of cell, but averages about 0.07 V for many cells, including most neurons. We will use this value in our discussion, usually expressing it as -70 mV (see Figure 12–8•). The minus sign signifies that the inner surface of the cell membrane is negatively charged with respect to the exterior.

Positive and negative charges attract one another. If nothing separates them, oppositely charged ions will move together and eliminate the potential difference between them. A movement of charges to eliminate a potential difference is called a **current**. If a barrier (such as a cell membrane) separates the oppositely charged ions, the amount of current depends on how easily the ions can cross the membrane. The **resistance** of the membrane is a measure of how much the membrane restricts ion movement. If the resistance is high, the current is very small, because few ions can cross the membrane. If the resistance is low, the current is very large, because ions flood across the membrane. The resistance of a cell membrane can be changed by the opening or closing of ion channels. The ensuing changes result in currents that bring ions into or out of the cytoplasm.

The Electrochemical Gradient Electrical gradients can either reinforce or oppose the chemical gradient for each ion. The **electrochemical gradient** for a specific ion is the sum of the chemical and electrical forces acting on that ion across the cell membrane. The electrochemical gradients for K^+ and Na^+ are the primary factors affecting the resting potential of most cells, including neurons. We will consider the forces acting on each ion independently.

The intracellular concentration of potassium ions is relatively high, whereas the extracellular concentration is very low. Therefore, the chemical gradient for potassium ions tends to drive them out of the cell, as indicated by the black arrow in Figure 12–9a•. However, the electrical gradient opposes this movement, because K^+ inside and outside of the cell are attracted to the negative charges on the inside of the cell membrane, and repelled by the positive charges on the outside of the cell membrane. The size and direction of the electrical gradient is indicated by the white arrow in Figure 12–9a•. The chemical gradient is strong enough to overpower the electrical gradient, but this weakens the force driving K^+ out of the cell; the net driving force is represented by the gray arrow.

If the cell membrane were freely permeable to K^+ but impermeable to other positively charged ions, potassium ions would continue to leave the cell until the electrical gradient (opposing the exit of K^+ from the cell) was as strong as the chemical gradient (driving K^+ out of the cell). The transmembrane potential at which there is no net movement of a particular ion across the cell membrane is called the *equilibrium potential* for that ion. For potassium ions, this equilibrium occurs at a transmembrane potential of about -90 mV, as illustrated in Figure 12–9b•. The resting membrane potential is typically -70 mV, a value very close

to the equilibrium potential for K^+; the difference is due primarily to the continuous leakage of Na^+ into the cell.

The sodium ion concentration in the extracellular fluid is relatively high, whereas that inside the cell is extremely low. As a result, there is a strong chemical gradient driving Na^+ into the cell (the black arrow in Figure 12–9c•). In addition, the extracellular sodium ions are attracted by the excess of negative charges on the inner surface of the cell membrane, and the relative size and direction of this electrical gradient is indicated by the white arrow in Figure 12–9c•. This means that electrical forces and chemical forces drive Na^+ into the cell, and the net driving force is represented by the gray arrow.

If the cell membrane were freely permeable to Na^+, these ions would continue to enter the cell until the interior of the cell membrane contained enough excess positive charges to reverse the electrical gradient. In other words, ion movement would continue until the interior developed such a strongly positive charge that repulsion between the positive charges would prevent any further net movement of Na^+ into the cell. The equilibrium potential for Na^+ is approximately + 66 mV, as illustrated in Figure 12–9d•. The resting potential is nowhere near that value, because the resting membrane permeability to Na^+ is very low, and be

cause ion pumps in the cell membrane are able to eject sodium ions as fast as they cross the membrane.

An electrochemical gradient is a form of *potential energy*. l**p. 94** Potential energy is stored energy—the energy of position, as exists in a stretched spring, a charged battery, or water behind a dam. Without a cell membrane, diffusion would eliminate all electrochemical gradients. In effect, the cell membrane acts like a dam across a river. Without the dam, water would simply respond to gravity and flow downstream, gradually losing energy. With the dam in place, even a small opening will release water under tremendous pressure. Similarly, any stimulus that increases the permeability of the cell membrane to sodium or potassium ions will produce sudden and dramatic ion movement. For example, a stimulus that opens sodium ion channels will trigger an immediate rush of Na^+ into the cell. The nature of the stimulus does not determine the amount of ion movement; if the stimulus opens the door, the electrochemical gradient will do the rest.

Active Forces across the Membrane:

The Sodium–Potassium Exchange Pump

We can compare a cell to a leaky fishing boat loaded with tiny fish. The hull represents the cell membrane; the fish, K^+; and the ocean water, Na^+. As the boat rumbles and rolls, water comes in through the cracks, and fish swim out. If the boat is to stay afloat and the catch kept, the water must be pumped out, and the lost fish recaptured.

Similarly, at the normal resting potential, the cell must bail out sodium ions that leak in and recapture potassium ions that leak out. The “bailing” occurs through the activity of an exchange pump powered by ATP. The ion pump involved is the carrier protein *sodium–potassium ATPase*. l**p. 90** This pump exchanges three intracellular sodium ions for two extracellular potassium ions. At the normal resting potential, this pump’s primary significance is that it ejects sodium ions as quickly as they enter the cell. Thus, the activity of the exchange pump exactly balances the passive forces of diffusion, and the resting potential remains stable.

Table 12–1 provides a summary of the important features of the resting potential.

Review transmembrane potential on the **IP CD-ROM: Nervous System I/The Membrane Potential.**

Changes in the Transmembrane Potential

As noted previously, the resting potential is the transmembrane potential of an “undisturbed” cell. Yet cells are dynamic structures that continually modify their activities, either in response to external stimuli or to perform specific functions. The transmembrane potential is equally dynamic, rising or falling in response to temporary changes in membrane permeability. Those changes result from the opening or closing of specific membrane channels.

Membrane channels control the movement of ions across the cell membrane. Our discussion will focus on the permeability of the membrane to sodium and potassium ions, which are the primary determinants of the transmembrane potential of many cell types, including neurons. Sodium and potassium ion channels are either passive or active.

Passive channels, or **leak channels**, are always open. However, their permeability can vary from moment to moment as the proteins that make up the channel change shape in response to local conditions. As noted earlier, sodium and potassium leak channels are important in establishing the normal resting potential of the cell (see Figure 12–8•).

Cell membranes also contain **active channels**, often called **gated channels**, which open or close in response to specific stimuli. Each gated channel can be in one of three states: (1) closed but capable of opening, (2) open (**activated**), or (3) closed and incapable of opening (**inactivated**).

Three classes of gated channels exist: chemically regulated channels, voltage-regulated channels, and mechanically regulated channels.

1. Chemically regulated channels open or close when they bind specific chemicals (Figure 12–10a•). The receptors that bind acetylcholine (ACh) at the neuromuscular junction are chemically regulated channels. l**p. 293** Chemically regulated channels are most abundant on the dendrites and cell body of a neuron, the areas where most synaptic communication occurs.

2. Voltage-regulated channels are characteristic of areas of **excitable membrane**, a membrane capable of generating and con

ducting an action potential. Examples of excitable membranes are the axons of unipolar and multipolar neurons, and the sarcolemma (including T tubules) of skeletal muscle fibers and cardiac muscle cells. l**pp. 295, 316** Voltage-regulated channels open or close in response to changes in the transmembrane potential. The most important voltage-regulated channels, for our purposes, are voltage-regulated sodium channels, potassium channels, and calcium channels. Sodium channels have two gates that function independently: an *activation gate* that opens on stimulation, letting sodium ions into the cell, and an *inactivation gate* that closes to stop the entry of sodium ions (Figure 12–10b•).

3. Mechanically regulated channels open or close in response to physical distortion of the membrane surface (Figure 12–10c•). Such channels are important in sensory receptors that respond to touch, pressure, or vibration. We will discuss these receptors in more detail in Chapter 15.

At the resting potential, most gated channels are closed. The opening of gated channels alters the rate of ion movement across the cell membrane and thus changes the transmembrane potential. The distribution of membrane channels can vary from one region of the cell membrane to another, affecting how and where a cell responds to specific stimuli. For example, whereas chemically regulated sodium channels are widespread on the surfaces of a neuron, voltage-regulated sodium channels are most abundant on the axon, its branches, and the synaptic terminals, and mechanically regulated channels are typically located only on the dendrites of sensory neurons. The functional implications of these differences in distribution will become apparent in later sections.

100 Keys | A transmembrane potential exists across the cell membrane. It is there because (1) the cytosol differs from extracellular fluid in chemical and ionic composition and (2) the cell membrane is selectively permeable. The transmembrane potential can change from moment to moment, as the cell membrane changes its permeability in response to chemical or physical stimuli.

Review membrane channels on the **IP CD-ROM: Nervous System I/Ion Channels.**

Graded Potentials

Graded potentials, or *local potentials*, are changes in the transmembrane potential that cannot spread far from the site of stimulation. Any stimulus that opens a gated channel will produce a graded potential. Figure 12–11• shows what happens when a resting membrane is exposed to a chemical that opens chemically regulated sodium channels. (For clarity, only gated channels are shown; leak channels are present, but they are not involved in the production of graded potentials.) Sodium ions enter the cell and are attracted to the negative charges along the inner surface of the membrane. The arrival and spreading out of additional positive charges shifts the transmembrane potential toward 0 mV (STEP 1). Any shift from the resting potential toward 0 mV is called a **depolarization**, a term that applies to changes in potential from -70 mV to smaller negative values (-65 mV, -45 mV, -10 mV), as well as to membrane potentials above 0 mV (+ 10 mV, + 30 mV).

At the resting potential, sodium ions are drawn to the outer surface of the cell membrane, attracted by the excess of negative ions on the inside of the membrane. As the cell membrane depolarizes, sodium ions are released from its outer surface. These ions, accompanied by other extracellular sodium ions, then move toward the open channels, replacing ions that have already entered the cell. This movement of positive charges parallel to the inner and outer surfaces of a membrane is called a **local current** (STEP 2).

The degree of depolarization decreases with distance away from the stimulation site, because the cytosol offers considerable resistance to ion movement, and because some of the sodium ions entering the cell then move back across the membrane through sodium leak channels. At some distance from the entry point, the effects on the transmembrane potential are undetectable (STEP 2). The maximum change in the transmembrane potential is proportional to the size of the stimulus, because that determines the number of open sodium channels. The more open channels, the more sodium ions enter the cell, the greater the membrane area affected, and the greater the degree of depolarization.

When a chemical stimulus is removed and normal membrane permeability is restored, the transmembrane potential soon returns to resting levels. The process of restoring the normal resting potential after depolarization is called **repolarization** (Figure 12–12a•). Repolarization typically involves a combination of ion movement through membrane channels and the activities of ion pumps, especially the sodium–potassium exchange pump.

Opening a gated potassium channel would have the opposite effect on the transmembrane potential as opening a gated sodium channel: The rate of potassium outflow would increase, and the interior of the cell would lose positive ions. The loss of positive ions produces **hyperpolarization**, an increase in the negativity of the resting potential from -70 mV to perhaps -80 mV or more (Figure 12–12b•). Again, a local current would distribute the effect to adjacent portions of the cell membrane, and the effect would decrease with distance from the open channel or channels. Graded potentials occur in the membranes of many types of cells—not just nerve and muscle cells, but epithelial cells, gland cells, adipocytes, and a variety of sensory receptors.

Graded potentials are often the trigger for specific cell functions; for example, a graded potential at the surface of a gland cell may trigger the exocytosis of secretory vesicles. Similarly, it is the graded depolarization of the motor end plate by ACh that triggers an action potential in adjacent portions of the sarcolemma. The motor end plate supports graded potentials, whereas the rest of the sarcolemma consists of excitable membrane. Table 12–2 summarizes the basic characteristics of graded potentials.

An interesting observation—that each neuron receives information in the form of graded potentials on its dendrites and cell body, and releases neurotransmitter in response to graded potentials at synaptic terminals—brings us to an important question: Given that even the largest graded potentials affect only a tiny area (perhaps only 1 mm in diameter), and that the axon of a typical sensory or motor neuron is so long that graded potentials on the dendrites and cell body can have no direct effect on the synaptic terminals, how can graded potentials on the dendrites and cell body create a graded potential at the synaptic terminals to trigger the release of neurotransmitter? The answer is that the graded potentials at opposite ends of the cell are linked by an action potential, which we will study next.

Action Potentials

Action potentials are propagated changes in the transmembrane potential that, once initiated, affect an entire excitable membrane. The first step in the generation of an action potential is the opening of voltage-regulated sodium ion channels at one site, usually the initial segment of the axon. The movement of sodium ions into the cell depolarizes adjacent sites, triggering the opening of additional voltage-regulated channels. The result is a chain reaction that spreads across the surface of the membrane like a line of falling dominoes. In this way, the impulse is propagated along the length of the axon, ultimately reaching the synaptic terminals.

The All-or-None Principle

The stimulus that initiates an action potential is a depolarization large enough to open voltage-regulated sodium channels. That opening occurs at a transmembrane potential known as the **threshold**. Threshold for an axon is typically between -60 mV and -55 mV, corresponding to a depolarization of 10–15 mV. A stimulus that shifts the resting membrane potential from -70 mV to
-62 mV will not produce an action potential, only a graded depolarization. When such a stimulus is removed, the transmembrane potential returns to the resting level. The depolarization of the initial segment of the axon is caused by local currents resulting from the graded depolarization of the axon hillock.

The initial depolarization acts like pressure on the trigger of a gun. If a slight pressure is applied, the gun will not fire. It will fire only when a certain minimum pressure is applied to the trigger. Once the pressure on the trigger reaches this threshold, the firing pin drops and the gun discharges. At that point, it no longer matters whether the pressure was applied gradually or suddenly or whether it was caused by the precise movement of just one finger or by the clenching of the entire hand. The speed and range of the bullet that leaves the gun do not change, regardless of the forces that were applied to the trigger.

In the case of an axon or another area of excitable membrane, a graded depolarization is analogous to the pressure on the trigger, and the action potential is like the firing of the gun. All stimuli that bring the membrane to threshold generate identical action potentials. In other words, the properties of the action potential are independent of the relative strength of the depolarizing stimulus, so long as that stimulus exceeds the threshold. This concept is called the **all-or-none principle**, because a given stimulus either triggers a typical action potential, or it does not produce one at all. The all-or-none principle applies to all excitable membranes.

We will now take a closer look at the mechanisms whereby action potentials are generated and propagated. Generation and propagation are closely related concepts, in terms of both time and space: An action potential must be generated at one site before it can be propagated away from that site.

Generation of Action Potentials

Figure 12–13• diagrams the steps involved in the generation of an action potential from the resting state. At the normal resting potential, the activation gates of the voltage-regulated sodium channels are closed. The steps are as follows:

Step 1 Depolarization to Threshold. Before an action potential can begin, an area of excitable membrane must be depolarized to its threshold by local currents.

Step 2 Activation of Sodium Channels and Rapid Depolarization. At threshold, the sodium activation gates open, and the cell membrane becomes much more permeable to Na^+. Driven by the large electrochemical gradient, sodium ions rush into the cytoplasm, and rapid depolarization occurs at the site. In less than a millisecond, the inner membrane surface has changed; it now contains more positive ions than negative ones, and the transmembrane potential has changed from -60 mV to positive values closer to the equilibrium potential for sodium ions.

Notice that the first two steps in the generation of an action potential are an example of positive feedback: A small depolarization triggers a larger depolarization.

Step 3 Inactivation of Sodium Channels and the Activation of Potassium Channels. As the transmembrane potential approaches

+ 30 mV, the inactivation gates of the voltage-regulated sodium channels begin closing. This step is known as **sodium channel inactivation**. While it is under way, voltage-regulated potassium channels are opening. At a transmembrane potential of + 30 mV, the cytosol along the interior of the membrane contains an excess of positive charges. Thus, in contrast to the situation in the resting membrane (p. 391), both the electrical *and* chemical gradients favor the movement of K^+ out of the cell. The sudden loss of positive charges then shifts the transmembrane potential back toward resting levels, and repolarization begins.

Step 4 The Return to Normal Permeability. The voltage-regulated sodium channels remain inactivated until the membrane has repolarized to near threshold levels. At this time, they regain their normal status: closed but capable of opening. The voltage-regulated potassium channels begin closing as the membrane reaches the normal resting potential (about -70 mV), but the process takes at least a millisecond. Over that period, potassium ions continue to move out of the cell at a faster rate than when they are at rest, producing a brief hyperpolarization that brings the transmembrane potential very close to the equilibrium potential for potassium (-90 mV). As the voltage-regulated potassium channels close, the transmembrane potential returns to normal resting levels. The membrane is now in a prestimulation condition, and the action potential is over.

The Refractory Period From the time an action potential begins until the normal resting potential has stabilized, the membrane will not respond normally to additional depolarizing stimuli. This period is known as the **refractory period** of the membrane. From the moment the voltage-regulated sodium channels open at threshold until sodium channel inactivation ends, the membrane cannot respond to further stimulation, because all the voltage-regulated sodium channels either are already open or are inactivated. This portion of the refractory period, the **absolute refractory period**, lasts 0.4–1.0 msec; the smaller the axon diameter, the longer the duration. The **relative refractory period** begins when the sodium channels regain their normal resting condition, and continues until the transmembrane potential stabilizes at resting levels. Another action potential can occur over this period if the membrane is sufficiently depolarized. That depolarization, however, requires a larger-than-normal stimulus, because (1) the

local current must deliver enough Na^+ to counteract the loss of positively charged K^+ through voltage-regulated K^+ channels, and (2) the membrane is hyperpolarized to some degree through most of the relative refractory period.

The Role of the Sodium–Potassium Exchange Pump In an action potential, depolarization results from the influx of Na^+ , and repolarization involves the loss of K^+ . Over time, the sodium–potassium exchange pump returns intracellular and extracellular ion concentrations to prestimulation levels. Compared with the total number of ions inside and outside the cell, however, the number involved in a single action potential is insignificant. Tens of thousands of action potentials can occur before intracellular ion concentrations change enough to disrupt the entire mechanism. Thus, the exchange pump is not essential to any single action potential.

However, a maximally stimulated neuron can generate action potentials at a rate of 1000 per second. Under these circumstances, the exchange pump is needed if ion concentrations are to remain within acceptable limits over a prolonged period. The sodium–potassium exchange pump requires energy in the form of ATP. Each time the pump exchanges two extracellular potassium ions for three intracellular sodium ions, one molecule of ATP must be broken down to ADP. The transmembrane protein of the exchange pump is called *sodium–potassium ATPase*, because it provides the energy to pump ions by splitting a phosphate group from a molecule of ATP, forming ADP. If the cell runs out of ATP, or if sodium–potassium ATPase is inactivated by a metabolic poison, a neuron will soon lose its ability to function.

Table 12–3 summarizes the generation of action potentials.

Propagation of Action Potentials

The sequence of events just described occurs in a relatively small portion of the total membrane surface. But we have already noted that, unlike graded potentials, which diminish rapidly with distance, action potentials spread and affect the entire excitable membrane. To understand the basic principle involved, imagine that you are standing by the doors of a movie theater at the start of a long line. Everyone is waiting for the doors to open. The manager steps outside and says to you, “Let everyone know that we’re opening in 15 minutes.” How would you spread the news?

If you treated the line as an inexcitable membrane, you would shout, “The doors open in 15 minutes!” as loudly as you could. The closest people in the line would hear the news very clearly, but those farther away might not hear the entire message, and those at the end of the line might not hear you at all. If, on the other hand, you treated the crowd as an excitable membrane, you would tell the message to the next person in line, with instructions to pass it on. In that way, the message would travel along the line undiminished, until everyone had heard the news. Such a message “moves” as each person repeats it to someone else. Distance is not a factor; the line can contain 50 people or 5000.

The situation just described is comparable to the way an action potential spreads along an excitable membrane. An action potential (message) is relayed from one location to another in a series of steps. At each step, the message is repeated. Because the same events take place over and over, the term **propagation** is preferable to the term *conduction*, which suggests a flow of charge similar to that which takes place in a conductor such as a copper wire. (In fact, axons are relatively poor conductors of electricity.) Action potentials may travel along an axon by continuous propagation (unmyelinated axons) or by saltatory propagation (myelinated axons).

Continuous Propagation The basic mechanism by which an action potential is propagated along an unmyelinated axon is known as **continuous propagation** (Figure 12–14•). For convenience, we will consider the membrane as a series of adjacent segments. The action potential begins at the initial segment. For a brief moment at the peak of the action potential, the transmembrane potential becomes positive rather than negative (STEP 1). A local current then develops as sodium ions begin moving in the cytosol and the extracellular fluid (STEP 2). The local current spreads in all directions, depolarizing adjacent portions of the membrane. The axon hillock cannot respond with an action potential (because like the rest of the cell body, it lacks voltage-gated channels), but when the initial segment of the axon is depolarized to threshold, an action potential develops there. The process then continues in a chain reaction (STEPS 3, 4). Eventually, the most distant portions of the cell membrane will be affected. As in our "movie line" model, the message is being relayed from one location to another. At each step along the way, the message is retold, so distance has no effect on the process. The action potential reaching the synaptic knob is identical to the one generated at the initial segment, and the net effect is the same as if a single action potential had traveled across the surface of the membrane.

Each time a local current develops, the action potential moves forward, but not backward, because the previous segment of the axon is still in the absolute refractory period. As a result, an action potential always proceeds away from the site of generation and cannot reverse direction. For a second action potential to occur at the same site, a second stimulus must be applied.

In continuous propagation, an action potential appears to move across the surface of the membrane in a series of tiny steps. Even though the events at any one location take only about a millisecond, the sequence must be repeated at each step along the way. Continuous propagation along unmyelinated axons occurs at a speed of about 1 meter per second (approximately 2 mph).

Saltatory Propagation Saltatory propagation in the CNS and PNS carries nerve impulses along an axon much more rapidly than does continuous propagation. To get the general idea, let's return to the line in front of the movie theater, and assume that it takes 1 second to relay the message to another person. In a model of continuous propagation, the people are jammed together. In 4 seconds, four people would have heard the news, and the message would have moved perhaps 2 meters along the line. In a model of saltatory propagation, in contrast, the people in the line are spaced 5 meters apart. So after 4 seconds the same message would have moved 20 meters.

In a myelinated axon, the "people" are the nodes, and the spaces between them are the internodes wrapped in myelin (see Figures 12–4b and 12–5a•). Continuous propagation cannot occur along a myelinated axon, because myelin increases resistance to the flow of ions across the membrane. Ions can readily cross the cell membrane just at the nodes. As a result, only the nodes can respond to a depolarizing stimulus.

When an action potential appears at the initial segment of a myelinated axon, the local current skips the internodes and depolarizes the closest node to threshold (Figure 12–15•). Because the nodes may be 1–2 mm apart in a large myelinated axon, the action potential “jumps” from node to node rather than moving along the axon in a series of tiny steps. This process is called **saltatory propagation** (*saltare*, leaping). In addition to being faster, saltatory propagation also uses proportionately less energy, because less surface area is involved and fewer sodium ions must be pumped out of the cytoplasm.

Table 12–4 reviews the key differences between graded potentials and action potentials.

Axon Diameter and Propagation Speed

As we have seen, the presence of myelin greatly increases the propagation speed of action potentials. The diameter of the axon also affects the propagation speed, although the effects are less dramatic. Axon diameter is important because in order to depolarize adjacent portions of the cell membrane, ions must move through the cytoplasm. Cytoplasm offers resistance to ion movement, although much less resistance than the cell membrane. In this instance, an axon behaves like an electrical cable: The larger the diameter, the lower the resistance. (That is why motors with large current demands, such as the starter on a car, an electric stove, or a big air conditioner, use such thick wires.)

Axons are classified into three groups according to the relationships among the diameter, myelination, and propagation speed:

1. **Type A fibers** are the largest axons, with diameters ranging from 4 to 20 mm. These fibers are myelinated axons that carry action potentials at speeds of up to 140 meters per second, or more than 300 mph.
2. **Type B fibers** are smaller myelinated axons, with diameters of 2 – 4 mm. Their propagation speeds average around 18 meters per second, or roughly 40 mph.
3. **Type C fibers** are unmyelinated and less than 2 mm in diameter. These axons propagate action potentials at the leisurely pace of 1 meter per second, or a mere 2 mph.

The relative importance of myelin becomes apparent by noting that in comparing Type C to Type A fibers, the diameter increases tenfold but the propagation speed increases by 140 times.

Type A fibers carry to the CNS sensory information about position, balance, and delicate touch and pressure sensations from the skin surface. The motor neurons that control skeletal muscles also send their commands over large, myelinated Type A axons. Type B fibers and Type C fibers carry information to the CNS; they deliver temperature, pain, and general touch and pressure sensations, and carry instructions to smooth muscle, cardiac muscle, glands, and other peripheral effectors.

Not every axon in the nervous system is large and myelinated, most likely because that would be physically impossible. If all sensory information were carried by large Type A fibers, your peripheral nerves would be the size of garden hoses, and your spinal cord would be the diameter of a garbage can. Instead, only about one-third of all axons carrying sensory information are myelinated, and most sensory information arrives over slender Type C fibers. In essence, information transfer in the nervous system represents a compromise between conduction time and available space. Messages are routed according to priority: Urgent news— sensory information about things that threaten survival and motor commands that prevent injury—travels over Type A fibers (the equivalent of Express Mail). Less urgent sensory information and motor commands are relayed by Type B fibers (Regular Mail) or Type C fibers (Bulk Mail).

100 Keys | “Information” travels within the nervous system primarily in the form of propagated electrical signals known as action potentials. The most important information—including vision and balance sensations, and the motor commands to skeletal muscles—is carried by large-diameter myelinated axons.

Concept Check

What effect would a chemical that blocks the sodium channels in neuron cell membranes have on a neuron’s ability to depolarize?

What effect would decreasing the concentration of extracellular potassium ions have on the transmembrane potential of a neuron?

Which of the following axons is myelinated: one that propagates action potentials at 50 meters per second, or one that carries them at 1 meter per second?

Answers begin on p. A–1

Review action potential generation on the **IP CD-ROM: Nervous System I/The Action Potential.**

Synaptic Activity

Objectives

- Describe the general structure of synapses in the CNS and PNS.
- Discuss the events that occur at a chemical synapse.
- Describe the major types of neurotransmitters and neuromodulators, and discuss their effects on postsynaptic membranes.

In the nervous system, messages move from one location to another in the form of action potentials along axons. These electrical events are also known as **nerve impulses**. To be effective, a message must be not only propagated along an axon but also transferred in some way to another cell. At a synapse between two neurons, the impulse passes from the **presynaptic neuron** to the **postsynaptic neuron**. A synapse may also involve other types of postsynaptic cells. For example, the neuromuscular junction is a synapse where the postsynaptic cell is a skeletal muscle fiber. We will now take a closer look at the mechanisms involved in synaptic function.

General Properties of Synapses

A synapse may be *electrical*, with direct physical contact between the cells, or *chemical*, involving a neurotransmitter.

Electrical Synapses

At **electrical synapses**, the presynaptic and postsynaptic membranes are locked together at gap junctions (see Figure 4–2•, p. 109).

The lipid portions of the opposing membranes, separated by only 2 nm, are held in position by binding between integral membrane proteins called *connexons*. These proteins contain pores that permit the passage of ions between the cells. Because the two cells are linked in this way, changes in the transmembrane potential of one cell will produce local currents that affect the other cell as if the two shared a common membrane. As a result, an electrical synapse propagates action potentials quickly and efficiently from one cell to the next.

Electrical synapses are located in both the CNS and PNS, but they are extremely rare. They are present in some areas of the brain, including the *vestibular nuclei,* in the eye, and in at least one pair of PNS ganglia (the *ciliary ganglia*).

Chemical Synapses

The situation at a **chemical synapse** is far more dynamic than that at an electrical synapse, because the cells are not directly coupled. For example, an action potential that reaches an electrical synapse will *always* be propagated to the next cell. But at a chemical synapse, an arriving action potential *may or may not* release enough neurotransmitter to bring the postsynaptic neuron to threshold. In addition, other factors may intervene and make the postsynaptic cell more or less sensitive to arriving stimuli. In essence, the postsynaptic cell at a chemical synapse is not a slave to the presynaptic neuron; its activity can be adjusted, or “tuned,” by a variety of factors.

Chemical synapses are by far the most abundant type of synapse. Most synapses between neurons, and all communications between neurons and other types of cells, involve chemical synapses. Normally, communication across a chemical synapse can occur in only one direction: from the presynaptic membrane to the postsynaptic membrane.

Although acetylcholine is the neurotransmitter that has received the most attention, there are other important chemical transmitters. Based on their effects on postsynaptic membranes, neurotransmitters are often classified as excitatory or inhibitory. **Excitatory**

neurotransmitters cause depolarization and promote the generation of action potentials, whereas **inhibitory neurotransmitters** cause hyperpolarization and suppress the generation of action potentials.

This classification is useful, but not always precise. For example, acetylcholine typically produces a depolarization in the postsynaptic membrane, but acetylcholine released at neuromuscular junctions in the heart has an inhibitory effect, producing a transient hyperpolarization of the postsynaptic membrane. This situation highlights an important aspect of neurotransmitter function: *The effect of a neurotransmitter on the postsynaptic membrane depends on the properties of the receptor, not on the nature of the neurotransmitter*.

We will continue our discussion of chemical synapses with a closer look at a synapse that releases the neurotransmitter **acetylcholine (ACh)**. We will then briefly examine the activities of other important neurotransmitters that will be encountered in later chapters.

Cholinergic Synapses

Synapses that release ACh are known as **cholinergic synapses**. The neuromuscular junction is an example of a cholinergic synapse. l**p. 293** ACh, the most widespread (and best-studied) neurotransmitter, is released (1) at all neuromuscular junctions involving skeletal muscle fibers, (2) at many synapses in the CNS, (3) at all neuron-to-neuron synapses in the PNS, and (4) at all neuromuscular and neuroglandular junctions within the parasympathetic division of the ANS.

At a cholinergic synapse between two neurons, the presynaptic and postsynaptic membranes are separated by a synaptic cleft that averages 20 nm (0.02 mm) in width. Most of the ACh in the synaptic knob is packaged in synaptic vesicles, each containing several thousand molecules of the neurotransmitter. A single synaptic knob may contain a million such vesicles.

Events at a Cholinergic Synapse

Figure 12–16• diagrams the events that occur at a cholinergic synapse after an action potential arrives at a synaptic knob. For convenience, we will assume that this synapse is adjacent to the initial segment of the axon, a common arrangement that is relatively easy to illustrate.

Step 1 An Action Potential Arrives and Depolarizes the Synaptic Knob (see Figure 12–16•). The normal stimulus for neurotransmitter release is the depolarization of the synaptic knob by the arrival of an action potential.

Step 2 Extracellular Calcium Ions Enter the Synaptic Knob, Triggering the Exocytosis of ACh. The depolarization of the synaptic knob opens voltage-regulated calcium channels. In the brief period during which these channels remain open, calcium ions rush into the knob. Their arrival triggers exocytosis and the release of ACh into the synaptic cleft. The ACh is released in packets of roughly 3000 molecules, the average number of ACh molecules in a single vesicle. The release of ACh stops very soon, because the calcium ions that triggered exocytosis are rapidly removed from the cytoplasm by active transport mechanisms; they are either pumped out of the cell or transferred into mitochondria, vesicles, or the endoplasmic reticulum.

Step 3 ACh Binds to Receptors and Depolarizes the Postsynaptic Membrane. The ACh released through exocytosis diffuses across the synaptic cleft toward receptors on the postsynaptic membrane. These receptors are chemically regulated ion channels. The primary response is an increased permeability to Na^+, producing a depolarization that lasts about 20 msec.2

This depolarization is a graded potential: The greater the amount of ACh released at the presynaptic membrane, the larger the depolarization. If the depolarization brings the adjacent area of excitable membrane to threshold, an action potential will appear in the postsynaptic neuron.

Step 4 ACh Is Removed by AChE. The effects on the postsynaptic membrane are temporary, because the synaptic cleft and the postsynaptic membrane contain the enzyme *acetylcholinesterase* (*AChE,* or *cholinesterase*). Roughly half of the ACh released at the presynaptic membrane is broken down before it reaches receptors on the postsynaptic membrane. ACh molecules that succeed in binding to receptor sites are generally broken down within 20 msec of their arrival.

AChE breaks down molecules of ACh into **acetate** and **choline**. The choline is actively absorbed by the synaptic knob and is

used to synthesize more ACh, using acetate provided by *coenzyme A (CoA)*. (Recall from Chapter 2 that coenzymes derived from vitamins are required in many enzymatic reactions. l**p. 53**) Acetate diffusing away from the synapse can be absorbed and metabolized by the postsynaptic cell or by other cells and tissues.

Table 12–5 summarizes the events that occur at a cholinergic synapse.

Synaptic Delay

A 0.2–0.5-msec **synaptic delay** occurs between the arrival of the action potential at the synaptic knob and the effect on the postsynaptic membrane. Most of that delay reflects the time involved in calcium influx and neurotransmitter release, not in the neu-rotransmitter’s diffusion—the synaptic cleft is narrow, and neurotransmitters can diffuse across it in very little time.

Although a delay of 0.5 msec is not very long, in that time an action potential may travel more than 7 cm (about 3 in.) along a myelinated axon. When information is being passed along a chain of interneurons in the CNS, the cumulative synaptic delay may exceed the propagation time along the axons. This is why reflexes are important for survival—they involve only a few synapses and thus provide rapid and automatic responses to stimuli. The fewer synapses involved, the shorter the total synaptic delay and the faster the response. The fastest reflexes have just one synapse, with a sensory neuron directly controlling a motor neuron. The muscle spindle reflexes, discussed in Chapter 13, are an important example.

Synaptic Fatigue

Because ACh molecules are recycled, the synaptic knob is not totally dependent on the ACh synthesized in the cell body and delivered by axoplasmic transport. But under intensive stimulation, resynthesis and transport mechanisms may be unable to keep pace with the demand for neurotransmitter. **Synaptic fatigue** then occurs, and the synapse remains inactive until ACh has been replenished.

The Activities of Other Neurotransmitters

The nervous system relies on a complex form of chemical communication. Whereas it was once thought that neurons responded to a single neurotransmitter, we now realize that each neuron is continuously exposed to a variety of neurotransmitters. Some usually have excitatory effects, others usually have inhibitory effects. Yet in all cases, the observed effects depend on the nature of the receptor rather than the structure of the neurotransmitter.

Major categories of neurotransmitters include *biogenic amines*, *amino acids*, *neuropeptides*, *dissolved gases*, and a variety of other compounds. Here we will consider only a few of the most important neurotransmitters; we will encounter additional examples in later chapters.

- **Norepinephrine** (nor-ep-i-NEF-rin), or **NE**, is a neurotransmitter that is widely distributed in the brain and in portions of the ANS. Norepinephrine is also called *noradrenaline*, and synapses that release NE are known as **adrenergic synapses**. Norepinephrine typically has an excitatory, depolarizing effect on the postsynaptic membrane, but the mechanism is quite distinct from that of ACh. We will consider specifics in Chapter 16.

¯O

Dopamine (D

¯e

-puh-m n), a CNS neurotransmitter released in many areas of the brain, may have either inhibitory or excitatory effects. Inhibitory effects play an important role in our precise control of movements. For example, dopamine release in one portion of the brain prevents the overstimulation of neurons that control skeletal muscle tone. If the neurons that produce dopamine are damaged or destroyed, the result can be the characteristic rigidity and stiffness of *Parkinson's disease*, a condition we will describe in Chapter 14. At other sites, dopamine release has excitatory effects. Cocaine inhibits the removal of dopamine from synapses in specific areas of the brain. The resulting rise in dopamine concentrations at these synapses is responsible for the "high" experienced by cocaine users.

•

Serotonin (ser-o-T

¯O

-nin) is another important CNS neurotransmitter. Inadequate serotonin production can have widespread

•

effects on a person's attention and emotional states and may be responsible for many cases of severe chronic depression. *Fluoxetine* (*Prozac*), *Paxil*, *Zoloft*, and related antidepressant drugs inhibit the reabsorption of serotonin by synaptic knobs (hence their classification as *s*elective *s*erotonin *r*euptake *i*nhibitors, or *SSRIs*). This inhibition leads to increased serotonin concentrations at synapses; over time, the increase may relieve the symptoms of depression. Interactions among serotonin, norepinephrine, and other neurotransmitters are thought to be involved in the regulation of sleep and wake cycles.

Gamma aminobutyric (a-M

R-ik) **acid**, or **GABA**, generally has an inhibitory effect. Although roughly 20 per

•

cent of the synapses in the brain release GABA, its functions remain incompletely understood. In the CNS, GABA release appears to reduce anxiety, and some antianxiety drugs work by enhancing this effect. AM: How Drugs Disrupt Neural Function

The functions of many neurotransmitters are not well understood. In a clear demonstration of the principle “the more you look, the more you see,” at least 50 neurotransmitters have been identified, including certain amino acids, peptides, polypeptides, prostaglandins, and ATP. In addition, two gases, nitric oxide and carbon monoxide, are now known to be important neurotransmitters. Nitric oxide (NO) is generated by synaptic terminals that innervate smooth muscle in the walls of blood vessels in the PNS, and at synapses in several regions of the brain. Carbon monoxide (CO), best known as a component of automobile exhaust, is also generated by specialized synaptic knobs in the brain, where it functions as a neurotransmitter. Our knowledge of the significance of these compounds and the mechanisms involved in their synthesis and release remains incomplete.

100 Keys | At a chemical synapse, a synaptic terminal releases a neurotransmitter that binds to the postsynaptic cell membrane. The result is a temporary, localized change in the permeability or function of the postsynaptic cell. This change may have broader effects on the cell, depending on the nature and number of stimulated receptors. Many drugs affect the nervous system by stimulating receptors that otherwise respond only to neurotransmitters. These drugs can have complex effects on perception, motor control, and emotional states.

Review synaptic transmission on the **IP CD-ROM: Nervous System II/Synaptic Transmission.**

Neuromodulators

Although it is convenient to discuss each synapse as if it were releasing only one chemical, synaptic knobs may release a mixture of active compounds, either through diffusion across the membrane or via exocytosis, in the company of neurotransmitter molecules. These compounds may have a variety of functions. Those that alter the rate of neurotransmitter release by the presynaptic
neuron or change the postsynaptic cell’s response to neurotransmitters are called **neuromodulators** (noo-r
¯o
-MOD-

¯u
-l
¯a
-torz).
These substances are typically **neuropeptides**, small peptide chains synthesized and released by the synaptic knob. Most neuromodulators act by binding to receptors in the presynaptic or postsynaptic membranes and activating cytoplasmic enzymes.
Neuromodulators called **opioids** (
¯O

-p
¯e
-oydz) have effects similar to those of the drugs *opium* and *morphine*, because they
bind to the same group of postsynaptic receptors. Four classes of opioids are identified in the CNS: (1) **endorphins** (en-DOR-finz),
–

(2) **enkephalins** (en-KEF-a-linz), (3) **endomorphins**, and (4) **dynorphins** (d -NOR-finz). The primary function of opioids is

ı probably the relief of pain—they inhibit the release of the neurotransmitter *substance P* at synapses that relay pain sensations. Dynorphins have far more powerful analgesic (pain-relieving) effects than morphine or the other opioids.

In general, neuromodulators (1) have long-term effects that are relatively slow to appear, (2) trigger responses that involve a number of steps and intermediary compounds, (3) may affect the presynaptic membrane, the postsynaptic membrane, or both, and (4) can be released alone or in the company of a neurotransmitter. Table 12–6 lists major neurotransmitters and neuromodulators of the brain and spinal cord, and their primary effects (if known). In practice, it can be very difficult to distinguish neurotransmitters from neuromodulators on either biochemical or functional grounds: A neuropeptide may function in one site as a neuromodulator and in another as a neurotransmitter. For this reason, Table 12–6 does not distinguish between neurotransmitters and neuromodulators.

How Neurotransmitters and Neuromodulators Work

Functionally, neurotransmitters and neuromodulators fall into one of three groups: (1) *compounds that have a direct effect on membrane potential*, (2) *compounds that have an indirect effect on membrane potential*, or (3) *lipid-soluble gases that exert their effects inside the cell*.

Compounds that have direct effects on membrane potential exert those effects by opening or closing gated ion channels (Figure 12–17a•). Examples include ACh and the amino acids *glycine* and *aspartate*. Because these neurotransmitters alter ion movement across the membrane, they are said to have *ionotropic effects*. A few neurotransmitters, notably glutamate, GABA, NE, and serotonin, have both direct and indirect effects, because these compounds target two different classes of receptors. The direct effects are ionotropic; the indirect effects, which involve changes in the metabolic activity of the postsynaptic cell, are called *metabotropic*.

Compounds that have an indirect effect on membrane potential work through intermediaries known as *second messengers*. The neurotransmitter represents a *first messenger*, because it delivers the message to receptors on the cell membrane or within the cell. Second messengers are ions or molecules that are produced or released inside the cell when a first messenger binds to one of these receptors.

Many neurotransmitters—including epinephrine, norepinephrine, dopamine, serotonin, histamine, and GABA, as well as many neuromodulators—bind to receptors in the cell membrane. In these instances, the link between the first messenger and the second messenger involves a **G protein**, an enzyme complex coupled to a membrane receptor. The name *G protein* refers to the fact

that these proteins bind GTP, a high-energy compound introduced in Chapter 2. l**p. 56** There are several types of G proteins, but each type includes an enzyme that is “turned on” when an extracellular compound binds to the associated receptor at the cell surface.

Figure 12–17b• shows one possible result of this binding: the activation of the enzyme **adenylate cyclase**, also known as *adenylyl cyclase*. This enzyme converts ATP, the energy currency of the cell, to *cyclic-AMP*, a ring-shaped form of the compound AMP that was introduced in Chapter 2. l**p. 56** The conversion takes place at the inner surface of the cell membrane. Cyclic-AMP (cAMP) is a second messenger that may open membrane channels, activate intracellular enzymes, or both, depending on the nature of the postsynaptic cell. This is only an overview of the function of one type of G protein; we will examine several types of G proteins more closely in later chapters.

Two lipid-soluble gases, nitric oxide (NO) and carbon monoxide (CO), are now known to be important neurotransmitters in specific regions of the brain. Because they can diffuse through lipid membranes, these gases can enter the cell and bind to enzymes on the inner surface of the membrane or elsewhere in the cytoplasm (Figure 12–17c•). These enzymes then promote the appearance of second messengers that can affect cellular activity.

Concept Check

What effect would blocking voltage-regulated calcium channels at a cholinergic synapse have on synaptic communication? One pathway in the central nervous system consists of three neurons, another of five neurons. If the neurons in the two pathways are identical, which pathway will transmit impulses more rapidly?

Answers begin on p. A–1

Information Processing by Individual Neurons

Objective

- Discuss the interactions that make possible the processing of information in neural tissue.

A single neuron may receive information across thousands of synapses, and, as we have seen, some of the neurotransmitters arriving at the postsynaptic cell at any moment may be excitatory, whereas others may be inhibitory. The net effect on the transmembrane potential of the cell body—specifically, in the area of the axon hillock—determines how the neuron responds from moment to moment. If the net effect is a depolarization at the axon hillock, that depolarization will affect the transmembrane potential at the initial segment. If threshold is reached at the initial segment, an action potential will be generated and propagated along the axon.

Thus it is really the axon hillock that integrates the excitatory and inhibitory stimuli affecting the cell body and dendrites at any given moment. This integration process, which determines the rate of action potential generation at the initial segment, is the simplest level of **information processing** in the nervous system. The excitatory and inhibitory stimuli are integrated through interactions between *postsynaptic potentials*, which we discuss next. Higher levels of information processing involve interactions among neurons, and interactions among groups of neurons. These topics will be addressed in later chapters.

Postsynaptic Potentials

Postsynaptic potentials are graded potentials that develop in the postsynaptic membrane in response to a neurotransmitter. (Figure 12–12 illustrated graded depolarizations and hyperpolarizations.) Two major types of postsynaptic potentials develop at neuron-to-neuron synapses: excitatory postsynaptic potentials and inhibitory postsynaptic potentials.

An **excitatory postsynaptic potential**, or **EPSP**, is a graded depolarization caused by the arrival of a neurotransmitter at the postsynaptic membrane. An EPSP results from the opening of chemically regulated membrane channels that lead to depolarization of the cell membrane. For example, the graded depolarization produced by the binding of ACh is an EPSP. Because it is a graded potential, an EPSP affects only the area immediately surrounding the synapse, as shown in Figure 12–11•, p. 397.

We have already noted that not all neurotransmitters have an excitatory (depolarizing) effect. An **inhibitory postsynaptic potential**, or **IPSP**, is a graded hyperpolarization of the postsynaptic membrane. For example, an IPSP may result from the opening of chemically regulated potassium channels. While the hyperpolarization continues, the neuron is said to be **inhibited**, because a larger-than-usual depolarizing stimulus must be provided to bring the membrane potential to threshold. A stimulus sufficient to shift the transmembrane potential by 10 mV (from -70 mV to -60 mV) would normally produce an action potential, but if the transmembrane potential were reset at -85 mV by an IPSP, the same stimulus would depolarize it to only -75 mV, which is below threshold.

Review ion channels and postsynaptic potentials on the **IP CD-ROM: Nervous System II/Ion Channels.**

Summation

An individual EPSP has a small effect on the transmembrane potential, typically producing a depolarization of about 0.5 mV at the postsynaptic membrane. Before an action potential will arise in the initial segment, local currents must depolarize that region by at least 10 mV. Therefore, a single EPSP will not result in an action potential, even if the synapse is on the axon hillock. But individual EPSPs combine through the process of **summation**, which integrates the effects of all the graded potentials that affect one portion of the cell membrane. The graded potentials may be EPSPs, IPSPs, or both. We will consider EPSPs in our discussion.

Two forms of summation exist: temporal summation and spatial summation (Figure 12–18•).

Temporal summation (*tempus*, time) is the addition of stimuli occurring in rapid succession at a *single synapse* that is active *repeatedly*. This form of summation can be likened to using a bucket to fill up a bathtub; you can’t fill the tub with a single bucket of water, but you will fill it eventually if you keep repeating the process. In the case of temporal summation, the water in a bucket corresponds to the sodium ions that enter the cytoplasm during an EPSP. A typical EPSP lasts about 20 msec, but under maximum stimulation an action potential can reach the synaptic knob each millisecond. Figure 12–18a• shows what happens when a second EPSP arrives before the effects of the first EPSP have disappeared. Every time an action potential arrives, a group of vesicles discharges ACh into the synaptic cleft; every time more ACh molecules arrive at the postsynaptic membrane, more chemically regulated channels open, and the degree of depolarization increases. In this way, a series of small steps can eventually bring the initial segment to threshold.

Spatial summation occurs when simultaneous stimuli applied at different locations have a cumulative effect on the transmembrane potential. In other words, spatial summation involves *multiple synapses* that are active *simultaneously*. In terms of our bucket analogy, you could fill the bathtub immediately if 50 friends emptied their buckets into it all at the same time.

In spatial summation, more than one synapse is active at the same time (Figure 12–18b•), and each “pours” sodium ions across the postsynaptic membrane, producing a graded potential with localized effects. At each active synapse, the sodium ions that produce the EPSP spread out along the inner surface of the membrane and mingle with those entering at other synapses. As a result, the effects on the initial segment are cumulative. The degree of depolarization depends on how many synapses are active at any moment, and on their distance from the initial segment. As in temporal summation, an action potential results when the transmembrane potential at the initial segment reaches threshold.

Facilitation

Consider a situation in which summation of EPSPs is under way, but the initial segment has not been depolarized to threshold. The closer the initial segment is to threshold, the easier it will be for the *next* depolarizing stimulus to trigger an action potential. A neuron whose transmembrane potential shifts closer to threshold is said to be **facilitated**. The larger the degree of facilitation, the smaller is the additional stimulus needed to trigger an action potential. In a highly facilitated neuron, even a small depolarizing stimulus produces an action potential.

Facilitation can result from the summation of EPSPs or from the exposure of a neuron to certain drugs in the extracellular fluid. For example, the nicotine in cigarettes stimulates postsynaptic ACh receptors, producing prolonged EPSPs that facilitate CNS neurons.

Summation of EPSPs and IPSPs

Like EPSPs, IPSPs summate spatially and temporally. EPSPs and IPSPs reflect the activation of different types of chemically regulated channels, producing opposing effects on the transmembrane potential. The antagonism between IPSPs and EPSPs is an important mechanism in cellular information processing. In terms of our bucket analogy, EPSPs put water into the bathtub, and IPSPs take water out. If more buckets add water than remove water, the water level in the tub will rise. If more buckets remove water, the level will fall. If a bucket of water is removed every time another bucket is dumped in, the level will remain stable. Comparable interactions between EPSPs and IPSPs (Figure 12–19•) determine the transmembrane potential at the boundary between the axon hillock and the initial segment.

Neuromodulators, hormones, or both can change the postsynaptic membrane’s sensitivity to excitatory or inhibitory neurotransmitters. By shifting the balance between EPSPs and IPSPs, these compounds promote facilitation or inhibition of CNS and PNS neurons.

Review summation on the **IP CD-ROM: Nervous System II/Synaptic Potentials and Cellular Integration.**

Presynaptic Inhibition and Presynaptic Facilitation

Inhibitory or excitatory responses may occur not only at synapses involving the cell body and dendrites, but also at synapses found along an axon or its collaterals. At an *axoaxonal synapse*, a synapse occurs between the axons of two neurons. An axoaxonal synapse at the synaptic knob can either decrease (inhibit) or increase (facilitate) the rate of neurotransmitter release at the presynaptic membrane. In one form of **presynaptic inhibition**, the release of GABA inhibits the opening of voltage-regulated calcium channels in the synaptic knob (Figure 12–20a•). This inhibition reduces the amount of neurotransmitter released when an action potential arrives there, and thus reduces the effects of synaptic activity on the postsynaptic membrane.

In **presynaptic facilitation** (Figure 12–20b•), activity at an axoaxonal synapse increases the amount of neurotransmitter released when an action potential arrives at the synaptic knob. This increase enhances and prolongs the neurotransmitter's effects on the postsynaptic membrane. The neurotransmitter *serotonin* is involved in presynaptic facilitation. In the presence of serotonin released at an axoaxonal synapse, voltage-regulated calcium channels remain open longer.

The Rate of Generation of Action Potentials

In the nervous system, complex information is translated into action potentials that can be propagated along axons. On arrival, the message is often interpreted solely on the basis of the frequency of action potentials. For example, action potentials arriving at a neuromuscular junction at the rate of 1 per second may produce a series of isolated twitches in the associated skeletal muscle fiber, whereas at the rate of 100 per second they will cause a sustained tetanic contraction. Similarly, a few action potentials per second along a sensory fiber may be perceived as a featherlight touch, whereas hundreds of action potentials per second along that same axon may be perceived as unbearable pressure. In this section, we will examine factors that vary the rate of generation of action potentials. We will consider the functional significance of these changes in later chapters.

If a graded potential briefly depolarizes the axon hillock such that the initial segment reaches its threshold, an action potential will be propagated along the axon. Now consider what happens if the axon hillock *remains* depolarized past threshold for an extended period. The longer the initial segment remains above threshold, the more action potentials it will produce. The *frequency* of action potentials depends on the degree of depolarization above threshold: The greater the degree of depolarization, the higher the frequency of action potentials. The membrane can respond to a second stimulus as soon as the absolute refractory period ends. Holding the membrane above threshold has the same effect as applying a second, larger-than-normal stimulus.

The rate of generation of action potentials reaches a maximum when the relative refractory period has been completely eliminated. The maximum theoretical frequency is therefore established by the duration of the absolute refractory period. The absolute refractory period is shortest in large-diameter axons, in which the *theoretical* maximum frequency of action potentials is 2500 per second. However, the highest frequencies recorded from axons in the body range between 500 and 1000 per second.

Table 12–7 summarizes the basic principles of information processing.

100 Keys | In the nervous system, the changes in transmembrane potential that determine whether or not action potentials are generated represent the simplest form of information processing.

Concept Check

One EPSP depolarizes the initial segment from a resting potential of -70 mV to -65 mV, and threshold is at -60 mV. Will an action potential be generated?

If a second, identical EPSP occurs immediately after the first, will an action potential be generated?

If the two EPSPs occurred simultaneously, what form of summation would occur?

Answers begin on p. A–1

You are now familiar with the basic components of neural tissue, and the origin and significance of action potentials. In later chapters we will consider higher levels of anatomical and functional organization within the nervous system, examine information processing at these levels, and see how a single process—the generation of action potentials—can be responsible for the incredible diversity of sensations and movements that we experience each day. AM: Conditions That Disrupt Neural Function

Chapter Review

Selected Clinical Terminology

anticholinesterase drug: A drug that blocks the breakdown of ACh by AChE. [AM]

atropine: A drug that prevents ACh from binding to the postsynaptic membrane of cardiac muscle and smooth muscle cells. [AM]

demyelination: The destruction of the myelin sheaths around axons in the CNS and PNS. (p. 387 and [AM])

d-tubocurarine: A drug, derived from curare, that prevents ACh from binding to the postsynaptic membrane of skeletal muscle fibers.

[AM] **endorphins:** Neuropeptides produced in the brain and spinal cord that appear to relieve pain and to affect mood. (p. 408) **hyperkalemia:** An abnormal physiological state resulting from a high extracellular concentration of potassium. [AM] **neurotoxin:** A compound that disrupts normal nervous system function by interfering with the generation or propagation of action potentials. Examples include *tetrodotoxin (TTX)*, *saxitoxin (STX)*, and *ciguatoxin (CTX)*. [AM] **nicotine:** A compound found in tobacco that binds to specific ACh receptor sites and stimulates the postsynaptic membrane. [AM] **rabies:** A fatal disease caused by a virus that reaches the CNS via retrograde flow along peripheral axons. (p. 383 and [AM]) **Tay–Sachs disease:** A genetic abnormality involving the metabolism of gangliosides, important components of neuron cell membranes.

The result is a gradual deterioration of neurons due to the buildup of metabolic by-products and the release of lysosomal enzymes.

[AM]

Study Outline

An Overview of the Nervous System p. 380

1. The nervous system includes all the neural tissue in the body. The basic functional unit is the **neuron**.

The Anatomical Divisions of the Nervous System p. 380

2. The anatomical divisions of the nervous system are the **central nervous system (CNS)** (the brain and spinal cord) and the **peripheral nervous system (PNS)** (all the neural tissue outside the CNS). Bundles of **axons (***nerve fibers***)** in the PNS are called **nerves**.

The Functional Divisions of the Nervous System p. 380

3. Functionally, the PNS can be divided into an **afferent division**, which brings sensory information from **receptors** to the CNS, and an **efferent division**, which carries motor commands to muscles and glands called **effectors**.

4. The efferent division of the PNS includes the **somatic nervous system (SNS)**, which controls skeletal muscle contractions, and the **autonomic nervous system (ANS)**, which regulates smooth muscle, cardiac muscle, and glandular activity.

Neurons p. 380 The Structure of Neurons p. 381

1. The **perikaryon** of a multipolar neuron contains organelles, including **neurofilaments**, **neurotubules**, and **neurofibrils**. The **axon hillock** connects the **initial segment** of the **axon** to the **cell body**, or *soma*. The **axoplasm** contains numerous organelles. *(Figure 12–1)*

2. **Collaterals** may branch from an axon, with **telodendria** branching from the axon’s tip.

3. A **synapse** is a site of intercellular communication. A **synaptic knob** is the most common type of synaptic terminal. **Neurotransmitters** released from the synaptic knob of the presynaptic cell affect the postsynaptic cell, which may be a neuron or another type of cell. *(Figures 12–1, 12–2)*

The Classification of Neurons p. 383

4. Neurons are structurally classified as **anaxonic**, **bipolar**, **unipolar**, or **multipolar**. *(Figure 12–3)*

5. The three functional categories of neurons are sensory neurons, motor neurons, and interneurons.

6. **Sensory neurons**, which form the afferent division of the PNS, deliver information received from **interoceptors**, **exteroceptors**, and **proprioceptors** to the CNS.

7. **Motor neurons**, which form the efferent division of the PNS, stimulate or modify the activity of a peripheral tissue, organ, or organ system.

8. **Interneurons** (*association neurons*) are always located in the CNS and may be situated between sensory and motor neurons. They distribute sensory inputs and coordinate motor outputs.

Neuroglia p. 384 Neuroglia of the Central Nervous System p. 384

1. The four types of **neuroglia**, or *glial cells*, in the CNS are (1) **ependymal cells**, with functions related to the **cerebrospinal fluid (CSF)**; (2) **astrocytes**, the largest and most numerous neuroglia; (3) **oligodendrocytes**, which are responsible for the **myelination** of CNS axons; and (4) **microglia**, or phagocytic cells. *(Figure 12–4)*

Neuroglia of the Peripheral Nervous System p. 387

2. Neuron cell bodies in the PNS are clustered into **ganglia**. *(Figure 12–5)*

3. **Satellite cells**, or *amphicytes*, surround neuron cell bodies within ganglia. **Schwann cells** ensheath axons in the PNS. A single Schwann cell may myelinate one segment of an axon or enfold segments of several unmyelinated axons. *(Figure 12–5)*

100 Keys | p. 387

Neural Responses to Injuries p. 387

4. In the PNS, functional repair may follow **Wallerian degeneration**. In the CNS, many factors complicate the repair process and reduce the chances of functional recovery. *(Figure 12–6)*

Ion Movements and Electrical Signals p. 390

1. All normal neural functions depend on events that occur at the cell membrane. *(Figure 12–7)*

The Transmembrane Potential p. 390

2. The **electrochemical gradient** is the sum of all chemical and electrical forces acting across the cell membrane. *(Figures 12–8, 12–9)*

3. The sodium–potassium exchange pump stabilizes the resting potential at approximately -70 mV. *(Summary Table 12–1)*

Nervous System I/The Membrane Potential

Changes in the Transmembrane Potential p. 394

4. The cell membrane contains **passive (leak) channels**, which are always open, and **active (gated) channels**, which open or close in response to specific stimuli. *(Figure 12–8)*

5. The three types of gated channels are **chemically regulated channels**, **voltage-regulated channels**, and **mechanically regulated channels**. *(Figure 12–10)*

100 Keys | p. 396

Nervous System I/Ion Channels

Graded Potentials p. 396

6. A localized **depolarization** or **hyperpolarization** is a **graded potential** (a change in potential that decreases with distance). *(Figures 12–11, 12–12; Summary Table 12–2)*

Action Potentials p. 398

7**.** An **action potential** arises when a region of excitable membrane depolarizes to its **threshold**. The steps involved are, in order, membrane depolarization and the activation of sodium channels, sodium channel inactivation, potassium channel activation, and the return to normal permeability. *(Figure 12–13; Summary Table12–3; Table 12–4)*

8**.** The generation of an action potential follows the **all-or-none principle**. The **refractory period** lasts from the time an action potential begins until the normal resting potential has returned. *(Table 12–3; Table 12–4)*

9**.** In **continuous propagation**, an action potential spreads across the entire excitable membrane surface in a series of small steps. *(Figure 12–14)*

10**.** In **saltatory propagation**, an action potential appears to leap from node to node, skipping the intervening membrane surface. Saltatory propagation carries nerve impulses many times more rapidly than does continuous propagation. *(Figure 12–15)*

11. Axons are classified as **Type A fibers**, **Type B fibers**, or **Type C fibers** on the basis of their diameter, myelination, and propagation speed.

12. Compared with action potentials in neural tissue, those in muscle tissue have (1) higher resting potentials, (2) longer-lasting action potentials, and (3) slower propagation of action potentials.

100 Keys | p. 404

Nervous System I/The Action Potential

Synaptic Activity p. 404

1. An action potential traveling along an axon is a **nerve impulse**. At a synapse between two neurons, information passes from the **presynaptic neuron** to the **postsynaptic neuron.**

General Properties of Synapses p. 404

2. A synapse is either *electrical* (with direct physical contact between cells) or *chemical* (involving a neurotransmitter).

3. **Electrical synapses** occur in the CNS and PNS, but they are rare. At an electrical synapse, the presynaptic and postsynaptic cell membranes are bound by interlocking membrane proteins at a gap junction. Pores within these proteins permit the passage of local currents, and the two neurons act as if they share a common cell membrane.

4. **Chemical synapses** are more common than electrical synapses. **Excitatory neurotransmitters** cause depolarization and promote the generation of action potentials, whereas **inhibitory neurotransmitters** cause hyperpolarization and suppress the generation of action potentials.

5. The effect of a neurotransmitter on the postsynaptic membrane depends on the properties of the receptor, not on the nature of the neurotransmitter.

Cholinergic Synapses p. 405

6. **Cholinergic synapses** release the neurotransmitter **acetylcholine (ACh)**. Communication moves from the presynaptic neuron to the postsynaptic neuron across a synaptic cleft. A **synaptic delay** occurs because calcium influx and the release of the neurotransmitter takes an appreciable length of time. *(Figure 12–16)*

7. **Choline** released during the breakdown of ACh in the synaptic cleft is reabsorbed and recycled by the synaptic knob. If stores of ACh are exhausted, **synaptic fatigue** can occur. *(Summary Table 12–5)*

The Activities of Other Neurotransmitters p. 408

8. **Adrenergic synapses** release **norepinephrine (NE)**, also called *noradrenaline*. Other important neurotransmitters include **dopamine**, **serotonin**, and **gamma aminobutyric acid (GABA)**. *(Table 12–6)*

100 Keys | p. 408

Nervous System II/Synaptic Transmission

Neuromodulators p. 408

9. **Neuromodulators** influence the postsynaptic cell's response to neurotransmitters.

How Neurotransmitters and Neuromodulators Work p. 409

10. Neurotransmitters can have a direct or indirect effect on membrane potential, or they can exert their effects via lipid-soluble gases that diffuse across the cell membrane. *(Figure 12–17)*

Information Processing by Individual Neurons p. 412

1. Excitatory and inhibitory stimuli are integrated through interactions between **postsynaptic potentials**. This interaction is the simplest level of **information processing** in the nervous system.

Postsynaptic Potentials p. 412

2. A depolarization caused by a neurotransmitter is an **excitatory postsynaptic potential (EPSP)**. Individual EPSPs can combine through **summation**, which can be either **temporal** (occurring at a single synapse when a second EPSP arrives before the effects of the first have disappeared) or **spatial** (resulting from the cumulative effects of multiple synapses at various locations). *(Figure 12–18)*

3. Hyperpolarization of the postsynaptic membrane is an **inhibitory postsynaptic potential (IPSP)**.

4. The most important determinants of neural activity are EPSP–IPSP interactions. *(Figure 12–19)*

Nervous System II/Synaptic Transmission

Nervous System II/Synaptic Potentials and Cellular Integration

Presynaptic Inhibition and Presynaptic Facilitation p. 414

5. In **presynaptic inhibition**, GABA release at an *axoaxonal synapse* inhibits the opening of voltage-regulated calcium channels in the synaptic knob. This inhibition reduces the amount of neurotransmitter released when an action potential arrives at the synaptic knob.

(Figure 12–20a)

6. In **presynaptic facilitation**, activity at an axoaxonal synapse increases the amount of neurotransmitter released when an action potential arrives at the synaptic knob. This increase enhances and prolongs the effects of the neurotransmitter on the postsynaptic membrane. *(Figure 12–20b)*

The Rate of Generation of Action Potentials p. 415

7. The neurotransmitters released at a synapse have excitatory or inhibitory effects. The effect on the initial segment reflects an integration of the stimuli arriving at any moment. The frequency of generation of action potentials depends on the degree of depolarization above threshold at the axon hillock. *(Summary Table 12–7)*

8. Neuromodulators can alter either the rate of neurotransmitter release or the response of a postsynaptic neuron to specific neurotransmitters. Neurons may be facilitated or inhibited by extracellular chemicals other than neurotransmitters or neuromodulators.

(Summary Table 12–7)

9. The effect of a presynaptic neuron's activation on a postsynaptic neuron may be altered by other neurons. *(Table 12–7)*

10. The greater the degree of sustained depolarization at the axon hillock, the higher the frequency of generation of action potentials. At a frequency of about 1000 per second, the relative refractory period has been eliminated, and further depolarization will have no effect. *(Summary Table 12–7)*

100 Keys | p. 416

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. Regulation by the nervous system provides

(a) relatively slow, but long-lasting, responses to stimuli

(b) swift, long-lasting responses to stimuli

(c) swift, but brief, responses to stimuli

(d) relatively slow, short-lived responses to stimuli

2. The afferent division of the PNS

(a) brings sensory information to the CNS

(b) carries motor commands to muscles and glands

(c) processes and integrates sensory data

(d) is the seat of higher functions in the body

3. The part of the nervous system that controls voluntary contractions of skeletal muscles is the

(a) somatic nervous system

(b) autonomic nervous system

(c) visceral motor system

(d) sympathetic division of the ANS

4. Smooth muscle, cardiac muscle, and glands are among the targets of the

(a) somatic nervous system

(b) sensory neurons

(c) afferent division of the PNS

(d) autonomic nervous system

5. In the CNS, a neuron typically receives information from other neurons at its

(a) axon

(b) Nissl bodies

(c) dendrites

(d) nucleus

6. Phagocytic cells in neural tissue of the CNS are

(a) astrocytes **(b)** ependymal cells

(c) oligodendrocytes **(d)** microglia

7. The neural cells responsible for the analysis of sensory inputs and coordination of motor outputs are

(a) neuroglia

(b) interneurons

(c) sensory neurons

(d) motor neurons

8. Depolarization of a neuron cell membrane will shift the membrane potential toward

(a) 0mV **(b)** -70 mV

(c) -90 mV **(d)** a, b, and c are correct

9. The primary determinant of the resting membrane potential is

(a) the membrane permeability to sodium

(b) the membrane permeability to potassium

(c) intracellular negatively charged proteins

(d) negatively charged chloride ions in the ECF

10. Receptors that bind acetylcholine at the postsynaptic membrane are

(a) chemically regulated channels

(b) voltage-regulated channels

(c) passive channels

(d) mechanically regulated channels

11. What are the major components of **(a)** the central nervous system? **(b)** the peripheral nervous system?

12. Which two types of neuroglia insulate neuron cell bodies and axons in the PNS from their surroundings?

13. What three *functional* groups of neurons are found in the nervous system? What is the function of each type of neuron?

LEVEL 2 Reviewing Concepts

14. If the resting membrane potential is -70 mV and the threshold is -55 mV, a membrane potential of -60 mV will

(a) produce an action potential

(b) make it easier to produce an action potential

(c) make it harder to produce an action potential
(d) hyperpolarize the membrane

15. A graded potential
(a) decreases with distance from the point of stimulation
(b) spreads passively because of local currents
(c) may involve either depolarization or hyperpolarization
(d) a, b, and c are correct

16. During an absolute refractory period, the membrane
(a) continues to hyperpolarize
(b) cannot respond to further stimulation
(c) can respond to a larger-than-normal depolarizing stimulus
(d) will respond to summated stimulation

17. A neuron exhibiting facilitation requires a ___ additional stimulus to trigger an action potential.
(a) smaller depolarizing
(b) larger depolarizing
(c) smaller hyperpolarizing
(d) larger hyperpolarizing

18. Why can’t most neurons in the CNS be replaced when they are lost to injury or disease?
19. What is the difference between axoplasmic transport and retrograde flow?
20. What is the *functional* difference among voltage-regulated, chemically regulated, and mechanically regulated channels?
21. State the all-or-none principle of action potentials.
22. Describe the steps involved in the generation of an action potential.

23. What is meant by saltatory propagation? How does it differ from continuous propagation?

24. What are the functional differences among type A, B, and C fibers?

25. Describe the steps that take place at a typical cholinergic synapse.

26. What is the difference between temporal summation and spatial summation?

LEVEL 3 Critical Thinking and Clinical Applications

27. Harry has a kidney condition that causes changes in his body's electrolyte levels (concentration of ions in the extracellular fluid). As a result, he is exhibiting tachycardia, an abnormally fast heart rate. Which ion is involved, and how does a change in its concentration cause Harry's symptoms?

28. Twenty neurons synapse with a single receptor neuron. Fifteen of the 20 neurons release neurotransmitters that produce EPSPs at the postsynaptic membrane, and the other five release neurotransmitters that produce IPSPs. Each time one of the neurons is stimulated, it releases enough neurotransmitter to produce a 2-mV change in potential at the postsynaptic membrane. If the threshold of

the postsynaptic neuron is 10 mV, how many of the excitatory neurons must be stimulated to produce an action potential in the rceptor neuron if all five inhibitory neurons are stimulated? (Assume that spatial summation occurs.)

29. In multiple sclerosis, there is progressive and intermittent damage to the myelin sheath of peripheral nerves. This results in poor motor control of the affected area. Why does destruction of the myelin sheath affect motor control?

30. What factor would determine the maximum frequency of action potentials that could be conducted by an axon?

1The term *synaptic knob* is widely recognized and will be used throughout this text. However, the same structures are also called terminal buttons, terminal boutons, end bulbs, or neuropods.

2These channels also let potassium ions out of the cell, but because sodium ions are driven by a much stronger electrochemical gradient, the net effect is a slight depo

larization of the postsynaptic membrane.

| SUMMARY TABLE 12–1 | THE RESTING POTENTIAL

- Because the cell membrane is highly permeable to potassium ions, the resting potential is fairly close to -90 mV, the equilibrium potential for K^+.
- Although the electrochemical gradient for sodium ions is very large, the membrane's permeability to these ions is very low. Consequently, Na^+ has only a small effect on the normal resting potential, making it just slightly less negative than it would otherwise be.
- The sodium–potassium exchange pump ejects 3 Na^+ ions for every 2 K^+ ions that it brings into the cell. It thus serves to stabilize the resting potential when the ratio of Na^+ entry to K^+ loss through passive channels is 3 : 2.

- At the normal resting potential, these passive and active mechanisms are in balance. The resting potential varies widely with the type of cell. A typical neuron has a resting potential of approximately -70 mV.

| SUMMARY TABLE 12–2 | GRADED POTENTIALS

Graded potentials, whether depolarizing or hyperpolarizing, share four basic characteristics:

1. The transmembrane potential is most affected at the site of stimulation, and the effect decreases with distance.
2. The effect spreads passively, owing to local currents.
3. The graded change in membrane potential may involve either depolarization or hyperpolarization. The nature of the change is determined by the proper

ties of the membrane channels involved. For example, in a resting membrane, the opening of sodium channels will cause depolarization, whereas the opening of potassium channels will cause hyperpolarization.

4. The stronger the stimulus, the greater is the change in the transmembrane potential and the larger is the area affected.

| SUMMARY TABLE 12–3 | GENERATION OF ACTION POTENTIALS

STEP 1: Depolarization to threshold

- A graded depolarization brings an area of excitable membrane to thereshold (-60 mV).

STEP 2: Activation of sodium channels and rapid depolarization

- The voltage-regulated sodium channel open (sodium channel activation).
- Sodium ions, driven by electrical attraction and the chemical gradient, flood into the cell.
- The transmembrane potential goes from -60 mV the treshold level, toward + 30 mV.

STEP 3: Inactivation of sodium channels and activation of potassium channels

- The voltage-regulated sodium channels close (sodium channel inactivation occurs) at + 30 mV.
- The voltage-regulated potassium channels are now open, and potassium ions diffuse out of the cell.
- Repolarization begins.

STEP 4: Return to normal permeability

- The voltage-regulated sodium channels regain their normal properties in 0.4–1.0 msec. The membrane is now capable of generating another action potential if a larger-than-normal stimulus is provided.

- The voltage-regulated potassium channels begin closing at -70 mV Because they do not all close at the same time, potassium loss continues and a tempo
rary hyperpolarization to approximately -90 mV occurs.
- At the end of relative refractory period, all voltage-regulated channels have closed and the membrane is back to is resting state.

TABLE 12–4 A Comparison of Graded Potentials and Action Potentials

Graded Potentials Action Potentials

Depolarizing or hyperpolarizing No threshold value Amount of depolarization or hyperpolarization depends on intensity
of stimulus
Passive spread from site of stimulation
Effect on membrane potential decreases with distance from
stimulation site
No refractory period
Occur in most cell membranes Always depolarizing Depolarization to threshold must occur before action potential begins All-or-none phenomenon; all stimuli that exceed threshold will produce
identical action potentials
Action potential at one site depolarizes adjacent sites to threshold
Propagated along entire membrane surface without decrease in
strength
Refractory period occurs
Occur only in excitable membranes of specialized cells such as neurons
and muscle cells

TABLE 12–6 Representative Neurotransmitters and Neuromodulators

Class and
Neurotransmitter Chemical Structure Mechanism of Action Location(s) Comments

Acetylcholine Primarily direct, through CNS: Synapses throughout brain and Widespread in CNS and
binding to chemically spinal cord PNS; best known and
regulated channels PNS: Neuromuscular junctions; most studied of the
preganglionic synapses of ANS; neurotransmitters
neuroglandular junctions
of parasympathetic division and
(rarely) sympathetic division of ANS;
amacrine cells of retina

BIOGENIC AMINES

Norepinephrine Indirect: G proteins and CNS: Cerebral cortex, hypothalamus, Involved in attention and
second messengers brain stem, cerebellum, spinal cord consciousness, control of
PNS: Most neuromuscular body temperature, and
and neuroglandular junctions regulation of pituitary
of sympathetic division of ANS gland secretion

Epinephrine Indirect: G proteins and CNS: Thalamus, hypothalamus, Uncertain functions second messengers midbrain, spinal cord

Dopamine Indirect: G proteins and CNS: Hypothalamus, midbrain, limbic Regulation of subconscious
second messengers system, cerebral cortex, retina motor function; receptor
abnormalities have been
linked to development of

Serotonin Primarily indirect: G
proteins and second

	messengers hallucinogenic drugs,
Histamine	Indirect: G proteins and second messengers
AMINO ACIDS	
Excitatory:	
Glutamate	Indirect: G proteins and second messengers Direct: opens calcium
channels on pre- and	
	postsynaptic membranes
Aspartate	Direct or indirect (G proteins), depending on type of receptor skeletal muscles
Inhibitory:	
Gamma aminobutyric acid (GABA)	Direct or indirect (G proteins), depending on type of receptor
Glycine	Direct: Opens Cl- channels

TABLE 12–6 Continued

Class and Neurotransmitter	**Chemical Structure**	**Mechanism of Action**
NEUROPEPTIDES		
Substance P	Indirect: G proteins and second messengers	
Neuropeptide Y	*36-amino-acid peptide*	As above
Opioids		

Endorphins *31-amino-acid peptide* Indirect: G proteins and
second messengers

schizophrenia
CNS: Hypothalamus, limbic system, Important in emotional
cerebellum, spinal cord, retina states, moods, and body
temperature; several illicit
such as *Ecstasy*, target
serotonin receptors
CNS: Neurons in hypothalamus, Receptors are primarily
with axons projecting on presynaptic
throughout the brain membranes; functions in
sexual arousal, pain
threshold, pituitary
hormone secretion,
thirst, and blood
pressure control
CNS: Cerebral cortex and brain stem Important in memory
and learning; most
important excitatory
neurotransmitter in
the brain
CNS: Cerebral cortex, retina, and Used by pyramidal cells
spinal cord that provide voluntary
motor control over
CNS: Cerebral cortex, Direct effects: open Cl-
cerebellum, interneurons channels; indirect effects:
throughout brain and open channels and K+
spinal cord block entry of Ca2 +

CNS: Interneurons in brain stem, spinal cord, and retina	Produces postsynaptic inhibition; the poison *strychnine* produces fatal convulsions by blocking glycine receptors

Location(s)	**Comments**
CNS: Synapses of pain receptors within spinal cord, hypothalamus, and other areas of the brain PNS: Entericnervous system (network of neurons along the digestive tract)	Important in pain pathway, regulation of pituitary gland function, control of digestive tract reflexes
CNS: hypothalamus PNS: sympathetic neurons	Stimulates appetite and food intake
CNS: Thalamus, hypothalamus, brain stem, retina	Pain control; emotional and behavioral effects poorly understood

Enkephalins As above CNS: Basal nuclei, hypothalamus, As above
midbrain, pons, medulla oblongata,
spinal cord

Endomorphin *9-or 10-amino-acid peptide* As above CNS: Thalamus, hypothalamus, As above
basal nuclei

Dynorphin As above CNS: hypothalamus, As above
midbrain, medulla
oblongata

PURINES

ATP, GTP *(see Figure 2–24)* Direct or indirect (G CNS: Spinal cord
proteins), depending PNS: Autonomic ganglia
on type of receptor

Adenosine *(see Figure 2–24)* Indirect: G proteins and CNS: Cerebral cortex, Produces drowsiness;
second messengers hippocampus, cerebellum stimulatory effect of caffeine is due to inhibition of adenosine activity

HORMONES

ADH, oxytocin, Peptide containing fewer Typically indirect: G CNS: Brain (widespread) Numerous, complex, and
insulin,glucagon, than 200 amino acids proteins and second incompletely understood
secretin, CCK, GIP, messengers
VIP, inhibins, ANP,

BNP, and many others

GASES

Carbon monoxide (CO) C = 0 Indirect: By diffusion to CNS: Brain Localization and
enzymes activating PNS: Some neuromuscular and function poorly
second messengers neuroglandular junctions understood

Nitric oxide (NO) N = 0 As above CNS: Brain, especially at blood vessels
PNS: Some sympathetic neuromuscular
and neuroglandular junctions

LIPIDS

Anandamide Indirect: G proteins and CNS: cerebral cortex, Euphoria, drowsiness;

second messengers hippocampus, receptors are targeted
cerebellum by the active ingredient
in marijuana

| SUMMARY TABLE 12–7 | INFORMATION PROCESSING

- The neurotransmitters released at a synapse may have either excitatory or inhibitory effects. The effect on the axon’s initial segment reflects a summation of the stimuli that arrive at any moment. The frequency of generation of action potentials is an indication of the degree of sustained depolarization at the axon hillock.
- Neuromodulators can alter either the rate of neurotransmitter release or the response of a postsynaptic neuron to specific neurotransmitters.
- Neurons may be facilitated or inhibited by extracellular chemicals other than neurotransmitters or neuromodulators.
- The response of a postsynaptic neuron to the activation of a presynaptic neuron can be altered by (1) the presence of neuromodulators or other chemicals that cause facilitation or inhibition at the synapse, (2) activity under way at other synapses affecting the postsynaptic cell, and (3) modification of the rate of neurotransmitter release through presynaptic facilitation or presynaptic inhibition. Information is relayed in the form of action potentials. In general, the degree of sensory stimulation or the strength of the motor response is proportional to the frequency of action potentials.

Most PNS axons, whether myelinated or unmyelinated, are shielded from contact with the interstitial fluid by Schwann cells. **(a)** A myelinated axon, showing the organization of Schwann cells along the length of the axon. Also shown are stages in the formation of a myelin sheath by a single Schwann cell along a portion of a single axon (compare with myelin in the CNS, shown in *Figure 12–4b*). **(b)** The enfolding of a group of unmyelinated axons by a single Schwann cell. A series of Schwann cells is required to cover the axons along their entire length.
- **FIGURE 12–6** Peripheral Nerve Regeneration after Injury
- **FIGURE 12–7** An Overview of Neural Activities. The important membrane processes are shown in order of their presentation in the text. This figure will be repeated, in simplified form, as a Navigator icon in other figures whenever we are changing topics.
- **FIGURE 12–8** An Introduction to the Resting Potential. The resting potential is the transmembrane potential of an undisturbed cell. The phospholipid bilayer of the cell membrane is represented by a simple blue band. The Navigator icon highlights the resting potential to indicate “You are here!”
- **FIGURE 12–9** Electrochemical Gradients for Potassium and Sodium Ions
- **FIGURE 12–10** Gated Channels. Na^+ channels are shown here, but comparable gated channels regulate the movements of other cations and anions. **(a)** A chemically regulated Na^+ channel that opens in response to the presence of ACh at a binding site. **(b)** A voltage-

regulated Na^+ channel that responds to changes in the transmembrane potential. At the normal resting potential, the channel is closed; at a membrane potential

of -60 mV, the channel opens; at + 30 mV, the channel is inactivated. **(c)** A mechanically regulated channel, which opens in response to distortion of the membrane.

- **FIGURE 12–11** Graded Potentials. The depolarization radiates in all directions away from the source of stimulation. For clarity, only gated channels are shown; leak channels are present, but are not responsible for the production of graded potentials. Color changes in the phospholipid bilayer indicate that the resting potential has been disturbed and that the transmembrane potential is no longer -70 mV. Notice that the Navigator Icon now highlights the graded potential.
- **FIGURE 12–12** Depolarization, Repolarization, and Hyperpolarization. **(a)** Depolarization and repolarization in response to the application and removal of a stimulus that opens chemically regulated sodium channels. **(b)** Hyperpolarization in response to the application of a stimulus that opens chemically regulated potassium channels. When the stimulus is removed, the membrane potential returns to the resting level.
- **FIGURE 12–13**

The Generation of an Action Potential. For clarity, only gated channels are shown.

- **FIGURE 12–14** Continuous Propagation of an Action Potential along an Unmyelinated Axon. Events are best understood when the axon is viewed as a series of adjacent segments.
- **FIGURE 12–15** Saltatory Propagation along a Myelinated Axon. This process will continue along the entire length of the axon.
- **FIGURE 12–16** Events in the Functioning of a Cholinergic Synapse
- **FIGURE 12–17** Mechanisms of Neurotransmitter Function. **(a)** Direct effects on membrane channels. **(b)** Indirect effects mediated by G proteins. **(c)** Indirect effects mediated by intracellular enzymes.
- **FIGURE 12–18** Temporal and Spatial Summation. **(a)** Temporal summation occurs on a membrane that receives two depolarizing stimuli from the same source in rapid succession.

The effects of the second stimulus are added to those of the first. **(b)** Spatial summation occurs when sources of stimulation arrive simultaneously, but at different locations. Local currents spread the depolarizing effects, and areas of overlap experience the combined effects.

- **FIGURE 12–19**

Interactions between EPSPs and IPSPs. At time 1, a small depolarizing stimulus produces an EPSP. At time 2, a small hyperpolarizing stimulus produces an IPSP of comparable magnitude. If the two stimuli are applied simultaneously, as they are at time 3, summation occurs. Because the two are equal in size but have opposite effects, the membrane potential remains at the resting level. If the EPSP were larger, a net depolarization would result; if the IPSP were larger, a net hyperpolarization would result instead.

- **FIGURE 12–20** Presynaptic Inhibition and Presynaptic Facilitation. **(a)** Steps in presynaptic inhibition. **(b)** Steps in presynaptic facilitation.

General Organization of the Nervous System

Objective

- Describe the basic structural and organizational characteristics of the nervous system.

Organization is usually the key to success in any complex environment. A large corporation, for example, has both a system to distribute messages on specific topics and executive assistants who decide whether an issue can be ignored or easily responded to; only the most complex and important problems reach the desk of the president. The nervous system works in much the same way: It has input pathways that route sensations, and processing centers that prioritize and distribute information. There are also several levels that issue motor responses. Your conscious mind (the president) gets involved only in a fraction of the day-to-day activities; the other decisions are handled at lower levels that operate outside your awareness. This very efficient system works only because it is so highly organized.

Because the nervous system has so many components and does so much, even a relatively superficial discussion will take four chapters to complete. If our primary interest were the anatomy of this system, we would probably start with an examination of the central nervous system (brain and spinal cord) and then consider the peripheral nervous system (cranial nerves and spinal nerves). But our primary interest is how the nervous system *functions*, so we will consider the system from a functional perspective. The basic approach has been diagrammed in Figure 13–1•.

In the chapters that follow, we will look at increasing levels of structural and functional complexity. Chapter 12 provided the foundation by considering the function of individual neurons. In the current chapter, we consider the spinal cord and spinal nerves and the basic wiring of relatively simple *spinal reflexes*—rapid, automatic responses triggered by specific stimuli. Spinal reflexes are controlled in the spinal cord; whether they involve a single spinal segment or multiple segments, they can function without any input from the brain. For example, a reflex controlled in the spinal cord makes you drop a frying pan you didn’t realize was scalding hot. By the time the information reaches your brain and you become aware of the pain, you’ve already released the pan. Although there are much more complex spinal reflexes, this functional pattern still applies; a reflex provides a quick, automatic response to a specific stimulus.

Your spinal cord is structurally and functionally integrated with your brain. Chapter 14 provides an overview of the major components and functions of the brain and cranial nerves. It also discusses the *cranial reflexes*, relatively localized reflex responses comparable in organization and complexity to those of the spinal cord.

Chapters 15 and 16 consider the nervous system as an integrated functional unit. Chapter 15 deals with the interplay between centers in the brain and spinal cord that occurs in the processing of sensory information. It then examines the conscious and subconscious control of skeletal muscle activity provided by the *somatic nervous system* (SNS).

Chapter 16 continues with a discussion of the control of visceral functions by the *autonomic nervous system* (ANS). The ANS, which has processing centers in the brain, spinal cord, and peripheral nervous system, is responsible for the control of visceral effectors, such as peripheral smooth muscles, cardiac muscle, and glands. We then conclude this section of the book by examining what are often called *higher-order functions*: memory, learning, consciousness, and personality. These fascinating topics are difficult to investigate, but they can affect activity along the sensory and motor pathways and alter our perception of those activities.

With these basic principles, definitions, and strategies in mind, we can begin our examination of the levels of functional organization in the nervous system.

Gross Anatomy of the Spinal Cord

Objectives

- Discuss the structure and functions of the spinal cord.
- Describe the three meningeal layers that surround the central nervous system.
- Explain the roles of white matter and gray matter in processing and relaying sensory information and motor commands.

The adult spinal cord (Figure 13–2a•) measures approximately 45 cm (18 in.) in length and has a maximum width of roughly 14 mm (0.55 in.). Note that the cord itself is not as long as the vertebral column—instead, the adult spinal cord ends between vertebrae L1 and L2. The posterior (dorsal) surface of the spinal cord bears a shallow longitudinal groove, the **posterior median sulcus** (Figure 13–2b•). The **anterior median fissure** is a deeper groove along the anterior (ventral) surface.

The amount of gray matter is greatest in segments of the spinal cord dedicated to the sensory and motor control of the limbs. These segments are expanded, forming the **enlargements** of the spinal cord. The **cervical enlargement** supplies nerves to the shoulder and upper limbs; the **lumbar enlargement** provides innervation to structures of the pelvis and lower limbs. Inferior to the lumbar enlargement, the spinal cord becomes tapered and conical; this region is the **conus medullaris**. The **filum terminale** ("terminal thread"), a slender strand of fibrous tissue, extends from the inferior tip of the conus medullaris. It continues along the length of the vertebral canal as far as the second sacral vertebra, where it provides longitudinal support to the spinal cord as a component of the *coccygeal ligament*.

The series of sectional views in Figure 13–2b• illustrates the variations in the relative mass of gray matter and white matter in the cervical, thoracic, lumbar, and sacral regions of the spinal cord. The entire spinal cord can be divided into 31 segments on the basis of the origins of the spinal nerves. Each segment is identified by a letter and number designation, the same method used to identify vertebrae. For example, C3, the segment in the uppermost section of Figure 13–2b•, is the third cervical segment.

Every spinal segment is associated with a pair of **dorsal root ganglia** (see Figure 13–2b•), situated near the spinal cord. These ganglia contain the cell bodies of sensory neurons. The axons of the neurons form the **dorsal roots**, which bring sensory information into the spinal cord. A pair of **ventral roots** contains the axons of motor neurons that extend into the periphery to control somatic and visceral effectors. On both sides, the dorsal and ventral roots of each segment pass between the vertebral canal and the periphery at the *intervertebral foramen* between successive vertebrae. The dorsal root ganglion lies between the pedicles of
the adjacent vertebrae. (You can review vertebral anatomy in Chapter 7. l**pp. 225–226**)

Distal to each dorsal root ganglion, the sensory and motor roots are bound together into a single **spinal nerve**. Spinal nerves are classified as **mixed nerves**—that is, they contain both afferent (sensory) and efferent (motor) fibers. There are 31 pairs of spinal nerves, each identified by its association with adjacent vertebrae. For example, we may speak of “cervical spinal nerves” or even “cervical nerves” when we make a general reference to spinal nerves of the neck. However, when we indicate specific spinal nerves, it is customary to give them a regional number, as indicated in Figure 13–2•. Each spinal nerve inferior to the first thoracic vertebra takes its name from the vertebra immediately superior to it. Thus, spinal nerve T1 emerges immediately inferior to vertebra T1, spinal nerve T2 follows vertebra T2, and so forth.

The arrangement differs in the cervical region, because the first pair of spinal nerves, C1, passes between the skull and the first cervical vertebra. For this reason, each cervical nerve takes its name from the vertebra immediately inferior to it. In other words, cervical nerve C2 *precedes* vertebra C2, and the same system is used for the rest of the cervical series. The transition from one numbering system to another occurs between the last cervical vertebra and first thoracic vertebra. The spinal nerve found at this location has been designated C8. Therefore, although there are only seven cervical vertebrae, there are *eight* cervical nerves.

The spinal cord continues to enlarge and elongate until an individual is approximately 4 years old. Up to that time, enlargement of the spinal cord keeps pace with the growth of the vertebral column. Throughout this period, the ventral and dorsal roots are very short, and they enter the intervertebral foramina immediately adjacent to their spinal segment. After age 4, the vertebral column continues to elongate, but the spinal cord does not. This vertebral growth moves the intervertebral foramina, and thus the spinal nerves, farther and farther from their original positions relative to the spinal cord. As a result, the dorsal and ventral roots gradually elongate, and the correspondence between the spinal segment and the vertebral segment is lost. For example, in adults, the sacral segments of the spinal cord are at the level of vertebrae L1–L2.

Because the adult spinal cord extends only to the level of the first or second lumbar vertebra, the dorsal and ventral roots of spinal segments L2 to S5 extend inferiorly, past the inferior tip of the conus medullaris. When seen in gross dissection, the filum terminale and the long ventral and dorsal roots resemble a horse’s tail. As a result, early anatomists called this complex the **cauda equina** (KAW-duh ek-W -nuh; *cauda*, tail + *equus*, horse).

I

Spinal Meninges

The vertebral column and its surrounding ligaments, tendons, and muscles isolate the spinal cord from the rest of the body, and these structures also provide protection against bumps, shocks, and blows to the skin of the back. The delicate neural tissues must also be protected from damaging contacts with the surrounding bony walls of the vertebral canal. The **spinal meninges** (me-NIN-jez; singular, *meninx*, membrane), a series of specialized membranes surrounding the spinal cord, provide the necessary physical stability and shock absorption. Blood vessels branching within these layers deliver oxygen and nutrients to the spinal cord.

The relationships among the spinal meninges are shown in Figure 13–3a•. The spinal meninges consist of three layers: (1) the *dura mater*, (2) the *arachnoid mater*, and (3) the *pia mater*. At the foramen magnum of the skull, the spinal meninges are continuous with the **cranial meninges**, which surround the brain. (We will discuss the cranial meninges, which have the same three layers, in Chapter 14.)

Bacterial or viral infection can cause **meningitis**, or inflammation of the meningeal membranes. Meningitis is dangerous because it can disrupt the normal circulatory and cerebrospinal fluid supplies, damaging or killing neurons and neuroglia in the affected areas. Although an initial diagnosis may specify the meninges of the spinal cord (*spinal meningitis*) or brain (*cerebral meningitis*), in later stages the entire meningeal system is usually affected. AM: Meningitis

The Dura Mater

The tough, fibrous **dura mater** (DOO-ruh MA-ter; *dura*, hard + *mater*, mother) is the layer that forms the outermost covering of the spinal cord (see Figure 13–3a•). This layer contains dense collagen fibers that are oriented along the longitudinal axis of the cord. Between the dura mater and the walls of the vertebral canal lies the **epidural space**, a region that contains areolar tissue, blood vessels, and a protective padding of adipose tissue (Figure 13–3b•).

The spinal dura mater does not have extensive, firm connections to the surrounding vertebrae. Longitudinal stability is provided by localized attachment sites at either end of the vertebral canal. Cranially, the outer layer of the spinal dura mater fuses with the periosteum of the occipital bone around the margins of the foramen magnum. There, the spinal dura mater becomes continuous with the cranial dura mater. Within the sacral canal, the spinal dura mater tapers from a sheath to a dense cord of collagen fibers that blends with components of the filum terminale to form the **coccygeal ligament** (see Figure 13–2a•). The coccygeal ligament continues along the sacral canal, ultimately blending into the periosteum of the coccyx. Lateral support for the spinal dura mater is provided by loose connective tissue and adipose tissue within the epidural space. In addition, this dura mater extends between adjacent vertebrae at each intervertebral foramen, fusing with the connective tissues that surround the spinal nerves.

Anesthetics are often injected into the epidural space. Introduced in this way, a drug should affect only the spinal nerves in the immediate area of the injection. The result is an *epidural block*—a temporary sensory loss or a sensory and motor paralysis, depending on the anesthetic selected. Epidural blocks in the inferior lumbar or sacral regions may be used to control pain during childbirth.

The Arachnoid Mater

In most anatomical and histological preparations, a narrow **subdural space** separates the dura mater from deeper meningeal layers. It is likely, however, that in life no such space exists, and that the inner surface of the dura mater is in contact with the outer surface of the **arachnoid** (a-RAK-noyd; *arachne*, spider) **mater**, the middle meningeal layer (see Figure 13–3b•). The inner surface of the dura mater and the outer surface of the arachnoid mater are covered by simple squamous epithelia. The arachnoid mater includes this epithelium, called the *arachnoid membrane*, and the *arachnoid trabeculae*, a delicate network of collagen and elastic fibers that extends between the arachnoid membrane and the outer surface of the pia mater. The intervening region is called the **subarachnoid space**. It is filled with **cerebrospinal fluid (CSF)**, which acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemical messengers, and waste products.

The spinal arachnoid mater extends inferiorly as far as the filum terminale, and the dorsal and ventral roots of the cauda equina lie within the fluid-filled subarachnoid space. In adults, the withdrawal of cerebrospinal fluid, a procedure known as a **spinal tap**, involves the insertion of a needle into the subarachnoid space in the inferior lumbar region. AM: Spinal Taps and Myelography

The Pia Mater

The subarachnoid space extends between the arachnoid epithelium and the innermost meningeal layer, the **pia mater** (*pia*, delicate + *mater*, mother). The pia mater consists of a meshwork of elastic and collagen fibers that is firmly bound to the underlying neural tissue (see Figure 13–3•). These connective-tissue fibers are extensively interwoven with those that span the subarachnoid space, firmly binding the arachnoid to the pia mater. The blood vessels servicing the spinal cord run along the surface of the spinal pia mater, within the subarachnoid space (Figure 13–4•).

Along the length of the spinal cord, paired **denticulate ligaments** extend from the pia mater through the arachnoid to the dura mater (see Figure 13–3b and 13–4•). Denticulate ligaments, which originate along either side of the spinal cord, prevent lateral (side-to-side) movement. The dural connections at the foramen magnum and the coccygeal ligament prevent longitudinal (superior–inferior) movement.

The spinal meninges accompany the dorsal and ventral roots as these roots pass through the intervertebral foramina. As the sectional view in Figure 13–3b• indicates, the meningeal membranes are continuous with the connective tissues that surround the spinal nerves and their peripheral branches.

Concept Check

Damage to which root of a spinal nerve would interfere with motor function?

Where is the cerebrospinal fluid that surrounds the spinal cord located?

Answers begin on p. A–1

Sectional Anatomy of the Spinal Cord

To understand the functional organization of the spinal cord, you must become familiar with its sectional organization (Figure 13–5•). Together, the anterior median fissure and the posterior median sulcus mark the division between the left and right sides of the spinal cord. The superficial white matter contains large numbers of myelinated and unmyelinated axons. The gray matter, dominated by the cell bodies of neurons, neuroglia, and unmyelinated axons, surrounds the narrow **central canal** and forms an H or butterfly shape. The projections of gray matter toward the outer surface of the spinal cord are called **horns**.

Organization of Gray Matter

The cell bodies of neurons in the gray matter of the spinal cord are organized into functional groups called *nuclei*. **Sensory nuclei** receive and relay sensory information from peripheral receptors. **Motor nuclei** issue motor commands to peripheral effectors. Although sensory and motor nuclei appear rather small in transverse section, they may extend for a considerable distance along the length of the spinal cord.

A frontal section along the length of the central canal of the spinal cord separates the sensory (posterior, or dorsal) nuclei from the motor (anterior, or ventral) nuclei. The **posterior gray horns** contain somatic and visceral sensory nuclei, whereas the **anterior gray horns** contain somatic motor nuclei. The **lateral gray horns**, located only in the thoracic and lumbar segments, contain visceral motor nuclei. The **gray commissures** (*commissura*, a joining together) posterior to and anterior to the central canal contain axons that cross from one side of the cord to the other before they reach a destination in the gray matter.

Figure 13–5a• shows the relationship between the function of a particular nucleus (sensory or motor) and its relative position in the gray matter of the spinal cord. The nuclei within each gray horn are also organized. In the cervical enlargement, for example, the anterior gray horns contain nuclei whose motor neurons control the muscles of the upper limbs. On each side of the spinal cord, in medial to lateral sequence, are somatic motor nuclei that control (1) muscles that position the pectoral girdle, (2) muscles that move the arm, (3) muscles that move the forearm and hand, and (4) muscles that move the hand and fingers. Within each of these regions, the motor neurons that control flexor muscles are grouped separately from those that control extensor muscles. Because the spinal cord is so highly organized, we can predict which muscles will be affected by damage to a specific area of gray matter.

Organization of White Matter

The white matter on each side of the spinal cord can be divided into three regions called **columns**, or *funiculi* (see Figure 13–5a•). The **posterior white columns** lie between the posterior gray horns and the posterior median sulcus. The **anterior white columns** lie between the anterior gray horns and the anterior median fissure. The anterior white columns are interconnected by the **anterior white commissure**, a region where axons cross from one side of the spinal cord to the other. The white matter between the anterior and posterior columns on each side makes up the **lateral white column**.

Each column contains tracts whose axons share functional and structural characteristics. A **tract**, or *fasciculus* (fa-SIK-u-lus; bundle), is a bundle of axons in the CNS that are relatively uniform with respect to diameter, myelination, and conduction speed. All the axons within a tract relay the same type of information (sensory or motor) in the same direction. Short tracts carry sensory or motor signals between segments of the spinal cord, and longer tracts connect the spinal cord with the brain. **Ascending tracts** carry sensory information toward the brain, and **descending tracts** convey motor commands to the spinal cord. We will describe the major tracts and their functions in Chapters 15 and 16. Because spinal tracts have very specific functions, damage to one produces a characteristic loss of sensation or motor control. AM: Damage to Spinal Tracts

100 Keys | The spinal cord has a narrow central canal surrounded by gray matter containing sensory and motor nuclei. Sensory nuclei are dorsal; motor nuclei are ventral. The gray matter is covered by a thick layer of white matter consisting of ascending and descending axons. These axons are organized in columns that contain axon bundles with specific functions. Because the spinal cord is so highly organized, it is often possible to predict the results of injuries to localized areas.

Concept Check

A person with polio has lost the use of his leg muscles. In which area of his spinal cord would you expect the virus-infected motor neurons to be? Which portion of the spinal cord would be affected by a disease that damages myelin sheaths?

Answers begin on p. A–1

Anatomy 360 | Review the anatomy of the spinal cord on the **Anatomy 360 CD-ROM: Nervous System/Central Nervous System/Spinal Cord.**

Spinal Nerves

Objectives

- Describe the major components of a spinal nerve.
- Relate the distribution pattern of spinal nerves to the regions they innervate.

Every segment of the spinal cord is connected to a pair of spinal nerves. Surrounding each spinal nerve is a series of connective

tissue layers (Figure 13–6•). These layers, best seen in sectional view, are comparable to those associated with skeletal muscles. l**p. 285** The **epineurium**, or outermost layer, consists of a dense network of collagen fibers. The fibers of the **perineurium**, the middle layer, extend inward from the epineurium. These connective tissue partitions divide the nerve into a series of compartments that contain bundles of axons, or *fascicles*. Delicate connective tissue fibers of the **endoneurium**, the innermost layer, extend from the perineurium and surround individual axons.

Arteries and veins penetrate the epineurium and branch within the perineurium. Capillaries leaving the perineurium branch in the endoneurium and supply the axons and Schwann cells of the nerve and the fibroblasts of the connective tissues.

As they extend into the periphery, the spinal nerves branch and interconnect, forming the peripheral nerves that innervate body tissues and organs. The connective tissue shealths of peripheral nerves are the same as, and continuous with, those of spinal nerves.

If a peripheral axon is severed but not displaced, normal function may eventually return as the cut stump grows across the site of injury, away from the cell body and along its former path. l**p. 389** Repairs made after an entire peripheral *nerve* has been damaged are generally incomplete, primarily because of problems with axon alignment and regrowth. Various technologically sophisticated procedures designed to improve nerve regeneration and repair are currently under evaluation. AM: Damage and Repair of Peripheral Nerves

Peripheral Distribution of Spinal Nerves

Figure 13–7• shows the distribution, or pathway, of a typical spinal nerve that originates from the thoracic or superior lumbar segments of the spinal cord. The spinal nerve forms just lateral to the intervertebral foramen, where the dorsal and ventral roots unite. We will now consider the peripheral distribution of a representative spinal nerve from the thoracic region.

The ventral root of each spinal nerve contains the axons of somatic motor and visceral motor neurons (Figure 13–7a•). Distally, the first branch from the spinal nerve carries visceral motor fibers to a nearby *sympathetic ganglion*, part of the *sympathetic division* of the autonomic nervous system. (Among its other functions, the sympathetic division is responsible for elevating metabolic rate and increasing alertness.) Because preganglionic axons are myelinated, this branch has a light color and is therefore known as the **white ramus** (“branch”). Postganglionic fibers that innervate smooth muscles, glands, and organs in the thoracic cavity extend directly from the ganglion to their respective effector organs. These axons form a series of **sympathetic nerves**.

Postganglionic fibers innervating glands and smooth muscles in the body wall or limbs return from the ganglion to rejoin the spinal nerve. These fibers, which are unmyelinated and have a darker color, form the **gray ramus**. The gray ramus is typically proximal to the white ramus; together, they are known as the *rami communicantes* (RA-mı ko-mu-ni-KAN-tez), or "communicating branches." The **dorsal ramus** of each spinal nerve contains somatic motor and visceral motor fibers that innervate the skin and skeletal muscles of the back. The axons in the relatively large **ventral ramus** supply the ventrolateral body surface, structures in the body wall, and the limbs.

The dorsal, ventral, and white rami also contain sensory (afferent) fibers (Figure 13–7b•). Somatic sensory information arrives over the dorsal and ventral rami; visceral sensory information reaches the dorsal root through the dorsal, ventral, and white rami.

The specific bilateral region of the skin surface monitored by a single pair of spinal nerves is known as a **dermatome**. Each pair of spinal nerves services its own dermatome (Figure 13–8•), although the boundaries of adjacent dermatomes overlap to some degree. Dermatomes are clinically important because damage or infection of a spinal nerve or dorsal root ganglion will produce a characteristic loss of sensation in the corresponding region of the skin. Additionally, characteristic signs may appear on the skin supplied by that specific nerve.

Peripheral *nerve palsies*, or **peripheral neuropathies**, are regional losses of sensory and motor function most often resulting from nerve trauma or compression. (You have experienced a mild, temporary palsy if your arm or leg has ever "fallen asleep" after you leaned or sat in an uncomfortable position.) The location of the affected dermatomes provides clues to the location of injuries along the spinal cord, but the information is not precise. More exact conclusions can be drawn if there is loss of motor control, on the basis of the origin and distribution of the peripheral nerves originating at nerve plexuses. For example, in the condition *shingles*, a virus infects dorsal root ganglia, causing a painful rash whose distribution corresponds to that of the affected sensory nerves. AM: Peripheral Neuropathies; Shingles and Hansen's Disease

100 Keys | Each peripheral nerve provides sensory and/or motor innervation to specific structures.

Nerve Plexuses

The simple distribution pattern of dorsal and ventral rami in Figure 13–7• applies to spinal nerves T1–T12. But in segments controlling the skeletal musculature of the neck, upper limbs, or lower limbs, the situation is more complicated. During development, small skeletal muscles innervated by different ventral rami typically fuse to form larger muscles with compound origins. The anatomical distinctions between the component muscles may disappear, but separate ventral rami continue to provide sensory innervation and motor control to each part of the compound muscle. As they converge, the ventral rami of adjacent spinal nerves blend their fibers, producing a series of compound nerve trunks. Such a complex interwoven network of nerves is called a **nerve plexus** (PLEK-sus; *plexus*, braid). The ventral rami form four major plexuses: (1) the *cervical plexus*, (2) the *brachial plexus*, (3) the *lumbar plexus*, and (4) the *sacral plexus* (Figure 13–9•). Because they form from the fusion of ventral rami, the nerves arising at these plexuses contain sensory as well as motor fibers (see Figure 13–7•).

In Chapter 11, we introduced the peripheral nerves that control the major axial and appendicular muscles. As we proceed, you may find it helpful to refer to the related tables in that chapter. l**pp. 338–371**

The Cervical Plexus

The **cervical plexus** consists of the ventral rami of spinal nerves C1–C5 (Figures 13–9, 13–10•; Table 13–1). The branches of the cervical plexus innervate the muscles of the neck and extend into the thoracic cavity, where they control the diaphragmatic muscles. The **phrenic nerve**, the major nerve of the cervical plexus, provides the entire nerve supply to the diaphragm, a key respiratory muscle. Other branches of this nerve plexus are distributed to the skin of the neck and the superior part of the chest.

The Brachial Plexus

The **brachial plexus** innervates the pectoral girdle and upper limb, with contributions from the ventral rami of spinal nerves C5
–T1 (Figures 13–9 and 13–11•; Table 13–2). The nerves that form this plexus originate from trunks and cords. **Trunks** are large bundles of axons contributed by several spinal nerves. **Cords** are smaller branches that originate at trunks. Both trunks and cords are named according to their location relative to the *axillary artery*, a large artery supplying the upper limb. Hence we have *superior*, *middle*, and *inferior trunks*, and *lateral*, *medial*, and *posterior cords*. The lateral cord forms the **musculocutaneous nerve** exclusively and, together with the medial cord, contributes to the **median nerve**. The **ulnar nerve** is the other major nerve of the medial cord. The posterior cord gives rise to the **axillary nerve** and the **radial nerve**. Table 13–2 provides further information about these and other major nerves of the brachial plexus.

The Lumbar and Sacral Plexuses

The **lumbar plexus** and the **sacral plexus** arise from the lumbar and sacral segments of the spinal cord, respectively. The nerves arising at these plexuses innervate the pelvic girdle and lower limbs (Figures 13–9 and Figure 13–12•). The individual nerves that form the lumbar and sacral plexuses are listed in Table 13–3.

The lumbar plexus contains axons from the ventral rami of spinal nerves T12–L4. The major nerves of this plexus are the **genitofemoral nerve**, the **lateral femoral cutaneous nerve**, and the **femoral nerve**. The sacral plexus contains axons from the ventral rami of spinal nerves L4–S4. Two major nerves arise at this plexus: the **sciatic nerve** and the **pudendal nerve**. The sciatic nerve passes posterior to the femur, deep to the long head of the biceps femoris muscle. As it approaches the knee, the sciatic nerve divides into two branches: the **fibular nerve** (or *peroneal nerve*) and the **tibial nerve**. The *sural nerve*, formed by branches of the fibular nerve, is a sensory nerve innervating the lateral portion of the foot. A section of this nerve is often removed for use in nerve grafts.

In discussions of motor performance, a distinction is usually made between the conscious ability to control motor function— something that requires communication and feedback between the brain and spinal cord—and automatic motor responses coordinated entirely within the spinal cord. These automatic responses, called *reflexes*, are relatively stereotyped motor responses to specific stimuli. The rest of this chapter looks at how sensory neurons, interneurons, and motor neurons interconnect, and how these interconnections produce both simple and complex reflexes. ATLAS: Embryology Summary 11: The Development of the Spinal Cord and Spinal Nerves

Concept Check

An anesthetic blocks the function of the dorsal rami of the cervical spinal nerves. Which areas of the body will be affected?

Injury to which of the nerve plexuses would interfere with the ability to breathe?

Compression of which nerve produces the sensation that your leg has “fallen asleep”?

Answers begin on p. A–1

Anatomy 360 | Review the anatomy of the peripheral nerves of the **Anatomy 360 CD-ROM: Nervous System/ Peripheral Nervous System/Spinal Nerves.**

Principles of Functional Organization

Objectives

- Discuss the significance of neuronal pools and describe the major patterns of interaction among neurons within and among these pools.
- Describe the steps in a neural reflex.
- Classify the types of reflexes and explain the functions of each.

The human body has about 10 million sensory neurons, one-half million motor neurons, and 20 *billion* interneurons. The sensory neurons deliver information to the CNS; the motor neurons distribute commands to peripheral effectors, such as skeletal muscles; and the interneurons interpret, plan, and coordinate the incoming and outgoing signals.

Neuronal Pools

The billions of interneurons of the CNS are organized into a much smaller number of **neuronal pools**—functional groups of interconnected neurons. A neuronal pool may be diffuse, involving neurons in several regions of the brain, or localized, with neurons restricted to one specific location in the brain or spinal cord. Estimates of the actual number of neuronal pools range between a few hundred and a few thousand. Each has a limited number of input sources and output destinations, and each may contain both excitatory and inhibitory neurons. The output of the entire neuronal pool may stimulate or depress activity in other parts of the brain or spinal cord, affecting the interpretation of sensory information or the coordination of motor commands.

The pattern of interaction among neurons provides clues to the functional characteristics of a neuronal pool. It is customary to refer to the “wiring diagrams” in Figure 13–13• as *neural circuits*, just as we refer to electrical circuits in the wiring of a house. We can distinguish five circuit patterns:

1. Divergence is the spread of information from one neuron to several neurons (see Figure 13–13•), or from one pool to multiple pools. Divergence permits the broad distribution of a specific input. Considerable divergence occurs when sensory neurons bring information into the CNS, for the information is distributed to neuronal pools throughout the spinal cord and brain. Visual information arriving from the eyes, for example, reaches your consciousness at the same time it is distributed to areas of the brain that control posture and balance at the subconscious level.

2. In **convergence**, several neurons synapse on a single postsynaptic neuron (see Figure 13–13•). Several patterns of activity in the presynaptic neurons can therefore have the same effect on the postsynaptic neuron. Through convergence, the same motor neurons can be subject to both conscious and subconscious control. For example, the movements of your diaphragm and ribs are now being controlled by your brain at the subconscious level. But the same motor neurons can also be controlled consciously, as when you take a deep breath and hold it. Two neuronal pools are involved, both synapsing on the same motor neurons.

3. In **serial processing**, information is relayed in a stepwise fashion, from one neuron to another or from one neuronal pool to the next (see Figure 13–13•). This pattern occurs as sensory information is relayed from one part of the brain to another. For example, pain sensations en route to your consciousness make two stops along the way, at neuronal pools along the pain pathway.

4. Parallel processing occurs when several neurons or neuronal pools process the same information simultaneously (see Figure 13–13•). Divergence must take place before parallel processing can occur. Thanks to parallel processing, many responses can occur simultaneously. For example, stepping on a sharp object stimulates sensory neurons that distribute the information to several neuronal pools. As a result of parallel processing, you might withdraw your foot, shift your weight, move your arms, feel the pain, and shout "Ouch!" all at the same time.

5. In **reverberation**, collateral branches of axons somewhere along the circuit extend back toward the source of an impulse and further stimulate the presynaptic neurons (see Figure 13–13•). Reverberation is like a positive feedback loop involving neurons: Once a reverberating circuit has been activated, it will continue to function until synaptic fatigue or inhibitory stimuli break the cycle. Reverberation can occur within a single neuronal pool, or it may involve a series of interconnected pools. Highly complicated examples of reverberation among neuronal pools in the brain may help maintain consciousness, muscular coordination, and normal breathing.

The functions of the nervous system depend on the interactions among neurons organized in neuronal pools. The most complex neural processing steps occur in the spinal cord and brain. The simplest, which occur within the PNS and the spinal cord, control reflexes that are a bit like Legos: Individually, they are quite simple, but they can be combined in a great variety of ways to create very complex responses. Reflexes are thus the basic building blocks of neural function, as you will see in the next section.

An Introduction to Reflexes

Conditions inside or outside the body can change rapidly and unexpectedly. **Reflexes** are rapid, automatic responses to specific stimuli. Reflexes preserve homeostasis by making rapid adjustments in the function of organs or organ systems. The response shows little variability: Each time a particular reflex is activated, it usually produces the same motor response. Chapter 1 introduced the basic functional components involved in all types of homeostatic regulation: a *receptor*, an *integration center*, and an *effector*. l**p. 11** Here we consider *neural reflexes*, in which sensory fibers deliver information from peripheral receptors to an integration center in the CNS, and motor fibers carry motor commands to peripheral effectors. We will examine *endocrine reflexes*, in which the commands to peripheral tissues and organs are delivered by hormones in the bloodstream, in Chapter 18.

The Reflex Arc

The “wiring” of a single reflex is called a **reflex arc**. A reflex arc begins at a receptor and ends at a peripheral effector, such as a muscle fiber or a gland cell. Figure 13–14• diagrams the five steps in a simple neural reflex known as a *stretch reflex*:

Step 1 The Arrival of a Stimulus and Activation of a Receptor. A *receptor* is either a specialized cell or the dendrites of a sensory neuron. Receptors are sensitive to physical or chemical changes in the body and to changes in the external environment. The general categories of sensory receptors were introduced in Chapter 12. l**p. 384** If you lean on a tack, for example, pain receptors in the palm of your hand are activated. These receptors, the dendrites of sensory neurons, respond to stimuli that cause or accompany tissue damage. (We will discuss the link between receptor stimulation and sensory neuron activation further in Chapter 15.)

Step 2 The Activation of a Sensory Neuron. When the dendrites are stretched, there is a graded depolarization that leads to the formation and propagation of action potentials along the axons of the sensory neurons. This information reaches the spinal cord by way of a dorsal root. In our example, STEP 1 and STEP 2 involve the same cell. However, the two steps may involve different cells. For example, reflexes triggered by loud sounds begin when receptor cells in the inner ear release neurotransmitters that stimulate sensory neurons.

Step 3 Information Processing. In our example, information processing begins when excitatory neurotransmitter molecules, released by the synaptic knob of a sensory neuron, arrive at the postsynaptic membrane of an interneuron. The neurotransmitter produces an excitatory postsynaptic potential (EPSP), which is integrated with other stimuli arriving at the postsynaptic cell at

that moment. l**p. 412** The information processing is thus performed by the interneuron. In the simplest reflexes, such as the *stretch reflex*, considered in a later section, the sensory neuron innervates a motor neuron directly. In that case, it is the motor neuron that performs the information processing. By contrast, complex reflexes introduced later in the chapter involve several interneurons, some releasing excitatory neurotransmitters (*excitatory interneurons*) and others inhibitory neurotransmitters (*inhibitory interneurons*).

Step 4 The Activation of a Motor Neuron. The axons of the stimulated motor neurons carry action potentials into the periphery— in this example, through the ventral root of a spinal nerve.

Step 5 The Response of a Peripheral Effector. The release of neurotransmitters by the motor neurons at synaptic knobs then leads to a response by a peripheral effector—in this case, a skeletal muscle whose contraction pulls your hand away from the tack.

A reflex response generally removes or opposes the original stimulus; in this case, the contracting muscle pulls your hand away from a painful stimulus. This reflex arc is therefore an example of *negative feedback*. l**p. 12** By opposing potentially harmful changes in the internal or external environment, reflexes play an important role in homeostatic maintenance. The immediate reflex response is typically not the only response to a stimulus. The other responses, which are directed by your brain, involve multiple synapses and take longer to organize and coordinate.

Classification of Reflexes

Reflexes are classified on the basis of (1) their development, (2) the nature of the resulting motor response, (3) the complexity of the neural circuit involved, or (4) the site of information processing. These categories are not mutually exclusive—they represent different ways of describing a single reflex.

Development of Reflexes **Innate reflexes** result from the connections that form between neurons during development. Such reflexes generally appear in a predictable sequence, from the simplest reflex responses (withdrawal from pain) to more complex motor patterns (chewing, suckling, or tracking objects with the eyes). The neural connections responsible for the basic motor patterns of an innate reflex are genetically or developmentally programmed. Examples include the reflexive removal of your hand from a hot stove top and blinking when your eyelashes are touched.

More complex, learned motor patterns are called **acquired reflexes**. An experienced driver steps on the brake when trouble appears ahead; a professional skier must make equally quick adjustments in body position while racing. These motor responses are rapid and automatic, but they were learned rather than preestablished. Such reflexes are enhanced by repetition. The distinction between innate and acquired reflexes is not absolute: Some people can learn motor patterns more quickly than others, and the differences probably have a genetic basis.

Most reflexes, whether innate or acquired, can be modified over time or suppressed through conscious effort. For example, while walking a tightrope over the Grand Canyon, you might ignore a bee sting on your hand, although under other circumstances you would probably withdraw your hand immediately, shouting and thrashing as well.

Nature of the Response **Somatic reflexes** provide a mechanism for the involuntary control of the muscular system. *Superficial reflexes* are triggered by stimuli at the skin or mucous membranes. *Stretch reflexes* are triggered by the sudden elongation of a tendon; a familiar example is the *patellar*, or *“knee-jerk,” reflex* that is usually tested during physical exams. These reflexes are also known as *deep tendon reflexes*, or *myotactic reflexes*. **Visceral reflexes**, or *autonomic reflexes,* control the activities of other systems. We will consider somatic reflexes in detail in this chapter and visceral reflexes in Chapter 16.

The movements directed by somatic reflexes are neither delicate nor precise. You might therefore wonder why they exist at all, because we have voluntary control over the same muscles. In fact, somatic reflexes are absolutely vital, primarily because they are *immediate*. Making decisions and coordinating voluntary responses take time, and in an emergency—when you slip while descending a flight of stairs, or lean your hand against a knife edge—any delay increases the likelihood of severe injury. Thus, somatic reflexes provide a rapid response that can be modified later, if necessary, by voluntary motor commands.

Complexity of the Circuit In the simplest reflex arc, a sensory neuron synapses directly on a motor neuron, which serves as the processing center. Such a reflex is a **monosynaptic reflex**. Transmission across a chemical synapse always involves a synaptic delay, but with only one synapse, the delay between the stimulus and the response is minimized. Most other types of reflexes have at least one interneuron between the sensory neuron and the motor neuron. The reflex diagrammed in Figure 13–14• is an example of this type of reflex. Such **polysynaptic reflexes** have a longer delay between stimulus and response. The length of the delay is proportional to the number of synapses involved. Polysynaptic reflexes can produce far more complicated responses than monosynaptic reflexes, because the interneurons can control motor neurons that activate several muscle groups simultaneously.

Processing Sites In **spinal reflexes**, the important interconnections and processing events occur in the spinal cord. We will discuss these reflexes further in the next section. Reflexes processed in the brain, called **cranial reflexes**, will be considered in Chapters 14, 16, and 17.

Spinal Reflexes

Objectives

- Distinguish among the types of motor responses produced by various reflexes.
- Explain how reflexes interact to produce complex behaviors.

Spinal reflexes range in complexity from simple monosynaptic reflexes involving a single segment of the spinal cord to polysynaptic reflexes that involve many segments. In the most complicated spinal reflexes, called **intersegmental reflex arcs**, many segments interact to produce a coordinated, highly variable motor response.

Monosynaptic Reflexes

In monosynaptic reflexes, there is little delay between sensory input and motor output. These reflexes control the most-rapid, stereotyped motor responses of the nervous system to specific stimuli.

The Stretch Reflex

The best-known monosynaptic reflex is the **stretch reflex**, which provides automatic regulation of skeletal muscle length. The **patellar reflex** is an example.When a physician taps your patellar tendon with a reflex hammer, receptors in the quadriceps muscle are stretched (Figure 13–15•). The distortion of the receptors in turn stimulates sensory neurons that extend into the spinal cord and synapse on motor neurons that control the motor units in the stretched muscle. This leads to a reflexive contraction of the stretched muscle that extends the knee in a brief kick. To summarize: The stimulus (increasing muscle length) activates a sensory neuron, which triggers an immediate motor response (contraction of the stretched muscle) that counteracts the stimulus. Because the action potentials traveling toward and away from the spinal cord are conducted along large, myelinated Type A fibers, the entire reflex is completed within 20–40 msec.

The receptors in stretch reflexes are called *muscle spindles*. (The sensory mechanism will be described in the next section.) The stretching of muscle spindles produces a sudden burst of activity in the sensory neurons that monitor them. This in turn leads to stimulation of motor neurons that control the motor units in the stretched muscle. The result is a rapid increase in muscle tone, and this returns the muscle spindles to their resting length. The rate of action potential generation in the sensory neurons then declines, causing a drop in muscle tone to resting levels.

Muscle Spindles

The sensory receptors involved in the stretch reflex are **muscle spindles**. Each consists of a bundle of small, specialized skeletal muscle fibers called **intrafusal muscle fibers** (Figure 13–16•). The muscle spindle is surrounded by larger **extrafusal muscle fibers**, which are responsible for the resting muscle tone and, at greater levels of stimulation, for the contraction of the entire muscle.

Each intrafusal fiber is innervated by both sensory and motor neurons. The dendrites of the sensory neuron spiral around the intrafusal fiber in a central sensory region. Axons from spinal motor neurons form neuromuscular junctions on either end of this fiber. Motor neurons innervating intrafusal fibers are called **gamma motor neurons**; their axons are called **gamma efferents**. An intrafusal fiber has one set of myofibrils at each end. Instead of extending the length of the muscle fiber, as in extrafusal fibers, these myofibrils run from the end of the intrafusal fiber only to the sarcolemma in the central region that is closely monitored by the sensory neuron. The gamma efferents enable the CNS to adjust the sensitivity of the muscle spindle. Before seeing how this is accomplished, we will consider the normal functioning of this sensory receptor and its effects on the surrounding extrafusal fibers.

The sensory neuron is always active, conducting impulses to the CNS. The axon enters the CNS in a dorsal root and synapses on motor neurons in the anterior gray horn of the spinal cord. Collaterals distribute the information to the brain, providing information about the state of the muscle spindle. Stretching the central portion of the intrafusal fiber distorts the dendrites and stimulates the sensory neuron, increasing the frequency of action potential generation. Compressing the central portion inhibits the sensory neuron, decreasing the frequency of action potential generation.

The axon of the sensory neuron synapses on CNS motor neurons that control the extrafusal muscle fibers of the same muscle. An increase in stimulation of the sensory neuron, caused by stretching of the intrafusal fiber, will increase stimulation to the motor neuron controlling the surrounding extrafusal fibers, so muscle tone increases. This increase provides automatic resistance that reduces the chance of muscle damage due to overstretching. The patellar reflex and similar reflexes serve this function. A decrease in the stimulation of the sensory neuron, due to compression of the intrafusal fiber, will lead to a decrease in the stimulation of the motor neuron controlling the surrounding extrafusal fibers, so muscle tone decreases. This decrease reduces resistance to the movement under way. For example, if your elbow is flexed and you let gravity extend it, the triceps brachii muscle, which is compressed by this movement, relaxes.

Many stretch reflexes are **postural reflexes**—reflexes that help us maintain a normal upright posture. Standing, for example, involves a cooperative effort on the part of many muscle groups. Some of these muscles work in opposition to one another, exerting forces that keep the body’s weight balanced over the feet. If the body leans forward, stretch receptors in the calf muscles are stimulated. Those muscles then respond by contracting, thereby returning the body to an upright position. If the muscles overcompensate and the body begins to lean back, the calf muscles relax. But then stretch receptors in muscles of the shins and thighs are stimulated, and the problem is corrected immediately.

Postural muscles generally have a firm muscle tone and extremely sensitive stretch receptors. As a result, very fine adjustments are continually being made, and you are not aware of the cycles of contraction and relaxation that occur. Stretch reflexes are only one type of postural reflex; there are many complex polysynaptic postural reflexes.

Now that you understand the basic stretch reflex, we can return to the role of the gamma efferents, which let the CNS adjust the sensitivity of muscle spindles. Gamma efferents play a vital role whenever voluntary contractions change the length of a muscle. Impulses arriving over gamma efferents cause the contraction of myofibrils in the intrafusal fibers as the biceps brachii muscle shortens. The myofibrils pull on the sarcolemma in the central portion of the intrafusal fiber—the region monitored by the sensory neuron—until that membrane is stretched to its normal resting length. As a result, the muscle spindles remain sensitive to any externally imposed changes in muscle length. Thus, if someone drops a ball into your palm when your elbow is partially flexed, the muscle spindles will automatically adjust the muscle tone to compensate for the increased load.

Concept Check

What is the minimum number of neurons in a reflex arc?

One of the first somatic reflexes to develop is the suckling reflex. Which type of reflex is this?

How would the stimulation of the muscle spindles involved in the patellar (knee-jerk) reflex by gamma motor neurons affect the speed of the reflex?

Answers begin on p. A–1

Polysynaptic Reflexes

Polysynaptic reflexes can produce far more complicated responses than can monosynaptic reflexes. One reason is that the interneurons involved can control several muscle groups. Moreover, these interneurons may produce either excitatory or inhibitory postsynaptic potentials (EPSPs or IPSPs) at CNS motor nuclei, so the response can involve the stimulation of some muscles and the inhibition of others.

The Tendon Reflex

The stretch reflex regulates the length of a skeletal muscle. The **tendon reflex** monitors the external tension produced during a muscular contraction and prevents tearing or breaking of the tendons. The sensory receptors for this reflex have not been identified, but they are distinct from both muscle spindles and proprioceptors in tendons. The receptors are stimulated when the collagen fibers are stretched to a dangerous degree. These receptors activate sensory neurons that stimulate inhibitory interneurons in the spinal cord. These interneurons in turn innervate the motor neurons controlling the skeletal muscle. The greater the tension in the tendon, the greater is the inhibitory effect on the motor neurons. As a result, a skeletal muscle generally cannot develop enough tension to break its tendons.

Withdrawal Reflexes

Withdrawal reflexes move affected parts of the body away from a stimulus. The strongest withdrawal reflexes are triggered by painful stimuli, but these reflexes are sometimes initiated by the stimulation of touch receptors or pressure receptors.

The **flexor reflex**, a representative withdrawal reflex, affects the muscles of a limb (Figure 13–17•). Recall from Chapter 9 and Chapter 11 that flexion is a reduction in the angle between two articulating bones, and that the contractions of flexor muscles perform this movement. l**pp. 264, 330** If you grab an unexpectedly hot pan on the stove, a dramatic flexor reflex will occur. When the pain receptors in your hand are stimulated, the sensory neurons activate interneurons in the spinal cord that stimulate motor neurons in the anterior gray horns. The result is a contraction of flexor muscles that yanks your hand away from the stove.

When a specific muscle contracts, opposing muscles must relax to permit the movement. For example, flexor muscles that bend the elbow (such as the biceps brachii muscle) are opposed by extensor muscles (such as the triceps brachii muscle) that straighten it out. A potential conflict exists: In theory, the contraction of a flexor muscle should trigger a stretch reflex in the extensors that would cause them to contract, opposing the movement. Interneurons in the spinal cord prevent such competition through **reciprocal inhibition**. When one set of motor neurons is stimulated, those neurons that control antagonistic muscles are inhibited. The term *reciprocal* refers to the fact that the system works both ways: When the flexors contract, the extensors relax; when the extensors contract, the flexors relax.

Withdrawal reflexes are much more complex than any monosynaptic reflex. They also show tremendous versatility, because the sensory neurons activate many pools of interneurons. If the stimuli are strong, interneurons will carry excitatory and inhibitory impulses up and down the spinal cord, affecting motor neurons in many segments. The end result is always the same: a coordinated movement away from the stimulus. But the distribution of the effects and the strength and character of the motor responses depend on the intensity and location of the stimulus. Mild discomfort might provoke a brief contraction in muscles of your hand and wrist. More powerful stimuli would produce coordinated muscular contractions affecting the positions of your hand, wrist, forearm, and arm. Severe pain would also stimulate contractions of your shoulder, trunk, and arm muscles. These contractions could persist for several seconds, owing to the activation of reverberating circuits. In contrast, monosynaptic reflexes are relatively invariable and brief; the patellar reflex is completed in roughly 20 msec.

Crossed Extensor Reflexes

The stretch, tendon, and withdrawal reflexes involve *ipsilateral reflex arcs* (*ipsi*, same + *lateral*, side): The sensory stimulus and the motor response occur on the same side of the body. The **crossed extensor reflex** (Figure 13–18•) involves a *contralateral reflex arc* (*contra*, opposite), because the motor response occurs on the side opposite the stimulus.

The crossed extensor reflex complements the flexor reflex, and the two occur simultaneously. When you step on a tack, while the flexor reflex pulls the affected foot away from the ground, the crossed extensor reflex straightens the other leg to support your body weight. In the crossed extensor reflex, the axons of interneurons responding to the pain cross to the other side of the spinal cord and stimulate motor neurons that control the extensor muscles of the uninjured leg. As a result, your opposite leg straightens to support the shifting weight. Reverberating circuits use positive feedback to ensure that the movement lasts long enough to be effective—all without motor commands from higher centers of the brain.

General Characteristics of Polysynaptic Reflexes

Polysynaptic reflexes range in complexity from a simple tendon reflex to the complex and variable reflexes associated with standing, walking, and running. Yet all polysynaptic reflexes share the following basic characteristics:

1. *They Involve Pools of Interneurons.* Processing occurs in pools of interneurons before motor neurons are activated. The result may be excitation or inhibition; the tendon reflex produces inhibition of motor neurons, whereas the flexor and crossed extensor reflexes direct specific muscle contractions.

2. *They Are Intersegmental in Distribution.* The interneuron pools extend across spinal segments and may activate muscle groups in many parts of the body.

3. *They Involve Reciprocal Inhibition.* Reciprocal inhibition coordinates muscular contractions and reduces resistance to movement. In the flexor and crossed extensor reflexes, the contraction of one muscle group is associated with the inhibition of opposing muscles.

4. *They Have Reverberating Circuits, Which Prolong the Reflexive Motor Response.* Positive feedback between interneurons that innervate motor neurons and the processing pool maintains the stimulation even after the initial stimulus has faded.

5. *Several Reflexes May Cooperate to Produce a Coordinated, Controlled Response.* As a reflex movement gets under way, antagonistic reflexes are inhibited. For example, during the stretch reflex, antagonistic muscles are inhibited; in the tendon reflex, antagonistic muscles are stimulated. In complex polysynaptic reflexes, commands may be distributed along the length of the spinal cord, producing a well-coordinated response.

Integration and Control of Spinal Reflexes

Objective

- Explain how higher centers control and modify reflex responses.

Reflex motor behaviors occur automatically, without instructions from higher centers. However, higher centers can have a profound effect on the performance of a reflex. Processing centers in the brain can facilitate or inhibit reflex motor patterns based in the spinal cord. Descending tracts originating in the brain synapse on interneurons and motor neurons throughout the spinal cord. These synapses are continuously active, producing EPSPs or IPSPs at the postsynaptic membrane.

Voluntary Movements and Reflex Motor Patterns

Spinal reflexes produce consistent, stereotyped motor patterns that are triggered by specific external stimuli. However, the same motor patterns can also be activated as needed by centers in the brain. By making use of these preexisting patterns, relatively few descending fibers can control complex motor functions. For example, the motor patterns for walking, running, and jumping are directed primarily by neuronal pools in the spinal cord. The descending pathways from the brain provide appropriate facilitation, inhibition, or “fine-tuning” of the established patterns. This is a very efficient system that is similar to a “macro” in word processing: A single command triggers a complex, predetermined sequence of events.

Motor control therefore involves a series of interacting levels. At the lowest level are monosynaptic reflexes that are rapid, but stereotyped and relatively inflexible. At the highest level are centers in the brain that can modulate or build on reflexive motor patterns.

100 Keys | Reflexes are rapid, automatic responses to stimuli that “buy time” for the planning and execution of more complex responses that are often consciously directed. The fastest reflexes are somatic motor reflexes that (1) involve myelinated axons, (2) involve only one segment of the spinal cord or one nucleus of the brain, and (3) are monosynaptic.

Reinforcement and Inhibition

A single EPSP may not depolarize the postsynaptic neuron sufficiently to generate an action potential, but it does make that neuron more sensitive to other excitatory stimuli. This process of *facilitation* was introduced in Chapter 12. Alternatively, an IPSP will make the neuron less responsive to excitatory stimulation, through the process of *inhibition*. l**p. 405** By stimulating excitatory or inhibitory interneurons within the brain stem or spinal cord, higher centers can adjust the sensitivity of reflexes by creating EPSPs or IPSPs at the motor neurons involved in reflex responses.

When many of the excitatory synapses are chronically active, the postsynaptic neuron can enter a state of generalized facilitation. This facilitation of reflexes can result in **reinforcement**, an enhancement of spinal reflexes. For example, a voluntary effort to pull apart clasped hands elevates the general state of facilitation along the spinal cord, reinforcing all spinal reflexes. If a stimulus fails to elicit a particular reflex response during a clinical exam, there can be many reasons for the failure: The person may be consciously suppressing the response, the nerves involved may be damaged, or there may be underlying problems inside the CNS. The clinician may then ask the patient to perform an action designed to provide reinforcement. Reinforced reflexes are usually too strong to suppress consciously; if the reflex still fails to appear, the likelihood of nerve or CNS damage is increased, and more sophisticated tests, such as nerve conduction studies or scans, may be ordered.

Other descending fibers have an inhibitory effect on spinal reflexes. In adults, stroking the sole of the foot produces a curling of the toes, called a **plantar reflex**, or *negative Babinski reflex*, after about a 1-second delay (Figure 13–19a•). Stroking an infant's foot on the side of the sole produces a fanning of the toes known as the **Babinski sign**, or *positive Babinski reflex*. This response disappears as descending motor pathways develop. If either the higher centers or the descending tracts are damaged, the Babinski sign will reappear in an adult (Figure 13–19b•). As a result, this reflex is often tested if CNS injury is suspected. Additional procedures for diagnosing CNS injuries are described in the *Applications Manual*. AM: Reflexes and Diagnostic Testing

Concept Check

A weight lifter is straining to lift a 200-kg barbell. Shortly after he lifts it to chest height, his muscles appear to relax and he drops the barbell. Which reflex has occurred?

During a withdrawal reflex, what happens to the limb on the side opposite the stimulus? What is this response called?

After injuring her back, Tina exhibits a positive Babinski reflex. What does this imply about Tina’s injury?

Answers begin on p. A–1

Chapter Review

Selected Clinical Terminology

Babinski sign *(positive Babinski reflex)***:** A spinal reflex in infants, consisting of a fanning of the toes and produced by stroking the sole of the foot; in adults, a Babinski sign indicates CNS injury. (p. 446) **epidural block:** The injection of anesthetic into the epidural space to eliminate sensory and motor innervation via spinal nerves in the

area of injection. (p. 426 and [AM]) **lumbar puncture:** A spinal tap performed between adjacent lumbar vertebrae inferior to the conus medullaris. [AM] **meningitis:** An inflammation of the meninges involving either the spinal cord (*spinal meningitis*) or the brain (*cerebral meningitis*); gen

erally caused by bacterial or viral pathogens. (p. 425 and [AM]) **myelography:** A diagnostic procedure in which a radiopaque dye is introduced into the cerebrospinal fluid to obtain an x-ray image of the spinal cord and cauda equina. [AM] **nerve growth factor:** A peptide factor that promotes the growth and maintenance of neurons. Other factors that are important to neuron growth and repair include BDNF, NT-3, NT-4, and GAP-43. [AM] **nerve palsies (peripheral neuropathies):** Regional losses of sensory and motor function as a result of nerve trauma or compression.

Common palsies include *radial nerve palsy, ulnar palsy, sciatica*, and *fibular palsy*. (p. 431 and [AM]) **paraplegia:** Paralysis involving a loss of motor control of the lower, but not the upper, limbs. [AM] **patellar reflex (knee-jerk reflex):** A stretch reflex resulting from the stimulation of stretch receptors in the quadriceps muscles. (p. 440) **plantar reflex** *(negative Babinski reflex)***:** A spinal reflex in adults, consisting of a curling of the toes and produced by stroking the sole of the foot. (p. 446) **quadriplegia:** Paralysis involving the loss of sensation and motor control of the upper and lower limbs. [AM] **shingles:** A condition caused by the infection of neurons in dorsal root ganglia by the varicella-zoster virus. The primary symptom is a painful rash along the sensory distribution of the affected spinal nerves. (p. 431 and [AM]) **spinal tap:** A procedure in which cerebrospinal fluid is removed from the subarachnoid space through a needle, generally inserted between the lumbar vertebrae. (p. 426 and [AM])

Study Outline

General Organization of the Nervous System p. 422

1. The CNS consists of the brain and spinal cord; the remainder of the nervous tissue forms the PNS. *(Figure 13–1)*

Gross Anatomy of the Spinal Cord p. 423

1. The adult spinal cord includes localized **enlargements**, which provide innervation to the limbs. The spinal cord has 31 segments, each associated with a pair of **dorsal roots** and a pair of **ventral roots**. *(Figure 13–2)*

2. The **filum terminale** (a strand of fibrous tissue), which originates at the **conus medullaris**, ultimately becomes part of the **coccygeal ligament**. *(Figure 13–2)*

3. **Spinal nerves** are **mixed nerves**: They contain both afferent (sensory) and efferent (motor) fibers.

Spinal Meninges p. 425

4. The **spinal meninges** provide physical stability and shock absorption for neural tissues of the spinal cord; the **cranial meninges** surround the brain. *(Figure 13–3)*

5. The **dura mater** covers the spinal cord; inferiorly, it tapers into the **coccygeal ligament**. The **epidural space** separates the dura mater from the walls of the vertebral canal. *(Figures 13–3, 13–4)*

6. Interior to the inner surface of the dura mater are the **subdural space**, the **arachnoid mater** (the second meningeal layer), and the **subarachnoid space**. The subarachnoid space contains **cerebrospinal fluid (CSF)**, which acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemical messengers, and waste products. *(Figures 13–3, 13–4)*

7. The **pia mater**, a meshwork of elastic and collagen fibers, is the innermost meningeal layer. **Denticulate ligaments** extend from the pia mater to the dura mater. *(Figures 13–3, 13–4)*

Sectional Anatomy of the Spinal Cord p. 427

8. The white matter of the spinal cord contains myelinated and unmyelinated axons, whereas the gray matter contains cell bodies of neurons and neuroglia and unmyelinated axons. The projections of gray matter toward the outer surface of the cord are called **horns**. *(Figure 13–5)*

9. The **posterior gray horns** contain somatic and visceral sensory nuclei; nuclei in the **anterior gray horns** function in somatic motor control. The **lateral gray horns** contain visceral motor neurons. The **gray commissures** contain axons that cross from one side of the spinal cord to the other. *(Figure 13–5)*

Anatomy 360 | Nervous System/Central Nervous System/ Spinal Cord

10. The white matter can be divided into six **columns** *(funiculi)*, each of which contains **tracts** *(fasciculi)*. **Ascending tracts** relay information from the spinal cord to the brain, and **descending tracts** carry information from the brain to the spinal cord. *(Figure 13–5)*

100 Keys | p. 429

Anatomy 360 | Nervous System/Central Nervous System/ Spinal Cord

Spinal Nerves p. 429

1. There are 31 pairs of spinal nerves. Each has an **epineurium** (outermost layer), a **perineurium**, and an **endoneurium** (innermost layer). *(Figure 13–6)*

Peripheral Distribution of Spinal Nerves p. 430

2. A typical spinal nerve has a **white ramus** (containing myelinated axons), a **gray ramus** (containing unmyelinated fibers that innervate glands and smooth muscles in the body wall or limbs), a **dorsal ramus** (providing sensory and motor innervation to the skin and muscles of the back), and a **ventral ramus** (supplying the ventrolateral body surface, structures in the body wall, and the limbs). Each pair of nerves monitors a region of the body surface called a **dermatome**. *(Figures 13–7, 13–8)*

100 Keys | p. 431

Nerve Plexuses p. 431

3. A complex, interwoven network of nerves is a **nerve plexus**. The four large plexuses are the **cervical plexus**, the **brachial plexus**, the **lumbar plexus**, and the **sacral plexus**. *(Figures 13–9 to 13–12; Tables 13–1 to 13–3)*

Anatomy 360 | Nervous System/Peripheral Nervous System/Spinal Nerves

Principles of Functional Organization p. 437

1. The body has sensory neurons, which deliver information to the CNS; motor neurons, which distribute commands to peripheral effectors; and interneurons, which interpret information and coordinate responses.

Neuronal Pools p. 438

2. A functional group of interconnected neurons is a **neuronal pool**.

3. The neural circuit patterns are **divergence**, **convergence**, **serial processing, parallel processing**, and **reverberation**. *(Figure 13–13)*

An Introduction to Reflexes p. 439

4. **Reflexes** are rapid, automatic responses to stimuli. A *neural reflex* involves sensory fibers delivering information to the CNS, and motor fibers carrying commands to the effectors via the PNS.

5. A **reflex arc** is the neural “wiring” of a single reflex. *(Figure 13–14)*

6. The five steps involved in a neural reflex are (1) the arrival of a stimulus and activation of a receptor, (2) the activation of a sensory neuron, (3) information processing in the CNS, (4) the activation of a motor neuron, and (5) a response by an effector. *(Figure 13–14)*

7. Reflexes are classified according to (1) their development, (2) the nature of the resulting motor response, (3) the complexity of the neural circuit involved, and (4) the site of information processing.

8. **Innate reflexes** result from the connections that form between neurons during development. **Acquired reflexes** are learned and typically are more complex.

9. **Somatic reflexes** control skeletal muscles; **visceral reflexes** (*autonomic reflexes*) control the activities of other systems.

10. In a **monosynaptic reflex—**the simplest reflex arc**—**a sensory neuron synapses directly on a motor neuron, which acts as the processing center. In a **polysynaptic reflex**, which has at least one interneuron between the sensory afferent and the motor efferent, there is a longer delay between stimulus and response.

11. Reflexes processed in the brain are **cranial reflexes**. In a **spinal reflex**, the important interconnections and processing events occur

in the spinal cord.

Spinal Reflexes p. 441

1. Spinal reflexes range from simple monosynaptic reflexes to more complex polysynaptic and **intersegmental reflexes**, in which many segments interact to produce a coordinated motor response.

Monosynaptic Reflexes p. 441

2. The **stretch reflex** (such as the **patellar**, or **knee-jerk**, **reflex**) is a monosynaptic reflex that automatically regulates skeletal muscle length and muscle tone. The sensory receptors involved are **muscle spindles**. *(Figures 13–15, 13–16)*

3. A **postural reflex** maintains one’s normal upright posture.

Polysynaptic Reflexes p. 443

4. Polysynaptic reflexes can produce more complicated responses than can monosynaptic reflexes. Examples include the **tendon reflex** (which monitors the tension produced during muscular contractions and prevents damage to tendons) and **withdrawal reflexes** (which move affected portions of the body away from a source of stimulation). The **flexor reflex** is a withdrawal reflex affecting the muscles of a limb. The **crossed extensor reflex** complements withdrawal reflexes. *(Figures 13–17, 13–18)*

5. All polysynaptic reflexes (1) involve pools of interneurons, (2) are intersegmental in distribution, (3) involve reciprocal inhibition, and (4) have reverberating circuits, which prolong the reflexive motor response. Several reflexes may cooperate to produce a coordinated response.

Integration and Control of Spinal Reflexes p. 445

1. The brain can facilitate or inhibit reflex motor patterns based in the spinal cord.

Voluntary Movements and Reflex Motor Patterns p. 445

2. Motor control involves a series of interacting levels. Monosynaptic reflexes form the lowest level; at the highest level are the centers in the brain that can modulate or build on reflexive motor patterns.

100 Keys | p. 445

Reinforcement and Inhibition p. 445

3. Facilitation can produce an enhancement of spinal reflexes known as **reinforcement**. Spinal reflexes may also be inhibited, as when the **plantar reflex** in adults replaces the **Babinski sign** in infants. *(Figure 13–19)*

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you’ll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The ventral roots of each spinal segment

(a) bring sensory information into the spinal cord

(b) control peripheral effectors

(c) contain the axons of somatic motor and visceral motor neurons

(d) both b and c are correct

2. Spinal nerves are called mixed nerves because they

(a) contain sensory and motor fibers

(b) exit at intervertebral foramina

(c) are associated with a pair of dorsal root ganglia

(d) are associated with dorsal and ventral roots

3. The adult spinal cord extends only to which vertebral level?

(a) coccyx

(b) sacral

(c) third or fourth lumbar

(d) first or second lumbar

(e) last thoracic

4. Which the following statements is false concerning the gray matter of the spinal cord?

(a) the gray matter is located in the interior of the spinal cord around the central canal

(b) the gray matter functions in processing neural information

(c) the gray matter is primarily involved in relaying information to the brain

(d) the gray matter contains motor neurons

(e) the gray matter is divided into regions called horns

5. The following are the steps involved in a reflex arc.

1. activation of a sensory neuron

2. activation of a motor neuron

3. response by an effector

4. arrival of a stimulus and activation of a receptor

5. information processing The proper sequence of these steps is

(a) 1, 3, 4, 5, 2 **(b)** 4, 5, 3, 1, 2

(c) 4, 1, 5, 2, 3 **(d)** 4, 3, 1, 5, 2

(e) 3, 1, 4, 5, 2

6. A sensory region monitored by the dorsal rami of a single spinal segment is

(a) a ganglion **(b)** a fascicle

(c) a dermatome **(d)** a ramus

7. The major nerve of the cervical plexus that innervates the diaphragm is the

(a) median nerve **(b)** axillary nerve

(c) phrenic nerve **(d)** fibular nerve

8. The genitofemoral, femoral, and lateral femoral cutaneous nerves are major nerves of the

(a) lumbar plexus **(b)** sacral plexus

(c) brachial plexus **(d)** cervical plexus

9. The synapsing of several neurons on the same postsynaptic neuron is called

(a) serial processing **(b)** reverberation

(c) divergence **(d)** convergence

10. The reflexes that control the most rapid, stereotyped motor responses of the nervous system to stimuli are

(a) monosynaptic reflexes

(b) polysynaptic reflexes

(c) tendon reflexes

(d) extensor reflexes

11. An example of a stretch reflex triggered by passive muscle movement is the

(a) tendon reflex **(b)** patellar reflex

(c) flexor reflex **(d)** ipsilateral reflex

12. The contraction of flexor muscles and the relaxation of extensor muscles illustrates the principle of

(a) reverberating circuitry

(b) generalized facilitation

(c) reciprocal inhibition

(d) reinforcement

13. Reflex arcs in which the sensory stimulus and the motor response occur on the same side of the body are

(a) contralateral **(b)** paraesthetic

(c) ipsilateral **(d)** monosynaptic

14. Proceeding inward from the outermost layer, number the following in the correct sequence:

(a) _____ walls of vertebral canal

(b) _____ pia mater

(c) _____ dura mater

(d) _____ arachnoid membrane

(e) _____ subdural space

(f) _____ subarachnoid space

(g) _____ epidural space

(h) _____ spinal cord

LEVEL 2 Reviewing Concepts

15. Explain the anatomical significance of the fact that spinal cord growth ceases at age 4.

16. List, in sequence, the five steps involved in a neural reflex.

17. Polysynaptic reflexes can produce far more complicated responses than can monosynaptic reflexes because

(a) the response time is quicker

(b) the response is initiated by highly sensitive receptors

(c) motor neurons carry impulses at a faster rate than do sensory neurons

(d) the interneurons involved can control several muscle groups

18. Why do cervical nerves outnumber cervical vertebrae?

19. If the anterior gray horns of the spinal cord were damaged, what type of control would be affected?

20. List all areas of the CNS where cerebrospinal fluid (CSF) is located. What are the functions of CSF?

21. What five characteristics are common to all polysynaptic reflexes?

22. Predict the effects on the body of a spinal cord transection at C7. How would these effects differ from those of a spinal cord transection at T10?

23. The subarachnoid space contains

(a) cerebrospinal fluid

(b) lymph

(c) air

(d) connective tissue and blood vessels

(e) denticulate ligaments

24. Side-to-side movements of the spinal cord are prevented by the

(a) filum terminale **(b)** denticulate ligaments

(c) dura mater **(d)** pia mater

(e) arachnoid mater

25. Ascending tracts

(a) carry sensory information to the brain

(b) carry motor information to the brain

(c) carry sensory information from the brain

(d) carry motor information from the brain

(e) connect perceptive areas with the brain

26. How does the stimulation of a sensory neuron that innervates an extrafusal muscle fiber affect muscle tone?

LEVEL 3 Critical Thinking and Clinical Applications

27. Mary complains that when she wakes up in the morning, her thumb and forefinger are always “asleep.” She mentions this condition to her physician, who asks Mary whether she sleeps with her wrists flexed. She replies that she does. The physician tells Mary that sleeping in that position may compress a portion of one of her peripheral nerves, producing her symptoms. Which nerve is involved?

28. The improper use of crutches can produce a condition known as “crutch paralysis,” characterized by a lack of response by the extensor muscles of the arm, and a condition known as “wrist drop,” consisting of an inability to extend the fingers and wrist. Which nerve is involved?

29. Bowel and bladder control involve spinal reflex arcs that are located in the sacral region of the spinal cord. In both instances two sphincter muscles, an inner sphincter of smooth muscle and an outer sphincter of skeletal muscle, control the passageway out of the body. How would a transection of the spinal cord at the L_1 level affect an individual’s bowel and bladder control?

30. Karen falls down a flight of stairs and suffers spinal cord damage due to hyperextension of the cord during the fall. The injury results in edema of the central cord with resulting compression of the anterior horn cells of the lumbar region. What symptoms would you expect to observe as a result of this injury?

TABLE 13–1 The Cervical Plexus

Nerve(s) Spinal Segments Distribution

Ansa cervicalis (superior C1 – C4 Five of the extrinsic laryngeal muscles: sternothyroid, sternohyoid, omohyoid,
and inferior branches) geniohyoid, and thyrohyoid muscles (via XII)

Lesser occipital, transverse C2 – C3 Skin of upper chest, shoulder, neck, and ear
cervical, supraclavicular,
and great auricular nerves

Phrenic nerve C3 – C5 Diaphragm

Cervical nerves C1 – C5 Levator scapulae, scalene, sternocleidomastoid, and trapezius muscles (with XI)

TABLE 13–2 The Brachial Plexus

Nerve(s) Spinal Segments Distribution

An Introduction to the Organization of the Brain

Objectives

- Name the major regions of the brain and describe their functions.
- Name the three primary brain vesicles and indicate which adult structures each gives rise to.
- Name the ventricles of the brain and describe their locations and the connections between them.

The adult human brain contains almost 98 percent of the body’s neural tissue. A “typical” brain weighs 1.4 kg (3 lb) and has a volume of 1200 cc (71 in.^{3}). Brain size varies considerably among individuals. The brains of males are, on average, about 10 percent larger than those of females, owing to differences in average body size. No correlation exists between brain size and intelligence. Individuals with the smallest brains (750 cc) and the largest brains (2100 cc) are functionally normal.

A Preview of Major Regions and Landmarks

The adult brain is dominated in size by the cerebrum (Figure 14–1•). Viewed from the anterior and superior surfaces, the **cerebrum** (SER-e-brum, or se-RE¯-brum) of the adult brain can be divided into large, paired **cerebral hemispheres**. The surfaces of the cerebral hemispheres are highly folded and covered by **neural cortex** (*cortex*, rind or bark), a superficial layer of gray matter. This *cerebral cortex* forms a series of elevated ridges, or **gyri** (JI¯-r ¯ı ; singular, *gyrus*) that serve to increase its surface area. The gyri are separated by shallow depressions called **sulci** (SUL-s) or by deeper grooves called **fissures**. The cerebrum is the seat of most

–

ı higher mental functions. Conscious thoughts, sensations, intellect, memory, and complex movements all originate in the cerebrum.

The **cerebellum** (ser-e-BEL-um) is partially hidden by the cerebral hemispheres, but it is the second-largest part of the brain. Like the cerebrum, the cerebellum has hemispheres that are covered by a layer of gray matter, the *cerebellar cortex*. The cerebellum adjusts ongoing movements by comparing arriving sensations with previously experienced sensations, allowing you to perform the same movements over and over.

The other major anatomical regions of the brain can best be examined after the cerebral and cerebellar hemispheres have been removed (see Figure 14–1•). The walls of the **diencephalon** (d -en-SEF-a-lon; *dia*, through + *cephalon*, head) are composed of

–

ı the **left thalamus** and **right thalamus** (THAL-a-mus; plural, *thalami*). Each thalamus contains relay and processing centers for sensory information. The **hypothalamus** (*hypo*-, below), or floor of the diencephalon, contains centers involved with emotions, autonomic function, and hormone production. The *infundibulum*, a narrow stalk, connects the hypothalamus to the **pituitary gland**, a component of the endocrine system. The hypothalamus and the pituitary gland are responsible for the integration of the nervous and endocrine systems.

The diencephalon is a structural and functional link between the cerebral hemispheres and the components of the brain stem.

The **brain stem** contains a variety of important processing centers and nuclei that relay information headed to or from the cerebrum or cerebellum. The brain stem includes the *mesencephalon*, *pons*, and *medulla oblongata*.[1]

- The **mesencephalon** (*mesos*, middle), or midbrain, contains nuclei that process visual and auditory information and control reflexes triggered by these stimuli. For example, your immediate, reflexive responses to a loud, unexpected noise (eye movements and head turning) are directed by nuclei in the midbrain. This region also contains centers that help maintain consciousness.

- The **pons** of the brain connects the cerebellum to the brain stem (*pons* is Latin for “bridge”). In addition to tracts and relay centers, the pons also contains nuclei involved with somatic and visceral motor control.
- The spinal cord connects to the brain at the **medulla oblongata**. Near the pons, the posterior wall of the medulla oblongata is thin and membranous. The inferior portion of the medulla oblongata resembles the spinal cord in that it has a narrow central canal. The medulla oblongata relays sensory information to the thalamus and to centers in other portions of the brain stem. The medulla oblongata also contains major centers that regulate autonomic function, such as heart rate, blood pressure, and digestion.

The boundaries and general functions of the diencephalon and brain stem are indicated in Figure 14–1•. In considering the individual components of the brain, we will begin at the inferior portion of the medulla oblongata. This region has the simplest organization found anywhere in the brain, and in many respects it resembles the spinal cord. We will then ascend to regions of increasing structural and functional complexity until we reach the cerebral cortex, whose functions and capabilities are as yet poorly understood.

Embryology of the Brain

To understand the internal organization of the adult brain, we must consider its embryological origins. The central nervous system (CNS) begins as a hollow cylinder known as the *neural tube*. This tube has a fluid-filled internal cavity, the *neurocoel*. In the cephalic portion of the neural tube, three areas enlarge rapidly through expansion of the neurocoel. This enlargement creates three prominent divisions called **primary brain vesicles**. The primary brain vesicles are named for their relative positions: the *prosencephalon* (pro¯z-en-SEF-a-lon; *proso*, forward + *enkephalos*, brain), or “forebrain”; the *mesencephalon*, or “midbrain”; and the *rhombencephalon* (rom-ben-SEF-a-lon), or “hindbrain.”

The fates of the three primary divisions of the brain are summarized in Table 14–1. The prosencephalon and rhombencephalon are subdivided further, forming **secondary brain vesicles**. The prosencephalon forms the **telencephalon** (tel-en-SEF-a-lon; *telos*, end) and the diencephalon. The telencephalon will ultimately form the cerebrum of the adult brain. The walls of the mesencephalon thicken, and the neurocoel becomes a relatively narrow passageway, comparable to the central canal of the spinal cord. The portion of the rhombencephalon adjacent to the mesencephalon forms the **metencephalon** (met-en-SEF-a-lon; *meta*, after). The dorsal portion of the metencephalon will become the cerebellum, and the ventral portion will develop into the pons. The portion of the rhombencephalon closer to the spinal cord forms the **myelencephalon** (m -el-en-SEF-a-lon; *myelon*, spinal cord),

–

ı which will become the medulla oblongata. ATLAS: Embryology Summary 12: The Development of the Brain and Cranial Nerves

Ventricles of the Brain

During development, the neurocoel within the cerebral hemispheres, diencephalon, metencephalon, and medulla oblongata expands to form chambers called **ventricles** (VEN-tri-kls). The ventricles are lined by cells of the *ependyma*. l**p. 386**

Each cerebral hemisphere contains a large **lateral ventricle** (Figure 14–2•). The **septum pellucidum**, a thin medial partition, separates the two lateral ventricles. Because there are *two* lateral ventricles, the ventricle in the diencephalon is called the **third ventricle**. Although the two lateral ventricles are not directly connected, each communicates with the third ventricle of the diencephalon through an **interventricular foramen** (*foramen of Monro*).

The mesencephalon has a slender canal known as the **mesencephalic aqueduct** (or *the aqueduct of the midbrain*, *aqueduct of Sylvius*, or *cerebral aqueduct*). This passageway connects the third ventricle with the **fourth ventricle**. The superior portion of the fourth ventricle lies between the posterior surface of the pons and the anterior surface of the cerebellum. The fourth ventricle extends into the superior portion of the medulla oblongata. This ventricle then narrows and becomes continuous with the central canal of the spinal cord.

The ventricles are filled with cerebrospinal fluid (CSF). The CSF continuously circulates from the ventricles and central canal into the *subarachnoid space* of the surrounding cranial meninges. The CSF passes between the interior and exterior of the CNS through three foramina in the roof of the fourth ventricle; these foramina will be described in a later section.

100 Keys | The brain is a large, delicate mass of neural tissue containing internal passageways and chambers filled with cerebrospinal fluid. Each of the five major regions of the brain has specific functions. As you ascend from the medulla oblongata (which connects to the spinal cord) to the cerebrum, those functions become more complex and variable. Conscious thought and intelligence are provided by the neural cortex of the cerebral hemispheres.

Concept Check

What brain regions make up the brain stem?

Which embryological structures are destined to form the cerebellum and pons?

Answers begin on p. A–1

Protection and Support of the Brain

Objectives

- Explain how the brain is protected and supported.
- Discuss the formation, circulation, and functions of the cerebrospinal fluid.

The delicate tissues of the brain are protected from mechanical forces by (1) the bones of the cranium, (2) the *cranial meninges*, and (3) cerebrospinal fluid. In addition, the neural tissue of the brain is biochemically isolated from the general circulation by the *blood–brain* *barrier*. Refer to Figures 7–3 and 7–4• (pp. 209–211) for a review of the bones of the cranium. We will discuss the other protective factors here.

The Cranial Meninges

The layers that make up the cranial meninges—the cranial dura mater, arachnoid mater, and pia mater—are continuous with those of the spinal meninges. l**p. 425** However, the cranial meninges have distinctive anatomical and functional characteristics (Figure 14–3a•):

- The cranial *dura mater* consists of outer and inner fibrous layers. The outer layer is fused to the periosteum of the cranial bones. As a result, there is no epidural space superficial to the dura mater, as occurs along the spinal cord. The outer, or *endosteal*, and inner, or *meningeal*, layers of the cranial dura mater are typically separated by a slender gap that contains tissue fluids and blood vessels, including several large venous sinuses. The veins of the brain open into these sinuses, which deliver the venous blood to the *internal jugular veins* of the neck.
- The cranial *arachnoid mater* consists of the arachnoid membrane (an epithelial layer) and the cells and fibers of the arachnoid trabeculae that cross the subarachnoid space to the pia mater. The arachnoid membrane covers the brain, providing a smooth surface that does not follow the brain’s underlying folds. This membrane is in contact with the inner epithelial layer of the dura mater. The subarachnoid space extends between the arachnoid membrane and the pia mater.
- The *pia mater* sticks to the surface of the brain, anchored by the processes of astrocytes. It extends into every fold, and accompanies the branches of cerebral blood vessels as they penetrate the surface of the brain to reach internal structures.

Dural Folds

In several locations, the inner layer of the dura mater extends into the cranial cavity, forming a sheet that dips inward and then returns. These **dural folds** provide additional stabilization and support to the brain. **Dural sinuses** are large collecting veins located within the dural folds. The three largest dural folds are called the falx cerebri, the tentorium cerebelli, and the falx cerebelli (Figure 14–3b•):

–

1. The **falx cerebri** (FALKS SER-e-br ; *falx*, curving or sickle-shaped) is a fold of dura mater that projects between the cerebral

ı hemispheres in the longitudinal fissure. Its inferior portions attach anteriorly to the crista galli and posteriorly to the *internal occipital crest*, a ridge along the inner surface of the occipital bone. The **superior sagittal sinus** and the **inferior sagittal sinus**, two large venous sinuses, lie within this dural fold. The posterior margin of the falx cerebri intersects the tentorium cerebelli.

2. The **tentorium cerebelli** (ten-TO-ree-

–e

-um ser-e-BEL-

–e

; *tentorium*, a covering) separates and protects the cerebellar hemispheres from those of the cerebrum. It extends across the cranium at right angles to the falx cerebri. The **transverse sinus** lies within the tentorium cerebelli.

3. The **falx cerebelli** divides the two cerebellar hemispheres along the midsagittal line inferior to the tentorium cerebelli.

The Protective Function of the Cranial Meninges

The overall shape of the brain roughly corresponds to that of the cranial cavity (see Figure 14–3a•). The massive cranial bones provide mechanical protection by cradling the brain, but they also pose a threat to safety that is countered by the cranial meninges and the CSF. The brain is like a person driving a car: If the car hits a tree, the car protects the driver from contact with the tree, but serious injury will occur unless a seat belt or airbag protects the driver from contact with the car. The tough, fibrous dural folds act like seat belts that hold the brain in position. The cerebrospinal fluid in the subarachnoid space acts like an airbag by cushioning against sudden jolts and shocks.

Cranial trauma is a head injury resulting from impact with another object. Each year in the United States, roughly 8 million cases of cranial trauma occur, but only 1 case in 8 results in serious brain damage. The percentage is relatively low because the cranial meninges and CSF are so effective in protecting the brain. AM: Cranial Trauma

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) completely surrounds and bathes the exposed surfaces of the CNS. The CSF has several important functions, including the following:

- **Cushioning Delicate Neural Structures.**
- **Supporting the Brain.** In essence, the brain is suspended inside the cranium and floats in the CSF. A human brain weighs about 1400 g in air, but only about 50 g when supported by CSF.
- **Transporting Nutrients, Chemical Messengers, and Waste Products.** Except at the choroid plexus, where CSF is produced, the ependymal lining is freely permeable and the CSF is in constant chemical communication with the interstitial fluid that surrounds the neurons and neuroglia of the CNS.

Because free exchange occurs between the interstitial fluid of the brain and the CSF, changes in CNS function can produce changes in the composition of the CSF. As noted in Chapter 13, a *spinal tap* can provide useful clinical information about CNS injury, infection, or disease. l**p. 426**

The Formation of CSF

The **choroid plexus** (*choroid*, vascular coat; *plexus*, network) consists of a combination of specialized ependymal cells and permeable capillaries involved in the production of cerebrospinal fluid. Two extensive folds of the choroid plexus originate in the roof of the third ventricle and extend through the interventricular foramina. These folds cover the floors of the lateral ventricles (Figure 14–4a•). In the inferior brain stem, a region of the choroid plexus in the roof of the fourth ventricle projects between the cerebellum and the pons.

Specialized ependymal cells, interconnected by tight junctions, surround the capillaries of the choroid plexus. The ependymal cells secrete CSF into the ventricles; they also remove waste products from the CSF and adjust its composition over time. The differences in composition between CSF and blood plasma (blood with the cellular elements removed) are quite pronounced. For example, the blood contains high concentrations of soluble proteins, but the CSF does not. The concentrations of individual ions and the levels of amino acids, lipids, and waste products are also different.

Circulation of CSF

The choroid plexus produces CSF at a rate of about 500 ml > day. The total volume of CSF at any moment is approximately 150 ml; thus, the entire volume of CSF is replaced roughly every eight hours. Despite this rapid turnover, the composition of CSF is closely regulated, and the rate of removal normally keeps pace with the rate of production.

The CSF circulates from the choroid plexus through the ventricles and fills the central canal of the spinal cord (see Figure 14–4a•). As the CSF circulates, diffusion between it and the interstitial fluid of the CNS is unrestricted between and across the ependymal cells. The CSF reaches the subarachnoid space through two **lateral apertures** and a single **median aperture**, openings in the roof of the fourth ventricle. Cerebrospinal fluid then flows through the subarachnoid space surrounding the brain, spinal cord, and cauda equina.

Fingerlike extensions of the arachnoid membrane, called the *arachnoid villi*, penetrate the meningeal layer of the dura mater and extend into the superior sagittal sinus. In adults, clusters of villi form large **arachnoid granulations** (Figure 14–4b•). Cerebrospinal fluid is absorbed into the venous circulation at the arachnoid granulations.

If the normal circulation or reabsorption of CSF is interrupted, a variety of clinical problems may appear. For example, a problem with the reabsorption of CSF in infancy is responsible for *hydrocephalus*, or “water on the brain.” Infants with this condition have enormously expanded skulls due to the presence of an abnormally large volume of CSF. In adults, a failure of reabsorption or a blockage of CSF circulation can distort and damage the brain. AM: Hydrocephalus

The Blood Supply to the Brain

As noted in Chapter 12, neurons have a high demand for energy, but they have neither energy reserves in the form of carbohydrates or lipids, nor oxygen reserves in the form of myoglobin. Your brain, with billions of neurons, is an extremely active organ with a continuous demand for nutrients and oxygen. These demands are met by an extensive circulatory supply. Arterial blood reaches the brain through the *internal carotid arteries* and the *vertebral arteries*. Most of the venous blood from the brain leaves the cranium in the *internal jugular veins*, which drain the dural sinuses. A head injury that damages cerebral blood vessels may cause bleeding into the dura mater, either near the dural epithelium or between the outer layer of the dura mater and the bones of the skull. These are serious conditions, because the blood entering these spaces compresses and distorts the relatively soft tissues of the brain.

Cerebrovascular diseases are cardiovascular disorders that interfere with the normal blood supply to the brain. The particular distribution of the vessel involved determines the signs and symptoms, and the degree of oxygen or nutrient starvation determines their severity. A **cerebrovascular accident (CVA)**, or *stroke*, occurs when the blood supply to a portion of the brain is shut off. Affected neurons begin to die in a matter of minutes.

The Blood–Brain Barrier

Neural tissue in the CNS is isolated from the general circulation by the **blood–brain barrier (BBB)**. This barrier exists because the endothelial cells that line the capillaries of the CNS are extensively interconnected by tight junctions. These junctions prevent the diffusion of materials between adjacent endothelial cells. In general, only lipid-soluble compounds (including carbon dioxide; oxygen; ammonia; lipids, such as steroids or prostaglandins; and small alcohols) can diffuse across the membranes of endothelial cells into the interstitial fluid of the brain and spinal cord. Water and ions must pass through channels in the apical and basal cell membranes. Larger, water-soluble compounds can cross the capillary walls only by active or passive transport.

The restricted permeability of the endothelial lining of brain capillaries is in some way dependent on chemicals secreted by astrocytes—cells that are in close contact with CNS capillaries. l**p. 386** The outer surfaces of the endothelial cells are covered by the processes of astrocytes. Because the astrocytes release chemicals that control the permeabilities of the endothelium to various substances, these cells play a key supporting role in the blood–brain barrier. If the astrocytes are damaged or stop stimulating the endothelial cells, the blood–brain barrier disappears.

The choroid plexus is not part of the neural tissue of the brain, so no astrocytes are in contact with the endothelial cells there. Substances do not have free access to the CNS, however, because a **blood–CSF barrier** is created by specialized ependymal cells. These cells, interconnected by tight junctions, surround the capillaries of the choroid plexus.

Transport across the blood–brain and blood–CSF barriers is selective and directional. Even the passage of small ions, such as sodium, hydrogen, potassium, or chloride, is controlled. As a result, the pH and concentrations of sodium, potassium, calcium, and magnesium ions in the blood and CSF are different. Some organic compounds are readily transported, and others cross only in minute amounts. Neurons have a constant need for glucose that must be met regardless of the relative concentrations in the blood and interstitial fluid. Even when circulating glucose levels are low, endothelial cells continue to transport glucose from the blood to the interstitial fluid of the brain. In contrast, only trace amounts of circulating norepinephrine, epinephrine, dopamine, and serotonin pass into the interstitial fluid or CSF of the brain. This limitation is important, because these compounds are neurotransmitters—their entry from the bloodstream (where concentrations can be relatively high) could result in the uncontrolled stimulation of neurons throughout the brain.

The blood–brain barrier remains intact throughout the CNS, with four noteworthy exceptions:

1. In portions of the hypothalamus, the capillary endothelium is extremely permeable. This permeability exposes hypothalamic nuclei to circulating hormones and permits the diffusion of hypothalamic hormones into the circulation.

2. Capillaries in the posterior lobe of the pituitary gland, which is continuous with the floor of the hypothalamus, are highly permeable. At this site, the hormones *ADH* and *oxytocin*, produced by hypothalamic neurons, are released into the circulation.

3. Capillaries in the *pineal gland* are also very permeable. The pineal gland, an endocrine structure, is located on the posterior, superior surface of the diencephalon. The capillary permeability allows pineal secretions into the general circulation.

4. Capillaries at the choroid plexus are extremely permeable. Although the capillary characteristics of the blood–brain barrier are lost there, the transport activities of specialized ependymal cells in the choroid plexus maintain the blood–CSF barrier.

Physicians must sometimes get specific compounds into the interstitial fluid of the brain to fight CNS infections or to treat other neural disorders. To do this, they must understand the limitations of the blood–brain and blood–CSF barriers. For example, when considering possible treatments, the antibiotic *tetracycline* isn’t used to treat meningitis or other CNS infections because this drug is excluded from the brain, whereas *sulfisoxazole* and *sulfadiazine* enter the CNS very rapidly.

100 Keys | The meninges stabilize the position of the brain within the cranial cavity, and cerebrospinal fluid provides protection against sudden jolts and shocks. CSF also provides nutrients and removes wastes generated by active neural tissues. The blood–brain barrier and the blood–CSF barrier selectively isolate the brain from chemicals in blood that might disrupt neural function.

Concept Check

What would happen if an interventricular foramen became blocked?

How would decreased diffusion across the arachnoid granulations affect the volume of cerebrospinal fluid in the ventricles?

Many water-soluble molecules that are relatively abundant in the blood occur in small amounts or not at all in the extracellular fluid of the brain. Why?

Answers begin on p. A–1

The Medulla Oblongata

Objectives

- Describe the anatomical differences between the medulla oblongata and the spinal cord.
- List the main components of the medulla oblongata and specify their functions.

The medulla oblongata is continuous with the spinal cord. Figure 14–5• shows the position of the medulla oblongata in relation to the other components of the brain stem and the diencephalon. This figure includes the attachment sites for 11 of the 12 pairs of cranial nerves. For the moment, we will identify the individual cranial nerves by Roman numerals only. (The full names and functions of these nerves will be introduced in a later section.)

In sectional view, the inferior portion of the medulla oblongata resembles the spinal cord, with a small central canal. However, the gray matter and white matter organization is more complex. As one ascends the medulla oblongata, the central canal opens into the fourth ventricle, and the similarity to the spinal cord all but disappears.

The medulla oblongata is a very busy place—all communication between the brain and spinal cord involves tracts that ascend or descend through the medulla oblongata. In addition, the medulla oblongata is a center for the coordination of relatively complex autonomic reflexes and the control of visceral functions.

The medulla oblongata (Figure 14–6a,b•) includes three groups of nuclei that we will encounter in later chapters:

1. *Autonomic Nuclei Controlling Visceral Activities.* The **reticular formation** is a loosely organized mass of gray matter that contains embedded nuclei. It extends from the medulla oblongata to the mesencephalon. The portion of the reticular formation in the medulla oblongata contains nuclei and centers responsible for the regulation of vital autonomic functions. These **reflex centers** receive inputs from cranial nerves, the cerebral cortex, and the brain stem. Their output controls or adjusts the activities of one or more peripheral systems. There are two major groups of reflex centers. The **cardiovascular centers** adjust the heart rate, the strength of cardiac contractions, and the flow of blood through peripheral tissues. (In terms of function, the cardiovascular centers are subdivided into **cardiac** (*kardia*, heart) and **vasomotor** (*vas*, canal) **centers**, but their anatomical boundaries are difficult to determine.) The **respiratory rhythmicity centers** set the basic pace for respiratory movements. Their activity is regulated by inputs from the apneustic and pneumotaxic centers of the pons.

2. *Sensory and Motor Nuclei of Cranial Nerves.* The medulla oblongata contains sensory and motor nuclei associated with five of the cranial nerves (VIII, IX, X, XI, and XII). These cranial nerves provide motor commands to muscles of the pharynx, neck, and back as well as to the visceral organs of the thoracic and peritoneal cavities. Cranial nerve VIII carries sensory information from receptors in the inner ear to the vestibular and cochlear nuclei, which extend from the pons into the medulla oblongata.

3. *Relay Stations along Sensory and Motor Pathways.* The **nucleus gracilis** and the **nucleus cuneatus** pass somatic sensory information to the thalamus. Tracts leaving these nuclei cross to the opposite side of the brain before reaching their destinations. This crossing over is called *decussation*

(d
¯e
-kuh-S
¯A

-shun; *decussatio*, crossing over). The **solitary nucleus** on either side receives visceral sensory information that

reaches the CNS from the spinal nerves and cranial nerves. This information is integrated and forwarded to other autonomic centers in the medulla oblongata and elsewhere. The **olivary nuclei** relay information to the cerebellar cortex about somatic motor commands as they are issued by motor centers at higher levels. The bulk of the olivary nuclei create the **olives**, prominent olive-shaped bulges along the ventrolateral surface of the medulla oblongata.

Table 14–2 summarizes the major components of the medulla oblongata.

The Pons

Objective

- List the main components of the pons and specify their functions.

The pons links the cerebellum with the mesencephalon, diencephalon, cerebrum, and spinal cord. Important features and regions of the pons are indicated in Figures 14–5 and 14–6c• and Table 14–2. The pons contains four groups of components:

1. *Sensory and Motor Nuclei of Cranial Nerves.* These cranial nerves (V, VI, VII, and VIII) innervate the jaw muscles, the anterior surface of the face, one of the extraocular muscles (the lateral rectus), and the sense organs of the inner ear (the *vestibular* and *cochlear nuclei*).

2. *Nuclei Involved with the Control of Respiration.* On each side of the pons, the reticular formation in this region contains two respiratory centers: the *apneustic center* and the *pneumotaxic center*. These centers modify the activity of the *respiratory rhythmicity center* in the medulla oblongata.

3. *Nuclei and Tracts That Process and Relay Information Heading to or from the Cerebellum.* The pons links the cerebellum with the brain stem, cerebrum, and spinal cord.

4. *Ascending, Descending, and Transverse Tracts.* Longitudinal tracts interconnect other portions of the CNS. The middle cerebellar peduncles are connected to the **transverse fibers**, which cross the anterior surface of the pons. These fibers are axons that link nuclei of the pons (*pontine nuclei*) with the cerebellar hemisphere of the opposite side.

The Cerebellum

Objective

- List the main components of the cerebellum and specify their functions.

The cerebellum (Figure 14–7• and Table 14–3) is an automatic processing center. It has two primary functions:

1. *Adjusting the Postural Muscles of the Body.* The cerebellum coordinates rapid, automatic adjustments that maintain balance and equilibrium. These alterations in muscle tone and position are made by modifying the activities of motor centers in the brain stem.

2. *Programming and Fine-Tuning Movements Controlled at the Conscious and Subconscious Levels.* The cerebellum refines learned movement patterns. This function is performed indirectly by regulating activity along motor pathways at the cerebral cortex, basal nuclei, and motor centers in the brain stem. The cerebellum compares the motor commands with proprioceptive information (position sense) and performs any adjustments needed to make the movement smooth.

The cerebellum has a complex, highly convoluted surface composed of neural cortex. The **folia** (F
¯O

-l
¯e
-uh; leaves), or folds

of the cerebellum surface, are less prominent than the folds in the surfaces of the cerebral hemispheres (Figure 14–7a•). The **anterior** and **posterior lobes** are separated by the **primary fissure**. Along the midline, a narrow band of cortex known as the **verm-**

¯u

-l

¯o

-NOD-

¯u

is (VER-mis; worm) separates the **cerebellar hemispheres**. The slender **flocculonodular** (flok-

-lar) **lobe** lies be

tween the roof of the fourth ventricle and the cerebellar hemispheres and vermis (Figure 14–7b•).

Like the cerebrum, the cerebellum has a superficial layer of neural cortex. The cerebellar cortex contains huge, highly branched

Purkinje (pur-KIN-j) **cells**. The extensive dendrites of each Purkinje cell receive input from up to 200,000 synapses. Internally, the white matter of the cerebellum forms a branching array that in sectional view resembles a tree. Anatomists call it the **arbor vitae**, or “tree of life.”

The cerebellum receives proprioceptive information from the spinal cord and monitors all proprioceptive, visual, tactile, balance, and auditory sensations received by the brain. Most axons that carry sensory information do not synapse in the cerebellar nuclei but pass through the deeper layers of the cerebellum on their way to the Purkinje cells of the cerebellar cortex. Information about the motor commands issued at the conscious and subconscious levels reaches the Purkinje cells indirectly, after being relayed by nuclei in the pons or by the **cerebellar nuclei** embedded within the arbor vitae.

Tracts that link the cerebellum with the brain stem, cerebrum, and spinal cord leave the cerebellar hemispheres as the superior, middle, and inferior cerebellar peduncles. The **superior cerebellar peduncles** link the cerebellum with nuclei in the midbrain, diencephalon, and cerebrum. The **middle cerebellar peduncles** are connected to a broad band of fibers that cross the ventral surface of the pons at right angles to the axis of the brain stem. The middle cerebellar peduncles also connect the cerebellar hemispheres with sensory and motor nuclei in the pons. The **inferior cerebellar peduncles** permit communication between the cerebellum and nuclei in the medulla oblongata and carry ascending and descending cerebellar tracts from the spinal cord.

The cerebellum can be permanently damaged by trauma or stroke, or temporarily affected by drugs such as alcohol. The re-

¯e

sult is **ataxia** (a-TAK-s

¯e

-uh; *ataxia*, lack of order), a disturbance in muscular coordination. In severe ataxia, the individual can

not sit or stand without assistance. AM: Cerebellar Dysfunction

Concept Check

Which part of the brain has a worm (vermis) and a tree (arbor vitae)? The medulla oblongata is one of the smallest sections of the brain, yet damage there can cause death, whereas similar damage in the cerebrum might go unnoticed. Why? If the respiratory center of the pons were damaged, what respiratory controls might be lost?

Answers begin on p. A–1

The Mesencephalon

Objective

- List the main components of the mesencephalon and specify their functions.

The external anatomy of the mesencephalon, or midbrain, is shown in Figure 14–5•, and the major nuclei are listed in Table 14–4 and shown in Figure 14–8•. The **tectum**, or roof of the mesencephalon, is the region posterior to the mesencephalic aqueduct. It contains two pairs of sensory nuclei known collectively as the **corpora quadrigemina** (KOR-po-ra qua-dri-JEM-i-nuh). These nuclei, the superior and inferior colliculi, process visual and auditory sensations. Each **superior colliculus** (KO-LIK- ¯u -lus; *colliculus,* a small hill) receives visual inputs from the lateral geniculate nucleus of the thalamus on that side. The **inferior colliculus** receives auditory data from nuclei in the medulla oblongata and pons. Some of this information may be forwarded to the medial geniculate on the same side. The superior colliculi control the reflex movements of the eyes, head, and neck in response to visual stimuli, such as a bright light. The inferior colliculi control reflex movements of the head, neck, and trunk in response to auditory stimuli, such as a loud noise.

The area anterior to the mesencephalic aqueduct is called the **tegmentum**. On each side, the tegmentum contains a red nucleus and the substantia nigra (Figure 14–8a•). The **red nucleus** contains numerous blood vessels, which give it a rich red color. This nucleus, which receives information from the cerebrum and cerebellum, issues subconscious motor commands that affect upper limb position and background muscle tone. The **substantia nigra** (N -gruh; *nigra*, black) is a nucleus that lies lateral to I¯the red nucleus. The gray matter in this region contains darkly pigmented cells, giving it a black color. The nerve fiber bundles on the ventrolateral surfaces of the mesencephalon (see Figures 14–5, p. 460, and 14–8b•) are the **cerebral peduncles** (*peduncles*, little feet). They contain (1) descending fibers that go to the cerebellum by way of the pons and (2) descending fibers that carry voluntary motor commands issued by the cerebral hemispheres.

The mesencephalon also contains the headquarters of the *reticular activating system (RAS),* a specialized component of the reticular formation. Stimulation of this region makes you more alert and attentive. We will consider the role of the RAS in the maintenance of consciousness in Chapter 16.

The Diencephalon

Objective

- List the main components of the diencephalon and specify their functions.

The diencephalon plays a vital role in integrating conscious and unconscious sensory information and motor commands. Figure 14–5• shows its position and its relationship to landmarks on the brain stem. The diencephalon consists of the epithalamus, thalamus, and hypothalamus.

The *epithalamus* is the roof of the diencephalon superior to the third ventricle. The anterior portion of the epithalamus contains an extensive area of choroid plexus that extends through the interventricular foramina into the lateral ventricles. The posterior portion of the epithalamus contains the **pineal gland** (see Figure 14–5c•), an endocrine structure that secretes the hormone **melatonin**. Melatonin is important in the regulation of day–night cycles and also in the regulation of reproductive functions. (We will describe the role of melatonin in Chapter 18.)

Most of the neural tissue in the diencephalon is concentrated in the *left thalamus* and *right thalamus*, which form the lateral walls, and the *hypothalamus*, which forms the floor. Ascending sensory information from the spinal cord and cranial nerves (other than the olfactory tract) synapses in a nucleus in the left or right thalamus before reaching the cerebral cortex and our conscious awareness. The hypothalamus contains centers involved with emotions and visceral processes that affect the cerebrum as well as other components of the brain stem. It also controls a variety of autonomic functions and forms the link between the nervous and endocrine systems.

The Thalamus

On each side of the diencephalon, the thalamus is the final relay point for ascending sensory information that will be projected to the primary sensory cortex. It acts as a filter, passing on only a small portion of the arriving sensory information. The thalamus also coordinates the activities of the basal nuclei and the cerebral cortex by relaying information between them.

The left thalamus and right thalamus are separated by the third ventricle. Each thalamus consists of a rounded mass of *thalamic nuclei* (Figure 14–9•). Viewed in a midsagittal section through the brain (see Figure 14–10a•), each thalamus extends from the anterior commissure to the inferior base of the pineal gland. A projection of gray matter called an **intermediate mass** extends into the ventricle from the thalamus on either side (see Figures 14–10 and 14–11•), although no fibers cross the midline.

Functions of Thalamic Nuclei

The thalamic nuclei deal primarily with the relay of sensory information to the basal nuclei and cerebral cortex. The five major groups of thalamic nuclei, listed in Table 14–5 and shown in Figure 14–9b•, are the anterior, medial, ventral, posterior, and lateral groups:

1. The *anterior group* includes the **anterior nuclei**, which are part of the *limbic system*. This system, which is involved with emotion and motivation, is discussed in a later section.

2. The nuclei of the *medial group* provide an awareness of emotional states by connecting emotional centers in the hypothalamus with the *frontal lobes* of the cerebral hemispheres. The medial group also receives and relays sensory information from other portions of the thalamus.

3. The nuclei of the *ventral group* relay information from the *basal nuclei* of the cerebrum and the cerebellum to somatic motor areas of the cerebral cortex. Ventral group nuclei also relay sensory information about touch, pressure, pain, temperature, and proprioception (position) to the sensory areas of the cerebral cortex.

4. The *posterior group* includes the pulvinar and the geniculate nuclei. The **pulvinar** integrates sensory information for projection to the cerebral cortex. The **lateral geniculate** (je-NIK-ū-lāt) **nucleus** (*genicula*, little knee) of each thalamus receives visual information over the *optic tract*, which originates at the eyes. The output of the lateral geniculate nucleus goes to the *occipital lobes* of the cerebral hemispheres and to the mesencephalon. The **medial geniculate nucleus** relays auditory information to the appropriate area of the cerebral cortex from specialized receptors of the inner ear.

5. The nuclei of the *lateral group* form feedback loops with the limbic system, described in a later section, and the *parietal lobes* of the cerebral hemispheres. The lateral group affects emotional states and the integration of sensory information.

The Hypothalamus

The hypothalamus (Figure 14–10a•) extends from the area superior to the *optic chiasm*, a crossover where the optic tracts from the eyes arrive at the brain, to the posterior margins of the **mamillary bodies** (*mamilla*, little breast). The mamillary bodies process sensory information, including olfactory sensations. They also contain motor nuclei that control reflex movements associated with eating, such as chewing, licking, and swallowing.

Immediately posterior to the optic chiasm, a narrow stalk called the **infundibulum** (in-fun-DIB-ū-lum; *infundibulum*, funnel) extends inferiorly, connecting the floor of the hypothalamus to the pituitary gland (Figure 14–10b•).

The floor of the hypothalamus between the infundibulum and the mamillary bodies is the **tuberal area** (*tuber*, swelling). The tuberal area contains nuclei that are involved with the control of pituitary gland function.

Functions of the Hypothalamus

The hypothalamus contains important control and integrative centers, in addition to those associated with the limbic system. These centers are shown in Figure 14–10a•, and their functions are summarized in Table 14–6. Hypothalamic centers may be stimulated by (1) sensory information from the cerebrum, brain stem, and spinal cord; (2) changes in the compositions of the CSF and interstitial fluid; or (3) chemical stimuli in the circulating blood that move rapidly across highly permeable capillaries to enter the hypothalamus (where there is no blood–brain barrier).

The hypothalamus performs the following functions:

1. *The Subconscious Control of Skeletal Muscle Contractions.* The hypothalamus directs somatic motor patterns associated with rage, pleasure, pain, and sexual arousal by stimulating centers in other portions of the brain. For example, the changes in facial expression that accompany rage and the basic movements associated with sexual activity are controlled by hypothalamic centers.

2. *The Control of Autonomic Function.* The hypothalamus adjusts and coordinates the activities of autonomic centers in the pons and medulla oblongata that regulate heart rate, blood pressure, respiration, and digestive functions.

3. *The Coordination of Activities of the Nervous and Endocrine Systems.* The hypothalamus coordinates neural and endocrine activities by inhibiting or stimulating endocrine cells in the pituitary gland through the production of *regulatory hormones*. These hormones are produced at the tuberal area and are released into local capillaries for transport to the anterior lobe of the pituitary gland.

4. *The Secretion of Two Hormones.* The hypothalamus secretes *antidiuretic hormone (ADH,* also called vasopressin*)*, which is produced by the **supraoptic nucleus** and restricts water loss at the kidneys, and *oxytocin* (OT), which is produced by the **para-ventricular nucleus** and stimulates smooth muscle contractions in the uterus and mammary glands of females and the prostate gland of males. These hormones are transported along axons that pass through the infundibulum to the posterior lobe of the pituitary gland. There the hormones are released into the blood for distribution throughout the body.

5. *The Production of Emotions and Behavioral Drives.* Specific hypothalamic centers produce sensations that lead to conscious or subconscious changes in behavior. For example, stimulation of the **feeding center** produces the sensation of hunger, and stimulation of the **thirst center** produces the sensation of thirst. These unfocused "impressions" originating in the hypothalamus are called **drives**. The conscious sensations are only part of the hypothalamic response. For instance, the thirst center also orders the release of ADH by neurons in the supraoptic nucleus.

6. *Coordination between Voluntary and Autonomic Functions.* When you think about a dangerous or stressful situation, your heart rate and respiratory rate go up and your body prepares for an emergency. These autonomic adjustments are made by the hypothalamus.

7. *The Regulation of Body Temperature.* The **preoptic area** of the hypothalamus coordinates the activities of other CNS centers and regulates other physiological systems to maintain normal body temperature. If body temperature falls, the preoptic area sends instructions to the *vasomotor center*, an autonomic center in the medulla oblongata that controls blood flow by regulating the diameter of peripheral blood vessels. In response, the vasomotor center decreases the blood supply to the skin, reducing the rate of heat loss.

8. *The Control of Circadian Rhythms.* The **suprachiasmatic nucleus** coordinates daily cycles of activity that are linked to the 24-hour day–night cycle. This nucleus receives input from the retina of the eye, and its output adjusts the activities of other hypothalamic nuclei, the pineal gland, and the reticular formation.

The Limbic System

Objective

- Identify the main components of the limbic system and specify their locations and functions.

The **limbic system** (*limbus*, border) includes nuclei and tracts along the border between the cerebrum and diencephalon. This system is a functional grouping rather than an anatomical one. Functions of the limbic system include (1) establishing emotional states; (2) linking the conscious, intellectual functions of the cerebral cortex with the unconscious and autonomic functions of the brain stem; and (3) facilitating memory storage and retrieval. Whereas the sensory cortex, motor cortex, and association areas of the cerebral cortex enable you to perform complex tasks, it is largely the limbic system that makes you *want* to do them. For this reason, the limbic system is also known as the *motivational system*.

Figure 14–11• focuses on major components of the limbic system. The **amygdaloid** (ah-MIG-da-loyd; *amygdale*, almond) **body** (Figure 14–11b•) appears to act as an interface between the limbic system, the cerebrum, and various sensory systems. It plays a role in the regulation of heart rate, in the control of the “fight or flight” response, and in linking emotions with specific memories. The **limbic lobe** of the cerebral hemisphere consists of the superficial folds, or *gyri*, and underlying structures adjacent to the diencephalon. The gyri curve along the *corpus callosum*, a fiber tract that links the two cerebral hemispheres, and continue onto the medial surface of the cerebrum lateral to the diencephalon (Figure 14–11a•). There are three gyri in the limbic lobe. The **cingulate** (SIN-gū-lāt) **gyrus** (*cingulum*, girdle or belt) sits superior to the corpus callosum. The **dentate gyrus** and the **parahippocampal** (pa-ra-hip-ō-KAM-pal) **gyrus** form the posterior and inferior portions of the limbic lobe. These gyri conceal the **hipp**

ocampus, a nucleus inferior to the floor of the lateral ventricle. To early anatomists, this structure resembled a sea horse (*hippocampus*); it is important in learning, especially in the storage and retrieval of new long-term memories.

The **fornix** (FOR-niks) is a tract of white matter that connects the hippocampus with the hypothalamus (see Figures 14–11 and 14–14c•, p. 473). From the hippocampus, the fornix curves medially, meeting its counterpart from the opposing hemisphere. The fornix proceeds anteriorly, inferior to the corpus callosum, before curving toward the hypothalamus. Many fibers of the fornix end in the mamillary bodies of the hypothalamus.

Several other nuclei in the wall (thalamus) and floor (hypothalamus) of the diencephalon are components of the limbic system. The *anterior nucleus* of the thalamus (see Figure 14–11b•) relays information from the mamillary body (of the hypothalamus) to the cingulate gyrus on that side. The boundaries between the hypothalamic nuclei of the limbic system are often poorly defined, but experimental stimulation has outlined a number of important hypothalamic centers responsible for the emotions of rage, fear, pain, sexual arousal, and pleasure. The stimulation of specific regions of the hypothalamus can also produce heightened alertness and a generalized excitement or generalized lethargy and sleep. These responses are caused by the stimulation or inhibition of the reticular formation. Although the reticular formation extends the length of the brain stem, its headquarters lies in the mesencephalon.

Table 14–7 summarizes the organization and functions of the limbic system.

Concept Check

Reflex movements of the eyes, head, and neck are controlled by which area(s) of the mesencephalon?

Damage to the lateral geniculate nuclei of the thalamus would interfere with the functions of which senses?

Which area of the diencephalon is stimulated by changes in body temperature?

Damage to the amygdaloid body would interfere with regulation of what division of the autonomic nervous system?

Answers begin on p. A–1

The Cerebrum

Objectives

- Identify the major anatomical subdivisions of the cerebrum.
- Locate the motor, sensory, and association areas of the cerebral cortex, and discuss their functions.
- Discuss the origin and significance of the major categories of brain waves seen in an electroencephalogram.

The cerebrum is the largest region of the brain. Conscious thoughts and all intellectual functions originate in the cerebral hemispheres. Much of the cerebrum is involved in the processing of somatic sensory and motor information. Gray matter in the cerebrum is located in the *cerebral cortex* and in deeper *basal nuclei*. The white matter of the cerebrum lies deep to the neural cortex and around the basal nuclei.

The Cerebral Cortex

As previously noted, a blanket of neural cortex covers the paired cerebral hemispheres, which dominate the superior and lateral surfaces of the cerebrum. The gyri increase the surface area of the cerebral hemispheres, and thus the number of cortical neurons they contain; the total surface area of the cerebral hemispheres is roughly equivalent to 2200 cm^2 (2.5 ft^2) of flat surface. The entire brain has enlarged over the course of human evolution, but the cerebral hemispheres have enlarged at a much faster rate than has the rest of the brain, reflecting the large numbers of neurons needed for complex analytical and integrative functions. Since the neurons involved are in the superficial layer of cortex, it is there that the expansion has been most pronounced. The only solution available, other than an enlargement of the entire skull, was for the cortical layer to fold like a crumpled piece of paper.

Landmarks and features on the surface of one cerebral hemisphere are shown in Figure 14–12a,b•. (The two cerebral hemispheres are almost completely separated by a deep **longitudinal fissure**, seen in Figure 14–13b•, p. 472). Each cerebral hemisphere can be divided into *lobes*, or regions, named after the overlying bones of the skull. Your brain has a unique pattern of sulci and gyri, as individual as a fingerprint, but the boundaries between lobes are reliable landmarks. On each hemisphere, the **central sulcus**, a deep groove, divides the anterior **frontal lobe** from the more posterior **parietal lobe**. The roughly horizontal **lateral sulcus** separates the frontal lobe from the **temporal lobe**. The **insula** (IN-su¯-luh; *insula*, island), an "island" of cortex, lies medial to the lateral sulcus. The more posterior **parieto-occipital sulcus** separates the parietal lobe from the **occipital lobe**.

Each lobe contains functional regions whose boundaries are less clearly defined. Some of these regions deal with sensory information, and others with motor commands. Keep in mind three points about the cerebral lobes:

1. *Each Cerebral Hemisphere Receives Sensory Information from, and Sends Motor Commands to, the Opposite Side of the Body.* For example, the motor areas of the left cerebral hemisphere control muscles on the right side, and the right cerebral hemisphere controls muscles on the left side. This crossing over has no known functional significance.

2. *The Two Hemispheres Have Different Functions, Even Though They Look Almost Identical.* We will discuss these differences in a later section.

3. *The Correspondence between a Specific Function and a Specific Region of the Cerebral Cortex Is Imprecise.* Because the boundaries are indistinct and have considerable overlap, one region may have several functions. Some aspects of cortical function, such as consciousness, cannot easily be assigned to any single region. However, we know that normal individuals use all portions of the brain.

The White Matter of the Cerebrum

The interior of the cerebrum consists primarily of white matter. The axons can be roughly classified as association fibers, commissural fibers, and projection fibers (Figure 14–13•).

- **Association fibers** interconnect areas of neural cortex within a single cerebral hemisphere. Shorter association fibers are called **arcuate** (AR-k¯u-¯at) **fibers**, because they curve in an arc to pass from one gyrus to another. Longer association fibers are organized into discrete bundles, or *fasciculi*. The **longitudinal fasciculi** connect the frontal lobe to the other lobes of the same hemisphere.
- **Commissural** (kom-I-sur-al) **fibers** (*commissura*, crossing over) interconnect and permit communication between the cerebral hemispheres. Bands of commissural fibers linking the hemispheres include the **corpus callosum** and the **anterior commissure**. The corpus callosum alone contains more than 200 million axons, carrying some 4 billion impulses per second!
- **Projection fibers** link the cerebral cortex to the diencephalon, brain stem, cerebellum, and spinal cord. All projection fibers must pass through the diencephalon, where axons heading to sensory areas of the cerebral cortex pass among the axons descending from motor areas of the cortex. In gross dissection, the ascending fibers and descending fibers look alike. The entire collection of projection fibers is known as the **internal capsule**.

The Basal Nuclei

While your cerebral cortex is consciously directing a complex movement or solving some intellectual puzzle, other centers of your cerebrum, diencephalon, and brain stem are processing sensory information and issuing motor commands outside your conscious awareness. Many of these activities, which occur at the subconscious level, are directed by the basal nuclei, or *cerebral nuclei*.

The **basal nuclei** are masses of gray matter that lie within each hemisphere deep to the floor of the lateral ventricle (Figure 14–14•). They are embedded in the white matter of the cerebrum, and the radiating projection fibers and commissural fibers travel around or between these nuclei. Historically, the basal nuclei have been considered part of a larger functional group known as the *basal ganglia*. This group included the basal nuclei of the cerebrum and the associated motor nuclei in the diencephalon and mesencephalon. Although we will consider the functional interactions among these components in Chapter 15, we will avoid the term "basal ganglia" because ganglia are otherwise restricted to the PNS.

The **caudate nucleus** has a massive head and a slender, curving tail that follows the curve of the lateral ventricle. The head of the caudate nucleus lies anterior to the **lentiform** (lens-shaped) **nucleus**. The lentiform nucleus consists of a medial **globus**
pallidus (GL
¯O

-bus PAL-i-dus; pale globe) and a lateral **putamen** (p
¯u
-T

¯A

-men). The term *corpus striatum* (striated body) has
been used to refer to the caudate and lentiform nuclei, or to the caudate nucleus and putamen. The name refers to the striated (striped) appearance of the internal capsule as it passes among these nuclei. The amygdaloid body, part of the limbic system, lies anterior to the tail of the caudate nucleus and inferior to the lentiform nucleus.

Functions of the Basal Nuclei

The basal nuclei are involved with the subconscious control of skeletal muscle tone and the coordination of learned movement patterns. Under normal conditions, these nuclei do not initiate particular movements. But once a movement is under way, the basal nuclei provide the general pattern and rhythm, especially for movements of the trunk and proximal limb muscles.

Information arrives at the caudate nucleus and putamen from sensory, motor, and integrative areas of the cerebral cortex. Processing occurs in these nuclei and in the adjacent globus pallidus. Most of the output of the basal nuclei leaves the globus pallidus and synapses in the thalamus. Nuclei in the thalamus then project the information to appropriate areas of the cerebral cortex. The basal nuclei alter the motor commands issued by the cerebral cortex through this feedback loop. For example:

- When you walk, the basal nuclei control the cycles of arm and thigh movements that occur between the time you decide to “start” walking and the time you give the “stop” order.
- As you begin a voluntary movement, the basal nuclei control and adjust muscle tone, particularly in the appendicular muscles, to set your body position. When you decide to pick up a pencil, you consciously reach and grasp with your forearm, wrist, and hand while the basal nuclei operate at the subconscious level to position your shoulder and stabilize your arm.

Clinical Note

Activity of the basal nuclei is inhibited by neurons in the substantia nigra of the mesencephalon, which release the neurotransmitter

dopamine. l**p. 408** If the substantia nigra is damaged or the neurons secrete less dopamine, basal nuclei become more active. The

result is a gradual, generalized increase in muscle tone and the appearance of symptoms characteristic of *Parkinson’s disease*. Peo ple with Parkinson’s disease have difficulty starting voluntary movements, because opposing muscle groups do not relax; they must be overpowered. Once a movement is under way, every aspect must be voluntarily controlled through intense effort and concentra tion. AM: The Basal Nuclei and Parkinson’s Disease

Concept Check

What name is given to axons carrying information between the brain and spinal cord, and what brain regions do they pass through?

What symptoms would you expect to observe in an individual who has damage to the basal nuclei?

Answers begin on p. A–1

Motor and Sensory Areas of the Cortex

The major motor and sensory regions of the cerebral cortex are listed in Table 14–8 and shown in Figure 14–15•. The central sulcus separates the motor and sensory areas of the cortex. The **precentral gyrus** of the frontal lobe forms the anterior border of the central sulcus. The surface of this gyrus is the **primary motor cortex**. Neurons of the primary motor cortex direct voluntary movements by controlling somatic motor neurons in the brain stem and spinal cord. These cortical neurons are called **pyramidal cells**, because their cell bodies resemble little pyramids.

The primary motor cortex is like the keyboard of a piano. If you strike a specific piano key, you produce a specific sound; if you stimulate a specific motor neuron in the primary motor cortex, you generate a contraction in a specific skeletal muscle.

Like the gauges in the dashboard of a car, the sensory areas of the cerebral cortex report key information. At each location, sensory information is reported in the pattern of neuron activity in the cortex. The **postcentral gyrus** of the parietal lobe forms the posterior border of the central sulcus, and its surface contains the **primary sensory cortex**. Neurons in this region receive somatic sensory information from receptors for touch, pressure, pain, vibration, taste, or temperature. We are aware of these sensations only when nuclei in the thalamus relay the information to the primary sensory cortex.

Sensations of sight, sound, smell, and taste arrive at other portions of the cerebral cortex (Figure 14–15a•). The **visual cortex** of the occipital lobe receives visual information, and the **auditory cortex** and **olfactory cortex** of the temporal lobe receive information about hearing and smell, respectively. The **gustatory cortex**, which receives information from taste receptors of the tongue and pharynx, lies in the anterior portion of the insula and adjacent portions of the frontal lobe.

Association Areas

The sensory and motor regions of the cortex are connected to nearby **association areas**, regions of the cortex that interpret incoming data or coordinate a motor response (see Figure 14–15a•). Like the information provided by the gauges in a car, the arriving information must be noticed and interpreted before the driver can take appropriate action. *Sensory association areas* are cortical regions that monitor and interpret the information that arrives at the sensory areas of the cortex. Examples include the somatic sensory association area, visual association area, and auditory association area.

The **somatic sensory association area** monitors activity in the primary sensory cortex. It is the somatic sensory association area that allows you to recognize a touch as light as the arrival of a mosquito on your arm (and gives you a chance to swat the mosquito before it bites).

The special senses of smell, sight, and hearing involve separate areas of the sensory cortex, and each has its own association area. These areas monitor and interpret arriving sensations. For example, the **visual association area** monitors the patterns of activity in the visual cortex and interprets the results. You see the symbols *c*, *a*, and *r* when the stimulation of receptors in your eyes leads to the stimulation of neurons in your visual cortex. Your visual association area recognizes that these are letters and that *c* + *a* + *r* = *car*. An individual with a damaged visual association area could scan the lines of a printed page and see rows of symbols that are clear, but would perceive no meaning from the symbols. Similarly, the **auditory association area** monitors sensory activity in the auditory cortex; word recognition occurs in this association area.

The **somatic motor association area**, or **premotor cortex**, is responsible for the coordination of learned movements. The primary motor cortex does nothing on its own, any more than a piano keyboard can play itself. The neurons in the primary motor cortex must be stimulated by neurons in other parts of the cerebrum. When you perform a voluntary movement, the instructions are relayed to the primary motor cortex by the premotor cortex. With repetition, the proper pattern of stimulation becomes stored in your premotor cortex. You can then perform the movement smoothly and easily by triggering the *pattern* rather than by controlling the individual neurons. This principle applies to any learned movement, from something as simple as picking up a glass to something as complex as playing the piano. One area of the premotor cortex, the *frontal eye field*, controls learned eye movements, such as when you scan these lines of type. Individuals with damage to the frontal eye field can understand written letters and words but cannot read, because their eyes cannot follow the lines on a printed page.

Integrative Centers

Integrative centers are areas that receive information from many association areas and direct extremely complex motor activities. These centers also perform complicated analytical functions. For example, the *prefrontal cortex* of the frontal lobe (Figure 14–15b•) integrates information from sensory association areas and performs abstract intellectual functions, such as predicting the consequences of possible responses.

Integrative centers are located in the lobes and cortical areas of both cerebral hemispheres. Integrative centers concerned with the performance of complex processes, such as speech, writing, mathematical computation, and understanding spatial relationships, are restricted to either the left or the right hemisphere. These centers include the *general interpretive area* and the *speech center*. The corresponding regions on the opposite hemisphere are also active, but their functions are less well defined.

The General Interpretive Area The **general interpretive area**, or *Wernicke’s area* (see Figure 14–15b•), also called the *gnostic area*, receives information from all the sensory association areas. This analytical center is present in only one hemisphere (typically the left). This region plays an essential role in your personality by integrating sensory information and coordinating access to complex visual and auditory memories. Damage to the general interpretive area affects the ability to interpret what is seen or heard, even though the words are understood as individual entities. For example, if your general interpretive area were damaged, you might still understand the meaning of the spoken words *sit* and *here*, because word recognition occurs in the auditory association areas. But you would be totally bewildered by the request *sit here*. Damage to another portion of the general interpretive area might leave you able to see a chair clearly, and to know that you recognize it, but you would be unable to name it because the connection to your visual association area has been disrupted.

The Speech Center Some of the neurons in the general interpretive area innervate the **speech center**, also called *Broca’s area* or the *motor speech area* (see Figure 14–15b•). This center lies along the edge of the premotor cortex in the same hemisphere as the general interpretive area (usually the left). The speech center regulates the patterns of breathing and vocalization needed for normal speech. This regulation involves coordinating the activities of the respiratory muscles, the laryngeal and pharyngeal muscles, and the muscles of the tongue, cheeks, lips, and jaws. A person with a damaged speech center can make sounds but not words.

The motor commands issued by the speech center are adjusted by feedback from the auditory association area, also called the *receptive speech area*. Damage to the related sensory areas can cause a variety of speech-related problems. (See the discussion of *aphasia* on p. 478.) Some affected individuals have difficulty speaking although they know exactly which words to use; others talk constantly but use all the wrong words.

The Prefrontal Cortex The **prefrontal cortex** of the frontal lobe (see Figure 14–15b•) coordinates information relayed from the association areas of the entire cortex. In doing so, it performs such abstract intellectual functions as predicting the consequences of events or actions. Damage to the prefrontal cortex leads to difficulties in estimating temporal relationships between events. Questions such as “How long ago did this happen?” or “What happened first?” become difficult to answer.

The prefrontal cortex has extensive connections with other cortical areas and with other portions of the brain. Feelings of frustration, tension, and anxiety are generated at the prefrontal cortex as it interprets ongoing events and makes predictions about future situations or consequences. If the connections between the prefrontal cortex and other brain regions are severed, the frustrations, tensions, and anxieties are removed. During the middle of the twentieth century, this rather drastic procedure, called **prefrontal lobotomy**, was used to “cure” a variety of mental illnesses, especially those associated with violent or antisocial behavior. After a lobotomy, the patient would no longer be concerned about what had previously been a major problem, whether psychological (hallucinations) or physical (severe pain). However, the individual was often equally unconcerned about tact, decorum, and toilet training. Drugs that target specific pathways and regions of the CNS have been developed, so lobotomies are no longer used to change behavior.

Brodmann’s Areas Early in the 20th century, numerous researchers attempted to describe and classify regional differences in the histological organization of the cerebral cortex. They hoped to correlate the patterns of cellular organization with specific functions. By 1919, at least 200 patterns had been described, but most of the classification schemes have since been abandoned. However, the cortical map prepared by Korbinian Brodmann in 1909 has proved useful to neuroanatomists. Brodmann, a German neurologist, described 47 patterns of cellular organization in the cerebral cortex. Several of these *Brodmann’s areas* are shown in Figure 14–15c•. Some correspond to known functional areas. For example, Brodmann’s area 44 corresponds to the speech center, and area 41 to the auditory cortex; area 4 follows the contours of the primary motor cortex. In other cases, the correspondence is less precise. For instance, Brodmann’s area 42 forms only a small portion of the auditory association area.

Hemispheric Lateralization

Each of the two cerebral hemispheres is responsible for specific functions that are not ordinarily performed by the opposite hemisphere. This regional specialization has been called *hemispheric lateralization*. Figure 14–16• indicates the major functional differences between the hemispheres. In most people, the left hemisphere contains the general interpretive and speech centers and is responsible for language-based skills. For example, reading, writing, and speaking are dependent on processing done in the left cerebral hemisphere. In addition, the premotor cortex involved with the control of hand movements is larger on the left side for right-handed individuals than for left-handed ones. The left hemisphere is also important in performing analytical tasks, such as mathematical calculations and logical decision making. For these reasons, the left cerebral hemisphere has been called the *dominant hemisphere*, or the *categorical hemisphere*.

The right cerebral hemisphere analyzes sensory information and relates the body to the sensory environment. Interpretive centers in this hemisphere permit you to identify familiar objects by touch, smell, sight, taste, or feel. For example, the right hemisphere plays a dominant role in recognizing faces and in understanding three-dimensional relationships. It is also important in analyzing the emotional context of a conversation—for instance, distinguishing between the threat “Get lost” and the question “Get lost?” Individuals with a damaged right hemisphere may be unable to add emotional inflections to their own words.

Left-handed people represent 9 percent of the human population; in most cases, although the primary motor cortex of the right hemisphere controls motor function for the dominant hand, the centers involved with speech and analytical function are in the left hemisphere. Interestingly, an unusually high percentage of musicians and artists are left-handed. The complex motor activities performed by these individuals are directed by the primary motor cortex and association areas on the right cerebral hemisphere, near the association areas involved with spatial visualization and emotions. AM: Disconnection Syndrome

Monitoring Brain Activity: The Electroencephalogram

The primary sensory cortex and the primary motor cortex have been mapped by direct stimulation in patients undergoing brain surgery. The functions of other regions of the cerebrum can be revealed by the behavioral changes that follow localized injuries or strokes, and the activities of specific regions can be examined by a PET scan or sequential MRI scans.

The electrical activity of the brain is commonly monitored to assess brain activity. Neural function depends on electrical events within the cell membrane of neurons. The brain contains billions of neurons, and their activity generates an electrical field that can be measured by placing electrodes on the brain or on the outer surface of the skull. The electrical activity changes constantly, as nuclei and cortical areas are stimulated or quiet down. A printed report of the electrical activity of the brain is called an **electroencephalogram (EEG)**. The electrical patterns observed are called *brain waves*.

Typical brain waves are shown in Figure 14–17a–d•. **Alpha waves** occur in the brains of healthy, awake adults who are resting with their eyes closed. Alpha waves disappear during sleep, but they also vanish when the individual begins to concentrate on some specific task. During attention to stimuli or tasks, alpha waves are replaced by higher-frequency **beta waves**. Beta waves are typical of individuals who are either concentrating on a task, under stress, or in a state of psychological tension. **Theta waves** may appear transiently during sleep in normal adults but are most often observed in children and in intensely frustrated adults. The presence of theta waves under other circumstances may indicate the presence of a brain disorder, such as a tumor. **Delta waves** are very-large-amplitude, low-frequency waves. They are normally seen during deep sleep in individuals of all ages. Delta waves are also seen in the brains of infants (in whom cortical development is still incomplete) and in awake adults when a tumor, vascular blockage, or inflammation has damaged portions of the brain.

Electrical activity in the two hemispheres is generally synchronized by a “pacemaker” mechanism that appears to involve the thalamus. Asynchrony between the hemispheres can therefore indicate localized damage or other cerebral abnormalities. For example, a tumor or injury affecting one hemisphere typically changes the pattern in that hemisphere, and the patterns of the two hemispheres are no longer aligned. A **seizure** is a temporary cerebral disorder accompanied by abnormal movements, unusual sensations, inappropriate behavior, or some combination of these symptoms. Clinical conditions characterized by seizures are known as seizure disorders, or *epilepsies*. Seizures of all kinds are accompanied by a marked change in the pattern of electrical activity recorded in an electroencephalogram. The change begins in one portion of the cerebral cortex but may subsequently spread across the entire cortical surface, like a wave on the surface of a pond.

The nature of the signs and symptoms produced depends on the region of the cortex involved. If a seizure affects the primary motor cortex, movements will occur; if it affects the auditory cortex, the individual will hear strange sounds. AM: Seizures and Epilepsies

Concept Check

Shelly suffers a head injury that damages her primary motor cortex. Where is this area located?

Which senses would be affected by damage to the temporal lobes of the cerebrum?

After suffering a stroke, Jake is unable to speak. He can understand what is said to him, and he can understand written messages, but he cannot express himself verbally. Which part of his brain has been affected by the stroke?

Paul is having a difficult time remembering facts and recalling long-term memories. Which part of his cerebrum is probably involved?

Answers begin on p. A–1

Cranial Reflexes

Objective

- Describe representative examples of cranial reflexes that produce somatic responses or visceral responses
to specific stimuli.

Cranial reflexes are monosynaptic and polysynaptic reflex arcs that involve the sensory and motor fibers of cranial nerves. Numerous examples of cranial reflexes will be encountered in later chapters, and this section will simply provide an overview and general introduction.

Table 14–10 lists representative examples of cranial reflexes and their functions. These reflexes are clinically important because they provide a quick and easy method for observing the condition of cranial nerves and specific nuclei and tracts in the brain. The somatic reflexes mediated by the cranial nerves are seldom more complex than the somatic reflexes of the spinal cord that

were discussed in Chapter 13. l**p. 440** Table 14–10 includes four representative somatic reflexes: the corneal reflex, the tympanic reflex, the auditory reflexes, and the vestibulo-ocular reflexes. These cranial reflexes are often used to check for damage to the cranial nerves or the associated processing centers in the brain.

The brain stem contains many reflex centers that control visceral motor activity. The motor output of these reflexes is distributed by the autonomic nervous system. As you will see in Chapter 16, the cranial nerves carry most of the commands issued by the parasympathetic division of the ANS, whereas spinal nerves T1 –L2 carry the sympathetic commands. Many of the centers that coordinate autonomic reflexes are located in the medulla oblongata. These centers can direct very complex visceral motor responses that are essential to the control of respiratory, digestive, and cardiovascular functions.

100 Keys | There are 12 pairs of cranial nerves. They are responsible for the special senses of smell, sight, and hearing/bal-ance; for control over the muscles of the eye, jaw, face, and tongue; and for control over the superficial muscles of the neck, back, and shoulders. Cranial nerves also provide sensory information from the face, neck, and upper chest, and autonomic (parasympathetic) innervation to organs in the thoracic and abdominopelvic cavities.

Anatomy 360 | Review the anatomy of the cranial nerves on the **Anatomy 360 CD-ROM: Nervous System/ Peripheral Nervous System/Cranial Nerves.**

Chapter Review

Selected Clinical Terminology

aphasia: A disorder that impairs the ability to speak or read. (p. 478)

ataxia: A disturbance of muscular coordination that, in severe cases, leaves the individual unable to stand without assistance. (p. 464)

Bell's palsy: A condition resulting from an inflammation of the facial nerve. (p. 484)

cerebrovascular accident (CVA), or *stroke***:** A condition in which the blood supply to a portion of the brain is shut off. (p. 458)

cranial trauma: A head injury resulting from violent contact with another object. (p. 456 and [AM])

disconnection syndrome: A condition in which the two cerebral hemispheres function independently. [AM]

dyslexia: A disorder affecting the comprehension and use of words. (p. 478)

electroencephalogram (EEG): A printed record of the brain's electrical activity over time. (p. 478)

epidural hemorrhage: A condition involving bleeding between the dura mater and the cranium, generally resulting from cranial trauma.

[AM]

hydrocephalus, or "water on the brain"**:** A condition resulting from interference with the normal circulation and/or reabsorption of cerebrospinal fluid. (p. 458) **Parkinson's disease** *(paralysis agitans)***:** A condition characterized by a pronounced increase in muscle tone, resulting from the excitation of neurons in the basal nuclei. (p. 474 and [AM]) **seizure:** A temporary disorder of cerebral function, accompanied by abnormal movements, unusual sensations, and/or inappropriate behavior. (p. 479 and [AM]) **subdural hemorrhage:** A condition in which blood accumulates under the dural epithelium in contact with the arachnoid membrane.

[AM]

tic douloureux: A disorder of the maxillary and mandibular branches of nerve V characterized by almost totally debilitating pain triggered by contact with the lip, tongue, or gums. (p. 483 and [AM])

Study Outline

An Introduction to the Organization of the Brain p. 452 A Preview of Major Regions and Landmarks p. 452

1. The six regions in the adult brain are the **cerebrum**, **cerebellum**, **diencephalon**, **mesencephalon** ("midbrain"), **pons**, and **medulla oblongata**. *(Figure 14–1)*

2. The brain contains extensive areas of **neural cortex**, a layer of gray matter on the surfaces of the cerebrum and cerebellum.

Embryology of the Brain p. 452

3. The brain forms from three swellings at the superior tip of the developing *neural tube*: the *prosencephalon*, the mesencephalon, and the *rhombencephalon*. The prosencephalon ("forebrain") forms the **telencephalon** (which becomes the cerebrum) and diencephalon; the rhombencephalon ("hindbrain") forms the **metencephalon** (cerebellum and pons) and **myelencephalon** (medulla oblongata).

(Table 14–1)

Ventricles of the Brain p. 453

4. The central passageway of the brain expands to form chambers called **ventricles** that contain cerebrospinal fluid. *(Figure 14–2)*

100 Keys | p. 455

Protection and Support of the Brain p. 455 The Cranial Meninges p. 455

1. The cranial meninges (the *dura mater*, *arachnoid*, and *pia mater*) are continuous with those of the spinal cord.

2. Folds of dura mater, including the **falx cerebri**, **tentorium cerebelli**, and **falx cerebelli**, stabilize the position of the brain. *(Figure 14–3)*

Cerebrospinal Fluid p. 456

3. Cerebrospinal fluid (CSF) (1) cushions delicate neural structures, (2) supports the brain, and (3) transports nutrients, chemical messengers, and waste products.

4. Cerebrospinal fluid is produced at the **choroid plexus**, reaches the subarachnoid space through the **lateral** and **median apertures**, and diffuses across the **arachnoid granulations** into the **superior sagittal sinus**. *(Figure 14–4)*

The Blood Supply to the Brain p. 458

5. The **blood–brain barrier (BBB)** isolates neural tissue from the general circulation.

6. The blood–brain barrier is incomplete in parts of the **hypothalamus**, the **pituitary gland**, the **pineal gland**, and the **choroid plexus**.

100 Keys | p. 459

The Medulla Oblongata p. 459

1. The medulla oblongata connects the brain and spinal cord. It contains relay stations such as the **olivary nuclei**, and **reflex centers**, including the **cardiovascular** and **respiratory rhythmicity centers**. The **reticular formation** begins in the medulla oblongata and extends into more superior portions of the brain stem. *(Figures 14–5, 14–6; Table 14–2)*

The Pons p. 462

1. The pons contains (1) sensory and motor nuclei for four cranial nerves; (2) nuclei that help control respiration; (3) nuclei and tracts linking the cerebellum with the brain stem, cerebrum, and spinal cord; and (4) ascending, descending and transverse tracts.
(Figure 14–6; Table 14–2)

The Cerebellum p. 462

1. The cerebellum adjusts postural muscles and programs and tunes ongoing movements. The **cerebellar hemispheres** consist of the **anterior** and **posterior lobes**, the **vermis**, and the **flocculonodular lobe**. *(Figure 14–7; Table 14–3)*

2. The **superior**, **middle**, and **inferior cerebellar peduncles** link the cerebellum with the brain stem, diencephalon, cerebrum, and spinal cord and interconnect the two cerebellar hemispheres.

The Mesencephalon p. 464

1. The **tectum** (roof of the mesencephalon) contains the **corpora quadrigemina** (**superior colliculi** and **inferior colliculi**). The tegmentum contains the **red nucleus**, the **substantia nigra**, the **cerebral peduncles**, and the headquarters of the reticular activating system (RAS). *(Figure 14–8; Table 14–4)*

The Diencephalon p. 465

1. The diencephalon is composed of the epithalamus, the hypothalamus, and the thalamus. *(Figures 14–9, 14–10)*

The Thalamus p. 466

2. The thalamus is the final relay point for ascending sensory information and coordinates the activities of the basal nuclei and cerebral cortex. *(Figures 14–9, 14–10; Table 14–5)*

The Hypothalamus p. 467

3. The hypothalamus can (1) control somatic motor activities at the subconscious level, (2) control autonomic function, (3) coordinate activities of the nervous and endocrine systems, (4) secrete hormones, (5) produce emotions and behavioral **drives**, (6) coordinate voluntary and autonomic functions, (7) regulate body temperature, and (8) coordinate circadian cycles of activity. *(Figure 14–10; Table 14–6)*

The Limbic System p. 469

1. The **limbic system**, or *motivational system*, includes the **amygdaloid body**, **cingulate gyrus**, **dentate gyrus**, **parahippocampal gyrus**, **hippocampus**, and **fornix**. The functions of the limbic system involve emotional states and related behavioral drives
(Figure 14–11; Table 14–7)

The Cerebrum p. 470 The Cerebral Cortex p. 470

1. The cortical surface contains **gyri** (elevated ridges) separated by **sulci** (shallow depressions) or **fissures** (deeper grooves). The **longitudinal fissure** separates the two **cerebral hemispheres**. The **central sulcus** separates the **frontal** and **parietal lobes**. Other sulci form the boundaries of the **temporal** and **occipital lobes**. *(Figure 14–12)*

The White Matter of the Cerebrum p. 472

2. The white matter of the cerebrum contains **association fibers**, **commissural fibers**, and **projection fibers**. *(Figure 14–13)*

The Basal Nuclei p. 472

3. The **basal nuclei** include the **caudate nucleus**, **globus pallidus**, and **putamen**; they control muscle tone and coordinate learned movement patterns and other somatic motor activities. *(Figure 14–14)*

Motor and Sensory Areas of the Cortex p. 474

4. The **primary motor cortex** of the **precentral gyrus** directs voluntary movements. The **primary sensory cortex** of the **postcentral gyrus** receives somatic sensory information from touch, pressure, pain, vibration, taste, and temperature receptors. *(Figure 14–15; Table 14–8)*

5. **Association areas**, such as the **somatic sensory association area**, **visual association area**, and **somatic motor association area (premotor cortex)**, control our ability to understand sensory information and coordinate a motor response. *(Figure 14–15)*

6. The **general interpretive area** receives information from all the sensory association areas. It is present in only one hemisphere— generally the left. *(Figure 14–15)*

7. The **speech center** regulates the patterns of breathing and vocalization needed for normal speech. *(Figure 14–15)*

8. The **prefrontal cortex** coordinates information from the secondary and special association areas of the entire cortex and performs abstract intellectual functions. *(Figure 14–15)*

9. The left hemisphere typically contains the general interpretive and speech centers and is responsible for language-based skills. The right hemisphere is typically responsible for spatial relationships and analyses. *(Figure 14–16)*

10. Brain activity is measured using an **electroencephalogram**. **Alpha waves** appear in healthy resting adults; **beta waves** occur when adults are concentrating; **theta waves** appear in children; and **delta waves** are normal during sleep. *(Figure 14–17)*

Anatomy 360 | Nervous System/Central Nervous System/ Brain

FOCUS: Cranial Nerves p. 480

11. We have 12 pairs of cranial nerves. Each nerve attaches to the ventrolateral surface of the brainstem near the associated sensory or motor nuclei. *(Figure 14–18)*

12. The **olfactory nerves** (I) carry sensory information responsible for the sense of smell. The olfactory afferents synapse within the **olfactory bulbs**. *(Figures 14–18, 14–19)*

13. The **optic nerves** (II) carry visual information from special sensory receptors in the eyes. *(Figures 14–18, 14–20)*

14. The **oculomotor nerves** (III) are the primary source of innervation for four of the extra-ocular muscles. *(Figure 14–21)*

15. The **trochlear nerves** (IV), the smallest cranial nerves, innervate the superior oblique muscles of the eyes. *(Figure 14–21)*

16. The **trigeminal nerves** (V), the largest cranial nerves, are mixed nerves with *ophthalmic*, *maxillary*, and *mandibular branches*. *(Figure 14–22)*

17. The **abducens nerves** (VI) innervate the lateral rectus muscles. *(Figure 14–21)*

18. The **facial nerves** (VII) are mixed nerves that control muscles of the scalp and face. They provide pressure sensations over the face and receive taste information from the tongue. *(Figure 14–23)*

19. The **vestibulocochlear nerves** (VIII) contain the **vestibular branch**, which monitors sensations of balance, position, and movement, and the **cochlear branch**, which monitors hearing receptors. *(Figure 14–24)*

20. The **glossopharyngeal nerves** (IX) are mixed nerves that innervate the tongue and pharynx and control the action of swallowing.

(Figure 14–25)

21. The **vagus nerves** (X) are mixed nerves that are vital to the autonomic control of visceral function. *(Figure 14–26)*

22. The **accessory nerves** (XI) have **internal branches**, which innervate voluntary swallowing muscles of the soft palate and pharynx, and **external branches**, which control muscles associated with the pectoral girdle. *(Figure 14–27)*

23. The **hypoglossal nerves** (XII) provide voluntary motor control over tongue movements. *(Figure 14–27)*

24. The branches and functions of the cranial nerves are summarized in *Summary Table 14–9*.

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The term *higher brain centers* refers to nuclei, centers, and cortical areas of the

(a) cerebrum **(b)** cerebellum

(c) diencephalon **(d)** all of the above

(e) a and c only

2. Which of the following is the site of cerebrospinal fluid production?

(a) dural sinus **(b)** choroid plexus

(c) falx cerebri **(d)** tentorium cerebelli

(e) insula

3. The pons contains

(a) sensory and motor nuclei for six cranial nerves

(b) nuclei concerned with control of blood pressure

(c) tracts that link the cerebellum with the brain stem

(d) no ascending or descending tracts

(e) both a and b

4. The dural fold that divides the two cerebellar hemispheres is the

(a) transverse sinus **(b)** falx cerebri

(c) tentorium cerebelli **(d)** falx cerebelli

5. Cerebrospinal fluid is produced and secreted in the

(a) hypothalamus **(b)** choroid plexus

(c) medulla oblongata **(d)** crista galli

6. The primary purpose of the blood–brain barrier is to

(a) provide the brain with oxygenated blood

(b) drain venous blood via the internal jugular veins

(c) isolate neural tissue in the CNS from the general circulation

(d) *a*, *b*, and *c* are correct

7. The centers in the pons that modify the activity of the respiratory rhythmicity centers in the medulla oblongata are the

(a) apneustic and pneumotaxic centers

(b) inferior and superior peduncles

(c) cardiac and vasomotor centers

(d) nucleus gracilis and nucleus cuneatus

8. The final relay point for ascending sensory information that will be projected to the primary sensory cortex is the

(a) hypothalamus **(b)** thalamus

(c) spinal cord **(d)** medulla oblongata

9. The establishment of emotional states is a function of the

(a) limbic system **(b)** tectum

(c) mamillary bodies **(d)** thalamus

10. Coordination of learned movement patterns at the subconscious level is performed by

(a) the cerebellum **(b)** the substantia nigra

(c) association fibers **(d)** the hypothalamus

11. The two cerebral hemispheres are functionally different, even though anatomically they appear the same.

(a) true **(b)** false

12. What are the three important functions of the CSF?

13. Which three areas in the brain are not isolated from the general circulation by the blood–brain barrier?

14. Using the mnemonic device “Oh, Once One Takes The Anatomy Final, Very Good Vacations Are Heavenly,” list the 12 pairs of cranial nerves and their functions.

LEVEL 2 Reviewing Concepts

15. Why can the brain respond to stimuli with greater versatility than the spinal cord?

16. Briefly summarize the overall function of the cerebellum.

17. The only cranial nerves that are attached to the cerebrum are the _____ nerves.

(a) optic **(b)** oculomotor

(c) trochlear **(d)** olfactory

(e) abducens

18. If symptoms characteristic of Parkinson's disease appear, which part of the mesencephalon is inhibited from secreting a neurotransmitter? Which neurotransmitter is it?

19. What role does the hypothalamus play in the body?

20. Stimulation of which part of the brain would produce sensations of hunger and thirst?

21. Which structure in the brain would your A & P instructor be referring to when talking about a nucleus that resembles a sea horse and that appears to be important in the storage and retrieval of long-term memories? In which functional system of the brain is it located?

22. What are the principal functional differences between the right and left hemispheres of the cerebrum?

23. Damage to the vestibular nucleus would lead to

(a) loss of sight

(b) loss of hearing

(c) inability to sense pain

(d) difficulty in maintaining balance

(e) inability to swallow

24. A cerebrovascular accident occurs when

(a) the reticular activating system fails to function

(b) the prefrontal lobe is damaged

(c) the blood supply to a portion of the brain is cut off

(d) a descending tract in the spinal cord is severed

(e) brain stem nuclei hypersecrete serotonin

25. What kinds of problems are associated with the presence of lesions in Wernicke's area and Broca's area?

LEVEL 3 Critical Thinking and Clinical Applications

26. Smelling salts can sometimes help restore consciousness after a person has fainted. The active ingredient of smelling salts is ammonia, and it acts by irritating the lining of the nasal cavity. Propose a mechanism by which smelling salts would raise a person from the unconscious state to the conscious state.

27. A police officer has just stopped Bill on suspicion of driving while intoxicated. The officer asks Bill to walk the yellow line on the road and then to place the tip of his index finger on the tip of his nose. How would these activities indicate Bill's level of sobriety? Which part of the brain is being tested by these activities?

28. Colleen falls down a flight of stairs and in process bumps her head several times. Shortly after her fall the stars to experience headaches and blurred vision. Diagnostic tests at the hospital reveal an epidural hematoma in the temporoparietal area that is expanding downward to press against the brain stem. What further symptoms would you expect to observe from this injury?

29. Meningitis is a condition in which the meninges of the brain become inflamed as the result of viral or bacterial infection. This condition can be life threatening. Why?

30. Infants have little to no control of the movements of their head. One of the consequences of this is that they are susceptible to shaken-baby syndrome. Shaken-baby syndrome is caused by vigorous shaking of an infant or young child by the arms, legs, chest, or shoulders. Forceful shaking can cause brain damage leading to mental retardation, speech and learning disabilities, paralysis, seizures, hearing loss, and even death. What areas of the brain might be affected in this syndrome, resulting in each of these symptoms?

[1] Some sources consider the brain stem to include the diencephalon. We will use the more restrictive definition here.

Clinical Note

Aphasia and Dyslexia

Aphasia (*a*-, without + *phasia*, speech) is a disorder affecting the ability to speak or read. *Global aphasia* results from extensive damage to the general interpretive area or to the associated sensory tracts. Affected individuals are unable to speak, to read, or to understand the speech of others. Global aphasia often accompanies a severe stroke or tumor that affects a large area of cortex, including the speech and language areas. Recovery is possible when the condition results from edema or hemorrhage, but the process often takes months or even years. AM: Aphasia

Dyslexia (*dys*-, difficult, faulty + *lexis*, diction) is a disorder affecting the comprehension and use of written words. *Developmental dyslexia* affects children; estimates indicate that up to 15 percent of children in the United States have some degree of dyslexia. Children with dyslexia have difficulty reading and writing, although their other intellectual functions may be normal or above normal. Their writing looks uneven and disorganized; letters are typically written in the wrong order (dig becomes *gid*) or reversed (*E* becomes). Recent evi-

E

dence suggests that at least some forms of dyslexia result from problems in processing, sorting, and integrating visual or auditory information.

Cranial Nerves

Cranial nerves are PNS components that connect directly to the brain. The twelve pairs of cranial nerves are visible on the ventrolateral surface of the brain stem (Figure 14–18•); each has a name related to its appearance or its appearance or function.

The number assigned to a cranial nerve roughly corresponds to the nerve’s position along the longitudinal axis of the brain, beginning at the cerebrum. Roman numerals are usually used. (You may sometimes encounter these numerals preceded by the prefix N or CN.)

Each cranial nerve attaches to the brain near the associated sensory or motor nuclei. The sensory nuclei act as switching centers, with the postsynaptic neurons relaying the information to other nuclei or to processing centers in the cerebral or cerebellar cortex. In a similar fashion, the motor nuclei receive convergent inputs from higher centers or from other nuclei along the brain stem.

In this section, we classify cranial nerves as primarily sensory, special sensory, motor, or mixed (sensory and motor). In this classification, sensory nerves carry somatic sensory information, including touch, pressure, vibration, temperature, or pain. Special sensory nerves carry the sensations of smell, sight, hearing, or balance. Motor nerves are dominated by the axons of somatic motor neurons; mixed nerves have a mixture of sensory and motor fibers. This is a useful classification scheme, but it is based on the primary function, and a cranial nerve can have important secondary functions. Three examples are worth noting:

1. The olfactory receptors, the visual receptors, and the receptors of the inner ear are innervated by cranial nerves that are dedicated almost entirely to carrying special sensory information. The sensation of taste, considered to be one of the special senses, is carried by axons that form only a small part of large cranial nerves that have other primary functions.

2. As elsewhere in the PNS, a nerve containing tens of thousands of motor fibers that lead to a skeletal muscle will also contain sensory fibers from muscle spindles and tendon organs in that muscle. We assume that these sensory fibers are present but ignore them in the classification of the nerve.

3. Regardless of their other functions, several cranial nerves (III, VII, IX, and X) distribute autonomic fibers to peripheral ganglia, just as spinal nerves deliver them to ganglia along the spinal cord. We will note the presence of small numbers of autonomic fibers (and will discuss them further in Chapter 16) but ignore them in the classification of the nerve.

The Olfactory Nerves (I)

Primary function: Special sensory (smell)

Origin: Receptors of olfactory epithelium

Pass through: Olfactory foramina in cribriform plate of ethmoid l**pp. 211, 216**

Destination: Olfactory bulbs

The first pair of cranial nerves (Figure 14–19•) carries special sensory information responsible for the sense of smell. The olfactory receptors are specialized neurons in the epithelium covering the roof of the nasal cavity, the superior nasal conchae, and the superior parts of the nasal septum. Axons from these sensory neurons collect to form 20 or more bundles that penetrate the cribriform plate of the ethmoid bone. These bundles are components of the **olfactory nerves** (I). Almost at once these bundles enter the **olfactory bulbs**, neural masses on either side of the crista galli. The olfactory afferents synapse within the olfactory bulbs. The axons of the postsynaptic neurons proceed to the cerebrum along the slender **olfactory tracts** (see Figures 14–18 and 14–19•).

Because the olfactory tracts look like typical peripheral nerves, anatomists about a century ago misidentified these tracts as the first cranial nerve. Later studies demonstrated that the olfactory tracts and bulbs are part of the cerebrum, but by then the numbering system was already firmly established. Anatomists were left with a forest of tiny olfactory nerve bundles lumped together as nerve I.

The olfactory nerves are the only cranial nerves attached directly to the cerebrum. The rest originate or terminate within nuclei of the diencephalon or brain stem, and the ascending sensory information synapses in the thalamus before reaching the cerebrum.

The Optic Nerves (II)

Primary function: Special sensory (vision)

Origin: Retina of eye

Pass through: Optic canals of sphenoid l**p. 215**

Destination: Diencephalon via the optic chiasm

The **optic nerves** (II) carry visual information from special sensory ganglia in the eyes. These nerves (Figure 14–20•) contain about 1 million sensory nerve fibers. The optic nerves pass through the optic canals of the sphenoid. Then they converge at the ventral, anterior margin of the diencephalon, at the **optic chiasm** (*chiasma*, a crossing). At the optic chiasm, fibers from the nasal half of each retina cross over to the opposite side of the brain.

The reorganized axons continue toward the lateral geniculate nuclei of the thalamus as the **optic tracts** (see Figures 14–18 and 14–20•). After synapsing in the lateral geniculates, projection fibers deliver the information to the visual cortex of the occipital lobe. With this arrangement, each cerebral hemisphere receives visual information from the lateral half of the retina of the eye on that side and from the medial half of the retina of the eye of the opposite side (Figure 14–16•, p. 477). Relatively few axons in the optic tracts bypass the lateral geniculate nuclei and synapse in the superior colliculus of the midbrain. We will consider that pathway in Chapter 17.

The Oculomotor Nerves (III)

Primary function: Motor (eye movements)

Origin: Mesencephalon

Pass through: Superior orbital fissures of sphenoid l**pp. 210, 215, 218, 220**

Destination: Somatic motor: superior, inferior, and medial rectus muscles; inferior oblique muscle; levator palpebrae superioris muscle. *Visceral motor*: intrinsic eye muscles

The mesencephalon contains the motor nuclei controlling the third and fourth cranial nerves. Each **oculomotor nerve** (III) innervates four of the six extra-ocular muscles that move the eye, and the levator palpebrae superioris muscle, which raises the upper eyelid (Figure 14–21•). On each side of the brain, nerve III emerges from the ventral surface of the mesencephalon and penetrates the posterior wall of the orbit at the superior orbital fissure. Individuals with damage to this nerve often complain of pain over the eye and double vision, because the movements of the left and right eyes cannot be coordinated properly.

The oculomotor nerve also delivers preganglionic autonomic fibers to neurons of the **ciliary ganglion**. The neurons of the ciliary ganglion control intrinsic eye muscles. These muscles change the diameter of the pupil, adjusting the amount of light entering the eye, and change the shape of the lens to focus images on the retina.

The Trochlear Nerves (IV)

Primary function: Motor (eye movements)

Origin: Mesencephalon

Pass through: Superior orbital fissures of sphenoid l**pp. 210, 215, 218, 220**

Destination: Superior oblique muscle

A **trochlear** (TR

¯O

K-l

¯e

-ar; *trochlea*, a pulley) **nerve** (IV), the smallest cranial nerve, innervates the superior oblique muscle of each eye (see

Figure 14–21•). The trochlea is a pulley-shaped, ligamentous sling. Each superior oblique muscle passes through a trochlea on its way to its insertion on the surface of the eye. An individual with damage to nerve IV or to its nucleus will have difficulty looking down and to the side.

The Abducens Nerves (VI)

Primary function: Motor (eye movements)

Origin: Pons

Pass through: Superior orbital fissures of sphenoid l**pp. 210, 215, 218, 220**

Destination: Lateral rectus muscle

The **abducens** (ab-D

¯U

-senz) **nerves** (VI) innervate the lateral rectus muscles, the sixth pair of extra-ocular muscles. Contraction of the lateral rectus muscle makes the eye look to the side; in essence, the *abducens* causes *abduction* of the eye. Each abducens nerve emerges from the inferior surface of the brain stem at the border between the pons and the medulla oblongata (see Figure 14–21•). Along with the oculomotor and trochlear nerves from that side, it reaches the orbit through the superior orbital fissure.

The Trigeminal Nerves (V)

Primary function: Mixed (sensory and motor) to face *Origin: Ophthalmic branch* (sensory): orbital structures, nasal cavity, skin of forehead, upper eyelid, eyebrow, nose (part). *Maxillary branch* (sensory): lower eyelid, upper lip, gums, and teeth; cheek; nose, palate, and pharynx (part). *Mandibular branch* (mixed): sensory from lower gums, teeth, and lips; palate and tongue (part); motor from motor nuclei of pons *Pass through (on each side):* Ophthalmic branch through superior orbital fissure, maxillary branch through foramen rotundum, mandibular branch through foramen ovale l**pp. 210, 211, 215, 220** *Destination:* Ophthalmic, maxillary and mandibular branches to sensory nuclei in pons; mandibular branch also innervates muscles of mastication l**p. 340**

The pons contains the nuclei associated with three cranial nerves (V, VI, and VII) and contributes to a fourth (VIII). The **trigeminal** (tr ¯ı -JEM-i-nal) **nerves** (V), the largest cranial nerves, are mixed nerves. Each provides both somatic sensory information from the head and face, and motor control over the muscles of mastication. Sensory (dorsal) and motor (ventral) roots originate on the lateral surface of the pons (Figure 14–22•). The sensory branch is larger, and the enormous **semilunar ganglion** contains the cell bodies of the sensory neurons. As the name implies, the trigeminal has three major branches; the relatively small motor root contributes to only one of the three. **Tic douloureux** (doo-loo-RUH; *douloureux*, painful) is a painful condition affecting the area innervated by the maxillary and mandibular branches of the trigeminal nerve. Sufferers complain of debilitating pain triggered by contact with the lip, tongue, or gums. The cause of the condition is unknown. AM: Tic Douloureux

The trigeminal nerve branches are associated with the *ciliary*, *sphenopalatine*, *submandibular*, and *otic ganglia*. These are autonomic (parasympathetic) ganglia whose neurons innervate structures of the face. However, although its nerve fibers may pass around or through these ganglia, the trigeminal nerve does not contain visceral motor fibers. We discussed the ciliary ganglion on page 000 and will describe the other ganglia next, with the branches of the *facial nerves* (VII) and the *glossopharyngeal nerves* (IX).

The Facial Nerves (VII)

Primary function: Mixed (sensory and motor) to face *Origin: Sensory*: taste receptors on anterior two thirds of tongue. *Motor*: motor nuclei of pons *Pass through:* Internal acoustic canals to the *facial canals*, which end at the stylomastoid foramina l**pp. 210, 211, 214** *Destination: Sensory*: sensory nuclei of pons. *Somatic motor*: muscles of facial expression. l**p. 336** *Visceral motor*: lacrimal (tear) gland

and nasal mucous glands by way of the pterygopalatine ganglion; submandibular and sublingual salivary glands by way of the submandibular ganglion

The **facial nerves** (VII) are mixed nerves. The cell bodies of the sensory neurons are located in the **geniculate ganglia**, and the motor nuclei are in the pons. On each side, the sensory and motor roots emerge from the pons and enter the internal acoustic canal of the temporal bone. Each facial nerve then passes through the facial canal to reach the face by way of the stylomastoid foramen. The nerve then splits to form the temporal, zygomatic, buccal, mandibular, and cervical branches (Figure 14–23•).

The sensory neurons monitor proprioceptors in the facial muscles, provide deep pressure sensations over the face, and receive taste information from receptors along the anterior two-thirds of the tongue. Somatic motor fibers control the superficial muscles of the scalp and face and deep muscles near the ear.

The facial nerves carry preganglionic autonomic fibers to the pterygopalatine and submandibular ganglia. Postganglionic fibers from the **pterygopalatine ganglia** innervate the lacrimal glands and small glands of the nasal cavity and pharynx. The **submandibular ganglia** innervate the *submandibular* and *sublingual* (*sub-*, under, + *lingual*, pertaining to the tongue) *salivary glands*.

Bell's palsy is a cranial nerve disorder that results from an inflammation of a facial nerve. The condition is probably due to a viral infection. Symptoms include paralysis of facial muscles on the affected side and loss of taste sensations from the anterior two-thirds of the tongue. The condition is usually painless and in most cases the symptons fade after a few weeks or months.

The Vestibulocochlear Nerves (VIII)

Primary function: Special sensory: balance and equilibrium (vestibular branch) and hearing (cochlear branch)

Origin: Monitor receptors of the inner ear (vestibule and cochlea)

Pass through: Internal acoustic canals of temporal bones l**pp. 211, 214**

Destination: Vestibular and cochlear nuclei of pons and medulla oblongata

The **vestibulocochlear nerves** (VIII) are also known as the *acoustic nerves*, the *auditory nerves*, and the *stato-acoustic nerves*. We will use *vestibulocochlear*, because this term indicates the names of the two major branches: the vestibular branch and the cochlear branch. Each vestibulocochlear nerve lies posterior to the origin of the facial nerve, straddling the boundary between the pons and the medulla oblongata (Figure 14–24•). This nerve reaches the sensory receptors of the inner ear by entering the internal acoustic canal in company with the facial nerve. Each vestibulocochlear nerve has two distinct bundles of sensory fibers. The **vestibular branch** (*vestibulum*, cavity) originates at the receptors of the *vestibule*, the portion of the inner ear concerned with balance sensations. The sensory neurons are located in an adjacent sensory ganglion, and their axons target the **vestibular nuclei** of the pons and medulla oblongata. These afferents convey information about the orientation and movement of the head. The **cochlear branch** (*cochlea*, snail shell) monitors the receptors in the *cochlea*, the portion of the inner ear that provides the sense of hearing. The cell bodies of the sensory neurons are located within a peripheral ganglion (the *spiral* *ganglion*), and their axons synapse within the **cochlear nuclei** of the pons and medulla oblongata. Axons leaving the vestibular and cochlear nuclei relay the sensory information to other centers or initiate reflexive motor responses. We will discuss balance and the sense of hearing in Chapter 17.

The Glossopharyngeal Nerves (IX)

Primary function: Mixed (sensory and motor) to head and neck *Origin: Sensory*: posterior one-third of the tongue, part of the pharynx and palate, carotid arteries of the neck. *Motor*: motor nuclei of medulla ob

longata *Pass through:* Jugular foramina between the occipital bone and the temporal bones l**pp. 210, 211** *Destination: Sensory*: sensory nuclei of medulla oblongata. *Somatic motor*: pharyngeal muscles involved in swallowing. *Visceral motor*: parotid

salivary gland by way of the otic ganglion

The medulla oblongata contains the sensory and motor nuclei of cranial nerves IX, X, XI, and XII, in addition to the vestibular nucleus of nerve VIII.

The **glossopharyngeal** (glos-

¯o

-fah-RIN-j

¯e

-al; *glossum*, tongue) **nerves** (IX) innervate the tongue and pharynx. Each glossopharyngeal nerve pen

etrates the cranium within the jugular foramen, with nerves X and XI.

The glossopharyngeal nerves are mixed nerves, but sensory fibers are most abundant. The sensory neurons on each side are in the **superior** (*jugular*) **ganglion** and **inferior** (*petrosal*) **ganglion** (Figure 14–25•). The sensory fibers carry general sensory information from the lining of the pharynx and the soft palate to a nucleus in the medulla oblongata. These nerves also provide taste sensations from the posterior third of the tongue and have special receptors that monitor the blood pressure and dissolved gas concentrations in major blood vessels.

The somatic motor fibers control the pharyngeal muscles involved in swallowing. Visceral motor fibers synapse in the **otic ganglion**, and postganglionic fibers innervate the parotid salivary gland of the cheek.

The Vagus Nerves (X)

Primary function: Mixed (sensory and motor), widely distributed in the thorax and abdomen

Origin: Sensory: pharynx (part), auricle and external acoustic canal, diaphragm, and visceral organs in thoracic and abdominopelvic cavities. *Motor*: motor nuclei in medulla oblongata *Pass through:* Jugular foramina between the occipital bone and the temporal bones l**pp. 210, 211** *Destination: Sensory*: sensory nuclei and autonomic centers of medulla oblongata. *Visceral motor*: muscles of the palate, pharynx, digestive,

respiratory, and cardiovascular systems in the thoracic and abdominal cavities

The **vagus** (V

¯A

-gus) **nerves** (X) arise immediately posterior to the attachment of the glossopharyngeal nerves. Many small rootlets contribute

to their formation, and developmental studies indicate that these nerves probably represent the fusion of several smaller cranial nerves during our evolutionary history. As the name suggests (*vagus*, wanderer), the vagus nerves branch and radiate extensively. Figure 14–26• shows only the general pattern of distribution.

Sensory neurons are located in the superior **jugular ganglion** and the inferior **nodose** (N

¯O

-d

¯o

s) **ganglion** (*node*, knot). Each vagus nerve provides somatic sensory information about the external acoustic canal (a portion of the external ear) and the diaphragm, and special sensory information from pharyngeal taste receptors. But most of the vagal afferents carry visceral sensory information from receptors along the esophagus, respiratory tract, and abdominal viscera as distant as the last portions of the large intestine. This visceral sensory information is vital to the autonomic control of visceral function.

The motor components of the vagus are equally diverse. Each vagus nerve carries preganglionic autonomic (parasympathetic) fibers that affect the heart and control smooth muscles and glands within the areas monitored by its sensory fibers, including the stomach, intestines, and gallbladder. Difficulty in swallowing is one of the most common signs of damage to either nerve IX or X, because damage to either one prevents the coordination of the swallowing reflex.

The Accessory Nerves (XI)

Primary function: Motor to muscles of the neck and upper back *Origin:* Motor nuclei of spinal cord and medulla oblongata *Pass through:* Jugular foramina between the occipital bone and the temporal bones l**pp. 210, 211** *Destination:* Internal branch innervates voluntary muscles of palate, pharynx, and larynx; external branch controls sternocleidomastoid and
trapezius muscles

The **accessory nerves** (XI) are also known as the *spinal accessory nerves* or the *spinoaccessory nerves*. Unlike other cranial nerves, each accessory nerve has some motor fibers that originate in the lateral part of the anterior gray horns of the first five cervical segments of the spinal cord (Figure 14–27•). These somatic motor fibers form the **spinal root** of nerve XI. They enter the cranium through the foramen magnum. They then join the motor fibers of the **cranial root**, which originates at a nucleus in the medulla oblongata. The composite nerve leaves the cranium through the jugular foramen and divides into two branches.

The **internal branch** of nerve XI joins the vagus nerve and innervates the voluntary swallowing muscles of the soft palate and pharynx and the intrinsic muscles that control the vocal cords. The **external branch** of nerve XI controls the sternocleidomastoid and trapezius muscles of the neck and back. l**pp. 342, 353** The motor fibers of this branch originate in the lateral gray part of the anterior horns of cervical spinal nerves C1 to C5.

The Hypoglossal Nerves (XII)

Primary function: Motor (tongue movements)

Origin: Motor nuclei of medulla oblongata

Pass through: Hypoglossal canals of occipital bone l**pp. 210, 211, 212**

Destination: Muscles of the tongue l**p. 341**

Each **hypoglossal** (h ¯ı -p o¯-GLOS-al) **nerve** (XII) leaves the cranium through the hypoglossal canal. The nerve then curves to reach the skeletal muscles of the tongue (see Figure 14–27•). This cranial nerve provides voluntary motor control over movements of the tongue. Its condition is checked by having you stick out your tongue. Damage to one hypoglossal nerve or to its associated nuclei causes the tongue to veer toward the affected side. Table 14–9 summarizes the basic distribution and function of each cranial nerve.

Cranial nerves are clinically important, in part because they can provide clues to underlying CNS problems. As a result, a number of standardized tests for cranial nerve function are used. AM: Cranial Nerve Tests

An Overview of Sensory Pathways and the Somatic Nervous System

Objective

- Specify the components of the afferent and efferent divisions of the nervous system and explain what is meant by the somatic nervous system.

The left-hand portion of Figure 15–1• provides an overview of the topics we will cover in this chapter. Our discussion will focus on the“ general senses” that provide information about the body and its environment. The “special senses”—smell, taste, sight, and hearing—will be considered in Chapter 17.

Specialized cells called *sensory receptors* monitor specific conditions in the body or the external environment. When stimulated, a receptor passes information to the CNS in the form of action potentials along the axon of a sensory neuron. Such axons are parts of *sensory pathways*—the nerves, nuclei, and tracts that deliver somatic and visceral sensory information to their final destinations inside the CNS. Taken together, the receptors, sensory neurons and sensory pathways constitute the afferent division
of the nervous system. l**p. 380**

Somatic and visceral sensory information often travel along the same pathway. Somatic sensory information is distributed to *sensory processing centers in the brain*—either the primary sensory cortex of the cerebral hemispheres or appropriate areas of the cerebellar hemispheres. Visceral sensory information is distributed primarily to reflex centers in the brain stem and diencephalon.

In this chapter we consider the somatic motor portion of the efferent division—the nuclei, motor tracts, and motor neurons that control peripheral effectors. Somatic motor commands—whether they arise at the conscious or subconscious levels—travel from motor centers in the brain along *somatic motor pathways*, which consist of motor nuclei, tracts, and nerves. The motor neurons and pathways that control skeletal muscles form the somatic nervous system (SNS).

Chapter 16 begins with a discussion of the visceral motor portion of the efferent division. All visceral motor commands are carried into the PNS by the autonomic nervous system (ANS). Both somatic and visceral motor commands may be issued in response to arriving sensory information, but these commands may be modified on the basis of planning, memories, and learning— the so-called *higher-order functions* of the brain that we will consider at the close of Chapter 16.

Sensory Receptors and Their Classification

Objectives

- Explain why receptors respond to specific stimuli, and how the organization of a receptor affects its sensitivity.
- Identify the receptors for the general senses, and describe how they function.

Sensory receptors are specialized cells or cell processes that provide your central nervous system with information about conditions inside or outside the body. The term **general senses** is used to describe our sensitivity to temperature, pain, touch, pressure, vibration, and proprioception. General sensory receptors are distributed throughout the body, and they are relatively simple in structure. Some of the information they send to the CNS reaches the primary sensory cortex and our awareness. As noted in Chapter 12, sensory information is interpreted on the basis of the frequency of arriving action potentials. l**p. 415** For example, when pressure sensations are arriving, the harder the pressure, the higher the frequency of action potentials. The arriving information is called a **sensation**. The conscious awareness of a sensation is called a **perception**.

The **special senses** are **olfaction** (smell), **vision** (sight), **gustation** (taste), **equilibrium** (balance), and **hearing**. These sensations are provided by receptors that are structurally more complex than those of the general senses. Special sensory receptors are located in **sense organs** such as the eye or ear, where the receptors are protected by surrounding tissues. The information these receptors provide is distributed to specific areas of the cerebral cortex (the auditory cortex, the visual cortex, and so forth) and to centers throughout the brain stem. We will consider the special senses in Chapter 17. AM: Analyzing Sensory Disorders

Sensory Receptors

Sensory receptors represent the interface between the nervous system and the internal and external environments. A sensory receptor detects an arriving stimulus and translates it into an action potential that can be conducted to the CNS. This translation process is called *transduction*. If transduction does not occur, as far as you are concerned, the stimulus doesn't exist. For example, bees can see ultraviolet light you can't see, and dogs can respond to sounds you can't hear. In each case the stimuli are there—but your receptors cannot detect them. AM: Transduction: A Closer Look

The Detection of Stimuli

Each receptor has a characteristic sensitivity. For example, a touch receptor is very sensitive to pressure but relatively insensitive to chemical stimuli, whereas a taste receptor is sensitive to dissolved chemicals but insensitive to pressure. This feature is called *receptor specificity*.

Specificity may result from the structure of the receptor cell, or from the presence of accessory cells or structures that shield the receptor cell from other stimuli. The simplest receptors are the dendrites of sensory neurons. The branching tips of these dendrites, called **free nerve endings**, are not protected by accessory structures. Free nerve endings extend through a tissue the way grass roots extend into the soil. They can be stimulated by many different stimuli and therefore exhibit little receptor specificity. For example, free nerve endings that respond to tissue damage by providing pain sensations may be stimulated by chemical stimulation, pressure, temperature changes, or trauma. Complex receptors, such as the eye's visual receptors, are protected by accessory cells and connective tissue layers. These cells are seldom exposed to any stimulus other than light and so provide very specific information.

The area monitored by a single receptor cell is its *receptive field* (Figure 15–2•). Whenever a sufficiently strong stimulus arrives in the receptive field, the CNS receives the information "stimulus arriving at receptor X." The larger the receptive field, the poorer your ability to localize a stimulus. A touch receptor on the general body surface, for example, may have a receptive field 7 cm (2.5 in.) in diameter. As a result, you can describe a light touch there as affecting only a general area, not an exact spot. On the tongue or fingertips, where the receptive fields are less than a millimeter in diameter, you can be very precise about the location of a stimulus.

An arriving stimulus can take many forms. It may be a physical force (such as pressure), a dissolved chemical, a sound, or light. Regardless of the nature of the stimulus, however, sensory information must be sent to the CNS in the form of action potentials, which are electrical events.

As noted earlier, transduction is the translation of an arriving stimulus into an action potential by a sensory receptor. Transduction begins when a stimulus changes the transmembrane potential of the receptor cell. This change, called a *receptor potential*, is either a graded depolarization or a graded hyperpolarization. The stronger the stimulus, the larger the receptor potential.

The typical receptors for the general senses are the dendrites of sensory neurons, and the sensory neuron is the receptor cell. Any receptor potential that depolarizes the cell membrane will bring the membrane closer to threshold. A receptor potential large enough to produce an action potential is called a *generator potential*.

Sensations of taste, hearing, equilibrium, and vision are provided by specialized receptor cells that communicate with sensory neurons across chemical synapses. The receptor cells develop graded receptor potentials in response to stimulation, and the change in membrane potential alters the rate of neurotransmitter release at the synapse. The result is a depolarization or hyperpolarization of the sensory neuron. If sufficient depolarization occurs, an action potential appears in the sensory neuron. In this case, the receptor potential and the generator potential occur in different cells: The receptor potential develops in the receptor cell, and the generator potential appears later, in the sensory neuron.

Whenever a generator potential appears, action potentials develop in the axon of a sensory neuron. For reasons discussed in

Chapter 12, the greater the degree of sustained depolarization at the axon hillock, the higher the frequency of action potentials in the afferent fiber. l**p. 415** The arriving information is then processed and interpreted by the CNS at the conscious and subconscious levels.

The Interpretation of Sensory Information

Sensory information that arrives at the CNS is routed according to the location and nature of the stimulus. Previous chapters emphasized the fact that axons in the CNS are organized in bundles with specific origins and destinations. Along sensory pathways, a series of neurons relays information from one point (the receptor) to another (a neuron at a specific site in the cerebral cortex). For example, sensations of touch, pressure, pain, and temperature arrive at the primary sensory cortex; visual, auditory, gustatory, and olfactory sensations reach the visual, auditory, gustatory, and olfactory regions of the cortex, respectively.

The link between peripheral receptor and cortical neuron is called a *labeled line*. Each labeled line consists of axons carrying information about one modality, or type of stimulus (touch, pressure, light, sound, and so forth). The CNS interprets the modality entirely on the basis of the labeled line over which it arrives. As a result, you cannot tell the difference between a true sensation and a false one generated somewhere along the line. For example, when you rub your eyes, you commonly see flashes of light. Although the stimulus is mechanical rather than visual, any activity along the optic nerve is projected to the visual cortex and experienced as a visual perception.

The identity of the active labeled line indicates the type of stimulus. Where it arrives within the sensory cortex determines its perceived location. For example, if activity in a labeled line that carries touch sensations stimulates the facial region of your primary sensory cortex, you perceive a touch on the face. All other characteristics of the stimulus—its strength, duration, and variation—are conveyed by the frequency and pattern of action potentials. The translation of complex sensory information into meaningful patterns of action potentials is called *sensory coding*.

Some sensory neurons, called **tonic receptors**, are always active. The frequency with which these receptors generate action potentials indicates the background level of stimulation. When the stimulus increases or decreases, the rate of action potential generation changes accordingly. Other receptors are normally inactive, but become active for a short time whenever a change occurs in the conditions they are monitoring. These receptors, called **phasic receptors**, provide information about the intensity and rate of change of a stimulus. Receptors that combine phasic and tonic coding can convey extremely complicated sensory information.

Adaptation

Adaptation is a reduction in sensitivity in the presence of a constant stimulus. You seldom notice the rumble of the tires when you ride in a car, or the background noise of the air conditioner, because your nervous system quickly adapts to stimuli that are painless and constant. *Peripheral adaptation* occurs when the level of receptor activity changes. The receptor responds strongly at first, but thereafter its activity gradually declines, in part because the size of the generator potential gradually decreases. This response is characteristic of phasic receptors, which are hence also called **fast-adapting receptors**. Temperature receptors (*thermoreceptors*) are phasic receptors; you seldom notice room temperature unless it changes suddenly. Tonic receptors show little peripheral adaptation and so are called **slow-adapting receptors**. Pain receptors (*nociceptors*) are slow-adapting receptors, which is one reason why pain sensations remind you of an injury long after the initial damage has occurred.

Adaptation also occurs along sensory pathways inside the CNS. For example, a few seconds after you have been exposed to a new smell, awareness of the stimulus virtually disappears, although the sensory neurons are still quite active. This process is known as *central adaptation*. Central adaptation generally involves the inhibition of nuclei along a sensory pathway.

Peripheral adaptation reduces the amount of information that reaches the CNS. Central adaptation at the subconscious level further restricts the amount of detail that arrives at the cerebral cortex. Most of the incoming sensory information is processed in centers along the spinal cord or brain stem at the subconscious level. Although this processing can produce reflexive motor responses, we are seldom consciously aware of either the stimuli or the responses.

The output from higher centers can increase receptor sensitivity or facilitate transmission along a sensory pathway. The reticular activating system in the mesencephalon helps focus our attention and thus heightens or reduces our awareness of arriving sensations. l**p. 464** This adjustment of sensitivity can occur under conscious or subconscious direction. When you “listen carefully,” your sensitivity and awareness of auditory stimuli increase. Output from higher centers can also inhibit transmission along a sensory pathway. Such inhibition occurs when you enter a noisy factory or walk along a crowded city street, as you automatically tune out the high level of background noise.

Now that we have examined the basic concepts of receptor function and sensory processing, we consider how those concepts apply to the general senses.

100 Keys | Stimulation of a receptor produces action potentials along the axon of a sensory neuron. The frequency or

pattern of action potentials contains information about the strength, duration, and variation of the stimulus. Your percep

tion of the nature of that stimulus depends on the path it takes inside the CNS.

The General Senses

Receptors for the general senses are scattered throughout the body and are relatively simple in structure. The simple classification scheme introduced in Chapter 12 divides them into exteroceptors, proprioceptors, and interoceptors. l**p. 384** *Exteroceptors* provide information about the external environment; *proprioceptors* report the positions of skeletal muscles and joints; *interoceptors* monitor visceral organs and functions.

A more detailed classification system divides the general sensory receptors into four types by the nature of the stimulus that excites them: *nociceptors* (pain), *thermoreceptors* (temperature), *mechanoreceptors* (physical distortion), and *chemoreceptors* (chemical concentration). Each class of receptors has distinct structural and functional characteristics. The difference between a somatic receptor and a visceral receptor is its location, not its structure. A pain receptor in the gut looks and acts like a pain receptor in the skin, but the two sensations are delivered to separate locations in the CNS. However, proprioception is a purely somatic sensation— there are no proprioceptors in the visceral organs of the thoracic and abdominopelvic cavities. Your mental map of your body doesn't include these organs; you cannot tell, for example, where your spleen, appendix, or pancreas is at the moment. The visceral organs also have fewer pain, temperature, and touch receptors than one finds elsewhere in the body, and the sensory information you receive is poorly localized because the receptive fields are very large and may be widely separated.

Although general sensations are widely distributed in the CNS, most of the processing occurs in centers along the sensory pathways in the spinal cord or brain stem. Only about 1 percent of the information provided by afferent fibers reaches the cerebral cortex and our awareness. For example, we usually do not feel the clothes we wear or hear the hum of the engine when riding in a car.

Nociceptors

Pain receptors, or **nociceptors**, are especially common in the superficial portions of the skin, in joint capsules, within the periostea of bones, and around the walls of blood vessels. Other deep tissues and most visceral organs have few nociceptors. Pain receptors are free nerve endings with large receptive fields (see Figure 15–2•). As a result, it is often difficult to determine the exact source of a painful sensation.

Nociceptors may be sensitive to (1) extremes of temperature, (2) mechanical damage, and (3) dissolved chemicals, such as chemicals released by injured cells. Very strong stimuli, however, will excite all three receptor types. For that reason, people describing very painful sensations—whether caused by acids, heat, or a deep cut—use similar descriptive terms, such as "burning."

Stimulation of the dendrites of a nociceptor causes depolarization. When the initial segment of the axon reaches threshold, an action potential heads toward the CNS.

Two types of axons—Type A and Type C fibers—carry painful sensations. l**p. 404** Myelinated Type A fibers carry sensations of **fast pain**, or *prickling pain*. An injection or a deep cut produces this type of pain. These sensations very quickly reach the CNS, where they often trigger somatic reflexes. They are also relayed to the primary sensory cortex and so receive conscious attention. In most cases, the arriving information permits the stimulus to be localized to an area several inches in diameter. AM: Acute and Chronic Pain

Slower, Type C fibers carry sensations of **slow pain**, or *burning and aching pain*. These sensations cause a generalized activation of the reticular formation and thalamus. The individual becomes aware of the pain but has only a general idea of the area affected.

Pain receptors are tonic receptors. Significant peripheral adaptation does not occur, and the receptors continue to respond as long as the painful stimulus remains. Painful sensations cease only after tissue damage has ended. However, central adaptation may reduce the *perception* of the pain while pain receptors remain stimulated. This effect involves the inhibition of centers in the thalamus, reticular formation, lower brain stem, and spinal cord.

An understanding of the origins of pain sensations and an ability to control or reduce pain levels have always been among the most important aspects of medical treatment. After all, it is usually pain that induces someone to seek treatment; conditions that are not painful are typically ignored or tolerated. Although we often use the term *pain pathways*, it is becoming clear that pain distribution and perception are extremely complex—more so than had previously been imagined. AM: Pain Mechanisms, Pathways, and Control: A Closer Look

The sensory neurons that bring pain sensations into the CNS release *glutamate* and/or *substance P* as neurotransmitters. These neurotransmitters produce facilitation of neurons along the pain pathways. As a result, the level of pain experienced (especially chronic pain) can be out of proportion to the amount of painful stimuli or the apparent tissue damage. This effect may be one reason why people differ so widely in their perception of the pain associated with childbirth, headaches, or back pain. This facilitation is also presumed to play a role in phantom limb pain; the sensory neurons may be inactive, but the hyperexcitable interneurons may continue to generate pain sensations.

The level of pain felt by an individual can be reduced by the release of endorphins and enkephalins within the CNS. As noted in Chapter 12, endorphins and enkephalins are neuromodulators whose release inhibits activity along pain pathways in the brain. l**p. 409** These compounds, structurally similar to morphine, are found in the limbic system, hypothalamus, and reticular formation. The pain centers in these areas also use substance P as a neurotransmitter. Endorphins bind to the presynaptic membrane and prevent the release of substance P, thereby reducing the conscious perception of pain, although the painful stimulus remains.

Thermoreceptors

Temperature receptors, or **thermoreceptors**, are free nerve endings located in the dermis, in skeletal muscles, in the liver, and in the hypothalamus. Cold receptors are three or four times more numerous than warm receptors. No structural differences between warm and cold thermoreceptors have been identified.

Temperature sensations are conducted along the same pathways that carry pain sensations. They are sent to the reticular formation, the thalamus, and (to a lesser extent) the primary sensory cortex. Thermoreceptors are phasic receptors: They are very active when the temperature is changing, but they quickly adapt to a stable temperature. When you enter an air-conditioned classroom on a hot summer day or a warm lecture hall on a brisk fall evening, the temperature change seems extreme at first, but you quickly become comfortable as adaptation occurs.

Mechanoreceptors

Mechanoreceptors are sensitive to stimuli that distort their cell membranes. These membranes contain *mechanically regulated ion channels* whose gates open or close in response to stretching, compression, twisting, or other distortions of the membrane. There are three classes of mechanoreceptors:

1. Tactile receptors provide the closely related sensations of touch, pressure, and vibration. Touch sensations provide information about shape or texture, whereas pressure sensations indicate the degree of mechanical distortion. Vibration sensations indicate a pulsing or oscillating pressure. The receptors involved may be specialized in some way. For example, rapidly adapting tactile receptors are best suited for detecting vibration. But your interpretation of a sensation as touch rather than pressure is typically a matter of the degree of stimulation, and not of differences in the type of receptor stimulated.

2. Baroreceptors (bar-

¯o
-r
¯e
-SEP-torz; *baro*-, pressure) detect pressure changes in the walls of blood vessels and in portions of the
digestive, reproductive, and urinary tracts.

3. Proprioceptors monitor the positions of joints and muscles. They are the most structurally and functionally complex of the general sensory receptors.

Tactile Receptors **Fine touch and pressure receptors** provide detailed information about a source of stimulation, including its exact location, shape, size, texture, and movement. These receptors are extremely sensitive and have relatively narrow receptive fields. **Crude touch and pressure receptors** provide poor localization and, because they have relatively large receptive fields, give little additional information about the stimulus.

Tactile receptors range in complexity from free nerve endings to specialized sensory complexes with accessory cells and supporting structures. Figure 15–3• shows six types of tactile receptors in the skin:

1. Free nerve endings sensitive to touch and pressure are situated between epidermal cells (Figure 15–3a•). There appear to be no structural differences between these receptors and the free nerve endings that provide temperature or pain sensations. These are the only sensory receptors on the corneal surface of the eye, but in other portions of the body surface, more specialized tactile receptors are probably more important. Free nerve endings that provide touch sensations are tonic receptors with small receptive fields.

2. Wherever hairs are located, the nerve endings of the **root hair plexus** monitor distortions and movements across the body surface (Figure 15–3b•). When a hair is displaced, the movement of the follicle distorts the sensory dendrites and produces action potentials.

These receptors adapt rapidly, so they are best at detecting initial contact and subsequent movements. Thus, you generally feel your clothing only when you move or when you consciously focus on tactile sensations from the skin.

3. Tactile discs, or *Merkel's* (MER-kelz) *discs*, are fine touch and pressure receptors (Figure 15–3c•). They are extremely sensitive tonic receptors, with very small receptive fields. The dendritic processes of a single myelinated afferent fiber make close contact with unusually large epithelial cells in the stratum germinativum of the skin; these *Merkel cells* were described in Chapter 5.

l**p. 156**

4. Tactile corpuscles, or *Meissner's* (M S-nerz) *corpuscles*, perceive sensations of fine touch and pressure and low-frequency vibration. They adapt to stimulation within a second after contact. Tactile corpuscles are fairly large structures, measuring roughly 100 mm in length and 50 mm in width. These receptors are most abundant in the eyelids, lips, fingertips, nipples, and external genitalia. The dendrites are highly coiled and interwoven, and they are surrounded by modified Schwann cells. A fibrous capsule surrounds the entire complex and anchors it within the dermis (Figure 15–3d•).

¯I

5. Lamellated (LAM-e-l

t-ed; *lamella*, a little thin plate) **corpuscles**, or *pacinian* (pa-SIN--an) *corpuscles*, are sensitive to deep pressure. Because they are fast-adapting receptors, they are most sensitive to pulsing or high-frequency vibrating stimuli. A single dendrite lies within a series of concentric layers of collagen fibers and supporting cells (specialized fibroblasts) (Figure 15–3e•). The entire corpuscle may reach 4 mm in length and 1 mm in diameter. The concentric layers, separated by interstitial fluid, shield the dendrite from virtually every source of stimulation other than direct pressure. Lamellated corpuscles

¯e

adapt quickly because distortion of the capsule soon relieves pressure on the sensory process. Somatic sensory information is provided by lamellated corpuscles located throughout the dermis, notably in the fingers, mammary glands, and external genitalia; in the superficial and deep fasciae; and in joint capsules. Visceral sensory information is provided by lamellated corpuscles in mesenteries, in the pancreas, and in the walls of the urethra and urinary bladder.

¯a

6. Ruffini (roo-F

¯E

-n

¯e

) **corpuscles** are also sensitive to pressure and distortion of the skin, but they are located in the reticular
(deep) dermis. These receptors are tonic and show little if any adaptation. The capsule surrounds a core of collagen fibers that are continuous with those of the surrounding dermis (Figure 15–3f•). In the capsule, a network of dendrites is intertwined with the collagen fibers. Any tension or distortion of the dermis tugs or twists the capsular fibers, stretching or compressing the attached dendrites and altering the activity in the myelinated afferent fiber.

Our sensitivity to tactile sensations may be altered by infection, disease, or damage to sensory neurons or pathways. As a result, mapping tactile responses can sometimes aid clinical assessment. Sensory losses with clear regional boundaries indicate trauma to spinal nerves. For example, sensory loss within the boundaries of a dermatome can help identify the affected spinal nerve or
nerves. l**p. 431** Regional sensitivity to light touch can be checked by gentle contact with a fingertip or a slender wisp of cotton. Vibration receptors are tested by applying the base of a vibrating tuning fork to the skin. We discuss more detailed procedures, such as the *two-point discrimination test*, in the *Applications Manual*. AM: Assessment of Tactile Sensitivities

Tickle and itch sensations are closely related to the sensations of touch and pain. The receptors involved are free nerve endings, and the information is carried by unmyelinated Type C fibers. Tickle sensations, which are usually (but not always) described as pleasurable, are produced by a light touch that moves across the skin. Psychological factors are involved in the interpretation of tickle sensations, and tickle sensitivity differs greatly among individuals. Itching is probably produced by the stimulation of the same receptors. Specific “itch spots” can be mapped in the skin, the inner surfaces of the eyelids, and the mucous membrane of the nose. Itch sensations are absent from other mucous membranes and from deep tissues and viscera. Itching is extremely unpleasant, even more unpleasant than pain. Individuals with extreme itching will scratch even when pain is the result. Itch receptors can be stimulated by the injection of histamine or proteolytic enzymes into the epidermis and superficial dermis. The precise receptor mechanism is unknown.

Baroreceptors Baroreceptors monitor changes in pressure. A baroreceptor consists of free nerve endings that branch within the elastic tissues in the wall of a distensible organ, such as a blood vessel or a portion of the respiratory, digestive, or urinary tract. When the pressure changes, the elastic walls of the tract recoil or expand. This movement distorts the dendritic branches and alters the rate of action potential generation. Baroreceptors respond immediately to a change in pressure, but they adapt rapidly, and the output along the afferent fibers gradually returns to normal.

Baroreceptors monitor blood pressure in the walls of major vessels, including the carotid artery (at the *carotid sinus*) and the aorta (at the *aortic sinus*). The information plays a major role in regulating cardiac function and adjusting blood flow to vital tissues. Baroreceptors in the lungs monitor the degree of lung expansion. This information is relayed to the respiratory rhythmicity centers, which set the pace of respiration. Comparable stretch receptors at various sites in the digestive and urinary tracts trigger a variety of visceral reflexes, including those of urination and defecation. We will describe those baroreceptor reflexes in chapters that deal with specific physiological systems.

Proprioceptors Proprioceptors monitor the position of joints, the tension in tendons and ligaments, and the state of muscular contraction. There are three major groups of proprioceptors:

1. *Muscle Spindles.* Muscle spindles monitor skeletal muscle length and trigger stretch reflexes. l**p. 442**

2. *Golgi Tendon Organs.* **Golgi tendon organs** are similar in function to Ruffini corpuscles but are located at the junction between a skeletal muscle and its tendon. In a Golgi tendon organ, dendrites branch repeatedly and wind around the densely packed collagen fibers of the tendon. These receptors are stimulated by tension in the tendon; they thus monitor the external tension developed during muscle contraction.

3. *Receptors in Joint Capsules.* Joint capsules are richly innervated by free nerve endings that detect pressure, tension, and movement at the joint. Your sense of body position results from the integration of information from these receptors with information provided by muscle spindles, Golgi tendon organs, and the receptors of the inner ear.

Proprioceptors do not adapt to constant stimulation, and each receptor continuously sends information to the CNS. A relatively small proportion of the arriving proprioceptive information reaches your awareness; most proprioceptive information is processed at subconscious levels.

Chemoreceptors

Specialized chemoreceptive neurons can detect small changes in the concentration of specific chemicals or compounds. In general, **chemoreceptors** respond only to water-soluble and lipid-soluble substances that are dissolved in the surrounding fluid. These receptors exhibit peripheral adaptation over a period of seconds, and central adaptation may also occur.

The chemoreceptors included in the general senses do not send information to the primary sensory cortex, so we are not consciously aware of the sensations they provide. The arriving sensory information is routed to brain stem centers that deal with the autonomic control of respiratory and cardiovascular functions. Neurons in the respiratory centers of the brain respond to the concentration of hydrogen ions (pH) and levels of carbon dioxide molecules in the cerebrospinal fluid. Chemoreceptive neurons are also located in the **carotid bodies**, near the origin of the internal carotid arteries on each side of the neck, and in the **aortic bodies**, between the major branches of the aortic arch. These receptors monitor the pH and the carbon dioxide and oxygen levels in arterial blood. The afferent fibers leaving the carotid or aortic bodies reach the respiratory centers by traveling within cranial nerves IX (glossopharyngeal) and X (vagus).

Concept Check

Receptor A has a circular receptive field with a diameter of 2.5 cm. Receptor B has a circular receptive field 7.0 cm in diameter. Which receptor will provide more precise sensory information? When the nociceptors in your hand are stimulated, what sensation do you perceive?

What would happen to you if the information from proprioceptors in your legs were blocked from reaching the CNS?

Answers begin on p. A–1

The Organization of Sensory Pathways

Objectives

- Identify the major sensory pathways.
- Explain how we can distinguish among sensations that originate in different areas of the body.

A sensory neuron that delivers sensations to the CNS is often called a **first-order neuron**. The cell body of a first-order general sensory neuron is located in a dorsal root ganglion or cranial nerve ganglion. In the CNS, the axon of that sensory neuron synapses on an interneuron known as a **second-order neuron**, which may be located in the spinal cord or brain stem. If the sensation is to reach our awareness, the second-order neuron synapses on a **third-order neuron** in the thalamus. Somewhere along its length, the axon of the second-order neuron crosses over to the opposite side of the CNS. As a result, the right side of the thalamus receives sensory information from the left side of the body, and vice versa.

The axons of the third-order neurons ascend without crossing over and synapse on neurons of the primary sensory cortex of the cerebral hemisphere. As a result, the right cerebral hemisphere receives sensory information from the left side of the body, and the left cerebral hemisphere receives sensations from the right side. The reason for this crossover is unknown. Although it has no apparent functional benefit, crossover occurs along sensory and motor pathways in all vertebrates.

Somatic Sensory Pathways

Somatic sensory pathways carry sensory information from the skin and musculature of the body wall, head, neck, and limbs. We will consider three major somatic sensory pathways: (1) the *posterior column pathway*, (2) the *anterolateral pathway*, and (3) the *spinocerebellar pathway*. These pathways utilize pairs of spinal tracts, symmetrically arranged on opposite sides of the spinal cord. All the axons within a tract share a common origin and destination.

Figure 15–4• indicates the relative positions of the spinal tracts involved. Note that tract names often give clues to their function. For example, if the name of a tract begins with *spino-*, the tract must *start* in the spinal cord and *end* in the brain. It must therefore be an ascending tract that carries sensory information. The rest of the name indicates the tract’s destination. Thus, a *spinothalamic tract* begins in the spinal cord and carries sensory information to the thalamus.

If, on the other hand, the name of a tract ends in -*spinal*, the tract *ends* in the spinal cord and *starts* in a higher center of the brain. It must therefore be a descending tract that carries motor commands. The first part of the name indicates the nucleus or cortical area of the brain where the tract originates. For example, a *corticospinal tract* carries motor commands from the cerebral cortex to the spinal cord. Such tracts will be considered later in the chapter.

The Posterior Column Pathway

The **posterior column pathway** carries sensations of highly localized ("fine") touch, pressure, vibration, and proprioception (Figure 15–5a•). This pathway, also known as the *dorsal column/medial lemniscus*, begins at a peripheral receptor and ends at the primary sensory cortex of the cerebral hemispheres. The spinal tracts involved are the left and right **fasciculus gracilis** (*gracilis*, delicate) and the left and right **fasciculus cuneatus** (*cuneus*, wedge-shaped). On each side of the posterior median sulcus, the fasciculus gracilis is medial to the fasciculus cuneatus.

The axons of the first-order neurons reach the CNS within the dorsal roots of spinal nerves and the sensory roots of cranial nerves. The axons ascending within the posterior column are organized according to the region innervated. Axons carrying sensations from the inferior half of the body ascend within the fasciculus gracilis and synapse in the nucleus gracilis of the medulla oblongata. Axons carrying sensations from the superior half of the trunk, upper limbs, and neck ascend in the fasciculus cuneatus and synapse in the nucleus cuneatus. l**p. 460**

Axons of the second-order neurons of the nucleus gracilis and nucleus cuneatus ascend to the thalamus. As they ascend, these axons cross over to the opposite side of the brain stem. The crossing of an axon from the left side to the right side, or vice versa, is called **decussation**. Once on the opposite side of the brain, the axons enter a tract called the **medial lemniscus** (*lemniskos*, ribbon). As it ascends, the medial lemniscus runs alongside a smaller tract that carries sensory information from the face, relayed from the sensory nuclei of the trigeminal nerve (V).

The axons in these tracts synapse on third-order neurons in one of the ventral nuclei of the thalamus. l**p. 466** These nuclei sort the arriving information according to (1) the nature of the stimulus and (2) the region of the body involved. Processing in the thalamus determines whether you perceive a given sensation as fine touch, or as pressure or vibration.

Our ability to localize the sensation—to determine precisely where on the body a specific stimulus originated—depends on the projection of information from the thalamus to the primary sensory cortex. Sensory information from the toes arrives at one end of the primary sensory cortex, and information from the head arrives at the other. When neurons in one portion of your primary sensory cortex are stimulated, you become aware of sensations originating at a specific location. If your primary sensory cortex were damaged or the projection fibers were cut, you could detect a light touch but would be unable to determine its source.

The same sensations are reported whether the cortical neurons are activated by axons ascending from the thalamus or by direct electrical stimulation. Researchers have electrically stimulated the primary sensory cortex in awake individuals during brain surgery and asked the subjects where they thought the stimulus originated. The results were used to create a functional map of the primary sensory cortex. Such a map, three of which are shown in Figure 15–5•, is called a **sensory homunculus** (“little man”).

The proportions of the sensory homunculus are very different from those of any individual. For example, the face is huge and distorted, with enormous lips and tongue, whereas the back is relatively tiny. These distortions occur because the area of sensory cortex devoted to a particular body region is proportional not to the region’s absolute size, but to the *number of sensory receptors* it contains. In other words, many more cortical neurons are required to process sensory information arriving from the tongue, which has tens of thousands of taste and touch receptors, than to analyze sensations originating on the back, where touch receptors are few and far between.

The Anterolateral Pathway

The **anterolateral pathway** provides conscious sensations of poorly localized (“crude”) touch, pressure, pain, and temperature. In this pathway, the axons of first-order sensory neurons enter the spinal cord and synapse on second-order neurons within the posterior gray horns. The axons of these interneurons cross to the opposite side of the spinal cord before ascending. This pathway includes relatively small tracts that deliver sensations to reflex centers in the brain stem as well as larger tracts that carry sensations destined for the cerebral cortex. We will ignore the smaller tracts in this discussion.

Sensations bound for the cerebral cortex ascend within the anterior or lateral spinothalamic tracts. The **anterior spinothalamic tracts** carry crude touch and pressure sensations (Figure 15–5b•), whereas the **lateral spinothalamic tracts** carry pain and temperature sensations (Figure 15–5c•). These tracts end at third-order neurons in the ventral nucleus group of the thalamus. After the sensations have been sorted and processed, they are relayed to the primary sensory cortex.

The perception that an arriving stimulus is painful rather than cold, hot, or vibrating depends on which second-order and third-order neurons are stimulated. The ability to localize that stimulus to a specific location in the body depends on the stimulation of an appropriate area of the primary sensory cortex. Any abnormality along the pathway can result in inappropriate sensations or inaccurate localization of the source. Consider these examples:

- An individual can experience painful sensations that are not real. For example, a person may continue to experience pain in an amputated limb. This *phantom limb pain* is caused by activity in the sensory neurons or interneurons along the anterolateral pathway. The neurons involved were once part of the labeled line that monitored conditions in the intact limb. These labeled lines and pathways are developmentally programmed, even individuals born without limbs can have phantom limb pain.
- An individual can feel pain in an uninjured part of the body when the pain actually originates at another location. For example, strong visceral pain sensations arriving at a segment of the spinal cord can stimulate interneurons that are part of the anterolateral pathway. Activity in these interneurons leads to the stimulation of the primary sensory cortex, so the individual feels pain in a specific part of the body surface. This phenomenon is called **referred pain**. Two familiar examples are (1) the pain of a heart attack, which is frequently felt in the left arm, and (2) the pain of appendicitis, which is generally felt first in the area around the navel and then in the right lower quadrant. These and additional examples are shown in Figure 15–6•.

The Spinocerebellar Pathway

The cerebellum receives proprioceptive information about the position of skeletal muscles, tendons, and joints along the **spinocerebellar pathway** (Figure 15–7•). This information does not reach our awareness. The axons of first-order sensory neurons synapse on interneurons in the dorsal gray horns of the spinal cord. The axons of these second-order neurons ascend in one of the spinocerebellar tracts:

- The **posterior spinocerebellar tracts** contain axons that do not cross over to the opposite side of the spinal cord. These axons reach the cerebellar cortex via the inferior cerebellar peduncle of that side.
- The **anterior spinocerebellar tracts** are dominated by axons that have crossed over to the opposite side of the spinal cord, although they do contain a significant number of uncrossed axons as well. The sensations carried by the anterior spinocerebellar tracts reach the cerebellar cortex via the superior cerebellar peduncle. Interestingly, many of the axons that cross over and ascend to the cerebellum then cross over again within the cerebellum, synapsing on the same side as the original stimulus. The functional significance of this “double cross” is unknown.

The information carried by the spinocerebellar pathway ultimately arrives at the *Purkinje cells* of the cerebellar cortex. l**p. 464** Proprioceptive information from each part of the body is relayed to a specific portion of the cerebellar cortex. We will consider the integration of proprioceptive information and the role of the cerebellum in somatic motor control in a later section. Table 15–1 reviews the somatic sensory pathways discussed in this section.

100 Keys | Most somatic sensory information is relayed to the thalamus for processing. A small fraction of the arriving
information is projected to the cerebral cortex and reaches our awareness.

Visceral Sensory Pathways

Visceral sensory information is collected by interoceptors monitoring visceral tissues and organs, primarily within the thoracic and abdominopelvic cavities. These interoceptors include nociceptors, thermoreceptors, tactile receptors, baroreceptors, and chemoreceptors, although none of them are as numerous as they are in somatic tissues. The axons of the first-order neurons usually travel in company with autonomic motor fibers innervating the same visceral structures.

Cranial nerves V, VII, IX, and X carry visceral sensory information from the mouth, palate, pharynx, larynx, trachea, esophagus, and associated vessels and glands. l**pp. 483–487** This information is delivered to the **solitary nucleus**, a large nucleus in the medulla oblongata. The solitary nucleus is a major processing and sorting center for visceral sensory information; it has extensive connections with the various cardiovascular and respiratory centers as well as with the reticular formation.

The dorsal roots of spinal nerves T1–L2 carry visceral sensory information provided by receptors in organs located between the diaphragm and the pelvic cavity. The dorsal roots of spinal nerves S2–S4 carry visceral sensory information from organs in the inferior portion of the pelvic cavity, including the last portion of the large intestine, the urethra and base of the urinary bladder, and the prostate gland (males) or the cervix of the uterus and adjacent portions of the vagina (females).

The first-order neurons deliver the visceral sensory information to interneurons whose axons ascend within the anterolateral pathway. Most of the sensory information is delivered to the solitary nucleus, and because it never reaches the primary sensory cortex we remain unaware of these sensations.

Concept Check

As a result of pressure on her spinal cord, Jill cannot feel touch or pressure on her lower limbs. Which spinal tract is being compressed?

Which spinal tract carries action potentials generated by nociceptors?

Which cerebral hemisphere receives impulses conducted by the right fasciculus gracilis?

Answers begin on p. A–1

The Somatic Nervous System

Objectives

- Describe the components, processes, and functions of the somatic motor pathways.
- Describe the levels of information processing involved in motor control.

Motor commands issued by the CNS are distributed by the somatic nervous system (SNS) and the autonomic nervous system (ANS). The somatic nervous system, also called the *somatic motor system*, controls the contractions of skeletal muscles. The output of the SNS is under voluntary control. The autonomic nervous system, or *visceral motor system*, controls visceral effectors, such as smooth muscle, cardiac muscle, and glands. We will examine the organization of the ANS in Chapter 16; our interest here is the structure of the SNS. Throughout this discussion we will use the terms *motor neuron* and *motor control* to refer specifically to somatic motor neurons and pathways that control skeletal muscles.

Somatic motor pathways always involve at least two motor neurons: an **upper motor neuron**, whose cell body lies in a CNS processing center, and a **lower motor neuron**, whose cell body lies in a nucleus of the brain stem or spinal cord. The upper motor neuron synapses on the lower motor neuron, which in turn innervates a single motor unit in a skeletal muscle. Activity in the upper motor neuron may facilitate or inhibit the lower motor neuron. Activation of the lower motor neuron triggers a contraction in the innervated muscle. Only the axon of the lower motor neuron extends outside the CNS. Destruction of or damage to a lower motor neuron eliminates voluntary and reflex control over the innervated motor unit.

Conscious and subconscious motor commands control skeletal muscles by traveling over three integrated motor pathways: the *corticospinal pathway*, the *medial pathway*, and the *lateral pathway*. Figure 15–8• indicates the positions of the associated motor (descending) tracts in the spinal cord. Activity within these motor pathways is monitored and adjusted by the basal nuclei and cerebellum. Their output stimulates or inhibits the activity of either (1) motor nuclei or (2) the primary motor cortex.

The Corticospinal Pathway

The **corticospinal pathway** (Figure 15–9•), sometimes called the *pyramidal system*, provides voluntary control over skeletal muscles. This system begins at the *pyramidal cells* of the primary motor cortex. l**p. 474** The axons of these upper motor neurons descend into the brain stem and spinal cord to synapse on lower motor neurons that control skeletal muscles. In general, the corticospinal pathway is direct: The upper motor neurons synapse directly on the lower motor neurons. However, the corticospinal pathway also works indirectly, as it innervates centers of the medial and lateral pathways.

The corticospinal pathway contains three pairs of descending tracts: (1) the *corticobulbar tracts*, (2) the *lateral corticospinal tracts*, and (3) the *anterior corticospinal tracts*. These tracts enter the white matter of the internal capsule, descend into the brain stem, and emerge on either side of the mesencephalon as the *cerebral peduncles*.

The Corticobulbar Tracts

Axons in the **corticobulbar** (kor-ti-ko¯-BUL-bar) **tracts** (*bulbar*, brain stem) synapse on lower motor neurons in the motor nuclei of cranial nerves III, IV, V, VI, VII, IX, XI, and XII. The corticobulbar tracts provide conscious control over skeletal muscles that move the eye, jaw, and face, and some muscles of the neck and pharynx. The corticobulbar tracts also innervate the motor centers of the medial and lateral pathways.

The Corticospinal Tracts

Axons in the **corticospinal tracts** synapse on lower motor neurons in the anterior gray horns of the spinal cord. As they descend, the corticospinal tracts are visible along the ventral surface of the medulla oblongata as a pair of thick bands, the **pyramids**. Along the length of the pyramids, roughly 85 percent of the axons cross the midline (decussate) to enter the descending **lateral corticospinal tracts** on the opposite side of the spinal cord. The other 15 percent continue uncrossed along the spinal cord as the **anterior**

corticospinal tracts. At the spinal segment it targets, an axon in the anterior corticospinal tract crosses over to the opposite side of the spinal cord in the anterior white commissure before synapsing on lower motor neurons in the anterior gray horns.

The Motor Homunculus

The activity of pyramidal cells in a specific portion of the primary motor cortex will result in the contraction of specific peripheral muscles. The identities of the stimulated muscles depend on the region of motor cortex that is active. As in the primary sensory cortex, the primary motor cortex corresponds point by point with specific regions of the body. The cortical areas have been mapped out in diagrammatic form, creating a **motor homunculus**. Figure 15–9• shows the motor homunculus of the left cerebral hemisphere and the corticospinal pathway controlling skeletal muscles on the right side of the body.

The proportions of the motor homunculus are quite different from those of the actual body, because the motor area devoted to a specific region of the cortex is proportional to the number of motor units involved in the region’s control, not to its actual size. As a result, the homunculus provides an indication of the degree of fine motor control available. For example, the hands, face, and tongue, all of which are capable of varied and complex movements, appear very large, whereas the trunk is relatively small. These proportions are similar to those of the sensory homunculus (see Figure 15–5•, pp. 504–505). The sensory and motor homunculi differ in other respects because some highly sensitive regions, such as the sole of the foot, contain few motor units, and some areas with an abundance of motor units, such as the eye muscles, are not particularly sensitive.

Clinical Note

The term **cerebral palsy** refers to a number of disorders that affect voluntary motor performance; they appear during infancy or childhood and persist throughout the life of the affected individual. The cause may be trauma associated with premature or unusually stressful birth, maternal exposure to drugs (including alcohol), or a genetic defect that causes the improper development of motor pathways. Problems during labor and delivery may produce compression or interruption of placental circulation or oxygen supplies. If the oxygen concentration in fetal blood declines significantly for as little as 5–10 minutes, CNS function can be permanently impaired. The cerebral cortex, cerebellum, basal nuclei, hippocampus, and thalamus are likely targets, producing abnormalities in motor skills, posture and balance, memory, speech, and learning abilities.

The Medial and Lateral Pathways

Several centers in the cerebrum, diencephalon, and brain stem may issue somatic motor commands as a result of processing performed at a subconscious level. These centers and their associated tracts were long known as the *extrapyramidal system (EPS)*, because it was thought that they operated independently of, and in parallel with, the *pyramidal system* (corticospinal pathway). This classification scheme is both inaccurate and misleading, because motor control is integrated at all levels through extensive feedback loops and interconnections. It is more appropriate to group these nuclei and tracts in terms of their primary functions: The components of the **medial pathway** help control gross movements of the trunk and proximal limb muscles, whereas those of the **lateral pathway** help control the distal limb muscles that perform more precise movements.

The medial and lateral pathways can modify or direct skeletal muscle contractions by stimulating, facilitating, or inhibiting lower motor neurons. It is important to note that the axons of upper motor neurons in the medial and lateral pathways synapse on the same lower motor neurons innervated by the corticospinal pathway. This means that the various motor pathways interact not only within the brain, through interconnections between the primary motor cortex and motor centers in the brain stem, but also through excitatory or inhibitory interactions at the level of the lower motor neuron.

The Medial Pathway

The medial pathway is primarily concerned with the control of muscle tone and gross movements of the neck, trunk, and proximal limb muscles. The upper motor neurons of the medial pathway are located in the *vestibular nuclei*, the *superior* and *inferior colliculi*, and the *reticular formation*.

The vestibular nuclei receive information, over the vestibulocochlear nerve (VIII), from receptors in the inner ear that monitor the position and movement of the head. These nuclei respond to changes in the orientation of the head, sending motor commands that alter the muscle tone, extension, and position of the neck, eyes, head, and limbs. The primary goal is to maintain posture and balance. The descending fibers in the spinal cord constitute the **vestibulospinal tracts**.

The superior and inferior colliculi are located in the *tectum*, or roof of the mesencephalon (see Figure 14–8b•, p. 465). The colliculi receive visual (superior) and auditory (inferior) sensations. Axons of upper motor neurons in the colliculi descend in the **tectospinal tracts**. These axons cross to the opposite side immediately, before descending to synapse on lower motor neurons in the brain stem or spinal cord. Axons in the tectospinal tracts direct reflexive changes in the position of the head, neck, and upper limbs in response to bright lights, sudden movements, or loud noises.

The reticular formation is a loosely organized network of neurons that extends throughout the brain stem. l**p. 459** The reticular formation receives input from almost every ascending and descending pathway. It also has extensive interconnections with the cerebrum, the cerebellum, and brain stem nuclei. Axons of upper motor neurons in the reticular formation descend into the **reticulospinal tracts** without crossing to the opposite side. The effects of reticular formation stimulation are determined by the region stimulated. For example, the stimulation of upper motor neurons in one portion of the reticular formation produces eye movements, whereas the stimulation of another portion activates respiratory muscles.

The Lateral Pathway

The lateral pathway is primarily concerned with the control of muscle tone and the more precise movements of the distal parts of the limbs. The upper motor neurons of the lateral pathway lie within the red nuclei of the mesencephalon. l**p. 464** Axons of upper motor neurons in the red nuclei cross to the opposite side of the brain and descend into the spinal cord in the **rubrospinal tracts** (*ruber*, red). In humans, the rubrospinal tracts are small and extend only to the cervical spinal cord. There they provide motor control over distal muscles of the upper limbs; normally, their role is insignificant as compared with that of the lateral corticospinal tracts. However, the rubrospinal tracts can be important in maintaining motor control and muscle tone in the upper limbs if the lateral corticospinal tracts are damaged.

Table 15–2 reviews the major descending (motor) tracts discussed in this section.

The Basal Nuclei and Cerebellum

The basal nuclei and cerebellum are responsible for coordination and feedback control over muscle contractions, whether those contractions are consciously or subconsciously directed.

The Basal Nuclei

The basal nuclei provide the background patterns of movement involved in voluntary motor activities. For example, they may control muscles that determine the background position of the trunk or limbs, or they may direct rhythmic cycles of movement, as in walking or running. These nuclei do not exert direct control over lower motor neurons. Instead, they adjust the activities of upper motor neurons in the various motor pathways based on input from all portions of the cerebral cortex, as well as from the substantia nigra.

The basal nuclei adjust or establish patterns of movement via two major pathways:

1. One group of axons synapses on thalamic neurons, whose axons extend to the premotor cortex, the motor association area that directs activities of the primary motor cortex. This arrangement creates a feedback loop that changes the sensitivity of the pyramidal cells and alters the pattern of instructions carried by the corticospinal tracts.

2. A second group of axons synapses in the reticular formation, altering the excitatory or inhibitory output of the reticulospinal tracts.

Two distinct populations of neurons exist: one that stimulates neurons by releasing acetylcholine (ACh), and another that inhibits neurons through the release of gamma aminobutyric acid (GABA). Under normal conditions, the excitatory interneurons are kept inactive, and the tracts leaving the basal nuclei have an inhibitory effect on upper motor neurons. In *Parkinson's disease*, the excitatory neurons become more active, leading to problems with the voluntary control of movement. l**p. 474**

If the primary motor cortex is damaged, the individual loses the ability to exert fine control over skeletal muscles. However, some voluntary movements can still be controlled by the basal nuclei. In effect, the medial and lateral pathways function as they usually do, but the corticospinal pathway cannot fine-tune the movements. For example, after damage to the primary motor cortex, the basal nuclei can still receive information about planned movements from the prefrontal cortex and can perform preparatory movements of the trunk and limbs. But because the corticospinal pathway is inoperative, precise movements of the forearms, wrists, and hands cannot occur. An individual in this condition can stand, maintain balance, and even walk, but all movements are hesitant, awkward, and poorly controlled.

The Cerebellum

The cerebellum monitors proprioceptive (position) sensations, visual information from the eyes, and vestibular (balance) sensations from the inner ear as movements are under way. Axons within the spinocerebellar tracts deliver proprioceptive information to the cerebellar cortex. Visual information is relayed from the superior colliculi, and balance information is relayed from the vestibular nuclei. The output of the cerebellum affects upper motor neuron activity in the corticospinal, medial, and lateral pathways.

All motor pathways send information to the cerebellum when motor commands are issued. As the movement proceeds, the cerebellum monitors proprioceptive and vestibular information and compares the arriving sensations with those experienced during previous movements. It then adjusts the activities of the upper motor neurons involved. In general, any voluntary movement begins with the activation of far more motor units than are required—or even desirable. The cerebellum acts like a brake, providing the inhibition needed to minimize the number of motor commands used to perform the movement. The pattern and degree of inhibition changes from moment to moment, and this makes the movement efficient, smooth, and precisely controlled.

The patterns of cerebellar activity are learned by trial and error, over many repetitions. Many of the basic patterns are established early in life; examples include the fine balancing adjustments you make while standing and walking. The ability to fine-tune a complex pattern of movement improves with practice, until the movements become fluid and automatic. Consider the relaxed, smooth movements of acrobats, golfers, and sushi chefs. These people move without thinking about the details of their movements. This ability is important, because when you concentrate on voluntary control, the rhythm and pattern of the movement usually fall apart as your primary motor cortex starts overriding the commands of the basal nuclei and cerebellum.

Clinical Note

Amyotrophic lateral sclerosis (ALS), commonly known as *Lou Gehrig's disease*, is a progressive, degenerative disorder that affects motor neurons in the spinal cord, brain stem, and cerebral hemispheres. The degeneration affects both upper and lower motor neurons. Because a motor neuron and its dependent muscle fibers are so intimately related, the destruction of CNS neurons causes atrophy of the associated skeletal muscles. Noted physicist Stephen Hawking has this condition. AM: Amyotrophic Lateral Sclerosis

Concept Check

For what anatomical reason does the left side of the brain control motor function on the right side of the body?

An injury involving the superior portion of the motor cortex affects which region of the body?

What effect would increased stimulation of the motor neurons of the red nucleus have on muscle tone?

Answers begin on p. A–1

Levels of Processing and Motor Control

All sensory and motor pathways involve a series of synapses, one after the other. Along the way, the information is distributed to processing centers operating at the subconscious level. Consider what happens when you stumble—you often recover your balance even as you become aware that a problem exists. Long before your cerebral cortex could assess the situation, evaluate possible responses (shift weight *here*, move leg *there*, and so on), and issue appropriate motor commands, monosynaptic and polysynaptic reflexes, perhaps adjusted by the brain stem and cerebellum, successfully prevented a fall. This is a general pattern; spinal and cranial reflexes provide rapid, involuntary, preprogrammed responses that preserve homeostasis over the short term. Voluntary responses are more complex and require more time to prepare and execute.

Cranial and spinal reflexes control the most basic motor activities. Integrative centers in the brain perform more elaborate processing, and as we move from the medulla oblongata to the cerebral cortex, the motor patterns become increasingly complex and variable. The most complex and variable motor activities are directed by the primary motor cortex of the cerebral hemispheres.

During development, the spinal and cranial reflexes are the first to appear. More complex reflexes and motor patterns develop as CNS neurons multiply, enlarge, and interconnect. The process proceeds relatively slowly, as billions of neurons establish trillions of synaptic connections. At birth, neither the cerebral nor the cerebellar cortex is fully functional. The behavior of newborn infants is directed primarily by centers in the diencephalon and brain stem.

Clinical Note

Although it may seem strange, physicians generally take newborn infants into a dark room and shine a light against the skull. They are checking for *anencephaly* (an-en-SEF-uh-l e¯), a rare condition in which the brain fails to develop at levels above the mesencephalon or lower diencephalon.

In most such cases, the cranium also fails to develop, and diagnosis is easy, but in some cases, a normal skull forms. In such instances, the cranium is empty and translucent enough to transmit light. Unless the condition is discovered right away, the parents may take the infant home, unaware of the problem. All the normal behavior patterns expected of a newborn are present, including suckling, stretching, yawning, crying, kicking, sticking fingers in the mouth, and tracking movements with the eyes. However, death will occur naturally within days or months.

This tragic condition provides a striking demonstration of the role of the brain stem in controlling complex motor patterns. During normal development, these patterns become incorporated into variable and versatile behaviors as control centers and analytical centers appear in the cerebral cortex.

100 Keys | Neurons of the primary motor cortex innervate motor neurons in the brain and spinal cord responsible for stimulating skeletal muscles. Higher centers in the brain can suppress or facilitate reflex responses; reflexes can complement or increase the complexity of voluntary movements.

Chapter Review

Selected Clinical Terminology

amyotrophic lateral sclerosis (ALS): A progressive, degenerative disorder affecting motor neurons of the spinal cord, brain stem, and cerebral hemispheres. (p. 513 and [AM]) **anencephaly:** A rare condition in which the brain fails to develop at levels above the mesencephalon or inferior part of the diencephalon. (p. 513)

cerebral palsy: A disorder that affects voluntary motor performance and arises in infancy or childhood as a result of prenatal trauma, drug exposure, or a congenital defect. (p. 510)

Study Outline

An Overview of Sensory Pathways and the Somatic Nervous System p. 496

1. The brain, spinal cord, and peripheral nerves continuously communicate with each other and with the internal and external environments. Information arrives via sensory receptors and ascends within the afferent division, while motor commands descend and are distributed by the efferent division. *(Figure 15–1)*

Sensory Receptors and Their Classification p. 496

1. A sensory receptor is a specialized cell or cell process that monitors specific conditions within the body or in the external environment. Arriving information is called a **sensation**; awareness of a sensation is a **perception**.

2. The **general senses** are pain, temperature, physical distortion, and chemical detection. Receptors for these senses are distributed throughout the body. **Special senses**, located in specific **sense organs**, are structurally more complex.

Sensory Receptors p. 497

3. Each receptor cell monitors a specific receptive field. *Transduction* begins when a large enough stimulus changes the *receptor potential* reaching *generator potential*. *(Figure 15–2)*

4. **Tonic receptors** are always active. **Phasic receptors** provide information about the intensity and rate of change of a stimulus. **Adaptation** is a reduction in sensitivity in the presence of a constant stimulus. Tonic receptors are **slow-adapting receptors**, while phasic receptors are **fast-adapting receptors**.

100 Keys | p. 498

The General Senses p. 498

5. Three types of **nociceptor** found in the body provide information on pain as related to extremes of temperature, mechanical damage, and dissolved chemicals. Myelinated Type A fibers carry **fast pain**. Slower, Type C fibers carry **slow pain**. *(Figure 15–2)*

6. **Thermoreceptors** are found in the dermis. **Mechanoreceptors** are sensitive to distortion of their membranes, and include **tactile receptors**, **baroreceptors**, and **proprioceptors**. There are six types of tactile receptors in the skin, and three kinds of proprioceptors. Chemoreceptors include **carotid bodies** and **aortic bodies**. *(Figure 15–3)*

The Organization of Sensory Pathways p. 503

1. Sensory neurons that deliver sensation to the CNS are referred to as **first-order neurons**. These synapse on **second-order neurons** in the brain stem or spinal cord. The next neuron in this chain is a **third-order neuron**, found in the thalamus.

Somatic Sensory Pathways p. 503

2. Three major somatic sensory pathways carry sensory information from the skin and musculature of the body wall, head, neck, and limbs: the *posterior column pathway*, the *anterolateral pathway*, and the *spinocerebellar pathway*. *(Figure 15–4)*

3. The **posterior column pathway** carries fine touch, pressure, and proprioceptive sensations. The axons ascend within the **fasciculus gracilis** and **fasciculus cuneatus** and relay information to the thalamus via the **medial lemniscus**. Before the axons enter the medial lemniscus, they cross over to the opposite side of the brain stem. This crossing over is called **decussation**. *(Figure 15–5; Table 15–1)*

4. The **anterolateral pathway** carries poorly localized sensations of touch, pressure, pain, and temperature. The axons involved decussate in the spinal cord and ascend within the **anterior** and **lateral spinothalamic tracts** to the ventral nuclei of the thalamus.

(Figures 15–5, 15–6; Table 15–1)

5. The **spinocerebellar pathway**, including the **posterior** and **anterior spinocerebellar tracts**, carries sensations to the cerebellum concerning the position of muscles, tendons, and joints. *(Figure 15–7; Table 15–1)*

100 Keys | p. 507

Visceral Sensory Pathways p. 507

6. Visceral sensory pathways carry information collected by interoceptors. Sensory information from cranial nerves V, VII, IX, and X is delivered to the **solitary nucleus** in the medulla oblongata. Dorsal roots of spinal nerves T1–L2 carry visceral sensory information from organs between the diaphragm and the pelvic cavity. Dorsal roots of spinal nerves S2–S4 carry sensory information from more inferior structures.

The Somatic Nervous System p. 508

1. Somatic motor (descending) pathways always involve an **upper motor neuron** (whose cell body lies in a CNS processing center) and a **lower motor neuron** (whose cell body is located in a nucleus of the brain stem or spinal cord). *(Figure 15–8)*

The Corticospinal Pathway p. 509

2. The neurons of the primary motor cortex are *pyramidal cells*. The **corticospinal pathway** provides voluntary skeletal muscle control. The **corticobulbar tracts** terminate at the cranial nerve nuclei; the **corticospinal tracts** synapse on lower motor neurons in the anterior gray horns of the spinal cord. The corticospinal tracts are visible along the medulla as a pair of thick bands, the **pyramids**, where most of the axons decussate to enter the descending **lateral corticospinal tracts**. Those that do not cross over enter the **anterior**

corticospinal tracts. The corticospinal pathway provides a rapid, direct mechanism for controlling skeletal muscles. *(Figure -15–9; Table 15–2)*

The Medial and Lateral Pathways p. 511

3. The **medial** and **lateral pathways** include several other centers that issue motor commands as a result of processing performed at a subconscious level. *(Table 15–2)*

4. The medial pathway primarily controls gross movements of the neck, trunk and proximal limbs. It includes the vestibulospinal, tectospinal, and reticulospinal tracts. The **vestibulospinal tracts** carry information related to maintaining balance and posture. Commands carried by the **tectospinal tracts** change the position of the head, neck, and upper limbs in response to bright lights, sudden movements, or loud noises. Motor commands carried by the **reticulospinal tracts** vary according to the region stimulated. *(Table 15–2)*

5. The lateral pathway consists of the **rubrospinal tracts**, which primarily control muscle tone and movements of the distal muscles of the upper limbs. *(Table 15–2)*

The Basal Nuclei and Cerebellum p. 511

6. The basal nuclei adjust the motor commands issued in other processing centers and provide background patterns of movement involved in voluntary motor activities.

7. The cerebellum monitors proprioceptive sensations, visual information, and vestibular sensations. The integrative activities performed by neurons in the cortex and nuclei of the cerebellum are essential for the precise control of movements.

Levels of Processing and Motor Control p. 513

8. Spinal and cranial reflexes provide rapid, involuntary, preprogrammed responses that preserve homeostasis. Voluntary responses are more complex and require more time to prepare and execute.

9. During development, the spinal and cranial reflexes are first to appear. Complex reflexes develop over years, as the CNS matures and the brain grows in size and complexity.

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive

Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The larger the receptive field, the

(a) larger the stimulus needed to stimulate a sensory receptor

(b) fewer sensory receptors there are

(c) harder it is to locate the exact point of stimulation

(d) larger the area of the somatosensory cortex in the brain that deals with the area

(e) closer together the receptor cells

2. The CNS interprets information entirely on the basis of the

(a) number of action potentials that it receives

(b) kind of action potentials that it receives

(c) line over which sensory information arrives

(d) intensity of the sensory stimulus

(e) number of sensory receptors that are stimulated

3. The area of sensory cortex devoted to a body region is relative to the

(a) size of the body area

(b) distance of the body area from the brain

(c) number of motor units in the area of the body

(d) number of sensory receptors in the area
of the body

(e) size of the nerves that serve the area of the body

4. __________ are receptors that are normally inactive, but become active for a short time whenever there is a change in the condition that they monitor.

5. Identify six types of tactile receptors located in the skin and describe their sensitivities.

6. What three types of mechanoreceptors respond to stretching, compression, twisting, or other distortions of the cell membrane?

7. What are the three major somatic sensory pathways, and what is the function of each pathway?

8. Which three pairs of descending tracts make up the corticospinal pathway?

9. Which three motor pathways make up the medial pathway?

10. What are the two primary functional roles of the cerebellum?

11. The corticospinal tract

(a) carries motor commands from the cerebral cortex to the spinal cord

(b) carries sensory information from the spinal cord to the brain

(c) starts in the spinal cord and ends in the brain

(d) a, b, and c are correct

12. What three steps are necessary for transduction to occur?

13. What three anatomical factors contribute to the maturation of the CNS and the refinement of motor skills?

LEVEL 2 Reviewing Concepts

14. Differentiate between a tonic receptor and a phasic receptor.

15. What is a motor homunculus? How does it differ from a sensory homunculus?

16. Describe the relationship among first-, second-, and third-order neurons.

17. Damage to the posterior spinocerebellar tract on the left side of the spinal cord at the L_1 level would interfere with

(a) coordinated movement of the right leg

(b) coordinated movement of the left leg

(c) coordinated movement of the right arm

(d) coordinated movement of the left arm

(e) both a and c

18. What effect does injury to the primary motor cortex have on peripheral muscles?

19. By which structures and in which part of the brain is the level of muscle tone in the body’s skeletal muscles controlled? How is this control exerted?

20. Explain the phenomenon of *referred pain* in terms of labeled lines and organization of sensory pathways.

LEVEL 3 Critical Thinking and Clinical Applications

21. Kelly is having difficulty controlling her eye movements and has lost some control of her facial muscles. After an examination and testing, Kelly’s physician tells her that her cranial nerves are perfectly normal but that a small tumor is putting pressure on certain fiber tracts in her brain. This pressure is the cause of Kelly’s symptoms. Where is the tumor most likely located?

22. Clerence, a construction worker, suffers a fractured skull when a beam falls on his head. Diagnostic tests indicate severe damage to the motor cortex. His wife is anxious to know if he will ever be able to move or walk again. What would you tell her?

23. Phil had to have his arm amputated after an accident. He tells you that he can sometimes still feel pain in his fingers even though the hand is gone. He says this is especially true when he bumps the stub. How can this be?

Survival under these conditions is possible because routine homeostatic adjustments in physiological systems are made by the **autonomic nervous system (ANS)**. The ANS coordinates cardiovascular, respiratory, digestive, urinary, and reproductive functions. In doing so, the ANS adjusts internal water, electrolyte, nutrient, and dissolved gas concentrations in body fluids—and it does so without instructions or interference from the conscious mind.

An Overview of the ANS

Objectives

- Compare the organization of the autonomic nervous system with that of the somatic nervous system.

- List the divisions of the ANS and give the functions of each.

Your conscious thoughts, plans, and actions represent a tiny fraction of the activities of the nervous system. In practical terms, your conscious thoughts and the somatic nervous system (SNS), which operates under conscious control, seldom have a direct effect on your long-term survival. Of course, the somatic nervous system can be important in moving you out of the way of a speeding bus or pulling your hand from a hot stove—but it was your conscious movements that put you in jeopardy in the first place. If all consciousness were eliminated, vital physiological processes would continue virtually unchanged; a night's sleep is not a life-threatening event. Longer, deeper states of unconsciousness are not necessarily more dangerous, as long as nourishment and other basic care is provided. People who have suffered severe brain injuries can survive in a coma for decades.

Figure 16–1• provides an overview of the material covered in this chapter. We'll begin by completing our discussion of the efferent division of the nervous system with an examination of the ANS. Our understanding of this system has had a profound effect on the practice of medicine. For example, in 1960, the five-year survival rate for patients surviving their first heart attack was very low, primarily because it was difficult and sometimes impossible to control high blood pressure. Forty years later, many survivors of heart attacks lead normal lives. This dramatic change occurred as we learned to manipulate the ANS with specific drugs and clinical procedures.

The interpretation of arriving sensory information and the commands issued by the SNS and ANS can be influenced or modified in response to conscious planning, memories, and learning—the so-called higher-order functions of the brain. This chapter includes an examination of these functions. We will conclude by considering the effects of aging on this system, and the interactions between the nervous system and other systems.

It is useful to compare the organization of the ANS with that of the SNS, which controls our skeletal muscles. We will focus on (1) the neural interactions that direct motor output and (2) the subdivisions of the ANS, based on structural and functional patterns of peripheral innervation.

Figure 16–2• compares the organization of the somatic and autonomic nervous systems.

Both are efferent divisions that carry motor commands; the SNS controls skeletal muscles and the ANS controls visceral effectors. The primary structural difference between the two is that in the SNS, motor neurons of the central nervous system exert direct control over skeletal muscles (Figure 16–2a•). In the ANS, by contrast, motor neurons of the central nervous system synapse on visceral motor neurons in autonomic ganglia, and these ganglionic neurons control visceral effectors (Figure 16–2b•).

The integrative centers for autonomic activity are located in the hypothalamus. The neurons in these centers are comparable to the upper motor neurons in the SNS. Visceral motor neurons in the brain stem and spinal cord are known as **preganglionic neurons**. These neurons are part of visceral reflex arcs, and most of their activities represent direct reflex responses, rather than responses to commands from the hypothalamus. The axons of preganglionic neurons are called **preganglionic fibers**. Preganglionic fibers leave the CNS and synapse on **ganglionic neurons—**visceral motor neurons in peripheral ganglia. These ganglia, which contain hundreds to thousands of ganglionic neurons, are called **autonomic ganglia**. Ganglionic neurons innervate visceral effectors such as cardiac muscle, smooth muscle, glands, and adipose tissues. The axons of ganglionic neurons are called **postganglionic fibers**, because they begin at the autonomic ganglia and extend to the peripheral target organs.

Somatic or visceral sensory information can trigger visceral reflexes, and the motor commands of those reflexes are distributed by the ANS. Sometimes those motor commands control the activities of target organs. For example, in cold weather, the ANS stimulates the arrector pili muscles and gives you “goosebumps.” l**p. 164** In other cases, the motor commands may alter some ongoing activity. A sudden, loud noise can startle you and make you jump, but thanks to the ANS, that sound can also increase your heart rate dramatically and temporarily stop all digestive gland secretion. These changes in visceral activity occur in response to the release of neurotransmitters by postganglionic fibers. As noted in Chapter 12, whether a specific neurotransmitter produces a stimulation or an inhibition of activity depends on the response of the membrane receptors, and we will consider the major types of receptors later in the chapter.

We will now turn to the anatomy and physiology of the ANS. We will then consider the nature of *visceral reflexes,* polysynaptic reflexes that regulate visceral function.

Divisions of the ANS

The ANS contains two primary subdivisions whose names are probably already familiar to you: the *sympathetic division* and the *parasympathetic division*. Most often, these two divisions have opposing effects; if the sympathetic division causes excitation, the parasympathetic causes inhibition. However, this is not always the case, because (1) the two divisions may work independently, with some structures innervated by only one division or the other, and (2) the two divisions may work together, each controlling one stage of a complex process. In general, the sympathetic division “kicks in” only during periods of exertion, stress, or emergency, and the parasympathetic division predominates under resting conditions.

In the **sympathetic division**, or *thoracolumbar* (thor-a-kō-LUM-bar) *division*, preganglionic fibers from the thoracic and superior lumbar segments of the spinal cord synapse in ganglia near the spinal cord. In this division of the ANS, therefore, the preganglionic fibers are short and the postganglionic fibers are long.

The sympathetic division prepares the body for heightened levels of somatic activity. When fully activated, this division produces what is known as the “fight or flight” response, which readies the body for a crisis that may require sudden, intense physical activity. An increase in sympathetic activity generally stimulates tissue metabolism and increases alertness. Imagine walking down a long, dark alley and hearing strange noises in the darkness ahead. Your body responds immediately, and you become more alert and aware of your surroundings. Your metabolic rate rises quickly, to as much as twice the resting level. Your digestive and urinary activities are suspended temporarily, and blood flow to your skeletal muscles increases. You begin breathing more quickly and more deeply. Both your heart rate and blood pressure increase, circulating your blood more rapidly. You feel warm and begin to perspire. The general pattern of responses to increased levels of sympathetic

activity can be summarized as follows: (1) heightened mental alertness, (2) increased metabolic rate, (3) reduced digestive and urinary functions, (4) activation of energy reserves,
(5) increased respiratory rate and dilation of respiratory passageways, (6) increased heart rate and blood pressure, and (7) activation of sweat glands.

In the **parasympathetic division**, or *craniosacral* (kr
¯a
-n
¯e
-

¯o
-S

A¯
-krul) *division*, preganglionic fibers originate in the brain
stem and the sacral segments of the spinal cord, and they synapse in ganglia very close to (or within) the target organs. Thus, in this division of the ANS, the preganglionic fibers are long and the postganglionic fibers are short. The parasympathetic division stimulates visceral activity; for example, it is responsible for the state of “rest and repose” that follows a big dinner. General parasympathetic activation conserves energy and promotes sedentary activities, such as digestion. Your body relaxes, energy demands are minimal, and both your heart rate and blood pressure are relatively low. Meanwhile, your digestive organs are highly stimulated. Your salivary glands and other secretory glands are active; your stomach is contracting; and smooth muscle contractions move materials along your digestive tract. This movement promotes defecation; at the same time, smooth muscle contractions along your urinary tract promote urination. The overall pattern of responses to increased levels of parasympathetic activity is as follows: (1) decreased metabolic rate, (2) decreased heart rate and blood pressure, (3) increased secretion by salivary and digestive glands, (4) increased

motility and blood flow in the digestive tract, and (5) stimulation of urination and defecation.

The ANS also includes a third division that most people have never heard of: the *enteric nervous system (ENS)*, an extensive network of neurons and nerve networks located in the walls of the digestive tract. Although the activities of the enteric nervous system are influenced by the sympathetic and parasympathetic divisions, many complex visceral reflexes are initiated and coordinated locally, without instructions from the CNS. Altogether, the ENS has roughly 100 million neurons—at least as many as the spinal cord—and all of the neurotransmitters found in the brain. In this chapter, we focus on the sympathetic and parasympathetic divisions that integrate and coordinate visceral functions throughout the body. We will consider the activities of the enteric nervous system when we discuss visceral reflexes later in this chapter, and when we examine the control of digestive functions in Chapter 24.

100 Keys | The autonomic nervous system operates largely outside our awareness. It includes: a sympathetic division concerned with increasing alertness, metabolic rate, and muscular abilities, and a parasympathetic division concerned with reducing metabolic rate and promoting visceral activities such as digestion.

Concept Check

How many motor neurons are required to conduct an action potential from the spinal cord to smooth muscles in the wall of the intestine?

While out for a brisk walk, Julie is suddenly confronted by an angry dog. Which division of the autonomic nervous system is responsible for the physiological changes that occur in Julie as she turns and runs?

On the basis of anatomy, how could you distinguish the sympathetic division from the parasympathetic division of the autonomic nervous system?

Answers begin on p. A–1

The Sympathetic Division

Objectives

. • Describe the structures and functions of the sympathetic division of the autonomic nervous system.

. • Describe the mechanisms of neurotransmitter release in the sympathetic division.

. • Describe the effects of sympathetic neurotransmitters on target organs and tissues.

Figure 16–3• depicts the overall organization of the sympathetic division of the ANS. This division consists of preganglionic neurons that are located between segments T1 and L2 of the spinal cord, and ganglionic neurons that are located in ganglia near the vertebral column. The cell bodies of the preganglionic neurons are situated in the lateral gray horns, and their axons enter the ventral roots of these segments. The ganglionic neurons occur in three locations (Figure 16–4•):

1. **1.** *Sympathetic Chain Ganglia.* **Sympathetic chain ganglia**, also called *paravertebral ganglia* or *lateral ganglia*, lie on both sides of the vertebral column (Figure 16–4a•). Neurons in these ganglia control effectors in the body wall, inside the thoracic cavity, and in the head and limbs.

2. **2.** *Collateral Ganglia.* **Collateral ganglia**, also known as *prevertebral ganglia,* are anterior to the vertebral bodies (Figure 16–4b•). Collateral ganglia contain ganglionic neurons that innervate tissues and organs in the abdominopelvic cavity.

3. **3.** *The Adrenal Medullae.* The center of each adrenal gland, an area known as the *adrenal medulla*, is a modified sympathetic ganglion (Figure 16–4c•). The ganglionic neurons of the adrenal medullae have very short axons; when stimulated, they release their neurotransmitters into the bloodstream. The release of neurotransmitters into a capillary, not at a synapse, allows them to function as hormones that affect target cells throughout the body.

In the sympathetic division, the preganglionic fibers are relatively short, because the ganglia are located relatively near the spinal cord. In contrast, postganglionic fibers are relatively long, except at the adrenal medullae.

Organization and Anatomy of the Sympathetic Division

The ventral roots of spinal segments T1 to L2 contain sympathetic preganglionic fibers. The basic pattern of sympathetic innervation in these regions was described in Figure 13–7a•, p. 430. After passing through the intervertebral foramen, each ventral root gives rise to a myelinated *white ramus*, which carries myelinated preganglionic fibers into a nearby sympathetic chain ganglion. These fibers may synapse within the sympathetic chain ganglia, at one of the collateral ganglia, or in the adrenal medullae (see Figure 16–4•). Extensive divergence occurs, with one preganglionic fiber synapsing on two dozen or more ganglionic neurons. Preganglionic fibers running between the sympathetic chain ganglia interconnect them, making the chain resemble a string of pearls. Each ganglion in the sympathetic chain innervates a particular body segment or group of segments.

Sympathetic Chain Ganglia

If a preganglionic fiber carries motor commands that target structures in the body wall or thoracic cavity, or in the head, neck, or limbs, it will synapse in one or more sympathetic chain ganglia. The paths of the unmyelinated postganglionic fibers differ, depending on whether their targets lie in the body wall or within the thoracic cavity:

- Postganglionic fibers that control visceral effectors in the body wall, head, neck, or limbs enter the *gray ramus* and return to the spinal nerve for subsequent distribution (see Figure 16–4a•, right). These postganglionic fibers innervate effectors such as the sweat glands of the skin and the smooth muscles in superficial blood vessels.
- Postganglionic fibers innervating structures in the thoracic cavity, such as the heart and lungs, form bundles known as **sympathetic nerves** (see Figure 16–4a•, left).

Although Figure 16–4a• shows sympathetic nerves on the left side and spinal nerve distribution on the right for the sake of clarity, in reality *both* innervation patterns occur on *each* side of the body.

Figure 16–5• provides a more detailed view of the structure of the ganglion chain and the sympathetic division as a whole. The left side of the image shows the distribution to the skin (and to skeletal muscles and other tissues of the body wall), whereas the right side depicts the innervation of visceral organs.

Each sympathetic chain contains 3 cervical, 10–12 thoracic, 4–5 lumbar, and 4–5 sacral ganglia, plus 1 coccygeal ganglion. (The numbers vary due to the occasional fusion of adjacent ganglia.) Preganglionic neurons are limited to spinal cord segments T1 –L2, and these spinal nerves have both white rami (myelinated preganglionic fibers) and gray rami (unmyelinated postganglionic fibers). The neurons in the cervical, inferior lumbar, and sacral sympathetic chain ganglia are innervated by preganglionic fibers that run along the axis of the chain. In turn, these chain ganglia provide postganglionic fibers, through gray rami, to the cervical, lumbar, and sacral spinal nerves. As a result, although only spinal nerves T1 –L2 have white rami, every spinal nerve has a gray ramus that carries sympathetic postganglionic fibers for distribution in the body wall.

About 8 percent of the axons in each spinal nerve are sympathetic postganglionic fibers. As a result, the spinal nerves, which provide somatic motor innervation to skeletal muscles of the body wall and limbs, also distribute sympathetic postganglionic fibers (see Figures 16–4a• and 16–5•). In the head and neck, postganglionic sympathetic fibers leaving the superior cervical sympathetic

ganglia supply the regions and structures innervated by cranial nerves III, VII, IX, and X.

l**pp. 482, 484, 486** AM: Hypersensitivity and Sympathetic Function

In summary:

. • The cervical, inferior lumbar, and sacral chain ganglia receive preganglionic innervation by preganglionic fibers from spinal segments T1 –L2, and every spinal nerve receives a gray ramus from a ganglion of the sympathetic chain.

. • Only the thoracic and superior lumbar ganglia (T1 – L2) receive preganglionic fibers from white rami.

. • Every spinal nerve receives a gray ramus from a ganglion of the sympathetic chain.

Collateral Ganglia

The abdominopelvic viscera receive sympathetic innervation via sympathetic preganglionic fibers that pass through the sympathetic chain without synapsing. They synapse in separate collateral ganglia (see Figures 16–3• and 16–4b•). Preganglionic fibers that innervate the collateral ganglia form the **splanchnic** (SPLANK-nik) **nerves**, which lie in the dorsal wall of the abdominal cavity. Although they originate as paired ganglia (left and right), the two usually fuse together, and in adults the collateral ganglia are typically single rather than paired.

Postganglionic fibers leaving the collateral ganglia extend throughout the abdominopelvic cavity, innervating a variety of visceral tissues and organs. The general functional pattern is (1) a reduction of blood flow and energy use by organs that are not important to short-term survival (such as the digestive tract) and (2) the release of stored energy reserves.

The splanchnic nerves innervate three collateral ganglia (see Figure 16–5•). Preganglionic fibers from the seven inferior thoracic segments end at either the **celiac** (SE¯-le¯-ak) **ganglion** or the **superior mesenteric ganglion**. These ganglia are embedded in an extensive network of autonomic nerves. Preganglionic fibers from the lumbar segments form splanchnic nerves that end at the **inferior mesenteric ganglion**. All three ganglia are named for their association with adjacent arteries:

- The celiac ganglion is named after the *celiac trunk*, a major artery supplying the stomach, spleen, and liver. The celiac ganglion most commonly consists of a pair of interconnected masses of gray matter situated at the base of that artery. The celiac ganglion may also form a single mass or many small, interwoven masses. Postganglionic fibers from this ganglion innervate the stomach, liver, gallbladder, pancreas, and spleen.
- The superior mesenteric ganglion is located near the base of the *superior mesenteric artery*, which provides blood to the stomach, small intestine, and pancreas. Postganglionic fibers leaving the superior mesenteric ganglion innervate the small intestine and the proximal two-thirds of the large intestine.
- The inferior mesenteric ganglion is located near the base of the *inferior mesenteric artery*, which supplies the large intestine and other organs in the inferior portion of the abdominopelvic cavity. Postganglionic fibers from this ganglion provide sympathetic innervation to the terminal portions of the large intestine, the kidney and urinary bladder,

and the sex organs.

The Adrenal Medullae

Preganglionic fibers entering an adrenal gland proceed to its center, a region called the **adrenal medulla** (see Figures 16–4c• and 16–5•). The adrenal medulla is a modified sympathetic ganglion where preganglionic fibers synapse on *neuroendocrine cells*, specialized neurons that secrete hormones (chemical messengers) into the bloodstream. The neuroendocrine cells of the adrenal medullae secrete the neurotransmitters *epinephrine (E)* and *norepinephrine (NE)*. Epinephrine, or *adrenaline*, accounts for 75–80 percent of the secretory output; the rest is NE, or *noradrenaline*.

The bloodstream then carries the neurotransmitters throughout the body, causing changes in the metabolic activities of many different cells. These effects resemble those produced by the stimulation of sympathetic postganglionic fibers. They differ, however, in two respects: (1) Cells not innervated by sympathetic postganglionic fibers are affected as well; and (2) the effects last much longer than those produced by direct sympathetic innervation, because the hormones continue to diffuse out of the bloodstream for an extended period.

Sympathetic Activation

The sympathetic division can change the activities of tissues and organs by releasing NE at peripheral synapses, and by distributing E and NE throughout the body in the bloodstream. The visceral motor fibers that target specific effectors, such as smooth muscle fibers in blood vessels of the skin, can be activated in reflexes that do not involve other visceral effectors. In a crisis, however, the entire division responds. This event, called **sympathetic activation**, is controlled by sympathetic centers in the hypothalamus. The effects are not limited to peripheral tissues; sympathetic activation also alters CNS activity.

When sympathetic activation occurs, an individual experiences the following changes:

. • Increased alertness via stimulation of the reticular activating system, causing the individual to feel “on edge.”

. • A feeling of energy and euphoria, often associated with a disregard for danger and a temporary insensitivity to painful stimuli.

. • Increased activity in the cardiovascular and respiratory centers of the pons and medulla oblongata, leading to elevations in blood pressure, heart rate, breathing rate, and depth of respiration.

. • A general elevation in muscle tone through stimulation of the medial and lateral pathways, so the person *looks* tense and may begin to shiver.

. • The mobilization of energy reserves, through the accelerated breakdown of glycogen in muscle and liver cells and the release of lipids by adipose tissues.

These changes, plus the peripheral changes already noted, complete the preparations necessary for the individual to cope with a stressful situation.

Anatomy 360 | Review the anatomy of the sympathetic division on the **Anatomy 360 CD-ROM: Nervous System/Autonomic Nervous System/Sympathetic Division.**

Neurotransmitters and Sympathetic Function

We have examined the distribution of sympathetic impulses and the general effects of sympathetic activation. We now consider the cellular basis of these effects on peripheral organs.

Neurotransmitter Release

The stimulation of sympathetic preganglionic neurons leads to the release of ACh at synapses with ganglionic neurons. Synapses that use ACh as a transmitter are called *cholinergic*. l**p. 405** The effect on the ganglionic neurons is always excitatory.

The stimulation of these ganglionic neurons leads to the release of neurotransmitters at specific target organs. The synaptic terminals are typically different from neuromuscular junctions of the somatic nervous system. Instead of forming synaptic knobs, telodendria form a branching network. Each branch resembles a string of pearls. Each “pearl,” a swollen segment called a **varicosity**, is packed with neurotransmitter vesicles (Figure 16–6•). Chains of varicosities pass along or near the surfaces of the effector cells. There are no specialized postsynaptic membranes, but membrane receptors are scattered across the surfaces of the target cells.

Most sympathetic ganglionic neurons release NE at their varicosities. Neurons that use NE as a neurotransmitter are called *adrenergic*. l**p. 408** The sympathetic division also contains a small, but significant, number of ganglionic neurons that release ACh rather than NE. Varicosities releasing ACh are located in the body wall, the skin, the brain, and skeletal muscles.

The NE released by varicosities affects its targets until it is reabsorbed or inactivated by enzymes. From 50 to 80 percent of the NE is reabsorbed by varicosities and either reused or broken down by the enzyme *monoamine oxidase (MAO)*. The rest of the NE diffuses out of the area or is broken down by the enzyme *catechol-O-methyltransferase (COMT)* in surrounding tissues.

In general, the effects of NE on the postsynaptic membrane persist for a few seconds, significantly longer than the 20-msec duration of ACh effects. (As usual, the responses of the target cells vary with the nature of the receptor on the postsynaptic membrane.) The effects of NE or E released by the adrenal medullae last even longer, because (1) the bloodstream does not contain MAO or COMT, and (2) most tissues contain relatively low concentrations of those enzymes. After the adrenal medullae are stimulated, tissue concentrations of NE and E throughout the body may remain elevated for as long as 30 seconds, and the effects may persist for several minutes.

Sympathetic Stimulation and the Release of NE and E

The effects of sympathetic stimulation result primarily from the interactions of NE and E with adrenergic membrane receptors. There are two classes of sympathetic receptors: *alpha receptors* and *beta receptors*. In general, norepinephrine stimulates alpha receptors to a greater degree than it does beta receptors, whereas epinephrine stimulates both classes of receptors. Thus, localized sympathetic activity, involving the release of NE at varicosities, primarily affects alpha receptors located near the active varicosities. By contrast, generalized sympathetic activation and the release of E by the adrenal medulla affect alpha and beta receptors throughout the body.

Alpha receptors and beta receptors are *G proteins*. As we saw in Chapter 12, the effects of stimulating such a receptor depend on the production of *second messengers*, intracellular intermediaries with varied functions. l**p. 411**

The stimulation of **alpha (Å) receptors** activates enzymes on the inside of the cell membrane. There are two types of alpha receptors: alpha-1 (a1) and alpha-2 (a2).

. • The function of a1, the more common type of alpha receptor, is the release of intracellular calcium ions from reserves in the endoplasmic reticulum. This action generally has an excitatory effect on the target cell. For example, the stimulation of a_1 receptors on the surfaces of smooth muscle cells is responsible for the constriction of peripheral blood vessels and the closure of sphincters along the digestive tract.

. • Stimulation of a_2 receptors results in a lowering of cyclic-AMP (cAMP) levels in the cytoplasm. Cyclic-AMP is an important second messenger that can activate or inactivate key enzymes. l**p. 411** This reduction generally has an inhibitory effect on the cell. The presence of a_2 receptors in the parasympathetic division helps coordinate sympathetic and parasympathetic activities. When the sympathetic division is active, the NE released binds to parasympathetic neuromuscular and neuroglandular junctions and inhibits their activity.

Beta (ı) receptors are located on the membranes of cells in many organs, including skeletal muscles, the lungs, the heart, and the liver. The stimulation of beta receptors triggers changes in the metabolic activity of the target cell. These changes occur indirectly, as each beta receptor is a G protein whose stimulation results in an increase in intracellular cAMP levels. There are two major types of beta receptors: beta-1 (b1) and beta-2 (b2).

• The stimulation of b1 receptors leads to an increase in metabolic activity. For example, the stimulation of b1 receptors on skeletal muscles accelerates the metabolic activities of the muscles. The stimulation of b1 receptors in the heart causes increases in heart rate and force of contraction.

. • The stimulation of b2 receptors causes inhibition, triggering a relaxation of smooth muscles along the respiratory tract. As a result, the diameters of the respiratory passageways increase, making breathing easier. This response accounts for the effectiveness of inhalers used to treat asthma.

. • A third type of beta receptor, beta-3 (b3), is found in adipose tissue.

Stimulation of b3 receptors leads to *lipolysis*, the breakdown of triglycerides stored within adipocytes. The fatty acids generated through lipolysis are released into the circulation for use by other tissues.

Sympathetic Stimulation and the Release of ACh and NO

Although the vast majority of sympathetic postganglionic fibers are adrenergic (release NE), a few are cholinergic (release ACh). These postganglionic fibers innervate sweat glands of the skin and the blood vessels to skeletal muscles and the brain. The activation of these sympathetic fibers stimulates sweat gland secretion and dilates the blood vessels.

In other regions of the body, ACh is released by the parasympathetic division rather than by the sympathetic division. However, neither the body wall nor skeletal muscles are innervated by the parasympathetic division, and in these areas both NE and ACh are needed to regulate visceral functions with precision. For example, whereas ACh causes dilation of most small peripheral arteries *(vasodilation)*, NE causes their constriction *(vasoconstriction)*. This means that the sympathetic division can increase blood flow to skeletal muscles, through activation of cholinergic terminals, at the same time that adrenergic terminals reduce the blood flow to other tissues in the body wall.

The sympathetic division also includes *nitroxidergic* synapses, which release *nitric oxide (NO)* as a neurotransmitter. Such synapses occur where neurons innervate smooth muscles in the walls of blood vessels in many regions, notably in skeletal muscles and the brain. The activity of these synapses produces vasodilation and increased blood flow through these regions.

Summary: The Sympathetic Division

To summarize our discussion of the sympathetic division:

1. **1.** The sympathetic division of the ANS includes two sets of sympathetic chain ganglia, one on each side of the vertebral column; three collateral ganglia anterior to the vertebral column; and two adrenal medullae.

2. **2.** The preganglionic fibers are short, because the ganglia are close to the spinal cord. The postganglionic fibers are longer and extend a considerable distance before reaching their target organs. (In the case of the adrenal medullae, very short axons end at capillaries that carry their secretions to the bloodstream.)

3. **3.** The sympathetic division shows extensive divergence, and a single preganglionic fiber may innervate two dozen or more ganglionic neurons in different ganglia. As a result, a single sympathetic motor neuron in the CNS can control a variety of visceral effectors and can produce a complex and coordinated response.

4. All preganglionic neurons release ACh at their synapses with ganglionic neurons. Most postganglionic fibers release NE, but a

few release ACh or NO.

4. **5.** The effector response depends on the second messengers activated when NE or E binds to alpha receptors or beta receptors.

Concept Check

Where do the nerves that synapse in collateral ganglia originate?

How would a drug that stimulates acetylcholine receptors affect the sympathetic nervous system?

An individual with high blood pressure is given a medication that blocks beta receptors. How could this medication help correct that person's condition?

Answers begin on p. A–1

The Parasympathetic Division

Objectives

. • Describe the structures and functions of the parasympathetic division of the autonomic nervous system.

. • Describe the mechanisms of neurotransmitter release in the parasympathetic division.

. • Describe the effects of parasympathetic neurotransmitters on target organs and tissues.

The parasympathetic division of the ANS (Figure 16–7•) consists of:

1. **1.** *Preganglionic Neurons in the Brain Stem and in Sacral Segments of the Spinal Cord.* The mesencephalon, pons, and medulla oblongata contain autonomic nuclei associated with cranial nerves III, VII, IX, and X. In sacral segments of the spinal cord, the autonomic nuclei lie in the lateral gray horns of spinal segments S2 – S4.
2. **2.** *Ganglionic Neurons in Peripheral Ganglia within or Adjacent to the Target Organs.* Preganglionic fibers of the parasympathetic division do not diverge as extensively as do those of the sympathetic division. A typical preganglionic fiber synapses on six to eight ganglionic neurons. These neurons may be situated in a **terminal ganglion**, located near the target organ, or in an **intramural ganglion** (*murus*, wall), which is embedded in the tissues of the target organ. Terminal ganglia are usually paired; examples include the parasympathetic ganglia associated with the cranial nerves. Intramural ganglia typically consist of interconnected masses and clusters of ganglion cells.

In contrast to the pattern in the sympathetic division, all these ganglionic neurons are located in the same ganglion, and their postganglionic fibers influence the same target organ. Thus, the effects of parasympathetic stimulation are more specific and localized than are those of the sympathetic division.

Organization and Anatomy of the Parasympathetic Division

Parasympathetic preganglionic fibers leave the brain as components of cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus) (Figure 16–8•). These fibers carry the cranial parasympathetic output. Parasympathetic fibers in the oculomotor, facial, and glossopharyngeal nerves control visceral structures in the head. These fibers synapse in the *ciliary*, *pteryg*

opalatine, *submandibular*, and *otic ganglia*. l**pp. 483, 484** Short postganglionic fibers continue to their peripheral targets. The vagus nerve provides preganglionic parasympathetic innervation to structures in the neck and in the thoracic and abdominopelvic cavity as distant as the distal portion of the large intestine. The vagus nerve alone provides roughly 75 percent of all parasympathetic outflow. The numerous branches of the vagus nerve intermingle with preganglionic and postganglionic fibers of the sympathetic division, forming plexuses comparable to those formed by spinal nerves innervating the limbs. These plexuses will be considered further in a later section.

The preganglionic fibers in the sacral segments of the spinal cord carry the sacral parasympathetic output. These fibers do not join the ventral roots of the spinal nerves. Instead, the preganglionic fibers form distinct **pelvic nerves**, which innervate intramural ganglia in the walls of the kidneys, urinary bladder, terminal portions of the large intestine, and sex organs.

Anatomy 360 | Review the anatomy of the parasympathetic division on the **Anatomy 360 CD-ROM: Nervous System/Au-tonomic Nervous System/Parasympathetic Division.**

Parasympathetic Activation

The major effects produced by the parasympathetic division include the following:

- Constriction of the pupils (to restrict the amount of light that enters the eyes) and focusing the lenses of the eyes on nearby objects.
- Secretion by digestive glands, including salivary glands, gastric glands, duodenal glands, intestinal glands, the pancreas (exocrine and endocrine), and the liver.
- The secretion of hormones that promote the absorption and utilization of nutrients by peripheral cells.
- Changes in blood flow and glandular activity associated with sexual arousal.
- An increase in smooth muscle activity along the digestive tract.
- The stimulation and coordination of defecation.
- Contraction of the urinary bladder during urination.
- Constriction of the respiratory passageways.
- A reduction in heart rate and in the force of contraction.
- Sexual arousal and the stimulation of sexual glands in both sexes.

These functions center on relaxation, food processing, and energy absorption. The parasympathetic division has been called the *anabolic system*, because its stimulation leads to a general increase in the nutrient content of the blood. (*Anabolic* comes from the Greek word *anabole*, which means “a rising up.”) Cells throughout the body respond to this increase by absorbing nutrients and using them to support growth, cell division, and the creation of energy reserves in the form of lipids or glycogen.

Neurotransmitters and Parasympathetic Function

All parasympathetic neurons release ACh as a neurotransmitter. The effects on the postsynaptic cell can vary widely, however, due to variations in the type of receptor or the nature of the second messenger involved.

Neurotransmitter Release

The neuromuscular and neuroglandular junctions of the parasympathetic division are small and have narrow synaptic clefts. The effects of stimulation are short-lived, because most of the ACh released is inactivated by *acetylcholinesterase (AChE)* at the synapse. Any ACh diffusing into the surrounding tissues will be inactivated by the enzyme *tissue cholinesterase*, also called *pseudocholinesterase*. As a result, the effects of parasympathetic stimulation are quite localized, and they last a few seconds at most.

Membrane Receptors and Responses

Although all the synapses (neuron to neuron) and neuromuscular or neuroglandular junctions (neuron to effector) of the parasympathetic division use the same transmitter, ACh, two types of ACh receptors occur on the postsynaptic membranes:

1. **1. Nicotinic** (nik-o¯-TIN-ik) **receptors** are located on the surfaces of ganglion cells of both the parasympathetic and sympathetic divisions, as well as at neuromuscular junctions of the somatic nervous system. Exposure to ACh always causes excitation of the ganglionic neuron or muscle fiber by the opening of chemically gated channels in the postsynaptic membrane.

2. **2. Muscarinic** (mus-ka-RIN-ik) **receptors** are located at cholinergic neuromuscular or neuroglandular junctions in the parasympathetic division, as well as at the few cholinergic junctions in the sympathetic division. Muscarinic receptors are G proteins (p. 412), and their stimulation produces longer-lasting effects than does the stimulation of nicotinic receptors. The response, which reflects the activation or inactivation of specific enzymes, can be excitatory or inhibitory.

The names *nicotinic* and *muscarinic* originated with researchers who found that dangerous environmental toxins bind to these receptor sites. Nicotinic receptors bind *nicotine*, a powerful toxin that can be obtained from a variety of sources, including tobacco leaves. Muscarinic receptors are stimulated by *muscarine*, a toxin produced by some poisonous mushrooms.

These compounds have discrete actions, targeting either the autonomic ganglia and skeletal neuromuscular junctions (nicotine) or the parasympathetic neuromuscular or neuroglandular junctions (muscarine). They produce dangerously exaggerated, uncontrolled responses due to abnormal stimulation of cholinergic or adrenergic receptors. Nicotine poisoning occurs if as little as 50 mg of the compound is ingested or absorbed through the skin. The signs and symptoms reflect widespread autonomic activation: vomiting, diarrhea, high blood pressure, rapid heart rate, sweating, and profuse salivation. Because the neuromuscular junctions of the somatic nervous system are stimulated, convulsions occur. In severe cases, the stimulation of nicotinic receptors inside the CNS can lead to coma and death within minutes. The signs and symptoms of muscarine poisoning are almost entirely restricted to the parasympathetic division: salivation, nausea, vomiting, diarrhea, constriction of respiratory passages, low blood pressure, and an abnormally slow heart rate (bradycardia).

Table 16–1 summarizes details about the adrenergic and cholinergic receptors of the ANS.

Summary: The Parasympathetic Division

In summary:

- The parasympathetic division includes visceral motor nuclei associated with cranial nerves III, VII, IX, and X and with sacral segments S2 – S4.
- Ganglionic neurons are located within or next to their target organs.
- The parasympathetic division innervates areas serviced by the cranial nerves and organs in the thoracic and abdominopelvic cavities.
- All parasympathetic neurons are cholinergic. Ganglionic neurons have nicotinic receptors, which are excited by ACh. Mus

carinic receptors at neuromuscular or neuroglandular junctions produce either excitation or inhibition, depending on the nature of the enzymes activated when ACh binds to the receptor.

- The effects of parasympathetic stimulation are generally brief and restricted to specific organs and sites.

100 Keys | The preganglionic neurons of the autonomic nervous system release acetylcholine (ACh) as a neurotransmitter. The ganglionic neurons of the sympathetic division primarily release norepinephrine as a neurotransmitter (and both NE and E as hormones at the adrenal medulla). The ganglionic neurons of the parasympathetic division release ACh as a neurotransmitter.

Concept Check

Which nerve is responsible for the parasympathetic innervation of the lungs, heart, stomach, liver, and pancreas, and parts of the small and large intestines? How would the stimulation of muscarinic receptors in cardiac muscle affect the heart?

Why is the parasympathetic division sometimes referred to as the anabolic system?

Answers begin on p. A–1

Interactions between the Sympathetic and Parasympathetic Divisions

Objectives

- Discuss the relationship between the two divisions of the autonomic nervous system and the significance of dual innervation.
- Explain the importance of autonomic tone.

Figure 16–9• and Table 16–2 compare key structural features of the sympathetic and parasympathetic divisions of the ANS. The distinctions have physiological and functional correlates. The sympathetic division has widespread impact, reaching organs and tissues throughout the body. The parasympathetic division innervates only visceral structures that are serviced by the cranial nerves or that lie within the abdominopelvic cavity. Although some organs are innervated by just one division, most vital organs receive **dual innervation**, receiving instructions from both the sympathetic and parasympathetic divisions. Where dual innervation exists, the two divisions commonly have opposing effects. Dual innervation with opposing effects is most evident in the digestive tract, heart, and lungs. At other sites, the responses may be separate or complementary. Table 16–3 provides a functional comparison of the two divisions, taking into account the effects of sympathetic or parasympathetic activity on specific organs and systems.

Anatomy of Dual Innervation

Parasympathetic postganglionic fibers from the ciliary, pterygopalatine, submandibular, and otic ganglia of the head accompany the cranial nerves to their peripheral destinations. The sympathetic innervation reaches the same structures by traveling directly from the superior cervical ganglia of the sympathetic chain.

In the thoracic and abdominopelvic cavities, the sympathetic postganglionic fibers mingle with parasympathetic preganglionic fibers, forming a series of nerve networks collectively called *autonomic plexuses*: the cardiac plexus, the pulmonary plexus, the esophageal plexus, the celiac plexus, the inferior mesenteric plexus, and the hypogastric plexus (Figure 16–10•). Nerves leaving these networks travel with the blood vessels and lymphatic vessels that supply visceral organs.

Autonomic fibers entering the thoracic cavity intersect at the **cardiac plexus** and the **pulmonary plexus**. These plexuses contain sympathetic and parasympathetic fibers bound for the heart and lungs, respectively, as well as the parasympathetic ganglia whose output affects those organs. The **esophageal plexus** contains descending branches of the vagus nerve and splanchnic nerves leaving the sympathetic chain on either side.

Parasympathetic preganglionic fibers of the vagus nerve enter the abdominopelvic cavity with the esophagus. There the fibers enter the **celiac plexus**, also known as the *solar plexus*. The celiac plexus and associated smaller plexuses, such as the **inferior mesenteric plexus**, innervate viscera within the abdominal cavity. The **hypogastric plexus** contains the parasympathetic outflow of the pelvic nerves, sympathetic postganglionic fibers from the inferior mesenteric ganglion, and splanchnic nerves from the sacral sympathetic chain.

This plexus innervates the digestive, urinary, and reproductive organs of the pelvic cavity.

Autonomic Tone

Even in the absence of stimuli, autonomic motor neurons show a resting level of spontaneous activity. The background level of activation determines an individual's **autonomic tone**. Autonomic tone is an important aspect of ANS function, just as muscle tone is a key aspect of SNS function. If a nerve is absolutely inactive under normal conditions, then all it can do is increase its activity on demand. But if the nerve maintains a background level of activity, it can increase or decrease its activity, providing a greater range of control options.

Autonomic tone is significant where dual innervation occurs and the two ANS divisions have opposing effects. It is even more important in situations in which dual innervation does not occur. To demonstrate how autonomic tone affects ANS function, we will consider one example of each situation.

The heart is an organ that receives dual innervation. Recall that the heart consists of cardiac muscle tissue, and that its contractions are triggered by specialized pacemaker cells. l**p. 134** The two autonomic divisions have opposing effects on heart function. Acetylcholine released by postganglionic fibers of the parasympathetic division causes a reduction in heart rate, whereas NE released by varicosities of the sympathetic division accelerates heart rate. Because autonomic tone is present, small amounts of both of these neurotransmitters are released continuously. However, parasympathetic innervation dominates under resting conditions. Heart rate can be controlled very precisely to meet the demands of active tissues through small adjustments in the balance between parasympathetic stimulation and sympathetic stimulation. In a crisis, stimulation of the sympathetic innervation and inhibition of the parasympathetic innervation accelerate the heart rate to the maximum extent possible.

The sympathetic control of blood vessel diameter demonstrates how autonomic tone allows fine adjustment of peripheral activities when the target organ is not innervated by both ANS divisions. Blood flow to specific organs must be controlled to meet the tissue demands for oxygen and nutrients. When a blood vessel dilates, blood flow through it increases; when it constricts, blood flow is reduced. Sympathetic postganglionic fibers that release NE innervate the smooth muscle cells in the walls of peripheral vessels. The background sympathetic tone keeps these muscles partially contracted, so the blood vessels are ordinarily at roughly half their maximum diameter. When increased blood flow is needed, the rate of NE release decreases and sympathetic cholinergic fibers are stimulated. As a result, the smooth muscle cells relax, the vessels dilate, and blood flow increases. By adjusting sympathetic tone and the activity of cholinergic fibers, the sympathetic division can exert precise control of vessel diameter over its entire range.

Integration and Control of Autonomic Functions

Objectives

. • Describe the hierarchy of interacting levels of control in the autonomic nervous system.

. • Define a visceral reflex and explain the significance of such reflexes.

Centers involved in somatic motor control are found in all portions of the CNS. The lowest level of regulatory control consists of the lower motor neurons involved in cranial and spinal reflex arcs. The highest level consists of the pyramidal motor neurons of the primary motor cortex, operating with the feedback from the cerebellum and basal nuclei.

The ANS is also organized into a series of interacting levels. At the bottom are visceral motor neurons in the lower brain stem and spinal cord that are involved in cranial and spinal visceral reflexes. **Visceral reflexes** provide automatic motor responses that can be modified, facilitated, or inhibited by higher centers, especially those of the hypothalamus.

For example, when a light is shined in one of your eyes, a visceral reflex constricts the pupils of *both* eyes (the *consensual light reflex*). The visceral motor commands are distributed by parasympathetic fibers. In darkness, your pupils dilate; this *pupillary reflex* is directed by sympathetic postganglionic fibers. However, the motor nuclei directing pupillary constriction or dilation are also controlled by hypothalamic centers concerned with emotional states. When you are queasy or nauseated, your pupils constrict; when you are sexually aroused, your pupils dilate.

Visceral Reflexes

Each **visceral reflex arc** consists of a receptor, a sensory neuron, a processing center (one or more interneurons), and two visceral motor neurons (Figure 16–11•). All visceral reflexes are polysynaptic; they are either long reflexes or short reflexes.

Long reflexes are the autonomic equivalents of the polysynaptic reflexes introduced in Chapter 13. l**p. 443** Visceral sensory neurons deliver information to the CNS along the dorsal roots of spinal nerves, within the sensory branches of cranial nerves, and within the autonomic nerves that innervate visceral effectors. The processing steps involve interneurons within the CNS, and the ANS carries the motor commands to the appropriate visceral effectors.

Short reflexes bypass the CNS entirely; they involve sensory neurons and interneurons whose cell bodies are located within autonomic ganglia. The interneurons synapse on ganglionic neurons, and the motor commands are then distributed by postganglionic fibers. Short reflexes control very simple motor responses with localized effects. In general, short reflexes may control patterns of activity in one small part of a target organ, whereas long reflexes coordinate the activities of an entire organ.

In most organs, long reflexes are most important in regulating visceral activities, but this is not the case with the digestive tract and its associated glands. In these areas, short reflexes provide most of the control and coordination required for normal functioning. The neurons involved form the *enteric nervous system*, introduced on p. 520. The ganglia in the walls of the digestive tract contain the cell bodies of visceral sensory neurons, interneurons, and visceral motor neurons, and their axons form extensive nerve nets. Although parasympathetic innervation of the visceral motor neurons can stimulate and coordinate various digestive activities, the enteric nervous system is quite capable of controlling digestive functions independent of the central nervous system. We will consider the functions of the enteric nervous system further in Chapter 24.

As we examine other body systems in later chapters, we will encounter many examples of autonomic reflexes involved in respiration, cardiovascular function, and other visceral activities. Some of the most important are previewed in Table 16–4. Notice that the parasympathetic division participates in a variety of reflexes that affect individual organs and systems. This specialization reflects the relatively specific and restricted pattern of innervation. In contrast, fewer sympathetic reflexes exist. The sympathetic division is typically activated as a whole, in part because it has such a high degree of divergence and in part because the release of hormones by the adrenal medullae produces widespread peripheral effects.

Higher Levels of Autonomic Control

The levels of activity in the sympathetic and parasympathetic divisions of the ANS are controlled by centers in the brain stem that regulate specific visceral functions. As in the SNS, in the ANS simple reflexes based in the spinal cord provide relatively rapid and automatic responses to stimuli. More complex sympathetic and parasympathetic reflexes are coordinated by processing centers in the medulla oblongata. In addition to the cardiovascular and respiratory centers, the medulla oblongata contains centers and nuclei involved with salivation, swallowing, digestive secretions, peristalsis, and urinary function. These centers are in turn subject

to regulation by the hypothalamus. l**p. 468**

The term *autonomic* was originally applied because the regulatory centers involved with the control of visceral function were thought to operate autonomously—that is, independent of other CNS activities. This view has been drastically revised in light of subsequent research. Because the hypothalamus interacts with all other portions of the brain, activity in the limbic system, thalamus, or cerebral cortex can have dramatic effects on autonomic function. For example, when you become angry, your heart rate accelerates, your blood pressure rises, and your respiratory rate increases; when you remember your last big dinner, your stomach “growls” and your mouth waters. AM: Biofeedback

The Integration of SNS and ANS Activities

Figure 16–12• and Table 16–5 indicate how the activities of the somatic nervous system (discussed in Chapter 15) and those of the autonomic nervous system are integrated. Although we have considered somatic and visceral motor pathways separately, the two have many parallels, in terms of both organization and function. Integration occurs at the level of the brain stem, and both systems are under the control of higher centers. AM: Pharmacology and the Autonomic Nervous System

Concept Check

What effect would the loss of sympathetic tone have on blood flow to a tissue? What physiological changes would you expect in a patient who is about to undergo a root canal and is quite anxious about the procedure? Harry has a brain tumor that is interfering with the function of his hypothalamus. Would you expect this tumor to interfere with autonomic function? Why or why not?

Answers begin on p. A–1

Higher-Order Functions

Objectives

. • Explain how memories are created, stored, and recalled.

. • Distinguish between the levels of consciousness and unconsciousness and identify the characteristics of brain activity associated with the different levels of sleep.

Higher-order functions share three characteristics:

1. **1.** The cerebral cortex is required for their performance, and they involve complex interactions among areas of the cortex and between the cerebral cortex and other areas of the brain.

2. **2.** They involve both conscious and unconscious information processing.

3. **3.** They are not part of the programmed “wiring” of the brain; therefore, the functions are subject to modification and adjustment over time.

In Chapter 14, we considered functional areas of the cerebral cortex and the regional specializations of the left and right cerebral hemispheres. l**pp. 474–478** In this section, we consider the mechanisms of memory and learning and describe the neural interactions responsible for consciousness, sleep, and arousal. In the next section, we will provide an overview of brain chemistry and its effects on behavior and personality.

Memory

What was the topic of the last sentence you read? What is your social security number? What does a hot dog taste like? Answering these questions involves accessing *memories*, stored bits of information gathered through experience. **Fact memories** are specific bits of information, such as the color of a stop sign or the smell of a perfume. **Skill memories** are learned motor behaviors. You can probably remember how to light a match or open a screw-top jar, for example. With repetition, skill memories become incorporated at the unconscious level. Examples include the complex motor patterns involved in skiing, playing the violin, and similar activities. Skill memories related to programmed behaviors, such as eating, are stored in appropriate portions of the brain stem. Complex skill memories involve the integration of motor patterns in the basal nuclei, cerebral cortex, and cerebellum.

Two classes of memories are recognized. **Short-term memories**, or *primary memories*, do not last long, but while they persist the information can be recalled immediately. Primary memories contain small bits of information, such as a person’s name or a telephone number. Repeating a phone number or other bit of information reinforces the original short-term memory and helps ensure its conversion to a long-term memory. **Long-term memories** last much longer, in some cases for an entire lifetime. The conversion from short-term to long-term memory is called **memory consolidation**. There are two types of long-term memory:

(1) *Secondary memories* are long-term memories that fade with time and may require considerable effort to recall. (2) *Tertiary memories* are long-term memories that are with you for a lifetime, such as your name or the contours of your own body. Relationships among these memory classes are diagrammed in Figure 16–13•.

Brain Regions Involved in Memory Consolidation and Access

The amygdaloid body and the hippocampus, two components of the limbic system (see Figure 14–11•, p. 469), are essential to memory consolidation. Damage to the hippocampus leads to an inability to convert short-term memories to new long-term memories, although existing long-term memories remain intact and accessible. Tracts leading from the amygdaloid body to the hypothalamus may link memories to specific emotions.

The **nucleus basalis**, a cerebral nucleus near the diencephalon, plays an uncertain role in memory storage and retrieval. Tracts connect this nucleus with the hippocampus, amygdaloid body, and all areas of the cerebral cortex. Damage to this nucleus is associated with changes in emotional states, memory, and intellectual function (as we will see in the discussion of Alzheimer’s disease later in this chapter).

Most long-term memories are stored in the cerebral cortex. Conscious motor and sensory memories are referred to the appropriate association areas. For example, visual memories are stored in the visual association area, and memories of voluntary motor activity are stored in the premotor cortex. Special portions of the occipital and temporal lobes are crucial to the memories of faces, voices, and words. In at least some cases, a specific memory probably depends on the activity of a single neuron. For example, in one portion of the temporal lobe an individual neuron responds to the sound of one word and ignores others. A specific neuron may also be activated by the proper combination of sensory stimuli associated with a particular individual, such as your grandmother. As a result, these neurons are called “grandmother cells.”

Information on one subject is parceled out to many different regions of the brain. Your memories of cows are stored in the visual association area (what a cow looks like, that the letters *c-o-w* mean “cow”), the auditory association area (the “moo” sound and how the word *cow* sounds), the speech center (how to say the word *cow*), and the frontal lobes (how big cows are, what they eat). Related information, such as how you feel about cows and what milk tastes like, is stored in other locations. If one of those storage areas is damaged, your memory will be incomplete in some way. How these memories are accessed and assembled on demand remains a mystery.

Cellular Mechanisms of Memory Formation and Storage

Memory consolidation at the cellular level involves anatomical and physiological changes in neurons and synapses. For legal, ethical, and logistical reasons, it is not possible to conduct much research on these mechanisms with human subjects. Research on other animals, commonly those with relatively simple nervous systems, has indicated that the following mechanisms may be involved:

- **Increased Neurotransmitter Release**. A synapse that is frequently active increases the amount of neurotransmitter it stores, and it releases more on each stimulation. The more neurotransmitter released, the greater the effect on the postsynaptic neuron.
- **Facilitation at Synapses**. When a neural circuit is repeatedly activated, the synaptic terminals begin continuously releasing neurotransmitter in small quantities. The neurotransmitter binds to receptors on the postsynaptic membrane, producing a graded depolarization that brings the membrane closer to threshold. The facilitation that results affects all neurons in the circuit.
- **The Formation of Additional Synaptic Connections**. Evidence indicates that when one neuron repeatedly communicates with another, the axon tip branches and forms additional synapses on the postsynaptic neuron. As a result, the presynaptic neuron will have a greater effect on the transmembrane potential of the postsynaptic neuron.

These processes create anatomical changes that facilitate communication along a specific neural circuit. This facilitated communication is thought to be the basis of memory storage. A single circuit that corresponds to a single memory has been called a **memory engram**. This definition is based on function rather than structure; we know too little about the organization and storage of memories to be able to describe the neural circuits involved. Memory engrams form as the result of experience and repetition. Repetition is crucial—that’s why you probably need to read these chapters more than once before an exam.

Efficient conversion of a short-term memory into a memory engram takes time, usually at least an hour. Whether that conversion will occur depends on several factors, including the nature, intensity, and frequency of the original stimulus. Very strong, repeated, or exceedingly pleasant or unpleasant events are most likely to be converted to long-term memories. Drugs that stimulate the CNS, such as caffeine and nicotine, may enhance memory consolidation through facilitation; we discussed the membrane effects of those drugs in Chapter 12. l**pp. 413–414**

The hippocampus plays a key role in the consolidation of memories. The mechanism, which remains unknown, is linked to the presence of *NMDA* (N-methyl D-aspartate) *receptors*, which are chemically gated calcium channels. When activated by the neurotransmitter *glycine*, the gates open and calcium enters the cell. Blocking NMDA receptors in the hippocampus prevents long-term memory formation.

Clinical Note

Amnesia is the loss of memory as a result of disease or trauma. The type of memory loss depends on the specific regions of the brain affected. For example, damage to the auditory association areas can make it difficult to remember sounds. Amnesia occurs suddenly or progressively, and recovery is complete, partial, or nonexistent, depending on the nature of the problem. In *retrograde amnesia* (*retro*-, behind), the individual loses memories of past events. Some degree of retrograde amnesia commonly follows a head injury; after a car wreck or a fall, many victims are unable to remember the moments preceding the accident. In *anterograde amnesia* (*antero*-, ahead), an individual may be unable to store additional memories, but earlier memories remain intact and accessible. The problem appears to involve an inability to generate long-term memories. Some degree of anterograde amnesia is a common sign of senility, a condition discussed further on p. 543. At least two drugs—*diazepam* (*Valium*) and *Halcion*—have been known to cause brief periods of anterograde amnesia. Brain injuries can cause more prolonged memory problems. A person with permanent anterograde amnesia lives in surroundings that are always new. Magazines can be read, chuckled over, and reread a few minutes later with equal pleasure, as if they had never been seen before. Clinicians must introduce themselves at every meeting, even if they have been treating the patient for years.

In *post-traumatic amnesia (PTA)*, a head injury produces a combination of retrograde and anterograde amnesias; the individual can neither remember the past nor consolidate memories of the present. The duration of the amnesia varies with the severity of the injury. AM: Amnesia

100 Keys | Memory storage involves anatomical as well as physiological changes in neurons. The hippocampus is involved

in the conversion of temporary, short-term memories into durable long-term memories.

Concept Check

List three characteristics of higher-order functions. After suffering a head injury in an automobile accident, David has difficulty comprehending what he hears or reads. This symptom might indicate damage to which portion of his brain? As you recall facts while you take your A&P test, which type of memory are you using?

Answers begin on p. A–1

States of Consciousness

The difference between a conscious individual and an unconscious one is obvious: A conscious individual is alert and attentive; an unconscious individual is not. However, there are many gradations of both states. Although *conscious* implies an awareness of and attention to external events and stimuli, a healthy conscious person can be nearly asleep, wide awake, or high-strung and jumpy. *Unconscious* can refer to conditions ranging from the deep, unresponsive state induced by anesthesia before major surgery, to deep sleep, to the light, drifting “nod” that occasionally plagues students who are reading anatomy and physiology textbooks.

The degree of wakefulness at any moment is an indication of the level of ongoing CNS activity. When you are asleep, you are unconscious but can still be awakened by normal sensory stimuli. Healthy individuals cycle between the alert, conscious state and sleep each day. When CNS function becomes abnormal or depressed, the state of wakefulness can be affected. An individual in a *coma*, for example, is unconscious and cannot be awakened, even by strong stimuli. As a result, clinicians are quick to note any change in the responsiveness of comatose patients. AM: Altered States

Sleep

Two general levels of sleep are recognized, each typified by characteristic patterns of brain wave activity (Figure 16–14a•):

1. **1.** In **deep sleep**, also called *slow wave* or *non-REM (NREM) sleep*, your entire body relaxes, and activity at the cerebral cortex is at a minimum. Heart rate, blood pressure, respiratory rate, and energy utilization decline by up to 30 percent.

2. **2.** During **rapid eye movement (REM) sleep**, active dreaming occurs, accompanied by changes in blood pressure and respiratory rate. Although the EEG resembles that of the awake state, you become even less receptive to outside stimuli than in deep sleep, and muscle tone decreases markedly. Intense inhibition of somatic motor neurons probably prevents you from physically producing the responses you envision while dreaming. The neurons controlling the eye muscles escape this inhibitory influence, and your eyes move rapidly as dream events unfold.

Periods of REM and deep sleep alternate throughout the night (Figure 16–14b•), beginning with a period of deep sleep that lasts about an hour and a half. Rapid eye movement periods initially average about 5 minutes in length, but they gradually increase to about 20 minutes over an eight-hour night. Each night we probably spend less than two hours dreaming, but variation among individuals is significant. For example, children devote more time to REM sleep than do adults, and extremely tired individuals have very short and infrequent REM periods.

Sleep produces only minor changes in the physiological activities of other organs and systems, and none of these changes appear to be essential to normal function. The significance of sleep must lie in its impact on the CNS, but the physiological or biochemical basis remains to be determined. We do know that protein synthesis in neurons increases during sleep. Extended periods without sleep will lead to a variety of disturbances in mental function. Roughly 25 percent of the U.S. population experiences some form of *sleep disorder*. Examples of such disorders include abnormal patterns or duration of REM sleep or unusual behaviors performed while sleeping, such as sleepwalking. In some cases, these problems begin to affect the individual's conscious activities. Slowed reaction times, irritability, and behavioral changes may result. AM: Sleep Disorders

Arousal and the Reticular Activating System

Arousal, or awakening from sleep, appears to be one of the functions of the reticular formation. The reticular formation is especially well suited for providing “watchdog” services, because it has extensive interconnections with the sensory, motor, and integrative nuclei and pathways all along the brain stem.

Your state of consciousness is determined by complex interactions between the reticular formation and the cerebral cortex.

One of the most important brain stem components is a diffuse network in the reticular formation known as the **reticular activating system (RAS)**. l**p. 464** This network extends from the medulla oblongata to the mesencephalon (Figure 16–15•). The output of the RAS projects to thalamic nuclei that influence large areas of the cerebral cortex. When the RAS is inactive, so is the cerebral cortex; stimulation of the RAS produces a widespread activation of the cerebral cortex.

The mesencephalic portion of the RAS appears to be the “headquarters” of the system. Stimulation of this area produces the most pronounced and long-lasting effects on the cerebral cortex. Stimulating other portions of the RAS seems to have an effect only to the degree that it changes the activity of the mesencephalic region. The greater the stimulation to the mesencephalic region of the RAS, the more alert and attentive the individual will be to incoming sensory information. The thalamic nuclei associated with the RAS may also play an important role in focusing attention on specific mental processes.

Sleep may be ended by any stimulus sufficient to activate the reticular formation and RAS. Arousal occurs rapidly, but the effects of a single stimulation of the RAS last less than a minute. Thereafter, consciousness can be maintained by positive feedback, because activity in the cerebral cortex, basal nuclei, and sensory and motor pathways will continue to stimulate the RAS.

After many hours of activity, the reticular formation becomes less responsive to stimulation. The individual becomes less alert and more lethargic. The precise mechanism remains unknown, but neural fatigue probably plays a relatively minor role in the reduction of RAS activity. Evidence suggests that the regulation of awake–asleep cycles involves an interplay between brain stem nuclei that use different neurotransmitters. One group of nuclei stimulates the RAS with norepinephrine and maintains the awake, alert state. The other group, which depresses RAS activity with serotonin, promotes deep sleep. These “dueling” nuclei are located in the brain stem.

100 Keys | An individual’s state of consciousness is variable and complex, ranging from energized and “hyper” to unconscious and comatose. During deep sleep, all metabolic functions are significantly reduced; during REM sleep, muscular activities are inhibited while cerebral activity is similar to that seen in awake individuals. Sleep disorders result in abnormal reaction times, mood swings, and behaviors. Awakening occurs when the reticular activating system becomes active; the greater the level of activity, the more alert the individual.

Brain Chemistry and Behavior

Objective

• Describe some of the ways in which the interactions of neurotransmitters influence brain function.

Changes in the normal balance between two or more neurotransmitters can profoundly affect brain function. For example, the interplay between populations of neurons releasing serotonin and norepinephrine considered in the previous section appears to be involved in the regulation of awake–asleep cycles. Another example concerns *Huntington’s disease*. The primary problem in this inherited disease is the destruction of ACh-secreting and GABA-secreting neurons in the basal nuclei. The reason for this destruction is unknown. Symptoms appear as the basal nuclei and frontal lobes slowly degenerate. An individual with Huntington’s disease has difficulty controlling movements, and intellectual abilities gradually decline. AM: Huntington’s Disease

In many cases, the importance of a specific neurotransmitter has been revealed during the search for a mechanism for the effects of administered drugs. Here are two examples:

1. **1.** *Lysergic acid diethylamide (LSD)* is a powerful hallucinogenic drug that activates serotonin receptors in the brain stem, hypothalamus, and limbic system. Compounds that merely enhance the effects of serotonin also produce hallucinations, whereas compounds that inhibit serotonin production or block its action cause severe depression and anxiety. The most effective antidepressive drug now in widespread use, *fluoxetine (Prozac)*, slows the removal of serotonin at synapses, causing an increase in serotonin concentrations at the postsynaptic membrane. Such drugs are classified as selective serotonin reuptake inhibitors (SSRIs). Other important SSRIs include Celexa, Luvox, Paxil, and Zoloft. It is now clear that an extensive network of tracts delivers serotonin to nuclei and higher centers throughout the brain, and variations in serotonin levels affect sensory interpretation and emotional states.

2. **2.** We have already seen that inadequate dopamine production causes the motor problems of Parkinson’s disease. l**p. 474** Amphetamines, or “speed,” stimulate dopamine secretion and, in large doses, can produce symptoms resembling those of *schizophrenia*, a psychological disorder marked by pronounced disturbances of mood, thought patterns, and behavior. Dopamine is thus important not only in the nuclei involved in the control of intentional movements, but in many other centers of the diencephalon and cerebrum. AM: Pharmacology and Drug Abuse

Aging and the Nervous System

Objective

• Summarize the effects of aging on the nervous system.

The aging process affects all body systems, and the nervous system is no exception. Anatomical and physiological changes begin shortly after maturity (probably by age 30) and accumulate over time. Although an estimated 85 percent of people above age 65 lead relatively normal lives, they exhibit noticeable changes in mental performance and in CNS function. Common age-related anatomical changes in the nervous system include the following:

. • **A Reduction in Brain Size and Weight.** This reduction results primarily from a decrease in the volume of the cerebral cortex. The brains of elderly individuals have narrower gyri and wider sulci than do those of young people, and the subarachnoid space is larger.

. • **A Reduction in the Number of Neurons.** Brain shrinkage has been linked to a loss of cortical neurons, although evidence indicates that neuronal loss does not occur (at least to the same degree) in brain stem nuclei.

. • **A Decrease in Blood Flow to the Brain.** With age, fatty deposits gradually accumulate in the walls of blood vessels. Just as a clog in a drain reduces water flow, these deposits reduce the rate of blood flow through arteries. (This process, called *arteriosclerosis,* affects arteries throughout the body; we will discuss it further in Chapter 21.) Even if the reduction in blood flow is not sufficient to damage neurons, it increases the chances that the affected vessel wall will rupture, damaging the surrounding neural tissue and producing symptoms of a *cerebrovascular accident (CVA),* or stroke.

. • **Changes in the Synaptic Organization of the Brain.** In many areas, the number of dendritic branches, spines, and interconnections appears to decrease. Synaptic connections are lost, and the rate of neurotransmitter production declines.

. • **Intracellular and Extracellular Changes in CNS Neurons.** Many neurons in the brain accumulate abnormal intracellular deposits, including lipofuscin and neurofibrillary tangles. **Lipofuscin** is a granular pigment with no known function. **Neurofibrillary tangles** are masses of neurofibrils that form dense mats inside the cell body and axon. **Plaques** are extracellular accumulations of fibrillar proteins, surrounded by abnormal dendrites and axons. Both plaques and tangles contain deposits of several peptides—primarily two forms of **amyloid** b(**A**b) protein—and appear in brain regions such as the hippocampus, specifically associated with memory processing. The significance of these histological abnormalities is unknown. Evidence indicates that they appear in all aging brains, but when present in excess, they seem to be associated with clinical abnormalities.

These anatomical changes are linked to functional changes. In general, neural processing becomes less efficient with age. Memory consolidation typically becomes more difficult, and secondary memories, especially those of the recent past, become harder to access. The sensory systems of the elderly—notably, hearing, balance, vision, smell, and taste—become less acute. Lights must be brighter, sounds louder, and smells stronger before they are perceived. Reaction times are slowed, and reflexes—even some withdrawal reflexes—weaken or disappear. The precision of motor control decreases, and it takes longer to perform a given motor pattern than it did 20 years earlier.

For roughly 85 percent of the elderly population, these changes do not interfere with their abilities to function in society. But for as yet unknown reasons, some elderly individuals become incapacitated by progressive CNS changes. These degenerative changes, which can include memory loss, anterograde amnesia, and emotional disturbances, are often lumped together under the general heading of *senile dementia*, or **senility**. By far the most common and incapacitating form of senile dementia is Alzheimer’s disease.

Concept Check

You are asleep. What would happen to you if your reticular activating system were suddenly stimulated?

What would be the effect of a drug that substantially increases the amount of serotonin released in the brain?

One of the problems associated with aging is difficulty in recalling things, or even a total loss of memory. What are some possible reasons for these changes?

Answers begin on p. A–1

Integration with Other Systems

Every moment of your life, billions of neurons in your nervous system are exchanging information across trillions of synapses and performing the most complex integrative functions in the body. As part of this process, the nervous system monitors all other systems and issues commands that adjust their activities. However, the significance and impact of these commands varies greatly from one system to another. The normal functions of the muscular system, for example, simply cannot be performed without instructions from the nervous system. By contrast, the cardiovascular system is relatively independent—the nervous system merely coordinates and adjusts cardiovascular activities to meet the circulatory demands of other systems. In the final analysis, the nervous system is like the conductor of an orchestra, directing the rhythm and balancing the performances of each section to produce a symphony, instead of simply a very loud noise.

Figure 16–16• diagrams the relationships between the nervous system and other physiological systems. We will explore many of these relationships in greater detail in subsequent chapters.

Clinical Patterns

Neural tissue is extremely delicate, and the characteristics of the extracellular environment must be kept within narrow homeostatic limits. When homeostatic regulatory mechanisms break down under the stress of genetic or environmental factors, infection, or trauma, symptoms of neurological disorders appear.

Literally hundreds of disorders affect the nervous system. These disorders can be roughly categorized into the following groups:

- *Infections*, which include diseases such as rabies and polio
- *Congenital disorders*, such as spina bifida and hydrocephalus
- *Degenerative disorders*, such as Parkinson’s disease and Alzheimer’s disease
- *Tumors* of neural origin
- *Trauma*, such as spinal cord injuries and concussions
- *Toxins*, such as heavy metals and the neurotoxins found in certain seafoods
- *Secondary disorders*, which are problems resulting from dysfunction in other systems; examples include strokes and several demyelination disorders

A standard physical examination includes a neurological component, which the physician uses to check the general status of the CNS and PNS. In *neurological examinations*, physicians attempt to trace the source of a specific problem by evaluating the sensory, motor, behavioral, and cognitive functions of the nervous system. Information on neurological exams, diagnostic tests, and a discussion of representative disorders in each of these classes can be found in the *Applications Manual*.

Chapter Review

Selected Clinical Terminology

alpha-blockers: Drugs that eliminate the peripheral vasoconstriction that accompanies sympathetic stimulation. [AM]

Alzheimer's disease: A progressive disorder marked by the loss of higher-order cerebral functions. (p. 543 and [AM])

amnesia: A temporary or permanent loss of memory. (p. 539 and [AM])

anterograde amnesia: Loss of the ability to store new memories. (p. 539 and [AM])

beta-blockers: Drugs that decrease heart rate and force of contraction, lowering peripheral blood pressure. [AM]

Huntington's disease: An inherited disease marked by a progressive deterioration of mental abilities and by motor disturbances. (p. 541

and [AM]) **parasympathetic blocking agents:** Drugs that target the muscarinic receptors at neuromuscular or neuroglandular junctions. [AM] **parasympathomimetic drugs:** Drugs that mimic parasympathetic stimulation and increase the activity along the digestive tract. [AM] **post-traumatic amnesia (PTA):** Loss of both past memories and the ability to consolidate new memories as a result of a head injury.

. (p. 539 and [AM]) **retrograde amnesia:** Loss of memory of past events. (p. 539 and [AM]) **schizophrenia:** A psychological disorder marked by pronounced disturbances of mood, thought patterns, and behavior. (p. 542) **senile dementia,** or *senility***:** A progressive loss of memory, spatial orientation, language, and personality as a consequence of aging.

. (p. 543 and [AM]) **sympathetic blocking agents:** Drugs that bind to receptor sites, preventing a normal response to neurotransmitters or sympathomimetic drugs. [AM] **sympathomimetic drugs:** Drugs that mimic the effects of sympathetic stimulation. [AM]

Study Outline

An Overview of the ANS 518

1. The **autonomic nervous system (ANS)** coordinates cardiovascular, respiratory, digestive, urinary, and reproductive functions. *(Figure 16–1)*

2. **Preganglionic neurons** in the CNS send axons to synapse on **ganglionic neurons** in **autonomic ganglia** outside the CNS. *(Figure 16–2)*

Divisions of the ANS p. 519

3. Preganglionic fibers from the thoracic and lumbar segments form the **sympathetic division**, or *thoracolumbar division* ("fight or flight" system), of the ANS. Preganglionic fibers leaving the brain and sacral segments form the **parasympathetic division**, or *craniosacral division* ("rest and repose" system).

100 Keys | p. 520

The Sympathetic Division p. 521

1. **1.** The sympathetic division consists of preganglionic neurons between segments T1 and L2, ganglionic neurons in ganglia near the vertebral column, and specialized neurons in the adrenal glands. *(Figure 16–3)*

2. **2.** The two types of sympathetic ganglia are **sympathetic chain ganglia** (*paravertebral ganglia*) and **collateral ganglia** (*prevertebral ganglia*). *(Figure 16–4)*

Organization and Anatomy of the Sympathetic Division p. 522

1. **3.** In spinal segments T1 –L2, ventral roots give rise to the myelinated white ramus which, in turn, leads to the sympathetic chain ganglia. *(Figures 16–4, 16–5)*

2. **4.** **Postganglionic fibers** targeting structures in the body wall and limbs rejoin the spinal nerves and reach their destinations by way of the dorsal and ventral rami. *(Figures 16–4, 16–5)*

3. **5.** Postganglionic fibers targeting structures in the thoracic cavity form **sympathetic nerves**, which go directly to their visceral destination. Preganglionic fibers run between the sympathetic chain ganglia and interconnect them. *(Figures 16–4, 16–5)*

4. **6.** The abdominopelvic viscera receive sympathetic innervation via preganglionic fibers that synapse within collateral ganglia. The preganglionic fibers that innervate the collateral ganglia form the **splanchnic nerves**. *(Figures 16–4, 16–5)*

5. **7.** The **celiac ganglion** innervates the stomach, liver, gallbladder, pancreas, and spleen; the **superior mesenteric ganglion** innervates the small intestine and initial segments of the large intestine; and the **inferior mesenteric ganglion** innervates the terminal portions of the large intestine, the kidneys and urinary bladder, and the sex organs. *(Figures 16–5, 16–10)*

6. **8.** Preganglionic fibers entering an adrenal gland synapse within the **adrenal medulla**. *(Figures 16–4, 16–5)*

Sympathetic Activation p. 524

9. In a crisis, the entire sympathetic division responds— an event called **sympathetic activation**. Its effects include increased alertness, a feeling of energy and euphoria, increased cardiovascular and respiratory activities, a general elevation in muscle tone, and a mobilization of energy reserves.

Anatomy 360 | Nervous System/Autonomic Nervous System/Sympathetic Division

Neurotransmitters and Sympathetic Function p. 525

1. **10.** The stimulation of the sympathetic division has two distinctive results: the release of either ACh or *norepinephrine (NE)* at specific locations, and the secretion of *epinephrine (E)* and NE into the general circulation.

2. **11.** Sympathetic ganglionic neurons end in telodendria studded with **varicosities** containing neurotransmitters. *(Figure 16–6)*

3. **12.** The two types of sympathetic receptors are **alpha receptors** and **beta receptors**.

4. **13.** Most postganglionic fibers are *adrenergic*; a few are *cholinergic* or *nitroxidergic*.

Summary: The Sympathetic Division p. 526

14. The sympathetic division includes two sympathetic chain ganglia, three collateral ganglia and two adrenal medullae. *(Figure 16–9; Summary Tables 16–2, 16–3)*

The Parasympathetic Division p. 527

1. The parasympathetic division includes preganglionic neurons in the brain stem and sacral segments of the spinal cord, and ganglionic neurons in peripheral ganglia located within (**intramural**) or next to (**terminal**) target organs. *(Figure 16–7)*

Organization and Anatomy of the Parasympathetic Division p. 528

2. Preganglionic fibers leave the brain as components of cranial nerves III, VII, IX, and X. Those leaving the sacral segments form **pelvic nerves**. *(Figure 16–8)*

Anatomy 360 | Nervous System/Autonomic Nervous System/Parasympathetic Division

Parasympathetic Activation p. 529

3. The effects produced by the parasympathetic division center on relaxation, food processing, and energy absorption.

Neurotransmitters and Parasympathetic Function p. 529

1. **4.** All parasympathetic preganglionic and postganglionic fibers release ACh. The effects are short-lived, because ACh is inactivated by *acetylcholinesterase (AChE)* and by *tissue cholinesterase*.

2. **5.** Postsynaptic membranes have two types of ACh receptors. The stimulation of **muscarinic receptors** produces a longer-lasting effect than does the stimulation of **nicotinic receptors**. *(Summary Table 16–1)*

Summary: The Parasympathetic Division p. 530

6. The parasympathetic division innervates areas serviced by cranial nerves and organs in the thoracic and abdominopelvic cavities.

(Figure 16–9)

100 Keys | p. 530

Interactions between the Sympathetic and Parasympathetic Divisions p. 531

1. **1.** The sympathetic division has widespread influence on visceral and somatic structures.

2. **2.** The parasympathetic division innervates only visceral structures that are serviced by cranial nerves or lying within the abdominopelvic cavity. Organs with **dual innervation** receive input from both divisions. *(Summary Tables 16–2, 16–3)*

Anatomy of Dual Innervation p. 531

1. **3.** In body cavities, the parasympathetic and sympathetic nerves intermingle to form a series of characteristic *autonomic plexuses* (nerve networks): the **cardiac**, **pulmonary**, **esophageal**, **celiac**, **inferior mesenteric**, and **hypogastric plexuses**. *(Figure 16–10)*

2. **4.** Important physiological and functional differences exist between the sympathetic and parasympathetic divisions. *(Figure 16–9; Summary Tables 16–2, 16–3)*

Autonomic Tone p. 533

5. Even when stimuli are absent, autonomic motor neurons show a resting level of activation, the **autonomic tone**.

Integration and Control of Autonomic Functions p. 534 Visceral Reflexes p. 535

1. **1.** **Visceral reflex arcs** perform the simplest function of the ANS, and can be either **long reflexes** (with interneurons) or **short reflexes** (bypassing the CNS). *(Figure 16–11)*

2. **2.** Parasympathetic reflexes govern respiration, cardiovascular functions, and other visceral activities. *(Table 16–4)*

Higher Levels of Autonomic Control p. 535

3. Levels of activity in the sympathetic and parasympathetic divisions of the ANS are controlled by centers in the brain stem that regulate specific visceral functions.

The Integration of SNS and ANS Activities p. 536

4. The SNS and ANS are organized in parallel. Integration occurs at the level of the brain stem and higher centers. *(Figure 16–12; Summary Table 16–5)*

Higher-Order Functions p. 537

1. Higher-order functions (1) are performed by the cerebral cortex and involve complex interactions among areas of the cerebral cortex and between the cortex and other areas of the brain, (2) involve conscious and unconscious information processing, and (3) are subject to modification and adjustment over time.

Memory p. 537

1. **2.** Memories can be classified as **short term** or **long term**.

2. **3.** The conversion from short-term to long-term memory is **memory consolidation**. *(Figure 16–13)*

3. **4.** **Amnesia** is the loss of memory as a result of disease or trauma.

100 Keys | p. 539

States of Consciousness p. 540

1. **5.** In **deep sleep** (*slow wave* or *non-REM sleep*), the body relaxes and cerebral cortex activity is low. In **rapid eye movement (REM) sleep**, active dreaming occurs. *(Figure 16–14)*

2. **6.** The **reticular activating system (RAS)**, a network in the reticular formation, is most important to arousal and the maintenance of consciousness. *(Figure 16–15)*

100 Keys | p. 541

Brain Chemistry and Behavior p. 541

1. Changes in the normal balance between two or more neurotransmitters can profoundly affect brain function.

Aging and the Nervous System p. 542

1. Age-related changes in the nervous system include a reduction in brain size and weight, a reduction in the number of neurons, a decrease in blood flow to the brain, changes in the synaptic organization of the brain, and intracellular and extracellular changes in CNS neurons.

Integration with Other Systems p. 543 Clinical Patterns p. 543

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The autonomic division of the nervous system directs

. **(a)** voluntary motor activity

. **(b)** conscious control of skeletal muscles

. **(c)** unconscious control of skeletal muscles

. **(d)** processes that maintain homeostasis

. **(e)** sensory input from the skin

2. The division of the autonomic nervous system that prepares the body for activity and stress is the _____ division.

. **(a)** sympathetic **(b)** parasympathetic

. **(c)** craniosacral **(d)** intramural

. **(e)** somatomotor

3. Effects produced by the parasympathetic branch of the autonomic nervous system include

. **(a)** dilation of the pupils

. **(b)** increased secretion by digestive glands

. **(c)** dilation of respiratory passages

. **(d)** increased heart rate

. **(e)** increased breakdown of glycogen by the liver

4. A progressive disorder characterized by the loss of higher- order cerebral functions is

. **(a)** Parkinson’s disease

. **(b)** parasomnia

. **(c)** Huntington’s disease

. **(d)** Alzheimer’s disease

1. **5.** Starting in the spinal cord, trace an impulse through the sympathetic division of the ANS until it reaches a target organ in the abdominopelvic region.

2. **6.** Which four ganglia serve as origins for postganglionic fibers that deal with the control of visceral structures in the head?

3. **7.** What are the components of a visceral reflex arc?

4. **8.** As a result of animal studies, what cellular mechanisms are through to be involved in memory formation and storage?

5. **9.** What physiological activities distinguish non-REM sleep from REM sleep?

6. **10.** What anatomical and functional changes in the brain are linked to alterations that occur with aging?

7. **11.** All preganglionic autonomic fibers release _____ at their synaptic terminals, and the effects are always _____.

. **(a)** norepinephrine; inhibitory

. **(b)** norepinephrine; excitatory

. **(c)** acetylcholine; excitatory

. **(d)** acetylcholine; inhibitory

12. The neurotransmitter at all synapses and neuromuscular or neuroglandular junctions in the parasympathetic division of the ANS is

. **(a)** epinephrine **(b)** norepinephrine

. **(c)** cyclic-AMP **(d)** acetylcholine

1. **13.** How does the emergence of sympathetic fibers from the spinal cord differ from the emergence of parasympathetic fibers?

2. **14.** Which three collateral ganglia serve as origins for ganglionic neurons that innervate organs or tissues in the abdominopelvic region?

3. **15.** What two distinctive results are produced by the stimulation of sympathetic ganglionic neurons?

4. **16.** Which four pairs of cranial nerves are associated with the cranial segment of the parasympathetic division of the ANS?

5. **17.** Which six plexuses in the thoracic and abdominopelvic cavities innervate visceral organs, and what are the effects of sympathetic versus parasympathetic stimulation?

6. **18.** What three characteristics are shared by higher-order functions?

LEVEL 2 Reviewing Concepts

19. Dual innervation refers to situations in which

. **(a)** vital organs receive instructions from both sympathetic and parasympathetic fibers

. **(b)** the atria and ventricles of the heart receive autonomic stimulation from the same nerves

. **(c)** sympathetic and parasympathetic fibers have similar effects

. **(d)** a, b, and c are correct

20. Damage to the hippocampus, a component of the limbic system, leads to

. **(a)** a loss of emotion due to forgetfulness

. **(b)** a loss of consciousness

. **(c)** a loss of long-term memory

. **(d)** an immediate loss of short-term memory

1. **21.** Why does sympathetic function remain intact even when the ventral roots of the

cervical spinal nerves are damaged?

2. **22.** During sympathetic stimulation, a person may begin to feel “on edge”; this is the result of

. **(a)** increased energy metabolism by muscle tissue
. **(b)** increased cardiovascular activity
. **(c)** stimulation of the reticular activating system
. **(d)** temporary insensitivity to painful stimuli
. **(e)** decreased levels of epinephrine in the blood

23. Under which set of circumstances would the diameter of peripheral blood vessels be the greatest?

. **(a)** increased sympathetic stimulation
. **(b)** decreased sympathetic stimulation
. **(c)** increased parasympathetic stimulation
. **(d)** decreased parasympathetic stimulation
. **(e)** both increased parasympathetic and sympathetic stimulation

24. A possible side effect of a drug used to open the airways of someone suffering from an asthma attack is

. **(a)** decreased activity of the digestive system
. **(b)** diarrhea
. **(c)** profuse urination
. **(d)** increased blood pressue
. **(e)** decreased heart rate

1. **25.** You are home alone at night when you hear what sounds like breaking glass. What physiological effects would this experience probably produce, and what would be their cause?

2. **26.** Why is autonomic tone a significant part of ANS function?

3. **27.** Nicotine stimulates cholingeric receptors of the autonomic nervous system. Based on this information, how would cigarette smoking affect the cardiovascular system?

4. **28.** The condition known as shock is characterized by a decreased return of venous blood to the heart. How could an upsetting situation such as the sight of a tragic accident or very bad news produce shock?

LEVEL 3 Critical Thinking and Clinical Applications

1. **29.** Phil is stung on his cheek by a wasp. Because Phil is allergic to wasp venom, his throat begins to swell and his respiratory passages constrict. Would acetylcholine or epinephrine be more helpful in relieving his symptoms? Why?

2. **30.** While studying the activity of smooth muscle in blood vessels, Shelly discovers that, when applied to muscle membrane, a molecule chemically similar to a neurotransmitter triggers an increase in intracellular calcium ions. Which neurotransmitter is the molecule mimicking, and to which receptors is it binding?

| SUMMARY TABLE 16–1 | ADRENERGIC AND CHOLINERGIC RECEPTORS OF THE ANS

Receptor	**Location(s)**	**Response(s)**	**Mechanism**
ADRENERGIC			
a1	Widespread, found in most tissues	Excitation, stimulation of metabolism	Enzyme activation; release of intracellular Ca2+
a2	Sympathetic neuromuscular or neuroglandular junctions	Inhibition of effector cell	Reduction of cAMP concentrations
	Parasympathetic neuromuscular	Inhibition of neurotransmitter	Reduction of cAMP concentrations

	or neuroglandular junctions	release

An Introduction to the Special Senses

Our knowledge of the world around us is limited to those characteristics that stimulate our sensory receptors. Although we may not realize it, our picture of the environment is incomplete. Colors we cannot distinguish guide insects to flowers; sounds we cannot hear and smells we cannot detect provide dolphins, dogs, and cats with important information about their surroundings.

What we *do* perceive varies considerably with the state of our nervous systems. For example, during sympathetic activation, we experience a heightened awareness of sensory information and hear sounds that would normally escape our notice. Yet, when concentrating on a difficult problem, we may remain unaware of relatively loud noises. Finally, our perception of any stimulus reflects activity in the cerebral cortex, and that activity can be inappropriate. In cases of phantom limb pain, for example, a person feels pain in a missing limb, and during an epileptic seizure, an individual may experience sights, sounds, or smells that have no physical basis.

Our discussion of the general senses and sensory pathways in Chapter 15 introduced basic principles of receptor function and sensory processing. We now turn our attention to the five *special senses:* olfaction, gustation, vision, equilibrium, and hearing. Although the sense organs involved are structurally more complex than those of the general senses, the same basic principles of receptor function apply. ATLAS: Embryology Summary 13: The Development of Special Sense Organs

Olfaction

Objectives

- Describe the sensory organs of smell and trace the olfactory pathways to their destinations in the brain.
- Explain what is meant by olfactory discrimination and briefly describe the physiology involved.

The sense of smell, more precisely called *olfaction*, is provided by paired **olfactory organs**. These organs are located in the nasal cavity on either side of the nasal septum (Figure 17–1a•). The olfactory organs are made up of two layers: the olfactory epithelium and the lamina propria. The **olfactory epithelium** (Figure 17–1b•) contains the **olfactory receptor cells**, supporting cells, and regenerative **basal cells** (*stem cells*). It covers the inferior surface of the cribriform plate, the superior portion of the perpendicular plate, and the superior nasal conchae of the ethmoid. l**p. 216** The underlying lamina propria consists of areolar tissue, numerous blood vessels, and nerves. This layer also contains **olfactory glands**, or *Bowman's glands*, whose secretions absorb water and form a thick, pigmented mucus.

When you inhale through your nose, the air swirls and eddies within the nasal cavity, and this turbulence brings airborne compounds to your olfactory organs. A normal, relaxed inhalation carries a small sample of the inhaled air (about 2 percent) to the olfactory organs. Sniffing repeatedly increases the flow of air across the olfactory epithelium, intensifying the stimulation of the olfactory receptors. However, those receptors can be stimulated only by water-soluble and lipid-soluble materials that can diffuse into the overlying mucus.

Olfactory Receptors

Olfactory receptors are highly modified neurons. The exposed tip of each receptor cell forms a prominent knob that projects beyond the epithelial surface (see Figure 17–1b•). The knob provides a base for up to 20 cilia that extend into the surrounding mucus. These cilia lie parallel to the epithelial surface, exposing their considerable surface area to dissolved compounds.

Olfactory reception occurs on the surfaces of the olfactory cilia as dissolved chemicals interact with receptors, called *odorant-binding proteins*, on the membrane surface. *Odorants* are chemicals that stimulate olfactory receptors. In general, odorants are small organic molecules; the strongest smells are associated with molecules of high solubility

both in water and in lipids. The receptors involved are G proteins; binding of an odorant to its receptor leads to the activation of adenylate cyclase, the enzyme that converts
ATP to cyclic-AMP (cAMP). l**p. 411** The cAMP then opens sodium channels in the membrane, resulting in a localized depolarization. If sufficient depolarization occurs, an action potential is triggered in the axon, and the information is relayed to the CNS.

Between 10 and 20 million olfactory receptors are packed into an area of roughly 5 cm^2 (0.8 $in.^2$) If we take into account the exposed ciliary surfaces, the actual sensory area probably approaches that of the entire body surface. Nevertheless, our olfactory sensitivities cannot compare with those of other vertebrates such as dogs, cats, or fishes. A German shepherd dog sniffing for smuggled drugs or explosives has an olfactory receptor surface 72 times greater than that of the nearby customs inspector!

Olfactory Pathways

The olfactory system is very sensitive. As few as four odorant molecules can activate an olfactory receptor. However, the activation of an afferent fiber does not guarantee an awareness of the stimulus. Considerable convergence occurs along the olfactory pathway, and inhibition at the intervening synapses can prevent the sensations from reaching the *olfactory cortex* of the cerebral hemispheres. l**p. 474** The olfactory receptors themselves adapt very little to a persistent stimulus. Rather, it is central adaptation which ensures that you quickly lose awareness of a new smell but retain sensitivity to others.

Axons leaving the olfactory epithelium collect into 20 or more bundles that penetrate the cribriform plate of the ethmoid bone to reach the *olfactory bulbs* of the cerebrum (see Figure 17–1•), where the first synapse occurs. Efferent fibers from nuclei elsewhere in the brain also innervate neurons of the olfactory bulbs. This arrangement provides a mechanism for central adaptation or facilitation of olfactory sensitivity. Axons leaving the olfactory bulb travel along the olfactory tract to reach the olfactory cortex, the hypothalamus, and portions of the limbic system.

Olfactory stimulation is the only type of sensory information that reaches the cerebral cortex directly; all other sensations are relayed from processing centers in the thalamus.

The parallel distribution of olfactory information to the limbic system and hypothalamus explains the profound emotional and behavioral responses, as well as the memories, that can be triggered by certain smells. The perfume industry, which understands the practical implications of these connections, expends considerable effort to develop odors that trigger sexual responses.

Olfactory Discrimination

The olfactory system can make subtle distinctions among 2000–4000 chemical stimuli. No apparent structural differences exist among the olfactory cells, but the epithelium as a whole contains receptor populations with distinct sensitivities. At least 50 “primary smells” are known, and it is almost impossible to describe these sensory impressions effectively. It appears likely that the CNS interprets each smell on the basis of the overall pattern of receptor activity.

Although the human olfactory organs can discriminate among many smells, acuity varies widely, depending on the nature of the odorant. Many odorants are detected in amazingly small concentrations. One example is beta-mercaptan, an odorant commonly added to natural gas, propane, and butane, which are otherwise odorless. Because we can smell beta-mercaptan in extremely low concentrations (a few parts per billion), its addition enables us to detect a gas leak almost at once and take steps to prevent an explosion.

Aging and Olfactory Sensitivity

The olfactory receptor population undergoes considerable turnover; new receptor cells are produced by the division and differentiation of basal cells in the epithelium. This turnover is one of the few examples of neuronal replacement in adult humans. Despite this process, the total number of receptors declines with age, and the remaining receptors become less sensitive. As a result, elderly individuals have difficulty detecting odors in low concentrations. This decline in the number of receptors accounts for Grandmother’s tendency to use too much perfume and explains why Grandfather’s aftershave seems so strong: They must apply more to be able to smell it.

Gustation

Objectives

- Describe the sensory organs of taste and trace the gustatory pathways to their destinations in the brain.
- Explain what is meant by gustatory discrimination and briefly describe the physiologic processes involved.

¯e

Gustation, or taste, provides information about the foods and liquids we consume. **Taste receptors**, or *gustatory* (GUS-ta-tor-) *receptors*, are distributed over the superior surface of the tongue and adjacent portions of the pharynx and larynx. The most important taste receptors are on the tongue; by the time we reach adulthood, the taste receptors on the pharynx, larynx, and epiglottis have decreased in importance and abundance. Taste receptors and specialized epithelial cells form sensory structures called **taste buds**. An adult has about 3000 taste buds.

The superior surface of the tongue bears epithelial projections called *lingual papillae* (pa-PIL-

;

¯e

papilla, a nipple-shaped

mound). The human tongue bears three types of lingual papillae (Figure 17–2•): (1) **filiform** (*filum*, thread) **papillae**, (2) **fungif-**

¯a

orm (*fungus*, mushroom) **papillae**, and (3) **circumvallate** (sir-kum-VAL-t) **papillae** (*circum*-, around tribution of these lingual papillae varies by region. Filiform papillae provide friction that helps the tongue move objects around in the mouth, but do not contain taste buds. Each small fungiform papilla contains about five taste buds; each large circumvallate papilla contains as many as 100 taste buds. The circumvallate papillae form a V near the posterior margin of the tongue.

Taste Receptors

Taste buds are recessed into the surrounding epithelium, isolated from the relatively unprocessed contents of the mouth. Each taste bud (Figure 17–2b,c•) contains about 40 slender, spindle-shaped cells of at least four different types. **Basal cells** appear to be stem cells. These cells divide to produce daughter cells that mature in stages; the cells of the last stage are called **gustatory cells**. Each gustatory cell extends slender microvilli, sometimes called *taste hairs*, into the surrounding fluids through the **taste pore**, a narrow opening.

Despite this relatively protected position, it's still a hard life: A typical gustatory cell survives for only about 10 days before it is replaced. Although everyone agrees that gustatory cells are taste receptors, it is not clear whether the cells at earlier stages of development also provide taste information. (Cells at all three stages are innervated by sensory neurons.)

+ *vallum,* wall). The dis

Gustatory Pathways

Taste buds are monitored by cranial nerves VII (facial), IX (glossopharyngeal), and X (vagus). The facial nerve monitors all the taste buds located on the anterior two-thirds of the tongue, from the tip to the line of circumvallate papillae. The circumvallate papillae and the posterior one-third of the tongue are innervated by the glossopharyngeal nerve. The vagus nerve innervates taste buds scattered on the surface of the epiglottis. The sensory afferents carried by these cranial nerves synapse in the solitary nucleus of the medulla oblongata, and the axons of the postsynaptic neurons enter the medial lemniscus. There, the neurons join axons that carry somatic sensory information on touch, pressure, and proprioception. After another synapse in the thalamus, the information is projected to the appropriate portions of the primary sensory cortex.

A conscious perception of taste is produced as the information received from the taste buds is correlated with other sensory data. Information about the texture of food, along with taste-related sensations such as “peppery” or “burning hot,” is provided by sensory afferents in the trigeminal nerve (V). In addition, the level of stimulation from the olfactory receptors plays an overwhelming role in taste perception. Thus, you are several thousand times more sensitive to “tastes” when your olfactory organs are fully functional. By contrast, when you have a cold and your nose is stuffed up, airborne molecules cannot reach your olfactory receptors, so meals taste dull and unappealing. This reduction in taste perception occurs even though the taste buds may be responding normally.

Gustatory Discrimination

You are probably already familiar with the four **primary taste sensations**: sweet, salty, sour, and bitter. There is some evidence for differences in sensitivity to tastes along the axis of the tongue, with greatest sensitivity to salty–sweet anteriorly and sour–bitter posteriorly. However, there are no differences in the structure of the taste buds, and taste buds in all portions of the tongue provide all four primary taste sensations.

Humans have two additional taste sensations that are less widely known:

- **Umami. Umami** (oo-MAH-m) is a pleasant taste that is characteristic of beef broth, chicken broth, and parmesan cheese. This

e¯taste is detected by receptors sensitive to the presence of amino acids (especially glutamate), small peptides, and nucleotides. The distribution of these receptors is not known in detail, but they are present in taste buds of the circumvallate papillae.

- **Water.** Most people say that water has no flavor. However, research on humans and other vertebrates has demonstrated the presence of **water receptors**, especially in the pharynx. The sensory output of these receptors is processed in the hypothalamus and affects several systems that affect water balance and the regulation of blood volume. For example, minor reductions in ADH secretion occur each time you take a long drink.

The mechanism behind gustatory reception resembles that of olfaction. Dissolved chemicals contacting the taste hairs bind to receptor proteins of the gustatory cell. The different tastes involve different receptor mechanisms. Salt receptors and sour receptors are chemically gated ion channels whose stimulation produces depolarization of the cell. Receptors responding to stimuli that produce sweet, bitter, and umami sensations are G proteins called **gustducins** (GUST-doos-inz)—protein complexes that use second messengers to produce their effects. The end result of taste receptor stimulation is the release of neurotransmitters by the receptor cell. The dendrites of the sensory afferents are tightly wrapped by folds of the receptor cell membrane, and neurotransmitter release leads to the generation of action potentials in the afferent fiber. Taste receptors adapt slowly, but central adaptation quickly reduces your sensitivity to a new taste.

The threshold for receptor stimulation varies for each of the primary taste sensations, and the taste receptors respond more readily to unpleasant than to pleasant stimuli. For example, we are almost a thousand times more sensitive to acids, which taste sour, than to either sweet or salty chemicals, and we are a hundred times more sensitive to bitter compounds than to acids. This sensitivity has survival value, because acids can damage the mucous membranes of the mouth and pharynx, and many potent biological toxins have an extremely bitter taste.

Taste sensitivity differs significantly among individuals. Many conditions related to taste sensitivity are inherited. The best-known example involves sensitivity to the compound *phenylthiourea*, also known as *phenylthiocarbamide*, or **PTC**. Roughly 70 percent of Caucasians can taste this substance; the other 30 percent are unable to detect it.

Aging and Gustatory Sensitivity

Our tasting abilities change with age. We begin life with more than 10,000 taste buds, but the number begins declining dramatically by age 50. The sensory loss becomes especially significant because, as we have already noted, aging individuals also experience a decline in the number of olfactory receptors. As a result, many elderly people find that their food tastes bland and unappetizing, whereas children tend to find the same foods too spicy.

100 Keys | Olfactory information is routed directly to the cerebrum, and olfactory stimuli have powerful effects on mood and behavior. Gustatory sensations are strongest and clearest when integrated with olfactory sensations.

Concept Check

When you first enter the A&P lab for dissection, you are very aware of the odor of preservatives. By the end of the lab period, the smell doesn’t seem to be nearly as strong. Why?

If you completely dry the surface of your tongue and then place salt or sugar crystals on it, you can’t taste them. Why not?

Your grandfather can’t understand why foods he used to enjoy just don’t taste the same anymore. How would you explain this to him?

Answers begin on p. A–1

Vision

Objectives

- Identify the accessory structures of the eye and explain their functions.
- Describe the internal structures of the eye and explain their functions.
- Explain how we are able to distinguish colors and perceive depth.
- Explain how light stimulates the production of nerve impulses and trace the visual pathways to their destinations in the brain.

We rely more on vision than on any other special sense. Our visual receptors are contained in the eyes, elaborate structures that enable us not only to detect light, but also to create detailed visual images. We will begin our discussion of these fascinating organs by considering the *accessory structures* of the eye, which provide protection, lubrication, and support.

Accessory Structures of the Eye

The **accessory structures** of the eye include the eyelids and the superficial epithelium of the eye, and the structures associated with the production, secretion, and removal of tears. Figure 17–3• shows the superficial anatomy of the eye and its accessory structures.

Eyelids and Superficial Epithelium of the Eye

The eyelids, or **palpebrae** (pal-P

¯E

-br

¯e

), are a continuation of the skin. Their continual blinking keeps the surface of the eye lubricated, and they act like windshield wipers, removing dust and debris. The eyelids can also close firmly to protect the delicate surface of the eye. The **palpebral fissure** is the gap that separates the free margins of the upper and lower eyelids. The two eyelids are connected, however, at the **medial canthus** (KAN-thus) and the **lateral canthus** (Figure 17–3a•). The **eyelashes**, along the margins of the eyelids, are very robust hairs that help prevent foreign matter (including insects) from reaching the surface of the eye.

The eyelashes are associated with unusually large sebaceous glands. Along the inner margin of the lid, modified sebaceous

¯O

–

glands called **tarsal glands**, or *Meibomian* (m -B

ı sticking together. (These glands are too small to be seen in Figure 17–3•.) At the medial canthus, the **lacrimal caruncle** (KAR-ung-kul), a mass of soft tissue, contains glands producing the thick secretions that contribute to the gritty deposits that sometimes appear after a good night’s sleep. These various glands are subject to occasional invasion and infection by bacteria. A *chalazion*

¯e

-an) *glands*, secrete a lipid-rich product that helps keep the eyelids from -m

(kah-LA¯

-z

¯e

-on; small lump), or cyst, generally results from the infection of a tarsal gland. An infection in a sebaceous gland of

one of the eyelashes, a tarsal gland, or one of the many sweat glands that open to the surface between the follicles produces a painful localized swelling known as a *sty*.

The skin covering the visible surface of the eyelid is very thin. Deep to the skin lie the muscle fibers of the *orbicularis oculi* and *levator palpebrae superioris muscles*. l**p. 338** These skeletal muscles are responsible for closing the eyelids and raising the upper eyelid, respectively.

The epithelium covering the inner surfaces of the eyelids and the outer surface of the eye is called the **conjunctiva** (kon-junk-

¯I

T -vuh). It is a mucous membrane covered by a specialized stratified squamous epithelium. The **palpebral conjunctiva** covers the inner surface of the eyelids, and the **ocular conjunctiva**, or *bulbar conjunctiva*, covers the anterior surface of the eye

¯e

(Figure 17–3b•). The ocular conjunctiva extends to the edges of the **cornea** (KOR-n -uh), a transparent part of the outer fibrous layer of the eye. The cornea is covered by a very delicate squamous *corneal epithelium*, five to seven cells thick, that is continuous with the ocular conjunctiva. A constant supply of fluid washes over the surface of the eyeball, keeping the ocular conjunctiva and cornea moist and clean. Goblet cells in the epithelium assist the accessory glands in providing a superficial lubricant that prevents friction and drying of the opposing conjunctival surfaces.

Conjunctivitis, or pinkeye, results from damage to, and irritation of, the conjunctival surface. The most obvious sign, redness, is due to the dilation of blood vessels deep to the conjunctival epithelium. This condition may be caused by pathogenic infection or by physical, allergic, or chemical irritation of the conjunctival surface.

The Lacrimal Apparatus

A constant flow of tears keeps conjunctival surfaces moist and clean. Tears reduce friction, remove debris, prevent bacterial infection, and provide nutrients and oxygen to portions of the conjunctival epithelium. The **lacrimal apparatus** produces, distributes, and removes tears. The lacrimal apparatus of each eye consists of (1) a *lacrimal gland* with associated ducts, (2) paired *lacrimal canaliculi*, (3) a *lacrimal sac*, and (4) a *nasolacrimal duct* (see Figure 17–3b•).

The pocket created where the palpebral conjunctiva becomes continuous with the ocular conjunctiva is known as the **fornix** of the eye (Figure 17–4a•). The lateral portion of the superior fornix receives 10–12 ducts from the **lacrimal gland**, or tear gland (see Figure 17–3b•). This gland is about the size and shape of an almond, measuring roughly 12–20 mm (0.5–0.75 in.). It nestles within a depression in the frontal bone, just inside the orbit and superior and lateral to the eyeball. l**p. 213** The lacrimal gland normally provides the key ingredients and most of the volume of the tears that bathe the conjunctival surfaces. The nutrient and oxygen demands of the corneal cells are supplied by diffusion from the lacrimal secretions, which are watery and slightly alkaline. They contain the antibacterial enzyme **lysozyme** and antibodies that attack pathogens before they enter the body.

The lacrimal gland produces about 1 ml of tears each day. Once the lacrimal secretions have reached the ocular surface, they mix with the products of accessory glands and the oily secretions of the tarsal glands. The result is a superficial “oil slick” that assists in lubrication and slows evaporation.

Blinking sweeps the tears across the ocular surface, and they accumulate at the medial canthus in an area known as the *lacrimal lake* (*lacus lacrimalis*), or “lake of tears.” The lacrimal lake covers the lacrimal caruncle, which bulges anteriorly. The **lacrimal puncta** (singular, *punctum*), two small pores, drain the lacrimal lake. They empty into the **lacrimal canaliculi**, small canals that

in turn lead to the **lacrimal sac** (see Figure 17–3b•), which nestles within the lacrimal sulcus of the orbit. l**p. 218** From the inferior portion of the lacrimal sac, the **nasolacrimal duct** passes through the *nasolacrimal canal*, formed by the lacrimal bone and the maxillary bone. The nasolacrimal duct delivers tears to the nasal cavity on that side. The duct empties into the *inferior meatus*, a narrow passageway inferior and lateral to the inferior nasal concha. When a person cries, tears rushing into the nasal cavity produce a runny nose, and if the lacrimal puncta can't provide enough drainage, the lacrimal lake overflows and tears stream across the face.

The Eye

The eyes are extremely sophisticated visual instruments—more versatile and adaptable than the most expensive cameras, yet compact and durable. Each eye is a slightly irregular spheroid with an average diameter of 24 mm (almost 1 in., a little smaller than a Ping-Pong ball) and a weight of about 8 g (0.28 oz). Within the orbit, the eyeball shares space with the extrinsic eye muscles, the lacrimal gland, and the cranial nerves and blood vessels that supply the eye and adjacent portions of the orbit and face. **Orbital fat** cushions and insulates the eye (see Figures 17–3b and 17–4c•).

The wall of the eye contains three distinct layers, or *tunics* (Figure 17–4b•): (1) an outer *fibrous tunic*, (2) an intermediate *vascular tunic*, and (3) an inner *neural tunic (retina)*. The visual receptors, or *photoreceptors*, are located in the neural tunic. The eyeball is hollow; its interior can be divided into two cavities (Figure 17–4c•). The large **posterior cavity** is also called the *vitreous chamber*, because it contains the gelatinous *vitreous body* (*vitreo*-, glassy). The smaller **anterior cavity** is subdivided into the *anterior* and *posterior chambers*. The shape of the eye is stabilized in part by the vitreous body and the clear *aqueous humor*, which fills the anterior cavity.

The Fibrous Tunic

The **fibrous tunic**, the outermost layer of the eye, consists of the *sclera* (SKLER-uh) and the *cornea*. The fibrous tunic (1) provides mechanical support and some degree of physical protection, (2) serves as an attachment site for the extrinsic eye muscles, and (3) contains structures that assist in the focusing process.

Most of the ocular surface is covered by the **sclera** (see Figure 17–4b,c•), or "white of the eye," which consists of a dense fibrous connective tissue containing both collagen and elastic fibers. This layer is thickest over the posterior surface of the eye, near the exit of the optic nerve, and thinnest over the anterior surface. The six extrinsic eye muscles insert on the sclera, blending their collagen fibers with those of the fibrous tunic. l**p. 336**

The surface of the sclera contains small blood vessels and nerves that penetrate the sclera to reach internal structures. The network of small vessels interior to the ocular conjunctiva generally does not carry enough blood to lend an obvious color to the sclera, but on close inspection, the vessels are visible as red lines against the white background of collagen fibers.

The transparent cornea is structurally continuous with the sclera; the border between the two is called the **limbus** (see Figures 17–3a, 17–4a,c•). Deep to the delicate corneal epithelium, the cornea consists primarily of a dense matrix containing multiple layers of collagen fibers, organized so as not to interfere with the passage of light. The cornea has no blood vessels; the superficial epithelial cells must obtain oxygen and nutrients from the tears that flow across their free surfaces. The cornea also has numerous free nerve endings, and it is the most sensitive portion of the eye.

Corneal damage may cause blindness even though the functional components of the eye— including the photoreceptors— are perfectly normal. The cornea has a very restricted ability to repair itself, so corneal injuries must be treated immediately to prevent serious vision losses. Restoring vision after corneal scarring generally requires the replacement of the cornea through a corneal transplant. Corneal replacement is probably the most common form of transplant surgery. Such transplants can be performed between unrelated individuals, because there are no blood vessels to carry white blood cells, which attack foreign tissues, into the area. Corneal grafts are obtained from the eyes of donors who have died from illness or accident. For best results, the tissues must be removed within five hours after the donor’s death.

The Vascular Tunic (Uvea)

¯e

¯U

The **vascular tunic**, or **uvea** (-v -uh), contains numerous blood vessels, lymphatic vessels, and the intrinsic (smooth) muscles of the eye (see Figure 17–4b,c•). The functions of this middle layer include (1) providing a route for blood vessels and lymphatics that supply tissues of the eye; (2) regulating the amount of light that enters the eye; (3) secreting and reabsorbing the *aqueous humor* that circulates within the chambers of the eye; and (4) controlling the shape of the *lens*, an essential part of the focusing process. The vascular tunic includes the *iris,* the *ciliary body,* and the *choroid*.

The Iris The **iris**, which is visible through the transparent corneal surface, contains blood vessels, pigment cells, and two layers of smooth muscle fibers called *pupillary muscles* (Figure 17–5•). When these muscles contract, they change the diameter of the **pupil**, or central opening of the iris. One group of smooth muscle fibers, the **pupillary constrictor muscles**, forms a series of concentric circles around the pupil. When these sphincter muscles contract, the diameter of the pupil decreases. A second group of smooth muscles, the **pupillary dilator muscles**, extends radially away from the edge of the pupil. Contraction of these muscles enlarges the pupil. Both muscle groups are controlled by the autonomic nervous system. For example, parasympathetic activation in response to bright light causes the pupils to constrict (the *consensual light reflex*), and sympathetic activation in response to dim light causes the pupils to dilate.

The body of the iris consists of a highly vascular, pigmented, loose connective tissue. The anterior surface has no epithelial covering; instead, it has an incomplete layer of fibroblasts and melanocytes. Melanocytes are also scattered within the body of the iris. The posterior surface is covered by a pigmented epithelium that is part of the neural tunic and contains melanin granules. Eye color is determined by genes that influence the density and distribution of melanocytes on the anterior surface and interior of the iris, as well as by the density of the pigmented epithelium. When the connective tissue of the iris contains few melanocytes, light passes through it and bounces off the pigmented epithelium. The eye then appears blue. Individuals with green, brown, or black eyes have increasing numbers of melanocytes in the body and surface of the iris. The eyes of human albinos appear a very pale gray or blue-gray.

The Ciliary Body At its periphery, the iris attaches to the anterior portion of the **ciliary body**, a thickened region that begins deep to the junction between the cornea and the sclera. The ciliary body extends posteriorly to the level of the **ora serrata** (O-ra

–

ser-RA-tuh; serrated mouth), the serrated anterior edge of the thick, inner portion of the neural tunic (see Figure 17–4a,c•). The bulk of the ciliary body consists of the **ciliary muscle**, a smooth muscular ring that projects into the interior of the eye. The epithelium covering this muscle is thrown into numerous folds called **ciliary processes**. The **suspensory ligaments** of the lens attach to the tips of these processes. The connective-tissue fibers of these ligaments hold the lens posterior to the iris and centered on the pupil. As a result, any light passing through the pupil will also pass through the lens.

The Choroid The **choroid** is a vascular layer that separates the fibrous and neural tunics posterior to the ora serrata (see Figure 17–4c•). Covered by the sclera and attached to the outermost layer of the retina, the choroid contains an extensive capillary network that delivers oxygen and nutrients to the retina. The choroid also contains melanocytes, which are especially numerous near the sclera.

The Neural Tunic (Retina)

The **neural tunic**, or **retina**, is the innermost layer of the eye. It consists of a thin, outer layer called the *pigmented part,* and a thick inner layer called the *neural part*. The pigmented part of the retina absorbs light that passes through the neural part, preventing light from bouncing back through the neural part and producing visual “echoes.” The pigment cells also have important biochemical interactions with the retina’s light receptors, which are located in the neural part of the retina. In addition to light receptors, the neural part of the retina contains supporting cells and neurons that perform preliminary processing and integration of visual information.

The two layers of the retina are normally very close together, but not tightly interconnected. The pigmented part of the retina continues over the ciliary body and iris; the neural part extends anteriorly only as far as the ora serrata. The neural part of the retina thus forms a cup that establishes the posterior and lateral boundaries of the posterior cavity (see Figure 17–4b,c•).

Clinical Note

A *retinopathy* is a disease of the retina. **Diabetic retinopathy** develops in many individuals with *diabetes mellitus*, an endocrine disorder that interferes primarily with glucose metabolism. Many systems are affected by diabetes, but serious cardiovascular problems are particularly common. Diabetic retinopathy, which develops over a period of years, results from the degeneration, rupture, and excessive growth of abnormal blood vessels that invade the retina and extend into the space between the pigment layer and the neural layer. Visual acuity is gradually lost through damage to photoreceptors (which are deprived of oxygen and nutrients), leakage of blood into the posterior chamber, and the overgrowth of blood vessels. Laser therapy can seal leaking vessels and block new vessel growth. The posterior chamber can be drained and the cloudy fluid replaced by a suitably clear substitute. This procedure is called a *vitrectomy*. However, these are only temporary fixes that must be periodically repeated, because they fail to correct the underlying metabolic problems.

Organization of the Retina In sectional view, the retina is seen to contain several layers of cells (Figure 17–6a•). The outermost layer, closest to the pigmented part of the retina, contains the **photoreceptors**, or cells that detect light.

The eye has two types of photoreceptors: rods and cones. **Rods** do not discriminate among colors of light. Highly sensitive to light, they enable us to see in dimly lit rooms, at twilight, and in pale moonlight. **Cones** provide us with color vision. Three types of cones are present, and their stimulation in various combinations provides the perception of different colors. Cones give us sharper, clearer images than rods do, but cones require more intense light. If you sit outside at sunset with your textbook open to a colorful illustration, you can detect the gradual shift in your visual system from cone-based vision (a clear image in full color) to rod-based vision (a relatively grainy image in black and white).

Rods and cones are not evenly distributed across the outer surface of the retina. Approximately 125 million rods form a broad band around the periphery of the retina; as you move away from the periphery, toward the center of the retina, the density of rods gradually decreases. In contrast, most of the roughly 6 milion cones are concentrated in the area where a visual image arrives after

it passes through the cornea and lens. This region, which is known as the **macula lutea** (MAK-

¯u

-luh LOO-t

¯e

-uh; yellow spot),

contains no rods. The very highest concentration of cones occurs at the center of the macula lutea, an area called the **fovea** (F

¯O

¯e

-uh; shallow depression), or *fovea centralis* (Figure 17–6c•). The fovea is the site of sharpest vision: When you look directly at an object, its image falls on this portion of the retina. An imaginary line drawn from the center of that object through the center of the lens to the fovea establishes the **visual axis** of the eye (see Figure 17–4c•).

You are probably already aware of the visual consequences of this distribution of photoreceptors. When you look directly at an object, you are placing its image on the fovea, the center of color vision. You see a very good image as long as there is enough light to stimulate the cones. But in very dim light, cones cannot function. That is why you can't see a dim star if you stare directly at it, but you can see it if you shift your gaze to one side or the other. Shifting your gaze moves the image of the star from the fovea, where it does not provide enough light to stimulate the cones, to the periphery, where it can affect the more sensitive rods.

Rods and cones synapse with roughly 6 million neurons called **bipolar cells** (see Figure 17–6a•), which in turn synapse within the layer of neurons called **ganglion cells** adjacent to the posterior cavity. A network of **horizontal cells** extends across the outer portion of the retina at the level of the synapses between photoreceptors and bipolar cells. A comparable layer of **amacrine** (AM-a-krin) **cells** occurs where bipolar cells synapse with ganglion cells. Horizontal and amacrine cells can facilitate or inhibit communication between photoreceptors and ganglion cells, thereby altering the sensitivity of the retina. The effect is comparable to adjusting the contrast on a television set. These cells play an important role in the eye's adjustment to dim or brightly lit environments.

The Optic Disc Axons from an estimated 1 million ganglion cells converge on the **optic disc**, a circular region just medial to the fovea. The optic disc is the origin of the optic nerve (II). From this point, the axons turn, penetrate the wall of the eye, and proceed toward the diencephalon (Figure 17–6b•). The *central retinal artery* and *central retinal vein*, which supply the retina, pass through the center of the optic nerve and emerge on the surface of the optic disc (Figure 17–6b,c•). The optic disc has no photoreceptors or other structures typical of the rest of the retina. Because light striking this area goes unnoticed, the optic disc is commonly called the **blind spot**. You do not notice a blank spot in your field of vision, primarily because involuntary eye movements keep the visual image moving and allow your brain to fill in the missing information. However, a simple activity using Figure 17–7• will prove that a blind spot really exists in your field of vision.

Clinical Note

Photoreceptors are entirely dependent on the diffusion of oxygen and nutrients from blood vessels in the choroid. In a **detached retina**, the neural part of the retina becomes separated from the pigmented part. This condition can result from a variety of factors, including a sudden blow to the eye. Unless the two parts of the neural tunic are reattached, the photoreceptors will degenerate and vision will be lost. The reattachment is generally performed by “welding” the two layers together using laser beams focused through the cornea. These beams heat the layers, thereby fusing them together at several points around the retina. However, the procedure destroys the photoreceptors and other cells at the “welds,” producing permanent blind spots.

The Chambers of the Eye

As noted earlier, the ciliary body and lens divide the interior of the eye into a large posterior cavity, or vitreous chamber, and a smaller anterior cavity (see Figure 17–4c•). The anterior cavity is subdivided into the **anterior chamber**, which extends from the cornea to the iris, and a **posterior chamber**, between the iris and the ciliary body and lens. The anterior and posterior chambers are filled with the fluid *aqueous humor*. The posterior cavity also contains aqueous humor, but most of its volume is taken up by a gelatinous substance known as the *vitreous body*, or *vitreous humor*.

Aqueous Humor **Aqueous humor** is a fluid that circulates within the anterior cavity, passing from the posterior to the anterior chamber through the pupil (Figure 17–8•). It also freely diffuses through the vitreous body and across the surface of the retina. Aqueous humor forms through active secretion by epithelial cells of the ciliary body’s ciliary processes. The epithelial cells regulate its composition, which resembles that of cerebrospinal fluid. Because aqueous humor circulates, it provides an important route for nutrient and waste transport, in addition to forming a fluid cushion.

The eye is filled with fluid, and fluid pressure in the aqueous humor helps retain the eye's shape. Fluid pressure also stabilizes the position of the retina, pressing the neural part against the pigmented part. In effect, the aqueous humor acts like the air inside a balloon. The eye's **intraocular pressure** can be measured in the anterior chamber, where the fluid pushes against the inner surface of the cornea. Intraocular pressure is most often checked by bouncing a tiny blast of air off the surface of the eye and measuring the deflection produced. Normal intraocular pressure ranges from 12 to 21 mm Hg.

Aqueous humor is secreted into the posterior chamber at a rate of 1–2 ml per minute. It leaves the anterior chamber at the same rate. After filtering through a network of connective tissues located near the base of the iris, aqueous humor enters the **canal of Schlemm**, or *scleral venous sinus*, a passageway that extends completely around the eye at the level of the limbus. Collecting channels deliver the aqueous humor from this canal to veins in the sclera. The rate of removal normally keeps pace with the rate of generation at the ciliary processes, and aqueous humor is removed and recycled within a few hours of its formation.

The Vitreous Body The posterior cavity of the eye contains the **vitreous body**, a gelatinous mass. The vitreous body helps stabilize the shape of the eye, which might otherwise distort as the extra-ocular muscles change its position within the orbit. Specialized cells embedded in the vitreous body produce the collagen fibers and proteoglycans that account for the gelatinous consistency of this mass. Unlike the aqueous humor, the vitreous body is formed during development of the eye and is not replaced.

The Lens

The **lens** lies posterior to the cornea, held in place by the suspensory ligaments that originate on the ciliary body of the choroid (see Figures 17–4b, p. 556, and 17–8•). The primary function of the lens is to focus the visual image on the photoreceptors. The lens does so by changing its shape.

The lens consists of concentric layers of cells that are precisely organized. A dense fibrous capsule covers the entire lens. Many of the capsular fibers are elastic. Unless an outside force is applied, they will contract and make the lens spherical. Around the edges of the lens, the capsular fibers intermingle with those of the suspensory ligaments. The cells in the interior of the lens are called **lens fibers**. These highly specialized cells have lost their nuclei and other organelles. They are slender and elongate and are filled with transparent proteins called **crystallins**, which are responsible for both the clarity and the focusing power of the lens. Crystallins are extremely stable proteins that remain intact and functional for a lifetime without the need for replacement.

The transparency of the lens depends on a precise combination of structural and biochemical characteristics. When that balance becomes disturbed, the lens loses its transparency; this abnormality is known as a **cataract**. Cataracts can result from injuries, radiation, or reaction to drugs, but **senile cataracts**, a natural consequence of aging, are the most common form.

Over time, the lens turns yellowish and eventually begins to lose its transparency. As the lens becomes "cloudy," the individual needs brighter and brighter light for reading, and visual clarity begins to fade. If the lens becomes completely opaque, the person will be functionally blind, even though the photoreceptors are normal. Surgical procedures involve removal of the lens, either intact or after it has been shattered with high-frequency sound. The missing lens is replaced by an artificial substitute, and vision is then fine-tuned with glasses or contact lenses.

Refraction The retina has about 130 million photoreceptors, each monitoring light striking a specific site on the retina. A visual image results from the processing of information from all the receptors. The eye is often compared to a camera. To provide useful information, the lens of the eye, like a camera lens, must focus the arriving image. To say that an image is "in focus" means that the rays of light arriving from an object strike the sensitive surface of the retina (or photographic film) in precise order so as to form a miniature image of the object. If the rays are not perfectly focused, the image is blurry. Focusing normally occurs in two steps, as light passes through first the cornea and then the lens.

Light is **refracted**, or bent, when it passes from one medium to another medium with a different density. You can demonstrate this effect by sticking a pencil into a glass of water.

Because refraction occurs as the light passes into the air from the much denser water, the shaft of the pencil appears to bend sharply at the air–water interface.

In the human eye, the greatest amount of refraction occurs when light passes from the air into the corneal tissues, which have a density close to that of water. When you open your eyes under water, you cannot see clearly because refraction at the air–water interface has been eliminated; light passes unbent from one watery medium to another.

Additional refraction takes place when the light passes from the aqueous humor into the relatively dense lens. The lens provides the extra refraction needed to focus the light rays from an object toward a **focal point**—a specific point of intersection on the retina. The distance between the center of the lens and its focal point is the **focal distance** of the lens. Whether in the eye or in a camera, the focal distance is determined by two factors:

1. *The Distance from the Object to the Lens.* The closer an object is to the lens, the greater the focal distance (Figure 17–9a,b•).

2. *The Shape of the Lens.* The rounder the lens, the more refraction occurs, so a very round lens has a shorter focal distance than a flatter one (Figure 17b,c•).

Accommodation A camera focuses an image by moving the lens toward or away from the film. This method of focusing cannot work in our eyes, because the distance from the lens to the macula lutea cannot change. We focus images on the retina by changing the shape of the lens to keep the focal length constant, a process called **accommodation** (Figure 17–10•). During accommodation, the lens becomes rounder to focus the image of a nearby object on the retina; the lens flattens when we focus on a distant object.

The lens is held in place by the suspensory ligaments that originate at the ciliary body. Smooth muscle fibers in the ciliary body act like sphincter muscles. When the ciliary muscle contracts, the ciliary body moves toward the lens, thereby reducing the tension in the suspensory ligaments. The elastic capsule then pulls the lens into a more spherical shape that increases the refractive power of the lens, enabling it to bring light from nearby objects into focus on the retina (Figure 17–10a•). When the ciliary muscle relaxes, the suspensory ligaments pull at the circumference of the lens, making the lens flatter (Figure 17–10b•).

The greatest amount of refraction is required to view objects that are very close to the lens. The inner limit of clear vision, known as the *near point of vision*, is determined by the degree of elasticity in the lens. Children can usually focus on something 7–9 cm from the eye, but over time the lens tends to become stiffer and less responsive. A young adult can usually focus on objects 15–20 cm away. As aging proceeds, this distance gradually increases; the near point at age 60 is typically about 83 cm. (For more information on congenital and age-related changes in eye structure and function, see the Clinical Note “Accommodation Problems.”)

If light passing through the cornea and lens is not refracted properly, the visual image will be distorted. In the condition called **astigmatism**, the degree of curvature in the cornea or lens varies from one axis to another. Minor astigmatism is very common; the image distortion may be so minimal that people are unaware of the condition.

Image Reversal Thus far, we have considered light that originates at a single point, either near or far from the viewer. An object in view, however, is a complex light source that must be treated as a large number of individual points. Light from each point is focused on the retina as indicated in Figure 17–12a,b•. The result is the creation of a miniature image of the original, but the image arrives upside down and backward.

To understand why the image is reversed in this fashion, consider Figure 17–12c•, a sagittal section through an eye that is looking at a telephone pole. The image of the top of the pole lands at the bottom of the retina, and the image of the bottom hits the top of the retina. Now consider Figure 17–12d•, a horizontal section through an eye that is looking at a picket fence. The image of the left edge of the fence falls on the right side of the retina, and the image of the right edge falls on the left side of the retina. The brain compensates for this image reversal, and we are not aware of any difference between the orientation of the image on the retina and that of the object.

Visual Acuity Clarity of vision, or **visual acuity**, is rated against a “normal” standard. The standard vision rating of 20> 20 is defined as the level of detail seen at a distance of 20 feet

by an individual with normal vision. Vision rated as 20> 15 is better than average, because at 20 feet the person is able to see details that would be clear to a normal eye only at a distance of 15 feet. Conversely, a person with 20> 30 vision must be 20 feet from an object to discern details that a person with normal vision could make
out at a distance of 30 feet.

When visual acuity falls below 20> 200, even with the help of glasses or contact lenses, the individual is considered to be legally blind. There are probably fewer than 400,000 legally blind people in the United States; more than half are over 65 years old. The term *blindness* implies a total absence of vision due to damage to the eyes or to the optic pathways. Common causes of blindness include diabetes mellitus, cataracts, glaucoma, corneal scarring, detachment of the retina, accidental injuries, and hereditary factors that are as yet poorly understood.

Abnormal blind spots, or **scotomas** (sk
¯o
-T

¯O

-muhz), may appear in the field of vision at positions other than at the optic
disc. Scotomas are permanent abnormalities that are fixed in position. They may result from a compression of the optic nerve, damage to photoreceptors, or central damage along the visual pathway. *Floaters*, small spots that drift across the field of vision, are generally temporary phenomena that result from blood cells or cellular debris in the vitreous body. They can be detected by staring at a blank wall or a white sheet of paper.

100 Keys | Light passes through the conjunctiva and cornea, crosses the anterior cavity to reach the lens, transits the lens, crosses the posterior chamber, and then penetrates the neural tissue of the retina before reaching and stimulating the photoreceptors. Cones are most abundant at the fovea and macula lutea, and they provide high-resolution color vision in brightly lit environments. Rods dominate the peripheral areas of the retina, and they provide relatively low-resolution black-and-white vision in dimly lit environments.

Concept Check

Which layer of the eye would be affected first by the inadequate production of tears?

When the lens of your eye is very round, are you looking at an object that is close to you or far from you?

As Renee enters a dark room, most of the available light becomes focused on the fovea of her eye. Will she be able to see very clearly? How would a blockage of the canal of Schlemm affect your vision?

Answers begin on p. A–1

Visual Physiology

The rods and cones of the retina are called *photoreceptors* because they detect *photons*, basic units of visible light. Light energy is a form of *radiant energy* that travels in waves with a characteristic *wavelength* (distance between wave peaks).

Our eyes are sensitive to wavelengths of 700–400 nm, the spectrum of visible light. This spectrum, seen in a rainbow, can be remembered by the acronym ROY G. BIV (*R*ed, *O*range, *Y*ellow, *G*reen, *B*lue, *I*ndigo, *V*iolet). Photons of red light carry the least energy and have the longest wavelength, and those from the violet portion of the spectrum contain the most energy and have the shortest wavelength. Rods provide the central nervous system with information about the presence or absence of photons, without regard to their wavelength. Cones provide information about the wavelength of arriving photons, giving us a perception of color.

Anatomy of Rods and Cones

Figure 17–13a• compares the structures of rods and cones. The elongated **outer segment** of a photoreceptor contains hundreds to thousands of flattened membranous plates, or **discs**. The names *rod* and *cone* refer to the outer segment’s shape. In a rod, each disc is an independent entity, and the outer segment forms an elongated cylinder. In a cone, the discs are infoldings of the cell membrane, and the outer segment tapers to a blunt point.

A narrow connecting stalk attaches the outer segment to the **inner segment**, a region that contains all the usual cellular organelles. The inner segment makes synaptic contact with other cells, and it is here that neurotransmitters are released.

Visual Pigments The discs of the outer segment in both rods and cones contain special organic compounds called **visual pigments**. The absorption of photons by visual pigments is the first key step in the process of *photoreception*—the detection of light. Visual pigments are derivatives of the compound **rhodopsin** (ro¯-DOP-sin), or *visual purple*, the visual pigment found in rods (Figure 17–13b•). Rhodopsin consists of a protein, **opsin**, bound to the pigment **retinal** (RET-i-nal), or *retinene*, which is synthesized from **vitamin A**. One form of opsin is characteristic of all rods.

Cones contain the same retinal pigment that rods do, but in cones retinal is attached to other forms of opsin. The type of opsin present determines the wavelength of light that can be absorbed by retinal. Differential stimulation of these cone populations is the basis of color vision.

New discs containing visual pigment are continuously assembled at the base of the outer segment. A completed disc then moves toward the tip of the segment. After about 10 days, the disc will be shed in a small droplet of cytoplasm. Droplets with shed discs are absorbed by the pigment cells, which break down the membrane's components and reconvert the retinal to vitamin A. The vitamin A is then stored within the pigment cells for subsequent transfer to the photoreceptors.

The term **retinitis pigmentosa** (RP) refers to a collection of inherited retinopathies. Together, they are the most common inherited visual abnormality, affecting approximately 1 individual in 3000. The visual receptors gradually deteriorate, and blindness eventually results. The mutations that are responsible change the structure of the photoreceptors—specifically, the visual pigments of the membrane discs. It is not known how the altered pigments lead to the destruction of photoreceptors.

Photoreception

The cell membrane in the outer segment of the photoreceptor contains chemically regulated sodium ion channels. (Refer to the diagram of the resting state in Figure 17–14•.) In darkness, these gated channels are kept open in the presence of *cyclic-GMP* (*cyclic guanosine monophosphate*, or *cGMP*), a derivative of the high-energy compound *guanosine triphosphate* (GTP). Because the channels are open, the transmembrane potential is approximately

-40 mV, rather than the -70 mV typical of resting neurons. At the -40-mV transmembrane potential, the photoreceptor is continuously releasing neurotransmitters (in this case, glutamate) across synapses at the inner segment. The inner segment also continuously pumps sodium ions out of the cytoplasm. The movement of sodium ions into the outer segment, on to the inner segment, and out of the cell is known as the *dark current*.

The process of rhodopsin-based photoreception begins when a photon strikes the retinal portion of a rhodopsin molecule embedded in the membrane of the disc (see Figure 17–14•):

Step 1 Opsin Is Activated. The bound retinal molecule has two possible configurations: the **11-*cis*** form and the **11-*trans*** form. Normally, the molecule is in the 11-*cis* form; on absorbing light, it changes to the more linear 11-*trans* form. This change activates the opsin molecule.

Step 2 Opsin Activates Transducin, Which in Turn Activates Phosphodiesterase. **Transducin** is a G protein—a membrane-bound enzyme complex. l**p. 411** In this case, transducin is activated by opsin, and transducin in turn activates **phosphodiesterase (PDE)**.

Step 3 Cyclic-GMP (cGMP) Levels Decline, and Gated Sodium Channels Close. Phosphodiesterase is an enzyme that breaks down cGMP. The removal of cGMP from the gated sodium channels results in their inactivation. The rate of Na^+ entry into the cytoplasm then decreases.

Step 4 The Dark Current Is Reduced and the Rate of Neurotransmitter Release Declines. The reduction in the rate of Na^+ entry reduces the dark current. Because active transport continues to remove Na^+ from the cytoplasm, when the sodium channels close, the transmembrane potential drops toward -70 mV. As the membrane hyperpolarizes, the rate of neurotransmitter release decreases, indicating to the adjacent bipolar cell that the photoreceptor has absorbed a photon.

Recovery After Stimulation After absorbing a photon, retinal does not spontaneously revert to the 11-*cis* form. Instead, the entire rhodopsin molecule must be broken down and reassembled. Shortly after the change in shape occurs, the rhodopsin molecule begins to break down into retinal and opsin, a process known as **bleaching** (Figure 17–15•). Before it can recombine with opsin, the retinal must be enzymatically converted to the 11-*cis* form. This conversion requires energy in the form of ATP (adenosine triphosphate), and it takes time.

Bleaching contributes to the lingering visual impression you have after you see a flashbulb go off. Following intense exposure to light, a photoreceptor cannot respond to further stimulation until its rhodopsin molecules have been regenerated. As a result, a “ghost” image remains on the retina. Bleaching is seldom noticeable under ordinary circumstances, because the eyes are constantly making small, involuntary changes in position that move the image across the retina’s surface.

While the rhodopsin molecule is being reassembled, membrane permeability is returning to normal. Opsin is inactivated when bleaching occurs, and the breakdown of cGMP halts as a result. As other enzymes generate cGMP in the cytoplasm, the chemically gated sodium channels reopen.

As previously noted, the visual pigments of the photoreceptors are synthesized from vitamin A. The body contains vitamin A reserves sufficient for several months, and a significant amount is stored in the cells of the pigmented part of the retina. If dietary sources are inadequate, these reserves are gradually exhausted and the amount of visual pigment in the photoreceptors begins to decline. Daylight vision is affected, but in daytime the light is usually bright enough to stimulate any visual pigments that remain within the densely packed cone population of the fovea. As a result, the problem first becomes apparent at night, when the dim light proves insufficient to activate the rods. This condition, known as **night blindness**, can be treated by the administration of vitamin A. The body can convert the carotene pigments in many vegetables to vitamin A. Carrots are a particularly good source of carotene—hence the old adage that carrots are good for your eyes.

Color Vision

An ordinary lightbulb or the sun emits photons of all wavelengths. These photons stimulate both rods and cones. When all three types of cones are stimulated, or when rods alone are stimulated, you see a “white” light. Your eyes also detect photons that reach your retina after they bounce off objects around you. If photons of all colors bounce off an object, the object will appear white to you; if all the photons are absorbed by the object (so that none reach the retina), the object will appear black. An object will appear to have a particular color if it reflects (or transmits) photons from one portion of the visible spectrum and absorbs the rest.

The three types of cones are **blue cones**, **green cones**, and **red cones**. Each type has a different form of opsin and a sensitivity to a different range of wavelengths. Their stimulation in various combinations is the basis for color vision. In an individual with normal vision, the cone population consists of 16 percent blue cones, 10 percent green cones, and 74 percent red cones. Although their sensitivities overlap, each type is most sensitive to a specific portion of the visual spectrum (Figure 17–16•).

Color discrimination occurs through the integration of information arriving from all three types of cones. For example, the perception of yellow results from a combination of inputs from highly stimulated green cones, less strongly stimulated red cones, and relatively unaffected blue cones (see Figure 17–16•). If all three cone populations are stimulated, we perceive the color as white. Because we also perceive white if rods, rather than cones, are stimulated, everything appears black-and-white when we enter dimly lit surroundings or walk by starlight.

Persons who are unable to distinguish certain colors have a form of **color blindness**. The standard tests for color vision involve picking numbers or letters out of a complex colored picture (Figure 17–17•). Color blindness occurs when one or more classes of cones are nonfunctional. The cones may be absent, or they may be present but unable to manufacture the necessary visual pigments. In the most common type of color blindness (red–green color blindness), the red cones are missing, so the individual cannot distinguish red light from green light. Inherited color blindness involving one or two cone pigments is not unusual. Ten percent of all men show some color blindness, whereas the incidence among women is only about 0.67 percent. Total color blindness is extremely rare; only 1 person in 300,000 fails to manufacture any cone pigments. We will consider the inheritance of color blindness in Chapter 29.

Light and Dark Adaptation

The sensitivity of your visual system varies with the intensity of illumination. After 30 minutes or more in the dark, almost all visual pigments will be fully receptive to stimulation. This is the **dark-adapted state**. When dark-adapted, the visual system is extremely sensitive. For example, a single rod will hyperpolarize in response to a single photon of light. Even more remarkable, if as few as seven rods absorb photons at one time, you will see a flash of light.

When the lights come on, at first they seem almost unbearably bright, but over the next few minutes your sensitivity decreases as bleaching occurs. Eventually, the rate of bleaching is balanced by the rate at which they re-form. This condition is the **light-adapted state**. If you moved from the depths of a cave to the full sunlight of midday, your receptor sensitivity would decrease by a factor of 25,000.

A variety of central responses further adjust light sensitivity. Constriction of the pupil, via the *pupillary constrictor reflex*, reduces the amount of light entering your eye to one-thirtieth the maximum dark-adapted level. Dilating the pupil fully can produce a thirtyfold increase in the amount of light entering the eye, and facilitating some of the synapses along the visual pathway can perhaps triple its sensitivity. Hence, the efficiency of the entire system may increase by a factor of more than 1 million.

The Visual Pathway

The visual pathway begins at the photoreceptors and ends at the visual cortex of the cerebral hemispheres. In other sensory pathways we have examined, at most one synapse lies between a receptor and a sensory neuron that delivers information to the CNS. In the visual pathway, the message must cross two synapses (photoreceptor to bipolar cell, and bipolar cell to ganglion cell) before it heads toward the brain. The extra synapse increases the synaptic delay, but it provides an opportunity for the processing and integration of visual information before it leaves the retina.

Processing by the Retina

Each photoreceptor in the retina monitors a specific receptive field. The retina contains about 130 million photoreceptors, 6 million bipolar cells, and 1 million ganglion cells. Thus, a considerable amount of convergence occurs at the start of the visual pathway. The degree of convergence differs between rods and cones. Regardless of the amount of convergence, each ganglion cell monitors a specific portion of the field of vision.

As many as a thousand rods may pass information via their bipolar cells to a single ganglion cell. The ganglion cells that monitor rods, called **M cells** (*magnocells*; *magnus,* great), are relatively large. They provide information about the general form of an object, motion, and shadows in dim lighting. Because so much convergence occurs, the activation of an M cell indicates that light has arrived in a general area rather than at a specific location.

The loss of specificity due to convergence is partially overcome by the fact that the activity of ganglion cells varies according to the pattern of activity in their receptive field, which is generally circular. Typically, a ganglion cell responds differently to stimuli that arrive in the center of its receptive field than to stimuli that arrive at the edges (Figure 17–18•). Some ganglion cells (**oncenter neurons**) are excited by light arriving in the center of their sensory field and are inhibited when light strikes the edges of their receptive field. Others (**off-center neurons**) are inhibited by light in the central zone, but are stimulated by illumination at the edges. On-center and off-center neurons provide information about which portion of their receptive field is illuminated.

Cones typically show very little convergence; in the fovea, the ratio of cones to ganglion cells is 1:1. The ganglion cells that monitor cones, called **P cells** (*parvo cells*; *parvus*, small), are smaller and more numerous than M cells. P cells are active in bright light, and they provide information about edges, fine detail, and color. Because little convergence occurs, the activation of a P cell means that light has arrived at one specific location. As a result, cones provide more precise information about a visual image than do rods. In videographic terms, images formed by rods have a coarse, grainy, pixelated appearance that blurs details; by contrast, images produced by cones are fine-grained, of high density, sharp, and clear.

Central Processing of Visual Information

Axons from the entire population of ganglion cells converge on the optic disc, penetrate the wall of the eye, and proceed toward the diencephalon as the optic nerve (II). The two optic nerves, one from each eye, reach the diencephalon at the optic chiasm (Figure 17–19•). From that point, approximately half the fibers proceed toward the lateral geniculate nucleus of the same side of

the brain, whereas the other half cross over to reach the lateral geniculate nucleus of the opposite side. l**p. 466** From each lateral geniculate nucleus, visual information travels to the occipital cortex of the cerebral hemisphere on that side. The bundle of projection fibers linking the lateral geniculates with the visual cortex is known as the **optic radiation**. Collaterals from the fibers synapsing in the lateral geniculate continue to subconscious processing centers in the diencephalon and brain stem. For example, the pupillary reflexes and reflexes that control eye movement are triggered by collaterals carrying information to the superior colliculi.

The Field of Vision The perception of a visual image reflects the integration of information that arrives at the visual cortex of the occipital lobes. Each eye receives a slightly different visual image, because (1) the foveas are 5–7.5 cm apart, and (2) the nose and eye socket block the view of the opposite side. **Depth perception**, an interpretation of the three-dimensional relationships among objects in view, is obtained by comparing the relative positions of objects within the images received by the two eyes.

When you look straight ahead, the visual images from your left and right eyes overlap (see Figure 17–19•). The image received by the fovea of each eye lies in the center of the region of overlap. A vertical line drawn through the center of this region marks the division of visual information at the optic chiasm. Visual information from the left half of the combined field of vision reaches the visual cortex of your right occipital lobe; visual information from the right half of the combined field of vision arrives at the visual cortex of your left occipital lobe.

The cerebral hemispheres thus contain a map of the entire field of vision. As in the case of the primary sensory cortex, the map does not faithfully duplicate the relative areas within the sensory field. For example, the area assigned to the macula lutea and fovea covers about 35 times the surface it would cover if the map were proportionally accurate. The map is also upside down and backward, duplicating the orientation of the visual image at the retina.

The Brain Stem and Visual Processing Many centers in the brain stem receive visual information, either from the lateral geniculate nuclei or through collaterals from the optic tracts. Collaterals that bypass the lateral geniculates synapse in the superior colliculi or in the hypothalamus. The superior colliculi of the mesencephalon issue motor commands that control unconscious eye, head, or neck movements in response to visual stimuli. Visual inputs to the suprachiasmatic nucleus of the hypothalamus affect

the function of other brain stem nuclei. l**p. 469** The suprachiasmatic nucleus and the *pineal gland* of the epithalamus receive visual information and use it to establish a daily pattern of visceral activity that is tied to the day–night cycle. This **circadian rhythm** (*circa*, about + *dies*, day) affects your metabolic rate, endocrine function, blood pressure, digestive activities, awake–asleep cycle, and other physiological and behavioral processes.

Concept Check

If you had been born without cones in your eyes, would you still be able to see? Explain.

How could a diet deficient in vitamin A affect vision?

What effect would a decrease in phosphodiesterase activity in photoreceptor cells have on vision?

Answers begin on p. A–1

Equilibrium and Hearing

Objectives

- Describe the structures of the external and middle ears and explain how they function.
- Describe the parts of the inner ear and their roles in equilibrium and hearing.
- Trace the pathways for the sensations of equilibrium and hearing to their respective destinations in the brain.

The special senses of equilibrium and hearing are provided by the *inner ear,* a receptor complex located in the petrous part of the temporal bone of the skull. *Equilibrium* sensations inform us of the position of the head in space by monitoring gravity, linear acceleration, and rotation. *Hearing* enables us to detect and interpret sound waves. The basic receptor mechanism for both senses is the same. The receptors, called *hair cells,* are simple mechanoreceptors. The complex structure of the inner ear and the different arrangement of accessory structures enable hair cells to respond to different stimuli and thus to provide the input for both senses.

Anatomy of the Ear

The ear is divided into three anatomical regions: the external ear, the middle ear, and the inner ear (Figure 17–20•). The *external ear*—the visible portion of the ear—collects and directs sound waves toward the *middle ear*, a chamber located within the petrous portion of the temporal bone. Structures of the middle ear collect sound waves and transmit them to an appropriate portion of the *inner ear*, which contains the sensory organs for hearing and equilibrium.

The External Ear

The **external ear** includes the fleshy and cartilaginous **auricle**, or *pinna*, which surrounds the **external acoustic canal**, or *ear canal*. The auricle protects the opening of the canal and provides directional sensitivity; sounds coming from behind the head are blocked by the auricle, whereas sounds coming from the side or front are collected and channeled into the external acoustic canal. (When you "cup" your ear with your hand to hear a faint sound more clearly, you are exaggerating this effect.) The external acoustic canal is a passageway that ends at the **tympanic membrane**, also called the *tympanum* or *eardrum*. The tympanic membrane is a thin, semitransparent sheet that separates the external ear from the middle ear.

The tympanic membrane is very delicate. The auricle and the narrow external acoustic canal provide some protection from accidental injury. In addition, **ceruminous glands**—integumentary glands along the external acoustic canal—secrete a waxy material that helps deny access to foreign objects or small insects, as do many small, outwardly projecting hairs. These hairs also provide increased tactile sensitivity through their root hair plexuses. The slightly waxy secretion of the ceruminous glands, called **cerumen**, also slows the growth of microorganisms in the external acoustic canal and reduces the chances of infection.

The Middle Ear

The **middle ear**, or **tympanic cavity**, is an air-filled chamber separated from the external acoustic canal by the tympanic membrane. The middle ear communicates both with the *nasopharynx* (the superior portion of the pharynx), through the **auditory tube**, and with the mastoid air cells, through a number of small connections (Figures 17–20 and 17–21•). The auditory tube is also called the *pharyngotympanic tube* or the *Eustachian tube*. About 4 cm

(1.6 in.) long, it consists of two portions. The portion near the connection to the middle ear is relatively narrow and is supported by elastic cartilage. The portion near the opening into the nasopharynx is relatively broad and funnel shaped. The auditory tube permits the equalization of pressures on either side of the tympanic membrane. Unfortunately, the auditory tube can also allow microorganisms to travel from the nasopharynx into the middle ear. Invasion by microorganisms can lead to an unpleasant middle ear infection known as *otitis media*. AM: Otitis Media and Mastoiditis

The Auditory Ossicles The middle ear contains three tiny ear bones, collectively called **auditory ossicles**. The ear bones connect the tympanic membrane with one of the receptor complexes of the inner ear (see Figures 17–20 and 17–21•). The three auditory ossicles are the malleus, the incus, and the stapes. The **malleus** (*malleus*, hammer) attaches at three points to the interior surface of the tympanic membrane. The **incus** (*incus*, anvil) the middle ossicle, attaches the malleus to the **stapes** (*stapes*, stirrup), the inner ossicle. The edges of the base of the stapes are bound to the edges of the *oval window*, an opening in the bone that surrounds the inner ear. The articulations between the auditory ossicles are the smallest synovial joints in the body. Each has a tiny capsule and supporting extracapsular ligaments.

Vibration of the tympanic membrane converts arriving sound waves into mechanical movements. The auditory ossicles act as levers that conduct those vibrations to the inner ear. The ossicles are connected in such a way that an in–out movement of the tympanic membrane produces a rocking motion of the stapes. The ossicles thus function as a lever system that collects the force applied to the tympanic membrane and focuses it on the oval window. Because the tympanic membrane is 22 times larger and heavier than the oval window, considerable amplification occurs, so we can hear very faint sounds. But that degree of amplification can be a problem when we are exposed to very loud noises. In the middle ear, two small muscles protect the tympanic membrane and ossicles from violent movements under very noisy conditions:

1. The **tensor tympani** (TEN-sor tim-PAN-e¯) **muscle** is a short ribbon of muscle whose origin is the petrous portion of the temporal bone and the auditory tube, and whose

insertion is on the “handle” of the malleus. When the tensor tympani contracts, the malleus is pulled medially, stiffening the tympanic membrane. This increased stiffness reduces the amount of movement
possible. The tensor tympani muscle is innervated by motor fibers of the mandibular branch of the trigeminal nerve (V).

2. The **stapedius** (sta-P
¯E

-d
¯e
-us) **muscle**, innervated by the facial nerve (VII), originates from the posterior wall of the middle
ear and inserts on the stapes. Contraction of the stapedius pulls the stapes, reducing movement of the stapes at the oval window.

The Inner Ear

The senses of equilibrium and hearing are provided by receptors in the **inner ear** (Figures 17–20 and 17–22a•).

The superficial contours of the inner ear are established by a layer of dense bone known as the **bony labyrinth** (*labyrinthos*, network of canals). The walls of the bony labyrinth are continuous with the surrounding temporal bone. The inner contours of the bony labyrinth closely follow the contours of the **membranous labyrinth**, a delicate, interconnected network of fluid-filled tubes. The receptors of the inner ear are found within those tubes. Between the bony and membranous labyrinths flows the **perilymph** (PER-i-limf), a liquid whose properties closely resemble those of cerebrospinal fluid. The membranous labyrinth contains
endolymph (EN-d
¯o

-limf), a fluid with electrolyte concentrations different from those of typical body fluids. The physical relationships are indicated in Figure 17–22b•. (See Appendix IV for a chemical analysis of perilymph, endolymph, and other body fluids.)

The bony labyrinth can be subdivided into the *vestibule*, three *semicircular canals*, and the *cochlea* (see Figure 17–22a•). The **vestibule** (VES-ti-būl) consists of a pair of membranous sacs: the **saccule** (SAK-ūl) and the **utricle** (Ū-tri-kul), or *sacculus* and *utriculus*. Receptors in the saccule and utricle provide sensations of gravity and linear acceleration.

The **semicircular canals** enclose slender *semicircular ducts*. Receptors in the semicircular ducts are stimulated by rotation of the head. The combination of vestibule and semicircular canals is called the **vestibular complex**. The fluid-filled chambers within the vestibule are broadly continuous with those of the semicircular canals.

The **cochlea** (KOK-lē-uh; *cochlea*, a snail shell) is a spiral-shaped, bony chamber that contains the **cochlear duct** of the membranous labyrinth. Receptors within the cochlear duct provide the sense of hearing. The duct is sandwiched between a pair of perilymph-filled chambers. The entire complex makes turns around a central bony hub, much like a snail shell.

The walls of the bony labyrinth consist of dense bone everywhere except at two small areas near the base of the cochlear spiral (see Figure 17–20•). The **round window** is a thin, membranous partition that separates the perilymph of the cochlear chambers from the air-filled middle ear. Collagen fibers connect the bony margins of the opening known as the **oval window** to the base of the stapes.

Equilibrium

As just noted, equilibrium sensations are provided by receptors of the vestibular complex. The semicircular ducts convey information about rotational movements of the head. For example, when you turn your head to the left, receptors stimulated in the semicircular ducts tell you how rapid the movement is, and in which direction. The saccule and the utricle convey information about your position with respect to gravity. If you stand with your head tilted to one side, these receptors report the angle involved and whether your head tilts forward or backward. The saccule and the utricle are also stimulated by sudden acceleration. When your car accelerates from a stop, the saccular and utricular receptors give you the impression of increasing speed.

The Semicircular Ducts

Sensory receptors in the semicircular ducts respond to rotational movements of the head. These **hair cells** are active during a movement, but are quiet when the body is motionless. The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle (Figure 17–23a•). Each semicircular duct contains an **ampulla**, an expanded region that contains the receptors. The region in the wall of the ampulla that contains the receptors is known as a crista (Figure 17–23b•). Each crista is bound to a **cupula**

(K

¯U

-p
¯u

-luh), a gelatinous structure that extends the full width of the ampulla. The receptors in the cristae are called hair cells

(Figure 17–23b,d•).

Hair cells are the receptors found in other portions of the membranous labyrinth as well. Regardless of location, they are always surrounded by supporting cells and monitored by the dendrites of sensory neurons. The free surface of each hair cell supports 80–100 long **stereocilia** which resemble very long microvilli (see Figure 17–23d•). Each hair cell in the vestibule also con

–

I when an external force pushes against these processes, the distortion of the cell membrane alters the rate at which the hair cell releases chemical transmitters.

Hair cells provide information about the direction and strength of mechanical stimuli. The stimuli involved, however, depend on the hair cell's location: gravity or acceleration in the vestibule, rotation in the semicircular canals, and sound in the cochlea. The sensitivities of the hair cells differ, because each of these regions has different accessory structures that determine which stimulus will provide the force to deflect the kinocilia and stereocilia.

At a crista, the kinocilia and stereocilia of the hair cells are embedded in the cupula (see Figure 17–23b•). Because the cupula has a density very close to that of the surrounding endolymph, it essentially floats above the receptor surface. When your head rotates in the plane of the duct, the movement of endolymph along the length of the semicircular duct pushes the cupula to the side and distorts the receptor processes (Figure 17–23c•). Movement of fluid in one direction stimulates the hair cells, and movement in the opposite direction inhibits them. When the endolymph stops moving, the elastic nature of the cupula makes it return to its normal position.

Even the most complex movement can be analyzed in terms of motion in three rotational planes. Each semicircular duct re

tains a **kinocilium** (K

–o

-SIL-

‾e

-um), a single large cilium. Hair cells do not actively move their kinocilia or stereocilia. However,

-n

sponds to one of these rotational movements. A horizontal rotation, as in shaking your head “no,” stimulates the hair cells of the lateral semicircular duct. Nodding “yes” excites the anterior duct, and tilting your head from side to side activates receptors in the posterior duct.

The Utricle and Saccule

The utricle and saccule provide equilibrium sensations, whether the body is moving or is stationary. The two chambers are connected by a slender passageway that is continuous with the narrow endolymphatic duct. The **endolymphatic duct** ends in a blind pouch called the **endolymphatic sac** (see Figure 17–23a•). This sac projects through the dura mater that lines the temporal bone and into the subarachnoid space, where it is surrounded by a capillary network. Portions of the cochlear duct secrete endolymph continuously, and at the endolymphatic sac excess fluid returns to the general circulation as the capillaries absorb endolymph removed by a combination of active transport and vesicular transport.

The hair cells of the utricle and saccule are clustered in oval structures called **maculae** (MAK-

‾u

-l

‾e

; *macula*, spot)

(Figure 17–24a•). As in the ampullae, the hair cell processes are embedded in a gelatinous mass. However, the surface of this gelatinous material contains densely packed calcium carbonate crystals known as **statoconia** (*statos*, standing + *conia*, dust). The complex as a whole (gelatinous matrix and statoconia) is called an **otolith** (“ear stone”).

The macula of the saccule is diagrammed in Figure 17–24b•, and its function is shown in Figure 17–24c•. When your head is in the normal, upright position, the statoconia sit atop the macula (STEP 1). Their weight presses on the macular surface, pushing the hair cell processes down rather than to one side or another. When your head is tilted, the pull of gravity on the statoconia shifts them to the side, thereby distorting the hair cell processes (STEP 2). The change in receptor activity tells the CNS that your head is no longer level.

A similar mechanism accounts for your perception of linear acceleration when you are in a car that speeds up suddenly. The statoconia lag behind, and the effect on the hair cells is comparable to tilting your head back. Under normal circumstances, your nervous system distinguishes between the sensations of tilting and linear acceleration by integrating vestibular sensations with visual information. Many amusement park rides confuse your sense of equilibrium by combining rapid rotation with changes in position and acceleration while providing restricted or misleading visual information.

Pathways for Equilibrium Sensations

Hair cells of the vestibule and semicircular ducts are monitored by sensory neurons located in adjacent **vestibular ganglia**. Sensory fibers from these ganglia form the **vestibular branch** of the vestibulocochlear nerve (VIII). l**p. 485** These fibers innervate neurons within the pair of **vestibular nuclei** at the boundary between the pons and the medulla oblongata. The two vestibular nuclei have four functions:

1. Integrating sensory information about balance and equilibrium that arrives from both sides of the head.

2. Relaying information from the vestibular complex to the cerebellum.

3. Relaying information from the vestibular complex to the cerebral cortex, providing a conscious sense of head position and movement.

4. Sending commands to motor nuclei in the brain stem and spinal cord.

The reflexive motor commands issued by the vestibular nuclei are distributed to the motor nuclei for cranial nerves involved with eye, head, and neck movements (III, IV, VI, and XI). Instructions descending in the *vestibulospinal tracts* of the spinal cord adjust peripheral muscle tone and complement the reflexive movements of the head or neck. l**p. 511** These pathways are indicated in Figure 17–25•.

The automatic movements of the eyes that occur in response to sensations of motion are directed by the *superior colliculi* of the mesencephalon. l**p. 464** These movements attempt to keep your gaze focused on a specific point in space, despite changes in body position and orientation. If your body is turning or spinning rapidly, your eyes will fix on one point for a moment and then jump ahead to another in a series of short, jerky movements. This type of eye movement can occur even when the body is stationary if either the brain stem or the inner ear is damaged. Individuals with this condition, which is called **nystagmus** (nis-TAG-mus), have trouble controlling their eye movements. Physicians commonly check for nystagmus by asking patients to watch a small penlight as it is moved across the field of vision. AM: Vertigo, Motion Sickness, and Ménière's Disease

Hearing

The receptors of the cochlear duct provide a sense of hearing that enables us to detect the quietest whisper, yet remain functional in a noisy room. The receptors responsible for auditory sensations are hair cells similar to those of the vestibular complex. However, their placement within the cochlear duct and the organization of the surrounding accessory structures shield them from stimuli other than sound.

In conveying vibrations from the tympanic membrane to the oval window, the auditory ossicles convert pressure fluctuations in air into much greater pressure fluctuations in the perilymph of the cochlea. These fluctuations stimulate hair cells along the cochlear spiral. The *frequency* of the perceived sound is determined by *which part* of the cochlear duct is stimulated. The *intensity* (volume) of the perceived sound is determined by *how many* of the hair cells at that location are stimulated. We will now consider the mechanics of this remarkably elegant process.

The Cochlear Duct

In sectional view (Figure 17–26a,b and 17–27a,b•), the cochlear duct, or *scala media*, lies between a pair of perilymphatic chambers: the **vestibular duct** (*scala vestibuli*) and the **tympanic duct** (*scala tympani*). The outer surfaces of these ducts are encased by the bony labyrinth everywhere except at the oval window (the base of the vestibular duct) and the round window (the base of the tympanic duct). Because the vestibular and tympanic ducts are interconnected at the tip of the cochlear spiral, they really form one long and continuous perilymphatic chamber. This chamber begins at the oval window; extends through the vestibular duct, around the top of the cochlea, and along the tympanic duct; and ends at the round window.

The cochlear duct is an elongated tubelike structure suspended between the vestibular duct and the tympanic duct. The hair cells of the cochlear duct are located in a structure called the **organ of Corti** (see Figures 17–26b and 17–27a,b•). This sensory structure sits on the **basilar membrane**, a membrane that separates the cochlear duct from the tympanic duct. The hair cells are arranged in a series of longitudinal rows. They lack kinocilia, and their stereocilia are in contact with the overlying **tectorial** (tek-TOR-e¯-al) **membrane** (*tectum*, roof). This membrane is firmly attached to the inner wall of the cochlear duct. When a portion of the basilar membrane bounces up and down, the stereocilia of the hair cells are pressed against the tectorial membrane and become distorted. The basilar membrane moves in response to pressure fluctuations within the perilymph. These pressure changes are triggered by sound waves arriving at the tympanic membrane. To understand this process, we must consider the basic properties of sound.

An Introduction to Sound

Hearing is the perception of sound, which consists of waves of pressure conducted through a medium such as air or water. In air, each *pressure wave* consists of a region where the air molecules are crowded together and an adjacent zone where they are farther apart (Figure 17–28a•). These waves are sine waves—that is, S-shaped curves that repeat in a regular pattern—and travel through the air at about 1235 km > h (768 mph).

The *wavelength* of sound is the distance between two adjacent wave crests (peaks) or, equivalently, the distance between two adjacent wave troughs (Figure 17–28b•). Wavelength is inversely related to **frequency**—the number of waves that pass a fixed reference point in a given time. Physicists use the term **cycles** rather than *waves*. Hence, the frequency of a sound is measured in terms of the number of cycles per second (cps), a unit called **hertz (Hz)**. What we perceive as the **pitch** of a sound is our sensory response to its frequency. A *high-frequency* sound (high pitch, short wavelength) might have a frequency of 15,000 Hz or more; a very *low-frequency* sound (low pitch, long wavelength) could have a frequency of 100 Hz or less.

It takes energy to produce sound waves. When you strike a tuning fork, it vibrates and pushes against the surrounding air, producing sound waves whose frequency depends on the instrument’s frequency of vibration. The harder you strike the tuning fork, the more energy you provide; the energy increases the **amplitude** of the sound wave (see Figure 17–28b•). The amplitude, or *intensity*, of a sound determines how loud it seems; the greater the energy content, the larger the amplitude, and the louder the sound. Sound energy is reported in **decibels** (DES-i-belz). Table 17–1 indicates the decibel levels of familiar sounds.

When sound waves strike an object, their energy is a physical pressure. You may have seen windows move in a room in which a stereo is blasting. The more flexible the object, the more easily it will respond to sound pressure. Even soft stereo music will vibrate a sheet of paper held in front of the speaker. Given the right combination of frequencies and amplitudes, an object will begin to vibrate at the same frequency as the sound, a phenomenon called *resonance*. The higher the decibel level, the greater the amount of vibration. For you to be able to hear any sound, your thin, flexible tympanic membrane must vibrate in resonance with the sound waves.

Probably more than 6 million people in the United States alone have at least a partial hearing deficit, due to problems with either the transfer of vibrations by the auditory ossicles or damage to the receptors or the auditory pathways. AM: Hearing Deficits

The Hearing Process

The process of hearing can be divided into six basic steps (Figure 17–29•):

Step 1 Sound Waves Arrive at the Tympanic Membrane. Sound waves enter the external acoustic canal and travel toward the tympanic membrane. The orientation of the canal provides some directional sensitivity. Sound waves approaching a particular side of the head have direct access to the tympanic membrane on that side, whereas sounds arriving from another direction must bend around corners or pass through the auricle or other body tissues.

Step 2 Movement of the Tympanic Membrane Causes Displacement of the Auditory Ossicles. The tympanic membrane provides a surface for the collection of sound, and it vibrates in resonance to sound waves with frequencies between approximately 20 and 20,000 Hz. When the tympanic membrane vibrates, so do the malleus and, through their articulations, the incus and stapes. In this way, the sound is amplified.

Step 3 Movement of the Stapes at the Oval Window Establishes Pressure Waves in the Perilymph of the Vestibular Duct. Liquids are incompressible: If you push down on one part of a water bed, the bed bulges somewhere else. Because the rest of the cochlea is sheathed in bone, pressure applied at the oval window can be relieved only at the round window. Although the stapes actually has a rocking movement, the in–out component is easiest to visualize and describe. Basically, when the stapes moves inward, the round window bulges outward, into the middle ear cavity. As the stapes moves in and out, vibrating at the frequency of the sound arriving at the tympanic membrane, it creates pressure waves within the perilymph.

Step 4 The Pressure Waves Distort the Basilar Membrane on Their Way to the Round Window of the Tympanic Duct. The pressure waves established by the movement of the stapes travel through the perilymph of the vestibular and tympanic ducts to reach the round window. In doing so, the waves distort the basilar membrane. The location of maximum distortion varies with the frequency of the sound, owing to regional differences in the width and flexibility of the basilar membrane along its length. High-frequency sounds, which have a very short wavelength, vibrate the basilar membrane near the oval window. The lower the frequency of the sound, the longer the wavelength, and the farther from the oval window the area of maximum distortion will be (Figure 17–30a–c•). Thus, information about frequency is translated into information about *position* along the basilar membrane.

The *amount* of movement at a given location depends on the amount of force applied by the stapes, which in turn is a function of energy content of the sound. The louder the sound, the more the basilar membrane moves.

Step 5 Vibration of the Basilar Membrane Causes Vibration of Hair Cells against the Tectorial Membrane. Vibration of the affected region of the basilar membrane moves hair cells against the tectorial membrane. This movement leads to the displacement of the stereocilia, which in turn opens ion channels in the hair cell membranes. The resulting inrush of ions depolarizes the hair cells, leading to the release of neurotransmitters and thus to the stimulation of sensory neurons.

The hair cells of the organ of Corti are arranged in several rows. A very soft sound may stimulate only a few hair cells in a portion of one row. As the intensity of a sound increases, not only do these hair cells become more active, but additional hair cells— at first in the same row and then in adjacent rows—are stimulated as well. The number of hair cells responding in a given region of the organ of Corti thus provides information on the intensity of the sound.

Step 6 Information about the Region and Intensity of Stimulation Is Relayed to the CNS over the Cochlear Branch of the Vestibulocochlear Nerve (VIII). The cell bodies of the bipolar sensory neurons that monitor the cochlear hair cells are located at the center of the bony cochlea, in the **spiral ganglion** (see Figure 17–27a•). From there, the information is carried by the cochlear branch of cranial nerve VIII to the cochlear nuclei of the medulla oblongata for subsequent distribution to other centers in the brain.

Auditory Pathways

Stimulation of hair cells activates sensory neurons whose cell bodies are in the adjacent spiral ganglion. The afferent fibers of those neurons form the **cochlear branch** of the vestibulocochlear nerve (VIII) (Figure 17–31•). These axons enter the medulla oblongata, where they synapse at the **dorsal** and **ventral cochlear nuclei**. From there, the information crosses to the opposite side of the brain and ascends to the inferior colliculus of the mesencephalon. This processing center coordinates a number of responses to acoustic stimuli, including auditory reflexes that involve skeletal muscles of the head, face, and trunk. These reflexes automatically change the position of your head in response to a sudden loud noise; you usually turn your head and your eyes toward the source of the sound.

Before reaching the cerebral cortex and your awareness, ascending auditory sensations synapse in the medial geniculate nucleus of the thalamus. Projection fibers then deliver the information to the auditory cortex of the temporal lobe. Information travels to the cortex over labeled lines: High-frequency sounds activate one portion of the cortex, low-frequency sounds another. In effect, the auditory cortex contains a map of the organ of Corti. Thus, information about *frequency*, translated into information about *position* on the basilar membrane, is projected in that form onto the auditory cortex, where it is interpreted to produce your subjective sensation of pitch.

An individual whose auditory cortex is damaged will respond to sounds and have normal acoustic reflexes, but will find it difficult or impossible to interpret the sounds and recognize a pattern in them. Damage to the adjacent association area leaves the ability to detect the tones and patterns, but produces an inability to comprehend their meaning.

Auditory Sensitivity

Our hearing abilities are remarkable, but it is difficult to assess the absolute sensitivity of the system. The range from the softest audible sound to the loudest tolerable blast represents a trillionfold increase in power. The receptor mechanism is so sensitive that, if we were to remove the stapes, we could, in theory, hear air molecules bouncing off the oval window. We never use the full potential of this system, because body movements and our internal organs produce squeaks, groans, thumps, and other sounds that are tuned out by central and peripheral adaptation. When other environmental noises fade away, the level of adaptation drops and the system becomes increasingly sensitive. For example, when you relax in a quiet room, your heartbeat seems to get louder and louder as the auditory system adjusts to the level of background noise.

Young children have the greatest hearing range: They can detect sounds ranging from a 20-Hz buzz to a 20,000-Hz whine. With age, damage due to loud noises or other injuries accumulates. The tympanic membrane gets less flexible, the articulations between the ossicles stiffen, and the round window may begin to ossify. As a result, older individuals show some degree of hearing loss.

100 Keys | Balance and hearing rely on the same basic types of sensory receptors (hair cells). The anatomical structure of the associated sense organ determines what stimuli affect the hair cells. In the semicircular ducts, the stimulus is fluid movement caused by head rotation in the horizontal, sagittal, or frontal planes. In the utricle and saccule, the stimuli are gravity-induced shifts in the position of attached otoliths. In the cochlea, the stimulus is movement of the tectorial membrane as pressure waves distort the basilar membrane.

Concept Check

If the round window were not able to bulge out with increased pressure in the perilymph, how would the perception of sound be affected?

How would the loss of stereocilia from hair cells of the organ of Corti affect hearing?

Why does a blockage of the auditory tube produce an earache?

Answers begin on p. A–1

Anatomy 360 | Review the anatomy of the ear on the **Anatomy 360 CD-ROM: Nervous System/Special Senses/Ear.**

Chapter Review

Selected Clinical Terminology

astigmatism: Reduction in visual acuity due to a curvature irregularity in the cornea or lens. (p. 565)

cataract: An abnormal condition in which the lens has lost its transparency. (p. 562)

color blindness: A condition in which a person is unable to distinguish certain colors. (p. 570)

conductive deafness: Deafness resulting from conditions in the outer or middle ear that block the transfer of vibrations from the tympanic membrane to the oval window. [AM]

detached retina: Delamination of a portion of the neural retina, which separates the photoreceptor layer from the pigment layer. If untreated, blindness can result in the affected area. (p. 561)

diabetic retinopathy: Deterioration of the retinal photoreceptor layer due to vascular damage and the overgrowth and rupture of blood vessels on the retinal surface. (p. 559)

glaucoma: A condition characterized by increased intraocular pressure due to the impaired reabsorption of aqueous humor; can result in blindness. (p. 562)

hyperopia, or *farsightedness:* A condition in which nearby objects are blurry, but distant objects are clear. (p. 564)

motion sickness: A condition resulting from conflicting visual and equilibrium sensory stimuli. Signs and symptoms can include headache, sweating, nausea, vomiting, and changes in mental state. [AM]

myopia, or *nearsightedness:* A condition in which vision at close range is normal, but distant objects appear blurry. (p. 564)

nerve deafness: Deafness resulting from problems within the cochlea or along the auditory pathway. [AM]

night blindness: Loss of visual acuity under dim light conditions due to inadequate visual pigment production, usually as a result of vitamin A deficiency. (p. 570)

nystagmus: Abnormal eye movements that may appear after brain stem or inner ear damage. (p. 579)

otitis media: Infection and tissue inflammation within the middle ear cavity. (p. 574 and [AM])

presbyopia: A type of hyperopia that develops with age as lenses become less elastic. (p. 564)

retinitis pigmentosa: A group of inherited retinopathies characterized by the progressive deterioration of photoreceptors, eventually resulting in blindness. (p. 567)

scotomas: Abnormal blind spots that are fixed in position. (p. 566)

Study Outline

Olfaction p. 550 Olfactory Receptors p. 551

1. The **olfactory organs** contain the **olfactory epithelium** with **olfactory receptors**, supporting cells, and **basal** (stem) **cells**. The surfaces of the olfactory organs are coated with the secretions of the **olfactory glands**. *(Figure 17–1)*

2. The olfactory receptors are highly modified neurons.

3. Olfactory reception involves detecting dissolved chemicals as they interact with odorant-binding proteins.

Olfactory Pathways p. 551

4. In olfaction, the arriving information reaches the information centers without first synapsing in the thalamus. *(Figure 17–1)*

Olfactory Discrimination p. 551

5. The olfactory system can distinguish thousands of chemical stimuli. The CNS interprets smells by the pattern of receptor activity.

6. The olfactory receptor population shows considerable turnover. The number of olfactory receptors declines with age.

Gustation p. 552

1. **Taste** (gustatory) **receptors** are clustered in **taste buds**.

2. Taste buds are associated with epithelial projections (*lingual papillae*) on the dorsal surface of the tongue. *(Figure 17–2)*

Taste Receptors p. 553

3. Each taste bud contains **basal cells**, which appear to be stem cells, and **gustatory cells**, which extend *taste hairs* through a narrow **taste pore**. *(Figure 17–2)*

Gustatory Pathways p. 553

4. The taste buds are monitored by cranial nerves that synapse within the solitary nucleus of the medulla oblongata and then on to the thalamus and the primary sensory cortex.

Gustatory Discrimination p. 553

5. The **primary taste sensations** are sweet, salt, sour, and bitter. Receptors also exist for **umami** and **water**.

6. Taste sensitivity exhibits significant individual differences, some of which are inherited.

7. The number of taste buds declines with age.

100 Keys | p. 554

Vision p. 554 Accessory Structures of the Eye p. 554

1. The **accessory structures** of the eye include the eyelids **(palpebrae)**, separated by the **palpebral fissure**, the **eyelashes**, and the **tarsal glands**. *(Figures 17–3, 17–4)*

2. An epithelium called the **conjunctiva** covers most of the exposed surface of the eye. The **cornea** is transparent. *(Figures 17–3, 17–4)*

3. The secretions of the **lacrimal gland** contain **lysozyme**. Tears collect in the *lacrimal lake* and reach the inferior meatus of the nose after they pass through the **lacrimal puncta**, the **lacrimal canaliculi**, the **lacrimal sac**, and the **nasolacrimal duct**. *(Figure 17–3)*

The Eye p. 557

4. The eye has three layers: an outer **fibrous tunic**, a middle **vascular tunic**, and an inner **neural tunic**. *(Figure 17–4)*

5. The fibrous tunic consists of the **sclera**, the cornea, and the **limbus**. *(Figure 17–4)*

6. The vascular tunic, or **uvea**, includes the **iris**, the **ciliary body**, and the **choroid**. The iris contains muscle fibers that change the diameter of the **pupil**. The ciliary body contains the **ciliary muscle** and the **ciliary processes**, which attach to the **suspensory ligaments** of the *lens*. *(Figures 17–4, 17–5)*

7. The neural tunic, or **retina**, consists of an outer *pigmented part* and an inner *neural part*; the latter contains visual receptors and associated neurons. *(Figures 17–4, 17–6)*

8. The retina contains two types of **photoreceptors: rods** and **cones**.

9. Cones are densely clustered in the **fovea**, at the center of the **macula lutea**. *(Figure 17–6)*

10. The direct line to the CNS proceeds from the photoreceptors to **bipolar cells**, then to **ganglion cells**, and, finally, to the brain via the optic nerve. The axons of ganglion cells converge at the **optic disc**, or **blind spot**. **Horizontal cells** and **amacrine cells** modify the signals passed among other components of the retina. *(Figures 17–6, 17–7)*

11. The ciliary body and lens divide the interior of the eye into a large **posterior cavity**, or *vitreous chamber*, and a smaller **anterior cavity**. The anterior cavity is subdivided into the **anterior chamber**, which extends from the cornea to the iris, and a **posterior chamber**, between the iris and the ciliary body and lens. *(Figure 17–8)*

12. The fluid **aqueous humor** circulates within the eye and reenters the circulation after diffusing through the walls of the anterior chamber and into the **canal of Schlemm**. *(Figure 17–8)*

13. The **lens** lies posterior to the cornea and forms the anterior boundary of the posterior cavity. This cavity contains the **vitreous body**, a gelatinous mass that helps stabilize the shape of the eye and support the retina. *(Figure 17–8)*

14. The lens focuses a visual image on the photoreceptors. The condition in which a lens has lost its transparency is a **cataract**.

15. Light is **refracted** (bent) when it passes through the cornea and lens. During **accommodation**, the shape of the lens changes to focus an image on the retina. “Normal” **visual acuity** is rated 20 > 20. *(Figures 17–9 to 17–12)*

100 Keys | p. 566

Visual Physiology p. 566

16. The two types of photoreceptors are rods, which respond to almost any photon, regardless of its energy content, and cones, which have characteristic ranges of sensitivity. *(Figure 17–13)*

17. Each photoreceptor contains an **outer segment** with membranous **discs**. A narrow stalk connects the outer segment to the **inner segment**. Light absorption occurs in the **visual pigments**, which are derivatives of **rhodopsin** (opsin plus the pigment retinal, which is synthesized from vitamin A). *(Figures 17–13 to 17–15)*

18. Color sensitivity depends on the integration of information from **red**, **green**, and **blue** cones. **Color blindness** is the inability to detect certain colors. *(Figures 17–16, 17–17)*

19. In the **dark-adapted state**, most visual pigments are fully receptive to stimulation. In the **light-adapted state**, the pupil constricts and **bleaching** of the visual pigments occurs.

The Visual Pathway p. 571

20. The ganglion cells that monitor rods, called **M cells** (*magnocells*), are relatively large. The ganglion cells that monitor cones, called **P cells** (*parvo cells*), are smaller and more numerous. *(Figure 17–18)*

21. Visual data from the left half of the combined field of vision arrive at the visual cortex of the right occipital lobe; data from the right half of the combined field of vision arrive at the visual cortex of the left occipital lobe. *(Figure 17–19)*

22. Depth perception is obtained by comparing relative positions of objects between the left- and right-eye images *(Figure 17–19)*

23. Visual inputs to the suprachiasmatic nucleus of the hypothalamus affect the function of other brain stem nuclei. This nucleus establishes a visceral **circadian rhythm**, which is tied to the day–night cycle and affects other metabolic processes.

Anatomy 360 | Nervous System/Special Senses/Eye

Equilibrium and Hearing p. 573

1. The senses of equilibrium and hearing are provided by the receptors of the inner ear.

Anatomy of the Ear p. 573

2. The ear is divided into the **external ear**, the **middle ear**, and the **inner ear**. *(Figure 17–20)*

3. The external ear includes the **auricle**, or *pinna*, which surrounds the entrance to the **external acoustic canal**, which ends at the **tympanic membrane** (*eardrum*). *(Figure 17–20)*

4. The middle ear communicates with the nasopharynx via the **auditory** (*pharyngotympanic*) **tube**. The middle ear encloses and protects the **auditory ossicles**. *(Figures 17–20, 17–21)*

5. The **membranous labyrinth** (the chambers and tubes) of the inner ear contains the fluid **endolymph**. The **bony labyrinth** surrounds and protects the membranous labyrinth and can be subdivided into the **vestibule**, the **semicircular canals**, and the **cochlea**.

(Figures 17–20, 17–22)

6. The vestibule of the inner ear encloses the **saccule** and **utricle**. The semicircular canals contain the **semicircular ducts**. The cochlea contains the **cochlear duct**, an elongated portion of the membranous labyrinth. *(Figure 17–22)*

7. The **round window** separates the **perilymph** from the air spaces of the middle ear. The **oval window** is connected to the base of the stapes. *(Figure 17–20)*

Equilibrium p. 576

8. The basic receptors of the inner ear are **hair cells**, which provide information about the direction and strength of mechanical stimuli. *(Figure 17–23)*

9. The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle. Each duct contains an **ampulla** with a gelatinous **cupula** and associated sensory receptors. *(Figures 17–22, 17–23)*

10. The saccule and utricle are connected by a passageway that is continuous with the **endolymphatic duct**, which terminates in the **endolymphatic sac**. ln the saccule and utricle, hair cells cluster within **maculae**, where their cilia contact the **otolith** (densely packed mineral crystals, called **statoconia**, in a matrix). *(Figures 17–23, 17–24)*

11. The vestibular receptors activate sensory neurons of the **vestibular ganglia**. The axons form the **vestibular branch** of the vestibulocochlear nerve (VIII), synapsing within the **vestibular nuclei**. *(Figure 17–25)*

Hearing p. 579

12. The cochlear duct lies between the **vestibular duct** and the **tympanic duct**. The hair cells of the cochlear duct lie within the **organ of Corti**. *(Figures 17–26, 17–27)*

13. The energy content of a sound determines its *intensity*, measured in **decibels**. Sound waves travel toward the tympanic membrane, which vibrates; the auditory ossicles conduct these vibrations to the inner ear. Movement at the oval window applies pressure to the perilymph of the vestibular duct. *(Figures 17–28, 17–29; Table 17–1)*

14. Pressure waves distort the **basilar membrane** and push the hair cells of the organ of Corti against the **tectorial membrane**. The **tensor tympani** and **stapedius muscles** contract to reduce the amount of motion when very loud sounds arrive. *(Figures 17–29, -17–30)*

15. The sensory neurons are located in the **spiral ganglion** of the cochlea. The afferent fibers of these neurons form the **cochlear branch** of the vestibulocochlear nerve (VIII), synapsing at the **cochlear nuclei**. *(Figure 17–31)*

Review Questions

MyA&P | Access more review material online at **MyA&P**. There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. A reduction in sensitivity in the presence of a constant stimulus is

(a) transduction **(b)** sensory coding

(c) line labeling **(d)** adaptation

2. A blind spot in the retina occurs where

(a) the fovea is located

(b) ganglion cells synapse with bipolar cells

(c) the optic nerve attaches to the retina

(d) rod cells are clustered to form the macula

(e) amacrine cells are located

3. Sound waves are converted into mechanical movements by the

(a) auditory ossicles **(b)** cochlea

(c) oval window **(d)** round window

(e) tympanic membrane

4. The basic receptors in the inner ear are the

(a) utricles **(b)** saccules

(c) hair cells **(d)** supporting cells

(e) ampullae

5. The retina is the

(a) vascular tunic **(b)** fibrous tunic

(c) neural tunic **(d)** a,b, and c are correct

6. At sunset, your visual system adapts to

(a) fovea vision **(b)** rod-based vision

(c) macular vision **(d)** cone-based vision

7. A better-than-average visual acuity rating is

(a) 20 > 20 **(b)** 20 > 30 **(c)** 15 > 20 **(d)** 20 > 15

8. The malleus, incus, and stapes are the tiny bones located in the

(a) outer ear **(b)** middle ear

(c) inner ear **(d)** membranous labyrinth

9. Receptors in the saccule and utricle provide sensations of

(a) angular acceleration

(b) hearing

(c) vibration

(d) gravity and linear acceleration

10. The organ of Corti is located in the _____ of the inner ear.

(a) utricle **(b)** bony labyrinth

(c) vestibule **(d)** cochlea

11. Auditory information about the frequency and intensity of stimulation is relayed to the CNS over the cochlear branch of cranial nerve

(a) IV **(b)** VI **(c)** VIII **(d)** X

12. What are the three types of papillae on the human tongue?

13. (a) What structures make up the fibrous tunic of the eye?

(b) What are the functions of the fibrous tunic?

14. What structures make up the vascular tunic of the eye?

15. What are the three auditory ossicles in the middle ear, and what are their functions?

LEVEL 2 Reviewing Concepts

16. Trace the olfactory pathway from the time an odor reaches the olfactory epithelium until it reaches its final destination in the brain.

17. Why are olfactory sensations long-lasting and an important part of our memories and emotions?

18. What is the usual result if a sebaceous gland of an eyelash or a tarsal gland becomes infected?

19. Displacement of sterocilia toward the kinocilium of a hair cell

(a) produces a depolarization of the membrane

(b) produces a hyperpolarization of the membrane

(c) decreases the membrane permeability to sodium ions

(d) increases the membrane permeability to potassium ions

(e) does not affect the transmembrane potential of the cell

20. Damage to the cupula of the lateral semicircular duct would interfere with the perception of

(a) the direction of gravitational pull

(b) linear acceleration

(c) horizontal rotation of the head

(d) vertical rotation of the head

(e) angular rotation of the head

21. When viewing an object *close* to you, your lens should be more _____.

(a) rounded **(b)** flattened

(c) convex **(d)** lateral

LEVEL 3 Critical Thinking and Clinical Applications

22. You are at a park watching some deer 35 feet away from you. A friend taps you on the shoulder to ask a question. As you turn to look at your friend, who is standing just 2 feet away, what changes would your eyes undergo?

23. Your friend Shelly suffers from myopia (nearsightedness). You remember from your physics class thay concave lenses cause light waves to converge and convex lenses spread light waves. What type of corrective lenses would you suggest to your friend?

(a) concave lenses

(b) convex lenses

24. Tom has surgery to remove polyps (growths) from his sinuses. After he heals from the surgery, he notices that his sense of smell is not as keen as it was before the surgery. Can you suggest a reason for this?

25. For a few seconds after you ride the express elevator from the 20th floor to the ground floor, you still feel as if you are descending, even though you have come to a stop. Why?

26. Juan has a disorder involving the saccule and the utricle. He is asked to stand with his feet together and arms extended forward. As long as he keeps his eyes open, he exhibits very little movement. But when he closes his eyes, his body begins to sway a great deal, and his arms tend to drift in the direction of the impaired vestibular receptors. Why does this occur?

TABLE 17–1 The Power Content of Representative Sounds

Typical Decibel Level	**Example**	**Dangerous Time Exposure**
0	Lowest audible sound	
30	Quiet library; soft whisper	
40	Quiet office; living room; bedroom away from traffic	
50	Light traffic at a distance; refrigerator; gentle breeze	
60	Air conditioner at 20 feet; conversation; sewing machine in operation	
70	Busy traffic; noisy restaurant	if continuous
80	Subway; heavy city traffic; alarm clock at 2 feet; factory noise	8 hours

90	Truck traffic; noisy home appliances; shop tools; gas lawn mower	Less than
100	Chain saw; boiler shop; pneumatic drill	2 hours
120	“Heavy metal” rock concert; sandblasting; thunderclap nearby	danger
140	Gunshot; jet plane	Immediate danger
160	Rocket launching pad	Hearing loss inevitable

Intercellular Communication

Objectives

- Explain the importance of intercellular communication and describe the mechanisms involved.
- Compare the modes of intercellular communication used by the endocrine and nervous systems and discuss the functional significance of the differences between the two systems.

To preserve homeostasis, cellular activities must be coordinated throughout the body. Neurons monitor or control specific cells or groups of cells. However, the number of cells innervated is only a small fraction of the total number of cells in the body, and the commands issued are very specific and of relatively brief duration. Many life processes are not short-lived; reaching adult stature takes decades. Maintenance of reproductive capabilities requires continual control for at least 30 years in the typical female, and even longer in the male. There is no way that the nervous system can regulate such long-term processes as growth, development, or reproduction, which involve or affect metabolic activities in virtually every cell and tissue. This type of regulation is provided by the endocrine system, which uses chemical messengers to relay information and instructions between cells. To understand how these messages are generated and interpreted, we need to take a closer look at how cells communicate with one another.

In a few specialized cases, cellular activities are coordinated by the exchange of ions and molecules between adjacent cells across gap junctions. This **direct communication** occurs between two cells of the same type, and the cells must be in extensive physical contact. The two cells communicate so closely that they function as a single entity. Gap junctions (1) coordinate ciliary movement among epithelial cells, (2) coordinate the contractions of cardiac muscle cells, and (3) facilitate the propagation of action potentials from one neuron to the next at electrical synapses.

Direct communication is highly specialized and relatively rare. Most of the communication between cells involves the release and receipt of chemical messages. Each cell continuously “talks” to its neighbors by releasing chemicals into the extracellular fluid. These chemicals tell cells what their neighbors are doing at any moment. The result is the coordination of tissue function at the local level. The use of chemical messengers to transfer information from cell to cell within a single tissue is called **paracrine communication**. The chemicals involved are called paracrine factors, also known as *local hormones*. Examples of paracrine factors in

clude the prostaglandins, introduced in Chapter 2, and the various growth factors, discussed in Chapter 3. l**pp. 46, 99**

Paracrine factors enter the bloodstream, but their concentrations are usually so low that distant cells and tissues are not affected. However, some paracrine factors, including several of the prostaglandins and related chemicals, have primary effects in their tissues of origin and secondary effects in other tissues and organs. When secondary effects occur, the paracrine factors are also acting as **hormones**—chemical messengers that are released in one tissue and transported in the bloodstream to alter the activities of specific cells in other tissues. Whereas most cells release paracrine factors, typical hormones are produced only by specialized cells. Nevertheless, the difference between paracrine factors and hormones is mostly a matter of degree. Paracrine factors can diffuse out of their tissue of origin and have widespread effects, and hormones can affect their tissues of origin as well as distant cells. By convention, a substance with effects outside its tissue of origin is called a *hormone* if its chemical structure is known, and a *factor* if that structure remains to be determined.

In intercellular communication, hormones are like letters, and the cardiovascular system is the postal service. A hormone released into the bloodstream is distributed throughout the body. Each hormone has **target cells**, specific cells that possess the receptors needed to bind and "read" the hormonal message when it arrives. But hormones are really like bulk mail advertisements— cells throughout the body are exposed to them whether or not they have the necessary receptors. At any moment, each individual cell can respond to only a few of the hormones present. The other hormones are ignored, because the cell lacks the receptors to read the messages they contain. The activity of hormones in coordinating cellular activities in tissues in distant portions of the body is called **endocrine communication**.

Hormones alter the operations of target cells by changing the types, quantities, or activities of important enzymes and structural proteins. In other words, a hormone may

- stimulate the synthesis of an enzyme or a structural protein not already present in the cytoplasm by activating appropriate genes in the cell nucleus;
- increase or decrease the rate of synthesis of a particular enzyme or other protein by changing the rate of transcription or translation; or
- turn an existing enzyme or membrane channel “on” or “off” by changing its shape or structure.

Through one or more of these mechanisms, a hormone can modify the physical structure or biochemical properties of its target cells. Because the target cells can be anywhere in the body, a single hormone can alter the metabolic activities of multiple tissues and organs simultaneously. These effects may be slow to appear, but they typically persist for days. Consequently, hormones are effective in coordinating cell, tissue, and organ activities on a sustained, long-term basis. For example, circulating hormones keep body water content and levels of electrolytes and organic nutrients within normal limits 24 hours a day throughout our entire lives.

Cells can respond to several different hormones simultaneously. Gradual changes in the quantities and identities of circulating hormones can therefore produce complex changes in the body’s physical structure and physiological capabilities. Examples include the processes of embryological and fetal development, growth, and puberty. Hormonal regulation is thus quite suitable for directing gradual, coordinated processes, but it is totally unable to handle situations requiring split-second responses. That kind of crisis management is the job of the nervous system.

Although the nervous system also relies primarily on chemical communication, it does not send messages through the bloodstream. Instead, neurons release a neurotransmitter at a synapse very close to target cells that bear the appropriate receptors. The command to release the neurotransmitter rapidly travels from one location to another in the form of action potentials propagated along axons. The nervous system thus acts like a telephone company, with a cable network carrying high-speed “messages” to specific destinations throughout the body. The effects of neural stimulation are generally short-lived, and they tend to be restricted to specific target cells—primarily because the neurotransmitter is rapidly broken down or recycled. This form of **synaptic communication** is ideal for crisis management: If you are in danger of being hit by a speeding bus, the nervous system can coordinate and direct your leap to safety. Once the crisis is over and the neural circuits quiet down, things soon return to normal.

Table 18–1 summarizes the ways cells and tissues communicate with one another. Viewed from a general perspective, the differences between the nervous and endocrine systems seem relatively clear. In fact, these broad organizational and functional distinctions are the basis for treating them as two separate systems. Yet when we consider them in detail, we see that the two systems are similarly organized:

- Both systems rely on the release of chemicals that bind to specific receptors on their target cells.
- The two systems share many chemical messengers; for example, norepinephrine and epinephrine are called *hormones* when released into the bloodstream, but *neurotransmitters* when released across synapses.
- Both systems are regulated primarily by negative feedback control mechanisms.
- The two systems share a common goal: to preserve homeostasis by coordinating and regulating the activities of other cells, tissues, organs, and systems.

Next we introduce the components and functions of the endocrine system and explore the interactions between the nervous and endocrine systems. We will consider specific endocrine organs, hormones, and functions in detail in later chapters.

An Overview of the Endocrine System

Objectives

- Compare the cellular components of the endocrine system with those of other tissues and systems.
- Compare the major structural classes of hormones.

- Explain the general mechanisms of hormonal action.
- Describe how endocrine organs are controlled.

The **endocrine system** includes all the endocrine cells and tissues of the body that produce hormones or paracrine factors with effects beyond their tissues of origin. As noted in Chapter 4, *endocrine cells* are glandular secretory cells that release their secretions into the extracellular fluid. This characteristic distinguishes them from *exocrine cells*, which secrete their products onto epithelial surfaces, generally by way of ducts. l**p. 117** The chemicals released by endocrine cells may affect only adjacent cells, as in the case of most paracrine factors, or they may affect cells throughout the body.

The tissues, organs, and hormones of the endocrine system are introduced in Figure 18–1•. Some of these organs, such as the pituitary gland, have endocrine secretion as a primary function. Others, such as the pancreas, have many other functions in addition to endocrine secretion; chapters on other systems consider such endocrine organs in more detail.

Classes of Hormones

Hormones can be divided into three groups on the basis of their chemical structure: (1) *amino acid derivatives*, (2) *peptide hormones*, and (3) *lipid derivatives* (Figure 18–2•).

Amino Acid Derivatives

Amino acid derivatives are relatively small molecules that are structurally related to amino acids, the building blocks of proteins.

l**p. 49** This group of hormones, sometimes known as the *biogenic amines*, are synthesized from the amino acids *tyrosine* (T

¯I

-

r

¯o

-s
¯e
n) and *tryptophan* (TRIP-t
¯o
-fan). Tyrosine derivatives include (1) thyroid hormones, produced by the thyroid gland, and
(2) the compounds epinephrine (E), norepinephrine (NE), and dopamine, which are sometimes called *catecholamines* (kat-e-K
¯O

-la-m
¯e
nz). The primary hormone derivative of tryptophan is melatonin (mel-a-T
¯

O
-nin), produced by the pineal gland.

Peptide Hormones

Peptide hormones are chains of amino acids. In general, peptide hormones are synthesized as prohormones—inactive molecules that are converted to active hormones either before or after they are secreted.

Peptide hormones can be divided into two groups. One group consists of glycoproteins. l**p. 53** These proteins are more than 200 amino acids long and have carbohydrate side chains. The glycoproteins include *thyroid-stimulating hormone (TSH)*, *luteinizing hormone (LH)*, and *follicle-stimulating hormone (FSH)* from the anterior lobe of the pituitary gland, as well as several hormones produced in other organs.

The second group of peptide hormones is large and diverse; it includes hormones that range from short polypeptide chains, such as *antidiuretic hormone (ADH)* and *oxytocin* (9 amino acids apiece), to small proteins, such as *growth hormone* (GH; 191 amino acids) and *prolactin* (PRL; 198 amino acids). This group includes all the hormones secreted by the hypothalamus, heart, thymus, digestive tract, pancreas, and posterior lobe of the pituitary gland, as well as most of the hormones secreted by the anterior lobe of the pituitary gland.

Lipid Derivatives

There are two classes of *lipid derivatives*: (1) *eicosanoids*, derived from *arachidonic* (a-rak-i-DON-ik) *acid*, a 20-carbon fatty acid, and (2) *steroid hormones*, derived from cholesterol.

Eicosanoids

–

Eicosanoids (-K

ı portant paracrine factors that coordinate cellular activities and affect enzymatic processes (such as blood clotting) in extracellular fluids. Some of the eicosanoids also have secondary roles as hormones.

¯O

-sa-noydz) are small molecules with a five-carbon ring at one end. These compounds are im-

Leukotrienes (loo-k

¯o

-TR

¯I

-

¯e

ns) are eicosanoids released by activated white blood cells, or *leukocytes*. Leukotrienes are im portant in coordinating tissue responses to injury or disease. **Prostaglandins**, a second group of eicosanoids, are produced in most tissues of the body. Within each tissue, the prostaglandins released are involved primarily in coordinating local cellular activities.

¯a

In some tissues, prostaglandins are converted to **thromboxanes** (throm-BOX-nz) and **prostacyclins** (pros-ta-S -klinz), which

I¯

also have strong paracrine effects.

Steroid Hormones **Steroid hormones** are lipids structurally similar to cholesterol (see Figure 2–16a•, p. 47). Steroid hormones are released by male and female reproductive organs (*androgens* by the testes, *estrogens* and *progestins* by the ovaries), the adrenal glands (*corticosteroids*), and the kidneys (*calcitriol*). The individual hormones differ in the side chains attached to the basic ring structure.

In the blood, steroid hormones are bound to specific transport proteins in the plasma. For this reason, they remain in circulation longer than do secreted peptide hormones. The liver gradually absorbs these steroids and converts them to a soluble form that can be excreted in the bile or urine.

Our focus in this chapter is on circulating hormones whose primary functions are the coordination of activities in many tissues and organs. We will consider eicosanoids in chapters that discuss individual tissues and organs, including Chapters 19 (the blood), 22 (the lymphatic system), and 28 (the reproductive system).

Secretion and Distribution of Hormones

Hormone release typically occurs where capillaries are abundant, and the hormones quickly enter the bloodstream for distribution throughout the body. Within the blood, hormones may circulate freely or bound to special carrier proteins. A freely circulating hormone remains functional for less than one hour, and sometimes for as little as two minutes. It is inactivated when (1) it diffuses out of the bloodstream and binds to receptors on target cells, (2) it is absorbed and broken down by cells of the liver or kidneys, or (3) it is broken down by enzymes in the plasma or interstitial fluids.

Thyroid hormones and steroid hormones remain in circulation much longer, because when these hormones enter the bloodstream, more than 99 percent of them become attached to special transport proteins. For each hormone an equilibrium state exists between the free and bound forms: As the free hormones are removed and inactivated, they are replaced by the release of bound hormones. At any given time, the bloodstream contains a substantial reserve (several weeks' supply) of bound hormones.

Mechanisms of Hormone Action

To affect a target cell, a hormone must first interact with an appropriate receptor. A hormone receptor, like a neurotransmitter receptor, is a protein molecule to which a particular molecule binds strongly. Each cell has receptors for responding to several different hormones, but cells in different tissues have different combinations of receptors. This arrangement is one reason hormones have differential effects on specific tissues. For every cell, the presence or absence of a specific receptor determines the cell's hormonal sensitivities. If a cell has a receptor that can bind a particular hormone, that cell will respond to the hormone's presence. If a cell lacks the proper receptor for that hormone, the hormone will have no effect on that cell.

Hormone receptors are located either on the cell membrane or inside the cell. Using a few specific examples, we will now introduce the basic mechanisms involved.

Hormones and Cell Membrane Receptors

The receptors for catecholamines (E, NE, and dopamine), peptide hormones, and eicosanoids are in the cell membranes of their respective target cells. Because catecholamines and peptide hormones are not lipid soluble, they are unable to penetrate a cell membrane. Instead, these hormones bind to receptor proteins at the *outer* surface of the cell membrane (extracellular receptors). Eicosanoids, which *are* lipid soluble, diffuse across the membrane to reach receptor proteins on the *inner* surface of the membrane (intracellular receptors).

First and Second Messengers A hormone that binds to receptors in the cell membrane cannot have a direct effect on the activities under way inside the target cell. Such a hormone cannot, for example, begin building a protein or catalyzing a specific reaction. Instead, the hormone uses an intracellular intermediary to exert its effects. The hormone, or **first messenger**, does something that leads to the appearance of a **second messenger** in the cytoplasm. The second messenger may act as an enzyme activator, inhibitor, or cofactor, but the net result is a change in the rates of various metabolic reactions. The most important second messengers are (1) *cyclic-AMP (cAMP)*, a derivative of ATP; (2) *cyclic-GMP (cGMP)*, a derivative of GTP, another high-energy compound; and (3) calcium ions.

The binding of a small number of hormone molecules to membrane receptors may lead to the appearance of thousands of second messengers in a cell. This process, which magnifies the effect of a hormone on the target cell, is called *amplification*. Moreover, the arrival of a single hormone may promote the release of more than one type of second messenger, or the production of a linked sequence of enzymatic reactions known as a *receptor cascade*. Through such mechanisms, the hormone can alter many aspects of cell function simultaneously.

The presence or absence of a hormone can also affect the nature and number of hormone receptor proteins in the cell membrane. **Down-regulation** is a process in which the presence of a hormone triggers a decrease in the number of hormone receptors. In down-regulation, when levels of a particular hormone are high, cells become less sensitive to it. Conversely, **up-regulation** is a process in which the absence of a hormone triggers an increase in the number of hormone receptors. In up-regulation, when levels of a particular hormone are low, cells become *more* sensitive to it.

The link between the first messenger and the second messenger generally involves a **G protein**, an enzyme complex coupled to a membrane receptor. The name *G protein* refers to the fact that these proteins bind GTP. l**p. 411** A G protein is activated when a hormone binds to its receptor at the membrane surface. What happens next depends on the nature of the G protein and its effects on second messengers in the cytoplasm; Figure 18–3• diagrams the major patterns of response to G protein activation.

G Proteins and CAMP Many G proteins, once activated, exert their effects by changing the concentration of the second messenger *cyclic-AMP* (cAMP) within the cell. In most cases, the result is an increase in cAMP levels, and this accelerates metabolic activity within the cell.

The steps involved in increasing cAMP levels are diagrammed in Figure 18–3• (left):

- The activated G protein activates the enzyme **adenylate cyclase**, also called *adenylyl cyclase*.
- Adenylate cyclase converts ATP to the ring-shaped molecule *cyclic-AMP*.
- Cyclic-AMP then functions as a second messenger, typically by activating a *kinase*. A kinase is an enzyme that performs *phosphorylation*, the attachment of a high-energy phosphate group ($PO4^{3-}$) to another molecule.
- Generally, the kinases activated by cyclic-AMP phosphorylate proteins. The effect on the target cell depends on the nature of the proteins affected. The phosphorylation of membrane proteins, for example, can open ion channels. In the cytoplasm, many important enzymes can be activated only by phosphorylation; one important example is the enzyme that releases glucose from glycogen reserves in skeletal muscles and the liver.

The hormones calcitonin, parathyroid hormone, ADH, ACTH, epinephrine, FSH, LH, TSH, and glucagon all produce their effects by this mechanism. The increase is usually short-lived, because the cytoplasm contains another enzyme, **phosphodiesterase (PDE)**, which inactivates cyclic-AMP by converting it to AMP (adenosine monophosphate).

Figure 18–3• (center) depicts one way the activation of a G protein can *lower* the concentration of cAMP within the cell. In this case, the activated G protein stimulates PDE activity and inhibits adenylate cyclase activity. Levels of cAMP then decline, because cAMP breakdown accelerates while cAMP synthesis is prevented. The decline has an inhibitory effect on the cell, because without phosphorylation, key enzymes remain inactive. This is the mechanism responsible for the inhibitory effects that follow the stimulation of a_2 adrenergic receptors by catecholamines, as discussed in Chapter 16. l**pp. 525–526**

G Proteins and Calcium Ions An activated G protein can trigger either the opening of calcium ion channels in the membrane or the release of calcium ions from intracellular stores. The steps involved are diagrammed in Figure 18–3• (right panel). The G protein first activates the enzyme *phospholipase C (PLC)*. This enzyme triggers a receptor cascade that begins with the production of **diacylglycerol (DAG)** and **inositol triphosphate (IP3)** from membrane phospholipids. The cascade then proceeds as follows:

- IP3 diffuses into the cytoplasm and triggers the release of Ca^{2+} from intracellular reserves, such as those in the smooth endoplasmic reticulum of many cells.
- The combination of DAG and intracellular calcium ions activates another membrane protein: **protein kinase C (PKC)**. The activation of PKC leads to the phosphorylation of calcium channel proteins, a process that opens the channels and permits the entry of extracellular Ca^{2+} . This sets up a positive feedback loop that rapidly elevates intracellular calcium ion concentrations.
- The calcium ions themselves serve as messengers, generally in combination with an intracellular protein called **calmodulin**.

Once it has bound calcium ions, calmodulin can activate specific cytoplasmic enzymes. This chain of events is responsible for the stimulatory effects that follow the activation of a1 receptors by epinephrine or norepinephrine. l**p. 525** Calmodulin activation is also involved in the responses to oxytocin and to several regulatory hormones secreted by the hypothalamus.

Hormones and Intracellular Receptors

Steroid hormones diffuse across the lipid part of the cell membrane and bind to receptors in the cytoplasm or nucleus. The hormone–receptor complexes then activate or deactivate specific genes (Figure 18–4a•). By this mechanism, steroid hormones can alter the rate of DNA transcription in the nucleus, and thus change the pattern of protein synthesis. Alterations in the synthesis of enzymes or structural proteins will directly affect both the metabolic activity and the structure of the target cell. For example, the sex hormone *testosterone* stimulates the production of enzymes and structural proteins in skeletal muscle fibers, causing an increase in muscle size and strength.

Thyroid hormones cross the cell membrane primarily by a transport mechanism. Once in the cytosol, these hormones bind to receptors within the nucleus and on mitochondria (Figure 18–4b•). The hormone–receptor complexes in the nucleus activate specific genes or change the rate of transcription. The change in rate affects the metabolic activities of the cell by increasing or decreasing the concentration of specific enzymes. Thyroid hormones bound to mitochondria increase the mitochondrial rates of ATP production.

100 Keys | Hormones coordinate cell, tissue, and organ activities on a sustained basis. They circulate in the extracellular fluid and bind to specific receptors on or in target cells. They then modify cellular activities by altering membrane permeability, activating or inactivating key enzymes, or changing genetic activity.

Control of Endocrine Activity

As noted earlier, the functional organization of the nervous system parallels that of the endocrine system in many ways. In Chapter 13, we considered the basic operation of neural reflex arcs, the simplest organizational units in the nervous system. l**p. 439** The most direct arrangement was a monosynaptic reflex, such as the stretch reflex. Polysynaptic reflexes provide more complex and variable responses to stimuli, and higher centers, which integrate multiple inputs, can facilitate or inhibit these reflexes as needed. **Endocrine reflexes** are the functional counterparts of neural reflexes.

Endocrine Reflexes

Endocrine reflexes can be triggered by (1) *humoral stimuli* (changes in the composition of the extracellular fluid), (2) *hormonal stimuli* (the arrival or removal of a specific hormone), or (3) *neural stimuli* (the arrival of neurotransmitters at neuroglandular junctions). In most cases, endocrine reflexes are controlled by negative feedback mechanisms: A stimulus triggers the production of a hormone whose direct or indirect effects reduce the intensity of the stimulus.

A simple endocrine reflex involves only one hormone. The endocrine cells involved respond directly to changes in the composition of the extracellular fluid. The secreted hormone adjusts the activities of target cells and restores homeostasis. Simple endocrine reflexes control hormone secretion by the heart, pancreas, parathyroid gland, and digestive tract.

More complex endocrine reflexes involve one or more intermediary steps and two or more hormones. The hypothalamus, which provides the highest level of endocrine control, integrates the activities of the nervous and endocrine systems in three ways (Figure 18–5•):

1. The hypothalamus secretes **regulatory hormones**, special hormones that control endocrine cells in the pituitary gland. The hypothalamic regulatory hormones control the secretory activities of endocrine cells in the anterior lobe of the pituitary gland. The hormones released by the anterior lobe, in turn, control the activities of endocrine cells in the thyroid, adrenal cortex, and reproductive organs.

2. The hypothalamus itself acts as an endocrine organ. Hypothalamic neurons synthesize hormones, transport them along axons
within the infundibulum, and release them into the circulation at the posterior lobe of the pituitary gland. We introduced two of these hormones, ADH and oxytocin, in Chapter 14.
l**p. 468**

3. The hypothalamus contains autonomic centers that exert direct neural control over the endocrine cells of the adrenal medullae. When the sympathetic division is activated, the adrenal medullae release hormones into the bloodstream.

The hypothalamus secretes regulatory hormones and ADH in response to changes in the composition of the circulating blood. The secretion of oxytocin (OT), E, and NE involves both neural and hormonal mechanisms. For example, the adrenal medullae secrete E and NE in response to action potentials rather than to circulating hormones. Such pathways are called *neuroendocrine reflexes*, because they include both neural and endocrine components. We will consider these reflex patterns in more detail as we examine specific endocrine tissues and organs.

In Chapter 15, we noted that sensory receptors provide complex information by varying the frequency and pattern of action potentials in a sensory neuron. In the endocrine system, complex commands are issued by changing the amount of hormone secreted and the pattern of hormone release. In a simple endocrine reflex, hormones are released continuously, but the rate of secretion rises and falls in response to humoral stimuli. For example, when blood glucose levels climb, the pancreas increases its secretion of *insulin*, a hormone that stimulates glucose absorption and utilization. As insulin levels rise, glucose levels decline; in turn, the stimulation of the insulin-secreting cells is reduced. As glucose levels return to normal, the rate of insulin secretion reaches resting levels. (This regulatory pattern, called *negative feedback*, was introduced in Chapter 1 when we considered the control of
body temperature. l**p. 12**)

In this example, the responses of the target cells change over time, because the effect of insulin is proportional to its concentration. However, the relationship between hormone concentration and target cell response is not always predictable. For instance, a hormone can have one effect at low concentrations and more exaggerated effects—or even different effects—at high concentrations. (We will consider specific examples later in the chapter.)

Several hypothalamic and pituitary hormones are released in sudden bursts called *pulses*, rather than continuously. When hormones arrive in pulses, target cells may vary their response with the frequency of the pulses. For example, the target cell response to one pulse every three hours can differ from the response when pulses arrive every 30 minutes. The most complicated hormonal instructions issued by the hypothalamus involve changes in the frequency of pulses *and* in the amount secreted in each pulse.

Concept Check

How could you distinguish between a neural inibits the enzime and an endocrine response on the basis of response time and duration? How would the presence of a molecule that inhibits the enzyme adenylate cyclase affect the activity of a hormone that produces its cellular effects by way of the second messenger cAMP? What primary factor determines each cell’s hormonal sensitivities?

Answers begin on p. A–1

The Pituitary Gland

Objectives

- Describe the location and structure of the pituitary gland and explain its structural and functional relationships with the hypothalamus.
- Identify the hormones produced by the anterior and posterior lobes of the pituitary gland and specify the functions of those hormones.
- Discuss the results of abnormal levels of pituitary hormone production.

Figure 18–6• shows the anatomical organization of the pituitary gland, or **hypophysis** (h - POF-i-sis). This small, oval gland lies

–

ı nestled within the *sella turcica*, a depression in the sphenoid bone (see Figure 7–8•, p. 215). The pituitary gland hangs inferior to the hypothalamus, connected by the slender, funnel-shaped structure called the **infundibulum** (in-fun-DIB-u¯-lum; funnel). The base of the infundibulum lies between the optic chiasm and the mamillary bodies. The pituitary gland is cradled by the sella turcica and held in position by the *diaphragma sellae*, a dural sheet that encircles the infundibulum. The diaphragma sellae locks the pituitary gland in position and isolates it from the cranial cavity.

The pituitary gland can be divided into posterior and anterior lobes on the basis of function and developmental anatomy. Nine important peptide hormones are released by the pituitary gland—seven by the anterior lobe and two by the posterior lobe. All nine hormones bind to membrane receptors, and all nine use cAMP as a second messenger. ATLAS: Embryology Summary 14: The Development of the Endocrine System

The Anterior Lobe

The **anterior lobe** of the pituitary gland, or **adenohypophysis** (ad-
-h -POF-i-sis), contains a variety of endocrine cells. The
ı anterior lobe can be subdivided into three regions: (1) the **pars distalis** (dis-TAL-is; distal part), the largest and most anterior portion of the pituitary gland; (2) an extension called the **pars tuberalis**, which wraps around the adjacent portion of the infundibulum; and (3) the slender **pars intermedia**, which forms a narrow band bordering the posterior lobe (see Figure 18–6•). An extensive capillary network radiates through these regions, giving every endocrine cell immediate access to the circulatory system.

The Hypophyseal Portal System

By secreting specific regulatory hormones, the hypothalamus controls the production of hormones in the anterior lobe. At the *median eminence*, a swelling near the attachment of the infundibulum, hypothalamic neurons release regulatory factors into the surrounding interstitial fluids. Their secretions enter the bloodstream quite easily, because the endothelial cells lining the capil

–

–e –o

-n

–a

laries in this region are unusually permeable. These **fenestrated** (FEN-es-tr -ted) **capillaries** (*fenestra*, window) allow relatively large molecules to enter or leave the circulatory system.

The capillary networks in the median eminence are supplied by the *superior hypophyseal artery* (Figure 18–7•). Before leaving the hypothalamus, the capillary networks unite to form a series of larger vessels that spiral around the infundibulum to reach the anterior lobe of the pituitary gland. Once within the anterior lobe, these vessels form a second capillary network that branches among the endocrine cells.

This vascular arrangement is unusual: A typical artery conducts blood from the heart to a capillary network, and a typical vein carries blood from a capillary network back to the heart. The vessels between the median eminence and the anterior lobe, however, carry blood from one capillary network to another. Blood vessels that link two capillary networks are called **portal vessels**; in this case, they have the histological structure of veins. The entire complex is a **portal system**. Portal systems are named after

–

their destinations; hence, this particular network is known as the **hypophyseal** (h -p ı

Portal systems provide an efficient means of chemical communication by ensuring that all the hypothalamic hormones entering the portal vessels will reach the target cells in the anterior lobe of the pituitary gland before being diluted through mixing with the general circulation. The communication is strictly one way, however, because any chemicals released by the cells “downstream” must do a complete circuit of the cardiovascular system before they reach the capillaries of the portal system.

Hypothalamic Control of the Anterior Lobe

Two classes of hypothalamic regulatory hormones exist: releasing hormones and inhibiting hormones. A **releasing hormone (RH)** stimulates the synthesis and secretion of one or more hormones at the anterior lobe, whereas an **inhibiting hormone (IH)** prevents the synthesis and secretion of hormones from the anterior lobe. An endocrine cell in the anterior lobe may be controlled by releasing hormones, inhibiting hormones, or some combination of the two. The regulatory hormones released at the hypothalamus are transported directly to the anterior lobe by the hypophyseal portal system.

The rate at which the hypothalamus secretes regulatory hormones is controlled by negative feedback. The primary regulatory patterns are diagrammed in Figure 18–8•; we will refer to them as we examine specific pituitary hormones.

Hormones of the Anterior Lobe

We will discuss seven hormones whose functions and control mechanisms are reasonably well understood: *thyroid-stimulating hormone, adrenocorticotropic hormone, follicle-stimulating hormone*, *luteinizing hormone*, *prolactin, growth hormone*, and *melanocyte-*

stimulating hormone. Of the six hormones produced by the pars distalis, four regulate the production of hormones by other endocrine glands. The names of these hormones indicate their activities, but many of the phrases are so long that abbreviations are often used instead.

The hormones of the anterior lobe are also called *tropic hormones* (*tropein*, to turn), because they "turn on" endocrine glands or support the functions of other organs. (Some sources call them *trophic hormones* [*trophein*, to nourish] instead.)

Thyroid-Stimulating Hormone **Thyroid-stimulating hormone (TSH)**, or *thyrotropin*, targets the thyroid gland and triggers the release of thyroid hormones. TSH is released in response to *thyrotropin-releasing hormone (TRH)* from the hypothalamus. As circulating concentrations of thyroid hormones rise, the rates of TRH and TSH production decline (see Figure 18–8a•).

Adrenocorticotropic Hormone **Adrenocorticotropic hormone (ACTH)**, also known as *corticotropin*, stimulates the release of steroid hormones by the *adrenal cortex*, the outer portion of the adrenal gland. ACTH specifically targets cells that produce *gluc-*

¯o

-FI-s

¯e

-al) **portal system**.

ocorticoids (gloo-k

¯o

-KOR-ti-koydz), hormones that affect glucose metabolism. ACTH release occurs under the stimulation of **-**

corticotropin-releasing hormone (CRH) from the hypothalamus. As glucocorticoid levels increase, the rates of CRH release and ACTH release decline (see Figure 18–8a•).

The Gonadotropins The hormones called **gonadotropins** (g

¯o

-nad-

¯o

-TR

¯O

-pinz) regulate the activities of the *gonads*. (These

organs—the testes and ovaries in males and females, respectively—produce reproductive cells as well as hormones.) The produc

tion of gonadotropins occurs under stimulation by gonadotropin-releasing hormone (GnRH) from the hypothalamus. An abnormally low production of gonadotropins produces **hypogonadism**. Children with this condition will not undergo sexual maturation, and adults with hypogonadism cannot produce functional sperm (males) or oocytes (females). The two gonadotropins are follicle-stimulating hormone and luteinizing hormone.

- **Follicle-stimulating hormone (FSH)**, or *follitropin*, promotes follicle development in females and, in combination with luteiniz

ing hormone, stimulates the secretion of *estrogens* (ES-tr

¯o

-jenz) by ovarian cells. *Estradiol* is the most important estrogen. In

males, FSH stimulates *sustentacular cells*, specialized cells in the tubules where sperm differentiate. In response, the sustentacular cells promote the physical maturation of developing sperm. FSH production is inhibited by *inhibin*, a peptide hormone released by cells in the testes and ovaries (see Figure 18–8a•). (The role of inhibin in suppressing the release of GnRH as well as FSH is under debate.)

•

Luteinizing (LOO-t -in--zing) **hormone (LH)**, or *lutropin*, induces *ovulation*, the production of reproductive cells in females.

ı It also promotes the secretion, by the ovaries, of estrogens and the *progestins* (such as *progesterone*), which prepare the body for possible pregnancy. In males, this gonadotropin is sometimes called *interstitial cell–stimulating hormone (ICSH)*, because it stim

¯

¯e

ulates the production of sex hormones by the *interstitial cells* of the testes. These sex hormones are called **androgens** (AN-dr

¯o

-jenz; *andros*, man), the most important of which is *testosterone*. LH production, like FSH production, is stimulated by GnRH from the hypothalamus. GnRH production is inhibited by estrogens, progestins, and androgens (see Figure 18–8a•).

Prolactin **Prolactin** (*pro-*, before + *lac*, milk) (**PRL**), or *mammotropin*, works with other hormones to stimulate mammary gland development. In pregnancy and during the nursing period that follows delivery, PRL also stimulates milk production by the mammary glands. The functions of PRL in males are poorly understood, but evidence indicates that PRL helps regulate androgen production by making interstitial cells more sensitive to LH.

Prolactin production is inhibited by **prolactin-inhibiting hormone (PIH)**—the neurotransmitter dopamine. The hypothalamus also secretes several *prolactin-releasing factors (PRF),* few of which have been identified. Circulating PRL stimulates PIH release and inhibits the secretion of PRF (see Figure 18–8b•).

Although PRL exerts the dominant effect on the glandular cells, normal development of the mammary glands is regulated by the interaction of several hormones. Prolactin, estrogens, progesterone, glucocorticoids, pancreatic hormones, and hormones produced by the placenta cooperate in preparing the mammary glands for secretion, and milk ejection occurs only in response to oxytocin release at the posterior lobe of the pituitary gland. We will describe the functional development of the mammary glands in Chapter 28.

Growth Hormone **Growth hormone** (GH), or **somatotropin** (*soma*, body), stimulates cell growth and replication by accelerating the rate of protein synthesis. Although virtually every tissue responds to some degree, skeletal muscle cells and chondrocytes (cartilage cells) are particularly sensitive to GH.

The stimulation of growth by GH involves two mechanisms. The primary mechanism, which is indirect, is best understood. Liver cells respond to the presence of GH by synthesizing and releasing **somatomedins**, or **insulin-like growth factors (IGFs)**, which are peptide hormones that bind to receptor sites on a variety of cell membranes (see Figure 18–8b•). In skeletal muscle fibers, cartilage cells, and other target cells, somatomedins increase the rate of uptake of amino acids and their incorporation into new proteins. These effects develop almost immediately after GH is released; they are particularly important after a meal, when the blood contains high concentrations of glucose and amino acids. In functional terms, cells can now obtain ATP easily through the aerobic metabolism of glucose, and amino acids are readily available for protein synthesis. Under these conditions, GH, acting through the somatomedins, stimulates protein synthesis and cell growth.

The direct actions of GH are more selective and tend not to appear until after blood glucose and amino acid concentrations have returned to normal levels:

- In epithelia and connective tissues, GH stimulates stem cell divisions and the differentiation of daughter cells. The subsequent growth of these daughter cells will be stimulated by somatomedins.
- In adipose tissue, GH stimulates the breakdown of stored triglycerides by adipocytes (fat cells), which then release fatty acids into the blood. As circulating fatty acid levels rise, many tissues stop breaking down glucose and start breaking down fatty acids to generate ATP. This process is termed a **glucose-sparing effect**.
- In the liver, GH stimulates the breakdown of glycogen reserves by liver cells, which then release glucose into the bloodstream. Because most other tissues are now metabolizing fatty acids rather than glucose, blood glucose concentrations begin to climb, perhaps to levels significantly higher than normal. The elevation of blood glucose levels by GH has been called a **diabetogenic effect**, because *diabetes mellitus*, an endocrine disorder we will consider later in the chapter, is characterized by abnormally high blood glucose concentrations.

The production of GH is regulated by **growth hormone–releasing hormone** (**GH–RH**, or *somatocrinin*) and **growth hormone–inhibiting hormone** (**GH–IH**, or *somatostatin*) from the hypothalamus. Somatomedins stimulate GH–IH and inhibit GH–RH (see Figure 18–8b•). AM: Growth Hormone Abnormalities

Melanocyte-Stimulating Hormone The pars intermedia may secrete two forms of **melanocyte-stimulating hormone (MSH)**, or *melanotropin*. As the name indicates, MSH stimulates the melanocytes of the skin, increasing their production of melanin, a brown, black, or yellow-brown pigment. l**p. 158** The release of MSH is inhibited by dopamine.

Melanocyte-stimulating hormone from the pituitary gland is important in the control of skin pigmentation in fishes, amphibians, reptiles, and many mammals other than primates. In humans, MSH is produced locally, within sun-exposed skin. The pars intermedia in adult humans is virtually nonfunctional, and the circulating blood usually does not contain MSH. However, MSH is secreted by the human pars intermedia (1) during fetal development, (2) in very young children, (3) in pregnant women, and (4) in the course of some diseases. The functional significance of MSH secretion under these circumstances is not known. The administration of a synthetic form of MSH causes the skin to darken, so MSH has been suggested as a means of obtaining a "sunless tan."

100 Keys | The hypothalamus produces regulatory factors that adjust the activities of the anterior lobe of the pituitary gland, which produces seven hormones. Most of these hormones control other endocrine organs, including the thyroid gland, adrenal gland, and gonads. The anterior lobe also produces growth hormone, which stimulates cell growth and protein synthesis. The posterior lobe of the pituitary gland releases two hormones produced in the hypothalamus; ADH restricts water loss and promotes thirst, and oxytocin stimulates smooth muscle contractions in the mammary glands and uterus (in females) and the prostate gland (in males).

The Posterior Lobe

The **posterior lobe** of the pituitary gland is also called the **neurohypophysis** (noo-ro¯-h - POF-i-sis), or *pars nervosa* (nervous

–

ı part), because it contains the axons of hypothalamic neurons. Neurons of the **supraoptic** and **paraventricular nuclei** manufacture antidiuretic hormone (ADH) and oxytocin, respectively. These products move along axons in the infundibulum to axon terminals, which end on the basal laminae of capillaries in the posterior lobe, by means of axoplasmic transport. l**p. 383**

Antidiuretic Hormone

Antidiuretic hormone (ADH), also known as *arginine vasopressin (AVP)*, is released in response to a variety of stimuli, most notably a rise in the solute concentration in the blood or a fall in blood volume or blood pressure. A rise in the solute concentration stimulates specialized hypothalamic neurons. Because they respond to a change in the osmotic concentration of body fluids, these neurons are called *osmoreceptors*. These osmoreceptors then stimulate the neurosecretory neurons that release ADH.

The primary function of ADH is to decrease the amount of water lost at the kidneys. With losses minimized, any water absorbed from the digestive tract will be retained, reducing the concentrations of electrolytes in the extracellular fluid. In high concentrations, ADH also causes *vasoconstriction,* a constriction of peripheral blood vessels that helps elevate blood pressure. ADH release is inhibited by alcohol, which explains the increased fluid excretion that follows the consumption of alcoholic beverages.

Clinical Note

Diabetes occurs in several forms, all characterized by excessive urine production (polyuria). Although diabetes can be caused by physical damage to the kidneys, most forms are the result of endocrine abnormalities. The two most prevalent forms are diabetes mellitus and diabetes insipidus. Diabetes mellitus is described on page 619. **Diabetes insipidus** generally develops because the posterior lobe of the pituitary gland no longer releases adequate amounts of ADH. Water conservation at the kidneys is impaired, and excessive amounts of water are lost in the urine. As a result, the individual is constantly thirsty, but the fluids consumed are not retained by the body.

Mild cases of diabetes insipidus may not require treatment if fluid and electrolyte intake keeps pace with urinary losses. In severe cases, the fluid losses can reach 10 liters per day, and dehydration and electrolyte imbalances are fatal without treatment. This condition can be effectively treated with desmopressin, a synthetic form of ADH.

Oxytocin

In women, **oxytocin** (*oxy*-, quick + *tokos*, childbirth), or **OT**, stimulates smooth muscle contraction in the wall of the uterus, promoting labor and delivery. After delivery, oxytocin stimulates the contraction of myoepithelial cells around the secretory alveoli and the ducts of the mammary glands, promoting the ejection of milk.

Until the last stages of pregnancy, the uterine smooth muscles are relatively insensitive to oxytocin, but sensitivity becomes more pronounced as the time of delivery approaches. The trigger for normal labor and delivery is probably a sudden rise in oxytocin levels at the uterus. There is good evidence, however, that oxytocin released at the posterior lobe plays only a supporting role, and that most of the oxytocin involved is secreted by the uterus and fetus.

Oxytocin secretion and milk ejection are part of a neuroendocrine reflex. The normal stimulus is an infant suckling at the breast, and sensory nerves innervating the nipples relay the information to the hypothalamus. Oxytocin is then released into the circulation at the posterior lobe, and the myoepithelial cells respond by squeezing milk from the secretory alveoli into large collecting ducts. This *milk let-down reflex* can be modified by any factor that affects the hypothalamus. For example, anxiety, stress, and other factors can prevent the flow of milk, even when the mammary glands are fully functional. In contrast, nursing mothers can become conditioned to associate a baby’s crying with suckling. In these women, milk let-down may begin as soon as they hear a baby cry.

Although the functions of oxytocin in sexual activity remain uncertain, it is known that circulating concentrations of oxytocin rise during sexual arousal and peak at orgasm in both sexes. Evidence indicates that in men, oxytocin stimulates smooth muscle contractions in the walls of the sperm duct (*ductus deferens*) and prostate gland. These actions may be important in *emission*—the ejection of secretions of the prostate gland, sperm, and the secretions of other glands into the male reproductive tract before ejaculation. Studies suggest that the oxytocin released in females during intercourse may stimulate smooth muscle contractions in the uterus and vagina that promote the transport of sperm toward the uterine tubes.

Summary: The Hormones of the Pituitary Gland

Figure 18–9• and Table 18–2 summarize important information about the hormonal products of the pituitary gland. Review these carefully before considering the structure and function of other endocrine organs.

Anatomy 360 | Review the anatomy of the pituitary gland on the **Anatomy 360 CD-ROM: Endocrine System/ Pituitary Gland.**

Concept Check

If a person were dehydrated, how would the amount of ADH released by the posterior lobe change?

A blood sample contains elevated levels of somatomedins. Which pituitary hormone would you expect to be elevated as well?

What effect would elevated circulating levels of cortisol, a steroid hormone from the adrenal cortex, have on the pituitary se

cretion of ACTH?

Answers begin on p. A–1

The Thyroid Gland

Objectives

- Describe the location and structure of the thyroid gland.

- Identify the hormones produced by the thyroid gland, specify the functions of those hormones, and discuss the results of abnormal levels of thyroid hormones.

The **thyroid gland** curves across the anterior surface of the trachea just inferior to the *thyroid* (“shield-shaped”) *cartilage*, which forms most of the anterior surface of the larynx (Figure 18–10a•). The two **lobes** of the thyroid gland are united by a slender connection, the **isthmus** (IS-mus). You can easily feel the gland with your fingers. When something goes wrong with it, the thyroid gland typically becomes visible as it swells and distorts the surface of the neck. The size of the gland is quite variable, depending on heredity and environmental and nutritional factors, but its average weight is about 34 g (1.2 oz). An extensive blood supply gives the thyroid gland a deep red color.

Thyroid Follicles and Thyroid Hormones

The thyroid gland contains large numbers of **thyroid follicles**, hollow spheres lined by a simple cuboidal epithelium (Figure 18–11a,b•). The follicle cells surround a **follicle cavity** that holds a viscous *colloid*, a fluid containing large quantities of dissolved proteins. A network of capillaries surrounds each follicle, delivering nutrients and regulatory hormones to the glandular cells and accepting their secretory products and metabolic wastes.

–

ı thyroid follicles (see Figure 18–10c•). Thyroglobulin molecules contain the amino acid *tyrosine*, the building block of thyroid hormones. The formation of thyroid hormones involves the following basic steps (Figure 18–11a•):

Step 1 Iodide ions are absorbed from the diet at the digestive tract and are delivered to the thyroid gland by the bloodstream. Carrier proteins in the basal membrane of the follicle cells actively transport iodide ions (I^-) into the cytoplasm. Normally, the follicle cells maintain intracellular concentrations of iodide that are many times higher than those in the extracellular fluid.

Step 2 The iodide ions diffuse to the apical surface of each follicle cell, where they are converted to an activated form of iodide (I^+) by the enzyme *thyroid peroxidase*. This reaction sequence which occurs at the lumenal membrane surface, also attaches one or two iodide ions to the tyrosine portions of a thyroglobulin molecule within the lumen.

Step 3 Tyrosine molecules to which iodide ions have been attached become linked by covalent bonds, forming molecules of thyroid hormones that remain incorporated into thyroglobulin. The pairing process is probably performed by thyroid peroxidase. The

Follicle cells synthesize a globular protein called **thyroglobulin** (th

¯o

-GLOB-

¯u

-lin) and secrete it into the colloid of the -r

¯e

¯

hormone **thyroxine** (th -ROKS-n), also known as *tetraiodothyronine* or

ı is a related molecule containing three iodide ions. Eventually, each molecule of thyroglobulin contains four to eight molecules of T3 or T4 hormones or both.

The major factor controlling the rate of thyroid hormone release is the concentration of TSH in the circulating blood (Figure 18–11b•). TSH stimulates iodide transport into the follicle cells and stimulates the production of thyroglobulin and thyroid peroxidase. TSH also stimulates the release of thyroid hormones. Under the influence of TSH, the following steps occur (see Figure 18–11a•):

Step 4 Follicle cells remove thyroglobulin from the follicles by endocytosis.

T4, contains four iodide ions. **Triiodothyronine**, or **T3,**

Step 5 Lysosomal enzymes break the thyroglobulin down, and the amino acids and thyroid hormones enter the cytoplasm. The amino acids are then recycled and used to synthesize more thyroglobulin.

Step 6 The released molecules of T3 and T4 diffuse across the basement membrane and enter the bloodstream. About 90 percent of all thyroid secretions is T4; T3 is secreted in comparatively small amounts.

Step 7 Roughly 75 percent of the T4 molecules and 70 percent of the T3 molecules entering the bloodstream become attached to transport proteins called **thyroid-binding globulins (TBGs)**. Most of the rest of the T4 and T3 in the circulation is attached to **transthyretin**, also known as *thyroid-binding prealbumin (TBPA)*, or to *albumin*, one of the plasma proteins. Only the relatively small quantities of thyroid hormones that remain unbound—roughly 0.3 percent of the circulating T3 and 0.03 percent of the circulating T4—are free to diffuse into peripheral tissues.

An equilibrium exists between the bound and unbound thyroid hormones. At any moment, free thyroid hormones are being bound to carriers at the same rate at which bound hormones are being released. When unbound thyroid hormones diffuse out of the bloodstream and into other tissues, the equilibrium is disturbed. The carrier proteins then release additional thyroid hormones until a new equilibrium is reached. The bound thyroid hormones represent a substantial reserve: The bloodstream normally contains more than a week's supply of thyroid hormones.

TSH plays a key role in both the synthesis and the release of thyroid hormones. In the absence of TSH, the thyroid follicles become inactive, and neither synthesis nor secretion occurs. TSH binds to membrane receptors and, by stimulating adenylate cyclase, activates key enzymes involved in thyroid hormone production (see Figure 18–3•, p. 597).

Functions of Thyroid Hormones

Thyroid hormones enter target cells by means of an energy dependent transport system, and they affect almost every cell in the body. Inside a target cell, they bind to receptors (1) in the cytoplasm, (2) on the surfaces of mitochondria, and (3) in the nucleus.

- Thyroid hormones bound to cytoplasmic receptors are essentially held in storage. If intracellular levels of thyroid hormones decline, the bound thyroid hormones are released into the cytoplasm.
- The thyroid hormones binding to mitochondria increase the rates of mitochondrial ATP production.

- The binding to receptors in the nucleus activates genes that control the synthesis of enzymes involved in energy transformation and utilization. One specific effect of binding to nuclear receptors is the accelerated production of sodium– potassium ATPase, the membrane protein responsible for the ejection of intracellular sodium and the recovery of extracellular potassium. As noted in Chapter 3, this exchange pump consumes large amounts of ATP. l**p. 91**

Thyroid hormones also activate genes that code for the synthesis of enzymes involved in glycolysis and ATP production. This effect, coupled with the direct effect of thyroid hormones on mitochondria, increases the metabolic rate of the cell. Because the cell consumes more energy and because this results in increased heat generation, the effect is called the **calorigenic effect** (*calor*, heat) of thyroid hormones. In young children, TSH production increases in cold weather; the calorigenic effect may help them adapt to cold climates. (This response does not occur in adults.) In growing children, thyroid hormones are also essential to normal development of the skeletal, muscular, and nervous systems.

The thyroid gland produces large amounts of T4, but T3 is primarily responsible for the observed effects of thyroid hormones: a strong, immediate, and short-lived increase in the rate of cellular metabolism. At any moment, T3 released from the thyroid gland accounts for only 10–15 percent of the T3 in peripheral tissues. However, enzymes in the liver, kidneys, and other tissues can convert T4 to T3. Roughly 85–90 percent of the T3 that reaches the target cells is produced by the conversion of T4 within peripheral tissues. Table 18–3 summarizes the effects of thyroid hormones on major organs and systems.

Iodine and Thyroid Hormones

Iodine in the diet is absorbed at the digestive tract as I^-. Each day the follicle cells in the thyroid gland absorb 120–150 mg of I^-, the minimum dietary amount needed to maintain normal thyroid function. The iodide ions are actively transported into the thyroid follicle cells, so the concentration of I^- inside thyroid follicle cells is generally about 30 times higher than that in the blood plasma. If plasma I^- levels rise, so do levels inside the follicle cells.

The thyroid follicles contain most of the iodide reserves in the body. The active transport mechanism for iodide is stimulated by TSH. The resulting increase in the rate of iodide movement into the cytoplasm accelerates the formation of thyroid hormones.

The typical diet in the United States provides approximately 500 mg of iodide per day, roughly three times the minimum daily requirement. Much of the excess is due to the addition of I^- to the table salt sold in grocery stores as “iodized salt.” Thus, iodide deficiency is seldom responsible for limiting the rate of thyroid hormone production. (This is not necessarily the case in other countries.) Excess I^- is removed from the blood at the kidneys, and each day a small amount of I^- (about 20 mg) is excreted by the liver into the *bile*, an exocrine product stored in the gallbladder. Iodide excreted at the kidneys is eliminated in urine; the I^- excreted in bile is eliminated in feces. The losses in the bile, which continue even if the diet contains less than the minimum iodide requirement, can gradually deplete the iodide reserves in the thyroid. Thyroid hormone production then declines, regardless of the circulating levels of TSH. AM: Thyroid Gland Disorders

The C Cells of the Thyroid Gland and Calcitonin

A second population of endocrine cells lies sandwiched between the cuboidal follicle cells and their basement membrane. These cells, which are larger than those of the follicular epithelium and do not stain as clearly, are the **C (clear) cells**, or *parafollicular cells* (see Figure 18–10b,c•). C cells produce the hormone **calcitonin (CT)**, which aids in the regulation of Ca^{2+} concentrations in body fluids. The functions of this hormone were introduced in Chapter 6. l**p. 198** The net effect of calcitonin release is a drop in the Ca^{2+} concentration in body fluids, accomplished by (1) the inhibition of osteoclasts, which slows the rate of Ca^{2+} release from bone, and (2) the stimulation of Ca^{2+} excretion at the kidneys.

The control of calcitonin secretion is an example of direct endocrine regulation: Neither the hypothalamus nor the pituitary gland is involved. The C cells respond directly to an elevation in the Ca^{2+} concentration of blood. When the concentration rises, calcitonin secretion increases. The Ca^{2+} concentration then drops, eliminating the stimulus and "turning off" the C cells.

Calcitonin is probably most important during childhood, when it stimulates bone growth and mineral deposition in the skeleton. It also appears to be important in reducing the loss of bone mass (1) during prolonged starvation and (2) in the late stages of pregnancy, when the maternal skeleton competes with the developing fetus for calcium ions absorbed by the digestive tract. The role of calcitonin in the healthy nonpregnant adult is unclear.

In several chapters, we have considered the importance of Ca^{2+} in controlling muscle cell and neuron activities. Calcium ion concentrations also affect the sodium permeabilities of excitable membranes. At high Ca^{2+} concentrations, sodium permeability decreases and membranes become less responsive. Such problems are relatively rare. Problems caused by lower-than-normal Ca^{2+} concentrations are equally dangerous and are much more common. When calcium ion concentrations decline, sodium permeabilities increase and cells become extremely excitable. If calcium levels fall too far, convulsions or muscular spasms can result. Maintenance of adequate calcium levels involves the *parathyroid glands* and *parathyroid hormone*.

Anatomy 360 | Review the anatomy of the thyroid gland on the **Anatomy 360 CD-ROM: Endocrine System/ Thyroid Gland.**

Review the hypothalamus, pituitary, and thyroid gland on the **IP CD-ROM: Endocrine System/The Hypothalamic–Pituitary**
Axis.

The Parathyroid Glands

Objective

- Describe the location of the parathyroid glands, the functions of the hormone they produce, and the effects of abnormal levels of parathyroid hormone production.

There are normally two pairs of **parathyroid glands** embedded in the posterior surfaces of the thyroid gland (Figure 18–12a•). The cells of the two adjacent glands are separated by the dense capsular fibers that surround each parathyroid gland. Altogether, the four parathyroid glands weigh a mere 1.6 g (0.06 oz). The histological appearance of a single parathyroid gland is shown in Figure 18–12b,c•. The parathyroid glands have at least two cell populations: The **chief cells** produce parathyroid hormone; the functions of the other cells, called *oxyphils*, are unknown.

Like the C cells of the thyroid gland, the chief cells monitor the circulating concentration of calcium ions. When the Ca^{2+} concentration of the blood falls below normal, the chief cells secrete **parathyroid hormone (PTH)**, or *parathormone*. The net result of PTH secretion is an increase in Ca^{2+} concentration in body fluids. Parathyroid hormone has four major effects:

1. It stimulates osteoclasts, accelerating mineral turnover and the release of Ca^{2+} from bone.

2. It inhibits osteoblasts, reducing the rate of calcium deposition in bone.

3. It enhances the reabsorption of Ca^{2+} at the kidneys, reducing urinary losses.

4. It stimulates the formation and secretion of *calcitriol* at the kidneys. In general, the effects of calcitriol complement or enhance $_{PO_4}3$

those of PTH, but one major effect of calcitriol is the enhancement of Ca^{2+} and absorption by the digestive tract.

l**p. 195**

Figure 18–13• illustrates the roles of calcitonin and PTH in regulating Ca^{2+} concentrations. It is likely that PTH, aided by calcitriol, is the primary regulator of circulating calcium ion concentrations in healthy adults. Information about the hormones of the thyroid gland and parathyroid glands is summarized in Table 18–4. AM: Disorders of Parathyroid Function

Anatomy 360 | Review the anatomy of the parathyroid gland on the **Anatomy 360 CD-ROM: Endocrine System/Parathy-roid Gland.**

100 Keys | The thyroid gland produces (1) hormones that adjust tissue metabolic rates and (2) a hormone that usually plays a minor role in calcium ion homeostasis by opposing the action of parathyroid hormone.

The Adrenal Glands

Objectives

- Describe the location, structure, and general functions of the adrenal glands.
- Identify the hormones produced by the adrenal cortex and medulla and specify the functions of each hormone.
- Discuss the results of abnormal levels of adrenal hormone production.

A yellow, pyramid-shaped **adrenal gland**, or *suprarenal* (soo-pra-RE¯-nal) *gland* (*supra*-, above + *renes*, kidneys), sits on the superior border of each kidney (Figure 18–14•). Each adrenal gland lies at roughly the level of the 12th rib and is firmly attached to the superior portion of each kidney by a dense fibrous capsule. The adrenal gland on each side nestles among the kidney, the diaphragm, and the major arteries and veins that run along the posterior wall of the abdominopelvic cavity. The adrenal glands project into the peritoneal cavity, and their anterior surfaces are covered by a layer of parietal peritoneum. Like other endocrine glands, the adrenal glands are highly vascularized.

A typical adrenal gland weighs about 5.0 g (0.18 oz), but its size can vary greatly as secretory demands change. The adrenal gland is divided into two parts with separate endocrine functions: a superficial **adrenal cortex** and an inner **adrenal medulla** (Figure 18–14b•).

The Adrenal Cortex

The yellowish color of the adrenal cortex is due to the presence of stored lipids, especially cholesterol and various fatty acids. The adrenal cortex produces more than two dozen steroid hormones, collectively called **adrenocortical steroids**, or simply **corticosteroids**. In the bloodstream, these hormones are bound to transport proteins called *transcortins*.

Corticosteroids are vital: If the adrenal glands are destroyed or removed, the individual will die unless corticosteroids are administered. Corticosteroids, like other steroid hormones, exert their effects by determining which genes are transcribed in the nuclei of their target cells, and at what rates. The resulting changes in the nature and concentration of enzymes in the cytoplasm affect cellular metabolism.

Deep to the adrenal capsule are three distinct regions, or zones, in the adrenal cortex (Figure 18–14c•): (1) an outer *zona glomerulosa*; (2) a middle *zona fasciculata*; and (3) an inner *zona reticularis*. Each zone synthesizes specific steroid hormones (Table 18–5).

The Zona Glomerulosa

The **zona glomerulosa** (glō-mer-ū-LŌ-suh), the outer region of the adrenal cortex, produces **mineralocorticoids**, steroid hormones that affect the electrolyte composition of body fluids. **Aldosterone** is the principal mineralocorticoid produced by the adrenal cortex.

The zona glomerulosa accounts for about 15 percent of the volume of the adrenal cortex (see Figure 18–14c•). A *glomerulus* is a little ball; as the term *zona glomerulosa* implies, the endocrine cells in this region form small, dense knots or clusters. This zone extends from the capsule to the radiating cords of the deeper zona fasciculata.

Aldosterone Aldosterone secretion stimulates the conservation of sodium ions and the elimination of potassium ions. This hormone targets cells that regulate the ionic composition of excreted fluids. It causes the retention of sodium ions at the kidneys, sweat glands, salivary glands, and pancreas, preventing Na^+ loss in urine, sweat, saliva, and digestive secretions. The retention of Na^+ is accompanied by a loss of K^+. As a secondary effect, the reabsorption of Na^+ enhances the osmotic reabsorption of water at the kidneys, sweat glands, salivary glands, and pancreas. The effect at the kidneys is most dramatic when normal levels of ADH are present. In addition, aldosterone increases the sensitivity of salt receptors in the taste buds of the tongue. As a result, interest in (and consumption of) salty food increases.

Aldosterone secretion occurs in response to a drop in blood Na^+ content, blood volume, or blood pressure, or to a rise in blood K^+ concentration. Changes in either Na^+ or K^+ concentration have a direct effect on the zona glomerulosa, but the secretory cells are most sensitive to changes in potassium levels. A rise in potassium levels is very effective in stimulating the release of aldosterone. Aldosterone release also occurs in response to *angiotensin II*. We will discuss this hormone, part of the *renin–angiotensin system*, later in this chapter. AM: Disorders of the Adrenal Cortex

The Zona Fasciculata

The **zona fasciculata** (fa-sik-ū-LA-tuh; *fasciculus*, little bundle) produces steroid hormones collectively known as **glucocorticoids**, due to their effects on glucose metabolism. This zone, which begins at the inner border of the zona glomerulosa and extends toward the adrenal medulla (see Figure 18–14c•), contributes about 78 percent of the cortical volume. The endocrine cells are larger and contain more lipids than those of the zona glomerulosa, and the lipid droplets give the cytoplasm a pale, foamy appearance. The cells of the zona fasciculata form individual cords composed of stacks of cells. Adjacent cords are separated by flattened blood vessels (sinusoids) with fenestrated walls.

The Glucocorticoids When stimulated by ACTH from the anterior lobe of the pituitary, the zona fasciculata secretes primarily **cortisol** (KOR-ti-sol), also called *hydrocortisone*, along with smaller amounts of the related steroid **corticosterone** (kor-ti-KOS-te-r

¯o

n). The liver converts some of the circulating cortisol to **cortisone**, another active glucocorticoid. Glucocorticoid secretion is

regulated by negative feedback: The glucocorticoids released have an inhibitory effect on the production of corticotropin-releasing hormone (CRH) in the hypothalamus, and of ACTH in the anterior lobe (see Figure 18–8a•, p. 603).

Effects of Glucocorticoids Glucocorticoids accelerate the rates of glucose synthesis and glycogen formation, especially in the liver. Adipose tissue responds by releasing fatty acids into the blood, and other tissues begin to break down fatty acids and proteins instead of glucose. This process is another example of a glucose-sparing effect (p. 604). AM: Disorders of the Adrenal Cortex

Glucocorticoids also show **anti-inflammatory** effects; that is, they inhibit the activities of white blood cells and other components of the immune system. “Steroid creams” are commonly used to control irritating allergic rashes, such as those produced by poison ivy, and injections of glucocorticoids may be used to control more severe allergic reactions. Glucocorticoids slow the migration of phagocytic cells into an injury site and cause phagocytic cells already in the area to become less active. In addition, mast cells exposed to these steroids are less likely to release histamine and other chemicals that promote inflammation.

l**pp. 135–136** As a result, swelling and further irritation are dramatically reduced. On the negative side, the rate of wound healing decreases, and the weakening of the region’s defenses makes it more susceptible to infectious organisms. For that reason, topical steroids are used to treat superficial rashes, but should never be applied to open wounds.

The Zona Reticularis

The **zona reticularis** (re-tik-

¯u

-LAR-is; *reticulum*, network) forms a narrow band bordering each adrenal medulla (see

Figure 18–14c•). This zone accounts for only about 7 percent of the total volume of the adrenal cortex. The endocrine cells of the zona reticularis form a folded, branching network, and fenestrated blood vessels wind among the cells.

The zona reticularis normally produces small quantities of androgens, the sex hormones produced in large quantities by the testes in males, under stimulation by ACTH. Once in the bloodstream, some of the androgens released by the zona reticularis are converted to estrogens, the dominant sex hormone in females. Adrenal androgens stimulate the development of pubic hair in boys and girls before puberty. While not important in adult men, in adult women adrenal androgens promote muscle mass, blood cell formation, and support the libido.

The Adrenal Medulla

The boundary between the adrenal cortex and the adrenal medulla is irregular, and the supporting connective tissues and blood vessels are extensively interconnected. The adrenal medulla is a pale gray or pink, owing in part to the many blood vessels in the area, and it contains large, rounded cells—similar to those in sympathetic ganglia that are innervated by preganglionic sympathetic fibers. The secretory activities of the adrenal medullae are controlled by the sympathetic division of the autonomic nervous sys

tem. l**p. 521**

The adrenal medulla contains two populations of secretory cells: One produces epinephrine (adrenaline), the other norepinephrine (noradrenaline). Evidence suggests that the two types of cells are distributed in different areas of the medulla and that their secretory activities can be independently controlled. The secretions are packaged in vesicles that form dense clusters just inside cell membranes. The hormones in these vesicles are continuously released at low levels by exocytosis. Sympathetic stimulation dramatically accelerates the rate of exocytosis and hormone release.

Epinephrine and Norepinephrine

Epinephrine makes up 75–80 percent of the secretions from the adrenal medullae, the rest being norepinephrine. The peripheral effects of these hormones, which result from interaction with alpha and beta receptors on cell membranes, were described in Chapter 16. l**pp. 525–526** Stimulation of a1 and b1 receptors, the most common types, accelerates the utilization of cellular energy and the mobilization of energy reserves.

Activation of the adrenal medullae has the following effects:

- In skeletal muscles, epinephrine and norepinephrine trigger a mobilization of glycogen reserves and accelerate the breakdown of glucose to provide ATP. This combination increases both muscular strength and endurance.
- In adipose tissue, stored fats are broken down into fatty acids, which are released into the bloodstream for use by other tissues for ATP production.
- In the liver, glycogen molecules are broken down. The resulting glucose molecules are released into the bloodstream, primarily for use by neural tissues, which cannot shift to fatty acid metabolism.
- In the heart, the stimulation of b1 receptors triggers an increase in the rate and force of cardiac muscle contraction.

The metabolic changes that follow the release of catecholamines such as E and NE are at their peak 30 seconds after adrenal stimulation, and they persist for several minutes thereafter. As a result, the effects produced by the stimulation of the adrenal medullae outlast the other signs of sympathetic activation. AM: Disorders of the Adrenal Medulla

100 Keys | The adrenal glands produce hormones that adjust metabolic activities at specific sites, affecting either the pattern of nutrient utilization, mineral ion balance, or the rate of energy consumption by active tissues.

Anatomy 360 | Review the anatomy of the adrenal gland on the **Anatomy 360 CD-ROM: Endocrine System/ Adrenal Glands.**

Concept Check

What symptoms would you expect to see in an individual whose diet lacks iodine?

When a person's thyroid gland is removed, signs of decreased thyroid hormone concentration do not appear until about one week later. Why? The removal of the parathyroid glands would result in a decrease in the blood concentration of which important mineral? What effect would elevated cortisol levels have on the level of glucose in the blood?

Answers begin on p. A–1

The Pineal Gland

Objective

- Describe the location of the pineal gland and the functions of the hormone that it produces.

The **pineal gland**, part of the epithalamus, lies in the posterior portion of the roof of the third ventricle. l**p. 465** The pineal

¯E

gland contains neurons, neuroglia, and special secretory cells called **pinealocytes** (pin

–

ı hormone **melatonin** from molecules of the neurotransmitter *serotonin*. Collaterals from the visual pathways enter the pineal gland and affect the rate of melatonin production, which is lowest during daylight hours and highest at night.

Among the functions suggested for melatonin in humans are the following:

- **Inhibiting Reproductive Functions.** In some mammals, melatonin slows the maturation of sperm, oocytes, and reproductive organs by reducing the rate of GnRH secretion. The significance of this effect in humans remains unclear, but circumstantial evidence suggests that melatonin may play a role in the timing of human sexual maturation. Melatonin levels in the blood decline at puberty, and pineal tumors that eliminate melatonin production cause premature puberty in young children.

- **Protecting against Damage by Free Radicals.** Melatonin is a very effective *antioxidant* that may protect CNS neurons from free radicals, such as nitric oxide (NO) or hydrogen peroxide (H2O2) that may be generated in active neural tissue.
- **Setting Circadian Rhythms.** Because pineal activity is cyclical, the pineal gland may also be involved with the maintenance of basic *circadian rhythms*—daily changes in physiological processes that follow a regular day–night pattern. l**p. 469** Increased melatonin secretion in darkness has been suggested as a primary cause of *seasonal affective disorder (SAD)*. This condition, char

acterized by changes in mood, eating habits, and sleeping patterns, can develop during the winter in people who live at high latitudes, where sunlight is scarce or lacking. AM: Light and Behavior

The Pancreas

Objectives

- Describe the location and structure of the pancreas.
- Identify the hormones produced by the pancreas, and specify the functions of those hormones.
- Discuss the results of abnormal levels of pancreatic hormone production.

The **pancreas** lies within the abdominopelvic cavity in the loop formed between the inferior border of the stomach and the proximal portion of the small intestine (see Figure 18–1•). It is a slender, pale organ with a nodular (lumpy) consistency (Figure 18–15a•). The pancreas is 20–25 cm (8–10 in.) long and weighs about 80 g (2.8 oz) in adults. We will consider its anatomy further in Chapter 24, because it is primarily an exocrine organ that makes digestive enzymes.

The **exocrine pancreas**, roughly 99 percent of the pancreatic volume, consists of clusters of gland cells, called *pancreatic acini*, and their attached ducts. Together, the gland and duct cells secrete large quantities of an alkaline, enzyme-rich fluid that reaches the lumen of the digestive tract through a network of secretory ducts.

The **endocrine pancreas** consists of small groups of cells scattered among the exocrine cells. The endocrine clusters are known as **pancreatic islets**, or the *islets of Langerhans* (LAN-ger-hanz) (Figure 18–15b•). Pancreatic islets account for only about 1 percent of all cells in the pancreas. Nevertheless, a typical pancreas contains roughly 2 million pancreatic islets.

The Pancreatic Islets

The pancreatic islets are surrounded by an extensive, fenestrated capillary network that carries pancreatic hormones into the bloodstream. Each islet contains four types of cells:

-al-

¯o

ts). These cells synthesize the-s

1. Alpha cells produce the hormone glucagon (GLOO-ka-gon). Glucagon raises blood glucose levels by increasing the rates of glycogen breakdown and glucose release by the liver.

2. Beta cells produce the hormone insulin (IN-suh-lin). Insulin lowers blood glucose levels by increasing the rate of glucose uptake and utilization by most body cells, and by increasing glycogen synthesis in skeletal muscles and the liver. Beta cells also secrete *amylin,* a recently discovered peptide hormone whose role is unclear.

3. Delta cells produce a peptide hormone identical to growth hormone–inhibiting hormone (GH–IH), a hypothalamic regulatory hormone. GH–IH suppresses the release of glucagon and insulin by other islet cells and slows the rates of food absorption and enzyme secretion along the digestive tract.

4. F cells produce the hormone **pancreatic polypeptide (PP)**. PP inhibits gallbladder contractions and regulates the production of some pancreatic enzymes, and it may also help control the rate of nutrient absorption by the digestive tract.

We will focus on insulin and glucagon, the hormones responsible for the regulation of blood glucose levels (Figure 18–16•). When blood glucose levels rise, beta cells secrete insulin, which then stimulates the transport of glucose across cell membranes. When blood glucose levels decline, alpha cells secrete glucagon, which stimulates glucose release by the liver.

Insulin

Insulin is a peptide hormone released by beta cells when glucose concentrations exceed normal levels (70–110 mg > dl). Secretion of this hormone is also stimulated by elevated levels of some amino acids, including arginine and leucine. Insulin exerts its effects on cellular metabolism in a series of steps that begins when insulin binds to receptor proteins on the cell membrane. Binding leads to the activation of the receptor, which functions as a kinase, attaching phosphate groups to intracellular enzymes. The phosphorylation of enzymes then produces primary and secondary effects in the cell, the biochemical details of which remain unresolved.

One of the most important of these effects is the enhancement of glucose absorption and utilization. Insulin receptors are present in most cell membranes; such cells are called *insulin dependent*. However, cells in the brain and kidneys, cells in the lining of the digestive tract, and red blood cells lack insulin receptors. These cells are called *insulin independent,* because they can absorb and utilize glucose without insulin stimulation.

The effects of insulin on its target cells include the following:

- **The Acceleration of Glucose Uptake (All Target Cells).** This effect results from an increase in the number of glucose transport proteins in the cell membrane. These proteins transport glucose into the cell by facilitated diffusion, a movement that follows the concentration gradient for glucose and for which ATP is not required.
- **The Acceleration of Glucose Utilization (All Target Cells) and Enhanced ATP Production.** This effect occurs for two reasons: (1) The rate of glucose use is proportional to its availability; when more glucose enters the cell, more is used. (2) Second messengers activate a key enzyme involved in the initial steps of glycolysis.

- **The Stimulation of Glycogen Formation (Skeletal Muscles and Liver Cells).** When excess glucose enters these cells, it is stored as glycogen.
- **The Stimulation of Amino Acid Absorption and Protein Synthesis.**
- **The Stimulation of Triglyceride Formation in Adipose Tissue.** Insulin stimulates the absorption of fatty acids and glycerol by adipocytes, which store these components as triglycerides. Adipocytes also increase their absorption of glucose; excess glucose is used in the synthesis of additional triglycerides.

In sum, insulin is secreted when glucose is abundant; the hormone stimulates glucose utilization to support growth and the establishment of carbohydrate (glycogen) and lipid (triglyceride) reserves. The accelerated use of glucose soon brings circulating glucose levels within normal limits.

Glucagon

When glucose concentrations fall below normal, alpha cells release glucagon and energy reserves are mobilized. When glucagon binds to a receptor in the target cell membrane, the hormone activates adenylate cyclase. As we have seen, cAMP acts as a second messenger that activates cytoplasmic enzymes (p. 596). The primary effects of glucagon are as follows:

- **Stimulating the Breakdown of Glycogen in Skeletal Muscle and Liver Cells.** The glucose molecules released will be either metabolized for energy (in skeletal muscle fibers) or released into the bloodstream (by liver cells).
- **Stimulating the Breakdown of Triglycerides in Adipose Tissue.** The adipocytes then release the fatty acids into the bloodstream for use by other tissues.
- **Stimulating the Production of Glucose in the Liver.** Liver cells absorb amino acids from the bloodstream, convert them to glucose, and release the glucose into the circulation. This process of glucose synthesis in the liver is called *gluconeogenesis* (gloo

k

‾o
-n
‾e
-

‾o
-JEN-e-sis).

The results are a reduction in glucose use and the release of more glucose into the bloodstream. Blood glucose concentrations soon rise toward normal levels.

Pancreatic alpha cells and beta cells monitor blood glucose concentrations, and the secretion of glucagon and insulin occur without endocrine or nervous instructions. Yet because the alpha cells and beta cells are highly sensitive to changes in blood glucose levels, any hormone that affects blood glucose concentrations will indirectly affect the production of both insulin and glucagon. Insulin production is also influenced by autonomic activity: Parasympathetic stimulation enhances insulin release, and sympathetic stimulation inhibits it.

Information about insulin, glucagon, and other pancreatic hormones is summarized in Table 18–6.

100 Keys | The pancreatic islets release insulin and glucagon. Insulin is released when blood glucose levels rise, and it stimulates glucose transport into, and utilization by, peripheral tissues. Glucagon is released when blood glucose levels decline, and it stimulates glycogen breakdown, glucose synthesis, and fatty acid release.

The Endocrine Tissues of Other Systems

Objective

- Describe the functions of the hormones produced by the kidneys, heart, thymus, testes, ovaries, and adipose tissue.

As noted earlier, many organs of other body systems have secondary endocrine functions. Examples are the intestines (digestive system), the kidneys (urinary system), the heart (cardiovascular system), the thymus (lymphatic system), and the *gonads*—the testes in males and the ovaries in females (reproductive system).

Over the last decade, several new hormones from these endocrine tissues have been identified. In many cases, their structures and modes of action remain to be determined, and they have not been described in this chapter. However, in one instance, a significant new hormone was traced to an unexpected site of origin and led to the realization that the body's adipose tissue represents an important endocrine organ. Although all of the details have yet to be worked out, we will consider the endocrine functions of adipose tissue in this section as well. Table 18–7 provides an overview of some of the hormones these organs produce.

The Intestines

The intestines, which process and absorb nutrients, release a variety of hormones that coordinate the activities of the digestive system. Although the pace of digestive activities can be affected by the autonomic nervous system, most digestive processes are hormonally controlled locally. These hormones will be described in Chapter 24.

The Kidneys

The kidneys release the steroid hormone *calcitriol*, the peptide hormone *erythropoietin*, and the enzyme *renin*. Calcitriol is important for calcium ion homeostasis; erythropoietin and renin are involved in the regulation of blood volume and blood pressure.

Calcitriol

Calcitriol is a steroid hormone secreted by the kidneys in response to the presence of parathyroid hormone (PTH) (Figure 18–17a•). *Cholecalciferol* (vitamin D3) is a related steroid that is synthesized in the skin or absorbed from the diet. Cholecalciferol is converted to calcitriol, although not directly. The term *vitamin D* applies to the entire group of related steroids, including calcitriol, cholecalciferol, and various intermediate products.

The best-known function of calcitriol is the stimulation of calcium and phosphate ion absorption along the digestive tract. The effects of PTH on Ca^{2+} absorption result primarily from stimulation of calcitriol release. Calcitriol's other effects on calcium metabolism include (1) stimulating the formation and differentiation of osteoprogenitor cells and osteoclasts, (2) stimulating bone resorption by osteoclasts, (3) stimulating Ca^{2+} reabsorption at the kidneys, and (4) suppressing PTH production. Evidence indicates that calcitriol also affects lymphocytes and keratinocytes in the skin; these effects have nothing to do with regulating calcium levels.

Erythropoietin

Erythropoietin (e-rith-r ¯o -POY- ¯e -tin; *erythros*, red + *poiesis*, making), or **EPO**, is a peptide hormone released by the kidneys in response to low oxygen levels in kidney tissues. EPO stimulates the production of red blood cells by bone marrow. The increase in the number of red blood cells elevates blood volume. Because these cells transport oxygen, the increase in their number improves oxygen delivery to peripheral tissues. We will consider EPO again in Chapter 19.

Renin

Renin is released by specialized kidney cells in response to (1) sympathetic stimulation or (2) a decline in renal blood flow. Once in the bloodstream, renin functions as an enzyme that starts an enzymatic cascade known as the *renin–angiotensin system* (Figure 18–17b•). First, renin converts **angiotensinogen**, a plasma protein produced by the liver, to angiotensin I. In the capillaries of the lungs, **angiotensin I** is then modified to the hormone **angiotensin II**, which stimulates the secretion of aldosterone by the adrenal cortex, and of

ADH at the posterior lobe of the pituitary gland. The combination of aldosterone and ADH restricts salt and water losses at the kidneys. Angiotensin II also stimulates thirst and elevates blood pressure.

Because renin plays such a key role in the renin–angiotensin system, many physiological and endocrinological references consider renin to be a hormone. We will take a closer look at the renin–angiotensin system when we examine the control of blood pressure and blood volume in Chapter 21.

The Heart

The endocrine cells in the heart are cardiac muscle cells in the walls of the *atria* (chambers that receive blood from the veins) and the *ventricles* (chambers that pump blood to the rest of the body). If blood volume becomes too great, these cells are stretched excessively, to the point at which they begin to secrete **natriuretic peptides** (nā-trē-ū-RET-ik; *natrium*, sodium + *ouresis*, making water). In general, the effects of natriuretic peptides oppose those of angiotensin II: Natriuretic peptides promote the loss of Na^+ and water at the kidneys, and inhibit renin release and the secretion of ADH and aldosterone. They also suppress thirst and prevent angiotensin II and norepinephrine from elevating blood pressure. The net result is a reduction in both blood volume and blood pressure, thereby reducing the stretching of the cardiac muscle cells in the heart walls. We will discuss two natriuretic peptides—*ANP* (atrial natriuretic peptide) and *BNP* (brain natriuretic peptide)—when we consider the control of blood pressure and volume in Chapters 21 and 26.

The Thymus

The **thymus** is located in the mediastinum, generally just deep to the sternum. The thymus produces several hormones that are important to the development and maintenance of immune defenses. **Thymosin** (THĪ-mō-sin) is the name originally given to an extract from the thymus that promotes the development and maturation of *lymphocytes*, the white blood cells responsible for immunity. The thymic extract actually contains a blend of several complementary hormones; the term *thymosins* is now sometimes used to refer to all thymic hormones. We will consider the histological organization of the thymus and the functions of the thymosins in Chapter 22.

The Gonads

Information about the reproductive hormones of the testes and ovaries is presented in Table 18–8. In males, the **interstitial cells** of the testes produce the male hormones known as androgens. The most important of these androgens is **testosterone** (tes-TOS-ter-ōn). During embryonic development, the production of testosterone affects the development of CNS structures, including hypothalamic nuclei, that will later influence sexual behaviors. **Sustentacular cells** in the testes support the differentiation and physical maturation of sperm. Under FSH stimulation, these cells secrete the hormone **inhibin**, which inhibits the secretion of FSH at the anterior lobe and perhaps suppresses GnRH release at the hypothalamus.

In females, steroid hormones called **estrogens** are produced in the ovaries under FSH and LH stimulation. The principal estrogen is **estradiol**. Circulating FSH stimulates the secretion of inhibin by ovarian cells, and inhibin suppresses FSH release through a feedback mechanism comparable to that in males.

At ovulation, an immature gamete, or oocyte, is released by follicles in the ovary. The remaining follicle cells then reorganize

¯e

into a *corpus luteum* (LOO-t -um; “yellow body”) that releases a mixture of estrogens and **progestins**. **Progesterone** (pr n), the principal progestin, has several important functions, summarized in Table 18–8.

¯o

-JES

ter-

¯o

During pregnancy, additional hormones produced by the placenta and uterus interact with those produced by the ovaries and the pituitary gland to promote normal fetal development and delivery. We will consider the endocrinological aspects of pregnancy in Chapter 29.

Adipose Tissue

Adipose tissue is a type of loose connective tissue introduced in Chapter 4. l**p. 121** Adipose tissue is known to produce two peptide hormones: *leptin* and *resistin*. **Leptin**, secreted by adipose tissue throughout the body, has several functions, the best known being the feedback control of appetite. When you eat, adipose tissue absorbs glucose and lipids and synthesizes triglycerides for storage. At the same time, it releases leptin into the bloodstream. Leptin binds to hypothalamic neurons involved with emotion and appetite control. The result is a sense of satiation and the suppression of appetite.

Leptin was first discovered in a strain of obese mice that had a defective leptin gene. The administration of leptin to these overweight mice quickly turned them into slim, athletic animals. The initial hope that leptin could be used to treat human obesity was soon dashed, however. Most obese people appear to have defective leptin receptors (or leptin pathways) in the appetite centers of the CNS. Their circulating leptin levels are already several times higher than those in individuals of normal body weight, so the administration of additional leptin would have no effect. Researchers are now investigating the structure of the receptor protein and the biochemistry of the pathway triggered by leptin binding.

Leptin must be present for there to be normal levels of GnRH and gonadotropin synthesis. This explains why (1) thin girls commonly enter puberty relatively late, (2) an increase in body fat content can improve fertility, and (3) women stop menstruating when their body fat content becomes very low.

It is now known that adipose tissue also produces a second hormone, tentatively called *resistin*. **Resistin** reduces insulin sensitivity throughout the body; it has been proposed as the “missing link” between obesity and type 2 diabetes. (See the Clinical Note “Diabetes Mellitus” on p. 619.) Experimental evidence from obese mice supports this linkage, and some drugs used to treat type 2 diabetes in humans suppress activity of the resistin gene.

Concept Check

Why does a person with type 1 or type 2 diabetes urinate frequently and have a pronounced thirst?

What effect would increased levels of glucagon have on the amount of glycogen stored in the liver?

Increased amounts of light would inhibit the production of which hormone?

Answers begin on p. A–1

Review endocrine glands on the **IP CD-ROM: Endocrine System/Endocrine System Review.**

Patterns of Hormonal Interaction

Objectives

- Explain how hormones interact to produce coordinated physiological responses.
- Identify the hormones of special importance to normal growth and discuss their roles.

- Define the general adaptation syndrome and compare homeostatic responses with stress responses.
- Describe the effects of hormones on behavior.

Although hormones are usually studied individually, the extracellular fluids contain a mixture of hormones whose concentrations change daily or even hourly. As a result, cells never respond to only one hormone; instead, they respond to multiple hormones simultaneously. When a cell receives instructions from two hormones at the same time, four outcomes are possible:

1. The two hormones may have **antagonistic** (opposing) **effects**, as in the case of PTH and calcitonin, or insulin and glucagon. The net result depends on the balance between the two hormones. In general, when antagonistic hormones are present, the observed effects are weaker than those produced by either hormone acting unopposed.

2. The two hormones may have additive effects, so that the net result is greater than the effect that each would produce acting alone. In some cases, the net result is greater than the *sum* of the hormones' individual effects. This phenomenon is called a **synergistic effect** (sin-er-JIS-tik; *synairesis*, a drawing together). An example is the glucose-sparing action of GH and glucocorticoids.

3. One hormone can have a **permissive effect** on another. In such cases, the first hormone is needed for the second to produce its effect. For example, epinephrine does not change energy consumption unless thyroid hormones are also present in normal concentrations.

4. Finally, hormones may produce different, but complementary, results in specific tissues and organs. These **integrative effects** are important in coordinating the activities of diverse physiological systems. The differing effects of calcitriol and parathyroid hormone on tissues involved in calcium metabolism are an example.

When multiple hormones are involved in the regulation of a complex process, it is very difficult to determine whether a hormone has synergistic, permissive, or integrative effects.

In this section, we will present three examples of processes regulated by hormones that interact in complex ways.

Role of Hormones in Growth

Normal growth requires the cooperation of several endocrine organs. Several hormones—GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones—are especially important, although many others have secondary effects on growth. The circulating concentrations of these hormones are regulated independently. Every time the hormonal mixture changes, metabolic operations are modified to some degree. The modifications vary in duration and intensity, producing unique individual growth patterns.

- ***Growth Hormone (GH).*** The effects of GH on protein synthesis and cellular growth are most apparent in children, in whom GH supports muscular and skeletal development. In adults, growth hormone assists in the maintenance of normal blood glucose concentrations and in the mobilization of lipid reserves stored in adipose tissues. It is not the primary hormone involved, however, and an adult with a GH deficiency but normal levels of thyroxine (T4), insulin, and glucocorticoids will have no physiological problems.
- ***Thyroid Hormones.*** Normal growth also requires appropriate levels of thyroid hormones. If these hormones are absent during fetal development or for the first year after birth, the nervous system will fail to develop normally, and mental retardation will result. If T4 concentrations decline later in life but before puberty, normal skeletal development will not continue.
- ***Insulin.*** Growing cells need adequate supplies of energy and nutrients. Without insulin, the passage of glucose and amino acids

across cell membranes will be drastically reduced or eliminated.
- ***Parathyroid Hormone (PTH) and Calcitriol.*** Parathyroid hormone and calcitriol promote the absorption of calcium salts for subsequent deposition in bone. Without adequate levels of both hormones, bones can still enlarge, but will be poorly mineralized, weak, and flexible. For example, in *rickets*, a condition typically caused by inadequate calcitriol production as a result of

vitamin D deficiency in growing children, the lower limb bones are so weak that they bend under the body’s weight. l**p. 198**

- ***Reproductive Hormones.*** The activity of osteoblasts in key locations and the growth of specific cell populations are affected by the presence or absence of reproductive hormones (androgens in males, estrogens in females). These sex hormones stimulate cell growth and differentiation in their target tissues. The targets differ for androgens and estrogens, and the differential growth induced by each accounts for gender-related differences in skeletal proportions and secondary sex characteristics.

The Hormonal Responses to Stress

Any condition—physical or emotional—that threatens homeostasis is a form of **stress**. Many stresses are opposed by specific homeostatic adjustments. For example, a decline in body temperature leads to shivering or changes in the pattern of blood flow, which can restore normal body temperature.

In addition, the body has a *general* response to stress that can occur while other, more specific, responses are under way. Exposure to a wide variety of stress-causing factors will produce the same general pattern of hormonal and physiological adjustments. These responses are part of the **general adaptation syndrome (GAS)**, also known as the **stress response**. The GAS, first described by Hans Selye in 1936, can be divided into three phases: the *alarm phase*, the *resistance phase*, and the *exhaustion phase* (Figure 18–18•).

The Alarm Phase

During the **alarm phase**, an immediate response to the stress occurs. This response is directed by the sympathetic division of the autonomic nervous system. In the alarm phase, (1) energy reserves are mobilized, mainly in the form of glucose, and (2) the body prepares to deal with the stress-causing factor by “fight or flight” responses. l**p. 520**

Epinephrine is the dominant hormone of the alarm phase, and its secretion accompanies a generalized sympathetic activation. The characteristics of the alarm phase include the following:

- Increased mental alertness.
- Increased energy consumption by skeletal muscles and many other tissues.
- The mobilization of energy reserves (glycogen and lipids).
- Changes in circulation, including increased blood flow to skeletal muscles and decreased blood flow to the skin, kidneys, and digestive organs.
- A drastic reduction in digestion and urine production.
- Increased sweat gland secretion.
- Increases in blood pressure, heart rate, and respiratory rate.

Although the effects of epinephrine are most apparent during the alarm phase, other hormones play supporting roles. For example, the reduction of water losses resulting from ADH production and aldosterone secretion can be very important if the stress involves a loss of blood.

The Resistance Phase

The temporary adjustments of the alarm phase are often sufficient to remove or overcome a stress. But some stresses, including starvation, acute illness, or severe anxiety, can persist for hours, days, or even weeks. If a stress lasts longer than a few hours, the individual enters the **resistance phase** of the GAS.

Glucocorticoids are the dominant hormones of the resistance phase. Epinephrine, GH, and thyroid hormones are also involved. Energy demands in the resistance phase remain higher than normal, owing to the combined effects of these hormones.

Neural tissue has a high demand for energy, and neurons must have a reliable supply of glucose. If blood glucose concentrations fall too far, neural function deteriorates. Glycogen reserves are adequate to maintain normal glucose concentrations during the alarm phase, but are nearly exhausted after several hours. The endocrine secretions of the resistance phase are coordinated to achieve four integrated results:

1. *The Mobilization of Remaining Lipid and Protein Reserves.* The hypothalamus produces GH–RH and CRH, stimulating the release of GH and, by means of ACTH, the secretion of glucocorticoids. Adipose tissues respond to GH and glucocorticoids by releasing stored fatty acids. Skeletal muscles respond to glucocorticoids by breaking down proteins and releasing amino acids into the bloodstream.

2. *The Conservation of Glucose for Neural Tissues.* Glucocorticoids and GH from the anterior lobe of the pituitary gland stimulate lipid metabolism in most tissues. These glucose-sparing effects maintain normal blood glucose levels even after long periods of starvation. Neural tissues do not alter their metabolic activities, however, and they continue to use glucose as an energy source.

3. *The Elevation and Stabilization of Blood Glucose Concentrations.* As blood glucose levels decline, glucagon and glucocorticoids stimulate the liver to manufacture glucose from other carbohydrates, from glycerol by way of triglycerides, and from amino acids provided by skeletal muscles. The glucose molecules are then released into the bloodstream, and blood glucose concentrations return to normal levels.

4. *The Conservation of Salts and Water, and the Loss of K and H* . Blood volume is conserved through the actions of ADH and aldosterone. As Na^+ is conserved, K^+ and H^+ are lost.

The body’s lipid reserves are sufficient to maintain the resistance phase for a period of weeks or even months. (These reserves account for the ability to endure lengthy periods of starvation.) But the resistance phase cannot be sustained indefinitely. If starvation is the primary stress, the resistance phase ends when lipid reserves are exhausted and structural proteins become the primary energy source. If another factor is the cause, the resistance phase ends due to complications brought about by hormonal side effects. Examples of hormone-related complications include the following:

- Although the metabolic effects of glucocorticoids are essential to normal resistance to stress, their anti-inflammatory action slows wound healing and increases the body’s susceptibility to infection.
- The continued conservation of fluids under the influence of ADH and aldosterone stresses the cardiovascular system by producing elevated blood volumes and higher-than-normal blood pressures.

- The adrenal cortex may become unable to continue producing glucocorticoids, quickly eliminating the ability to maintain acceptable blood glucose concentrations.

Poor nutrition, emotional or physical trauma, chronic illness, and damage to key organs such as the heart, liver, and kidneys hasten the end of the resistance phase.

The Exhaustion Phase

When the resistance phase ends, homeostatic regulation breaks down and the **exhaustion phase** begins. Unless corrective actions are taken almost immediately, the failure of one or more organ systems will prove fatal.

Mineral imbalances contribute to the existing problems with major systems. The production of aldosterone throughout the resistance phase results in a conservation of Na^+ at the expense of K^+. As the body's K^+ content declines, a variety of cells— notably neurons and muscle fibers—begin to malfunction. Although a single cause (such as heart failure) may be listed as the cause of death, the underlying problem is the inability to sustain the endocrine and metabolic adjustments of the resistance phase.

Review the stress response on the **IP CD-ROM: Endocrine System/Response to Stress.**

The Effects of Hormones on Behavior

As we have seen, many endocrine functions are regulated by the hypothalamus, and hypothalamic neurons monitor the levels of many circulating hormones. Other portions of the CNS are also quite sensitive to hormonal stimulation.

The clearest demonstrations of the behavioral effects of specific hormones involve individuals whose endocrine glands are oversecreting or undersecreting. But even normal changes in circulating hormone levels can cause behavioral changes. In *precocious* (premature) *puberty*, sex hormones are produced at an inappropriate time, perhaps as early as age 5 or 6. An affected child not only begins to develop adult secondary sex characteristics, but also undergoes significant behavioral changes. The "nice little kid" disappears, and the child becomes aggressive and assertive due to the effects of sex hormones on CNS function. Thus, behaviors that in normal teenagers are usually attributed to environmental stimuli, such as peer pressure, have a physiological basis as well. In adults, changes in the mixture of hormones reaching the CNS can have significant effects on intellectual capabilities, memory, learning, and emotional states.

Aging and Hormone Production

The endocrine system undergoes relatively few functional changes with age. The most dramatic exception is the decline in the concentrations of reproductive hormones. The effects of these hormonal changes on the skeletal system were noted in Chapter 6

p. 199; we will continue the discussion in Chapter29.

Blood and tissue concentrations of many other hormones, including TSH, thyroid hormones, ADH, PTH, prolactin, and glucocorticoids, remain unchanged with advancing age. Although circulating hormone levels may remain within normal limits, some endocrine tissues become less responsive to stimulation. For example, in elderly individuals, smaller amounts of GH and insulin are secreted after a carbohydrate-rich meal. The reduction in levels of GH and other tropic hormones affects tissues throughout the body; these hormonal effects are associated with the reductions in bone density and muscle mass noted in earlier chapters.

Finally, age-related changes in peripheral tissues may make them less responsive to some hormones. This loss of sensitivity has been documented in the case of glucocorticoids and ADH.

Integration with Other Systems

The endocrine system provides long-term regulation and adjustments of homeostatic mechanisms that affect many body functions. For example, the endocrine system regulates fluid and electrolyte balance, cell and tissue metabolism, growth and development, and reproductive functions. It also assists the nervous system in responding to stressful stimuli through the general adaptation syndrome.

The relationships between the endocrine system and the other body systems are summarized in Figure 18–19•. Not surprisingly, the most extensive interactions are with the nervous system. Although the hypothalamus modifies the activities of many endocrine organs via the anterior lobe of the pituitary gland, the presence of so many complex feedback loops makes it difficult to determine whether the endocrine system or the nervous system is really in charge. Moreover, many hormones also serve as neurotransmitters in the brain, spinal cord, and/or enteric nervous system. As a result, circulating hormones that cross the blood–brain barrier can have direct and widespread effects on neural—and neuroendocrine—activity.

Clinical Patterns

Homeostatic regulation of circulating hormone levels primarily involves negative feedback control mechanisms. The feedback loop involves an interplay between the endocrine organ and its target tissues, and endocrine disorders can result from abnormalities in the endocrine gland, the endocrine or neural regulatory mechanisms, or the target tissues. The net result may be overproduction (*hypersecretion*) or underproduction (*hyposecretion*) of hormones.

Primary disorders result from problems within the endocrine organ. The underlying cause may be a metabolic factor; hypothyroidism due to a lack of dietary iodine is an example. An endocrine organ may also malfunction due to physical damage that destroys cells or disrupts the normal blood supply. Congenital problems may also affect the regulation, production, or release of hormones by endocrine cells.

Secondary disorders result from problems in other organs or target tissues. Such disorders often involve the hypothalamus or pituitary gland. For example, if the hypothalamus produces inadequate levels of TRH, the anterior lobe secretes minimal amounts of TSH, and the individual will show signs of hypothyroidism.

Abnormalities in target cells can affect their sensitivity or responsiveness to a particular hormone. For example, type 2 diabetes results from a reduction in the target cell's sensitivity to insulin. The origin and diagnosis of endocrine disorders is discussed further in the *Applications Manual*.

Concept Check

Insulin lowers the level of glucose in the blood, and glucagon causes glucose levels to rise. What is this type of hormonal interaction called? The lack of which hormones would inhibit skeletal formation?

Why do levels of GH–RH and CRH rise during the resistance phase of the general adaptation syndrome?

Answers begin on p. A–1

Chapter Review

Selected Clinical Terminology

Addison's disease: A condition caused by the hyposecretion of glucocorticoids and mineralocorticoids; characterized by an inability to mobilize energy reserves and maintain normal blood glucose levels. [AM] **cretinism** *(congenital hypothyroidism)***:** A condition caused by hypothyroidism at birth or in infancy; marked by inadequate skeletal and nervous development and a metabolic rate as much as 40 percent below normal levels. [AM] **Cushing's disease:** A condition caused by the hypersecretion of glucocorticoids; characterized by the excessive breakdown and relocation of lipid reserves and proteins. [AM] **diabetes insipidus:** A disorder that develops when the posterior lobe of the pituitary gland no longer releases adequate amounts of ADH, or when the kidneys cannot respond to ADH. (p. 605) **diabetes mellitus:** A disorder that damages many organ systems; characterized by blood glucose concentrations high enough to overwhelm the kidneys' reabsorption capabilities. (p. 619 and [AM]) **diabetic retinopathy, nephropathy, neuropathy:** Disorders of the retina, kidneys, and peripheral nerves, respectively, related to diabetes mellitus; the conditions most often afflict middle-aged or older diabetics. (p. 619) **general adaptation syndrome (GAS):** The pattern of hormonal and physiological adjustments with which the body responds to all forms of stress. (p. 626) **glycosuria:** The presence of glucose in the urine. (p. 619) **goiter:** An abnormal enlargement of the thyroid gland. [AM] **hyperglycemia:** Abnormally high blood glucose levels. (p. 621)

hypocalcemic tetany: Muscle spasms affecting the face and upper extremities; caused by low Ca^{2+} concentrations in body fluids. [AM] **insulin-dependent diabetes** or *type 1 diabetes*, or *juvenile-onset diabetes***:** A type of diabetes mellitus; the primary cause is inadequate insulin production by the beta cells of the pancreatic islets. (p. 619 and [AM]) **myxedema:** Condition resulting from severe hyposecretion of thyroid hormones; characterized by subcutaneous swelling, hair loss, dry skin, low body temperature, muscle weakness, and slowed reflexes. [AM)

non-insulin-dependent diabetes or *type 2 diabetes,* or *maturity-onset diabetes***:** A type of diabetes mellitus in which insulin levels are

normal or elevated, but peripheral tissues no longer respond normally. (p. 619 and [AM]) **polyuria:** The production of excessive amounts of urine; a sign of diabetes. (p. 619) **seasonal affective disorder (SAD):** A condition characterized by depression, lethargy, an inability to concentrate, and altered sleep and

eating habits; linked to elevated melatonin levels in individuals exposed to only short periods of daylight. (p. 616 and [AM]) **thyrotoxicosis:** A condition caused by the oversecretion of thyroid hormones (hyperthyroidism). Signs and symptoms include increases in metabolic rate, blood pressure, and heart rate; excitability and emotional instability; and lowered energy reserves. [AM]

Study Outline

Intercellular Communication p. 591

1. In general, the nervous system performs short-term “crisis management,” whereas the endocrine system regulates longer-term, ongoing metabolic processes.

2. **Paracrine communication** involves the use of chemical signals to transfer information from cell to cell within a single tissue.

3. **Endocrine communication** is carried out by *endocrine cells* releasing chemicals called hormones into the circulation, which alters the metabolic activities of many tissues and organs simultaneously. Hormones exert their effects by modifying the activities of **target cells**. *(Table 18–1)*

An Overview of the Endocrine System p. 593

1. The endocrine system includes all the cells and endocrine tissues of the body that produce hormones or paracrine factors. *(Figure 18–1)*

Classes of Hormones p. 593

2. Hormones can be divided into three groups: *amino acid derivatives*; *peptide hormones*; and *lipid derivatives*, including **steroid hormones** and **eicosanoids**. *(Figure 18–2)*

Secretion and Distribution of Hormones p. 595

3. Hormones may circulate freely or bound to transport proteins. Free hormones are rapidly removed from the bloodstream.

Mechanisms of Hormone Action p. 595

4. Receptors for *catecholamines*, peptide hormones, and eicosanoids are in the cell membranes of target cells. Thyroid and steroid hormones cross the cell membrane and bind to receptors in the cytoplasm or nucleus, activating or inactivating specific genes. *(Figures 18–3, 18–4)*

100 Keys | p. 599

Control of Endocrine Activity p. 599

5. **Endocrine reflexes** are the functional counterparts of neural reflexes. *(Figure 18–5)*

6. The hypothalamus regulates the activities of the nervous and endocrine systems by (1) secreting **regulatory hormones**, which control the activities of endocrine cells in the anterior lobe of the pituitary gland, (2) acting as an endocrine organ by releasing hormones into the bloodstream at the posterior lobe of the pituitary gland, and (3) exerting direct neural control over the endocrine cells of the adrenal medullae. *(Figure 18–5)*

The Pituitary Gland p. 600

1. The **pituitary gland**, or **hypophysis**, releases nine important peptide hormones; all bind to membrane receptors and use cyclic-AMP as a second messenger. *(Figures 18–6 through 18–9; Table 18–2)*

The Anterior Lobe p. 601

2. The **anterior lobe (adenohypophysis)** of the pituitary gland can be subdivided into the **pars distalis**, the **pars intermedia**, and the **pars tuberalis**. *(Figure 18–6)*

3. At the median eminence of the hypothalamus, neurons release regulatory factors (either **releasing hormones, RH,** or **inhibiting hormones, IH**) into the surrounding interstitial fluids **fenestrated capillaries**. *(Figure 18–7)*

4. The **hypophyseal portal system** ensures that these regulatory factors reach the intended target cells before they enter the general circulation. *(Figure 18–7)*

5. **Thyroid-stimulating hormone (TSH)** triggers the release of thyroid hormones. *Thyrotropin-releasing hormone (TRH)* promotes the secretion of TSH. *(Figure 18–8)*

6. **Adrenocorticotropic hormone (ACTH)** stimulates the release of *glucocorticoids* by the adrenal cortex. Corticotropin-releasing hormone (CRH) causes the secretion of ACTH. *(Figure 18–8)*

7. **Follicle-stimulating hormone (FSH)** stimulates follicle development and estrogen secretion in females and sperm production in males. **Luteinizing hormone (LH)** causes *ovulation* and *progestin* production in females, and androgen production in males. Gonadotropin-releasing hormone (GnRH) promotes the secretion of both FSH and LH. *(Figure 18–8)*

8. **Prolactin (PRL)**, together with other hormones, stimulates both the development of the mammary glands and milk production.

(Figure 18–8)

9. **Growth hormone (GH**, or **somatotropin)** stimulates cell growth and replication through the release of **somatomedins** or **IGF**s from liver cells. The production of GH is regulated by **growth hormone–releasing hormone (GH–RH)** and **growth hormone–inhibiting hormone (GH–IH)**. *(Figure 18–8)*

10. Melanocyte-stimulating hormone (MSH) may be secreted by the pars intermedia during fetal development, early childhood, pregnancy, or certain diseases. This hormone stimulates melanocytes to produce melanin but its function in normal adults is not known.

100 Keys | p. 604

The Posterior Lobe p. 604

11. The **posterior lobe (neurohypophysis)** of the pituitary gland contains the unmyelinated axons of hypothalamic neurons. Neurons of the **supraoptic** and **paraventricular nuclei** manufacture **antidiuretic hormone (ADH)** and **oxytocin**, respectively. ADH decreases the amount of water lost at the kidneys and, in higher concentrations, elevates blood pressure. In women, oxytocin stimulates contractile cells in the mammary glands and has a stimulatory effect on smooth muscles in the uterus. *(Figure 18–9; Summary Table 18–2)*

Summary: The Hormones of the Pituitary Gland p. 605

Anatomy 360 | Endocrine System/Pituitary Gland

The Thyroid Gland p. 606

1. The thyroid gland lies anterior to the *thyroid cartilage* of the larynx and consists of two **lobes** connected by a narrow **isthmus**. *(Figure 18–10)*

Thyroid Follicles and Thyroid Hormones p. 606

2. The thyroid gland contains numerous **thyroid follicles**. Thyroid follicles release several hormones, including **thyroxine** and **triiodothyronine** *(Figures 18–10, 18–11; Table 18–4)*

3. Most of the thyroid hormones entering the bloodstream are attached to special **thyroid-binding globulins (TBGs)**; the rest are attached to **transthyretin** or albumin. *(Figure 18–11)*

Functions of Thyroid Hormones p. 610

4. Thyroid hormones are held in storage, bound to mitochondria (thereby increasing ATP production), or bound to receptors activating genes that control energy utilization. They also exert a **calorigenic effect**. *(Table 18–3)*

The C Cells of the Thyroid Gland and Calcitonin p. 610

5. The **C cells** of the thyroid follicles produce **calcitonin (CT)**, which helps regulate concentrations in body fluids, especially during childhood and pregnancy. *(Figure 18–10, Table 18–4)*

Endocrine System/The Hypothalamic-Pituitary Axis

Anatomy 360 | Endocrine System/Thyroid Gland

The Parathyroid Glands p. 611

1. Four **parathyroid glands** are embedded in the posterior surface of the thyroid gland. The **chief cells** produce **parathyroid hormone**

(PTH) in response to lower-than-normal concentrations of Ca^{2+} . The parathyroid glands, aided by *calcitriol*, are the primary regulators of blood calcium I levels in healthy adults. *(Figures 18–12, 18–13; Table 18–4)*

Anatomy 360 | Endocrine System/Parathyroid Gland

100 Keys | p. 612

The Adrenal Glands p. 613

1. One **adrenal** *(suprarenal)* **gland** lies along the superior border of each kidney. The gland is subdivided into the superficial **adrenal cortex** and the inner **adrenal medulla**. *(Figure 18–14)*

The Adrenal Cortex p. 613

2. The adrenal cortex manufactures steroid hormones called **adrenocortical steroids (corticosteroids)**. The cortex can be subdivided into three areas: (1) the **zona glomerulosa**, which releases **mineralocorticoids**, principally **aldosterone**; (2) the **zona fasciculata**, which produces **glucocorticoids**, notably **cortisol** and **corticosterone**; and (3) the **zona reticularis**, which produces androgens under ACTH stimulation. *(Figure 18–14; Table 18–5)*

The Adrenal Medulla p. 615

3. The adrenal medulla produces epinephrine (75–80 percent of medullary secretion) and norepinephrine (20–25 percent). *(Figure 18–14; Table 18–5)*

100 Keys | p. 616

Anatomy 360 | Endocrine System/Adrenal Glands

The Pineal Gland p. 616

1. The **pineal gland** contains **pinealocytes**, which synthesize **melatonin**. Suggested functions include inhibiting reproductive functions, protecting against damage by free radicals, and setting circadian rhythms.

The Pancreas p. 616 The Pancreatic Islets p. 617

1. The pancreas contains both exocrine and endocrine cells. Cells of the endocrine pancreas form clusters called **pancreatic islets** (*islets of Langerhans*). These islets contain **alpha cells** (which secrete the hormone glucagon), **beta cells** (which secrete **insulin**), **delta cells** (which secrete **somatostatin (GH-IH)**, and **F cells** (which secrete **pancreatic polypeptide**). *(Figure 18–15; Table 18–6)*

Insulin and Glucagon pp. 617, 619

2. Insulin lowers blood glucose by increasing the rate of glucose uptake and utilization; glucagon raises blood glucose by increasing the rates of glycogen breakdown and glucose manufacture in the liver. *(Figure 18–16, Table 18–6)*

100 Keys | p. 620

The Endocrine Tissues of Other Systems p. 620 The Intestines p. 621

1. The intestines produce hormones important to the coordination of digestive activities. *(Table 18–7)*

The Kidneys p. 621

2. Endocrine cells in the kidneys produce the hormones *calcitriol* and *erythropoietin* and the enzyme *renin*. *(Table 18–7)*

3. **Calcitriol** stimulates calcium and phosphate ion absorption along the digestive tract. *(Figure 18–17)*

4. **Erythropoietin (EPO)** stimulates red blood cell production by the bone marrow. *(Figure 18–17)*

5. **Renin** converts **angiotensinogen** to **angiotensin I**. In the capillaries of the lungs, the latter compound is converted to **angiotensin II**, a hormone that (1) stimulates the adrenal production of aldosterone, (2) stimulates the pituitary release of ADH, (3) promotes thirst, and (4) elevates blood pressure. *(Figure 18–17)*

The Heart p. 622

6. Specialized muscle cells in the heart produce **natriuretic peptides** (*ANP* and *BNP*) when the blood volume becomes excessive. In general, their actions oppose those of angiotensin II. *(Table 18–7)*

The Thymus p. 623

7. The thymus produces several hormones, collectively known as **thymosins**, which play a role in developing and maintaining normal immune defenses. *(Table 18–7)*

The Gonads p. 623

8. The **interstitial cells** of the testes produce androgens. **Testosterone** is the most important sex hormone in males. *(Table 18–8)*

9. In females, *oocytes* develop in follicles; follicle cells produce **estrogens**, especially **estradiol**. After ovulation, the remaining follicle cells reorganize into a *corpus luteum*. Those cells release a mixture of estrogens and **progestins**, especially **progesterone**. *(Table 18–8)*

Adipose Tissue p. 624

10. Adipose tissue secretes **leptin** (a feedback control for appetite) and **resistin** (which reduces insulin sensitivity).

Endocrine System/Endocrine System Review

Patterns of Hormonal Interaction p. 624

1. The hormones of the endocrine system often interact, producing (1) **antagonistic** (opposing) **effects;** (2) **synergistic** (additive) **effects;** (3) **permissive effects,** in which one hormone is necessary for another to produce its effect; or (4) **integrative effects,** in which hormones produce different, but complementary, results.

Role of Hormones in Growth p. 624

2. Normal growth requires the cooperation of several endocrine organs. Several hormones are especially important: GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones.

The Hormonal Responses to Stress p. 626

3. Any condition that threatens homeostasis is a **stress**. Our bodies respond to a variety of stress-causing factors through the **general adaptation syndrome (GAS)**, or **stress response**.

4. The GAS can be divided into three phases: (1) the **alarm phase** (an immediate, “fight or flight” response, under the direction of the sympathetic division of the ANS); (2) the **resistance phase**, dominated by glucocorticoids; and (3) the **exhaustion phase**, the eventual breakdown of homeostatic regulation and failure of one or more organ systems. *(Figure 18–18)*

Endocrine System/Response to Stress

The Effects of Hormones on Behavior p. 628

5. Many hormones affect the CNS; changes in the normal mixture of hormones can significantly alter intellectual capabilities, memory, learning, and emotional states.

Aging and Hormone Production p. 628

1. The endocrine system undergoes few functional changes with advanced age. The major changes include a decline in the concentration of growth hormone and reproductive hormones.

Integration with Other Systems p. 628

Review Questions

MyA&P | Access more review material online at **MyA&P.** There you'll find learning activities, case studies, quizzes, Interactive Physiology exercises, and more to help you succeed. To access the site, go to www.myaandp.com.

Answers to the Review Questions begin on page A–1.

LEVEL 1 Reviewing Facts and Terms

1. The use of a chemical messenger to transfer information from cell to cell within a single tissue is referred to as ___________ communication.

(a) direct **(b)** paracrine

(c) hormonal **(d)** endocrine

2. Cyclic-AMP functions as a second messenger to

(a) build proteins and catalyze specific reactions

(b) activate adenylate cyclase

(c) open ion channels and activate key enzymes in the cytoplasm

(d) bind the hormone–receptor complex to DNA segments

3. Adrenocorticotropic hormone (ACTH) stimulates the release of

(a) thyroid hormones by the hypothalamus

(b) gonadotropins by the adrenal glands

(c) growth hormones by the hypothalamus

(d) steroid hormones by the adrenal glands

4. FSH production in males supports

(a) the maturation of sperm by stimulating sustentacular cells

(b) the development of muscles and strength

(c) the production of male sex hormones

(d) an increased desire for sexual activity

5. The two hormones released by the posterior lobe are

(a) GH and gonadotropin **(b)** estrogen and progesterone

(c) GH and prolactin **(d)** ADH and oxytocin

6. All of the following are true of the endocrine system, *except*

(a) releases chemicals into the bloodstream for distribution throughout the body

(b) releases hormones that alter the metabolic activities of many different tissues and organs simultaneously

(c) produces effects that can last for hours, days, and even longer

(d) produces rapid, local, brief-duration responses to specific stimuli

(e) functions to control ongoing metabolic processes

7. A cell’s hormonal sensitivities are determined by the

(a) chemical nature of the hormone

(b) quantity of circulating hormone
(c) shape of the hormone molecules
(d) presence or absence of appropriate receptors
(e) thickness of the cell membrane

8. Endocrine organs can be regulated by all of the following, *except*
(a) hormones from other endocrine glands
(b) changes in the genetic makeup of certain hypothalamic cells
(c) direct neural stimulation
(d) changes in the composition of extracellular fluid
(e) releasing hormones from the hypothalamus

9. What three higher-level mechanisms are involved in integrating the activities of the nervous and endocrine systems?

10. Which seven hormones are released by the anterior lobe of the pituitary gland?

11. What six hormones primarily affect growth?

12. What five primary effects result from the action of thyroid hormones?

13. What effects do calcitonin and parathyroid hormone have on blood calcium levels?

14. What three zones make up the adrenal cortex, and what kinds of hormones are produced by each zone?

15. Which two hormones are released by the kidneys, and what is the importance of each hormone?

16. What are the four opposing effects of atrial natriuretic peptide and angiotensin II?

17. What four cell populations make up the endocrine pancreas? Which hormone does each type of cell produce?

LEVEL 2 Reviewing Concepts

18. What is the primary difference in the way the nervous and endocrine systems communicate with their target cells?

19. How can a hormone modify the activities of its target cells?

20. What is an endocrine reflex? Compare endocrine and neural reflexes.

21. How would blocking the activity of phosphodiesterase affect a cell that responds to hormonal stimulation by the cAMP second-messenger system?

22. How does control of the adrenal medulla differ from control of the adrenal cortex?

23. In studying a group of cells it is noticed that when stimulated by a particular hormone there is a marked increase in the activity of G proteins in the membrane. The hormone being studied is probably

(a) a steroid
(b) a peptide
(c) testosterone
(d) estrogen
(e) aldosterone

24. Increased blood calcium levels would result in *increased*
(a) secretion of calcitonin
(b) secretion of parathormone
(c) retention of calcium by the kidneys
(d) osteoclast activity
(e) excitability of neural membranes

25. In type 2 diabetes mellitus, insulin levels are frequently normal, yet the target cells are less sensitive to the effects of insulin. This suggests that the target cells
(a) are impermeable to insulin
(b) may lack enough insulin receptors
(c) cannot convert insulin to an active form
(d) have adequate internal supplies of glucose
(e) both b and c

LEVEL 3 Critical Thinking and Clinical Applications

26. Roger has been extremely thirsty; he drinks numerous glasses of water every day and urinates a great deal. Name two disorders that could produce these symptoms. What test could a clinician perform to determine which disorder Roger has?

27. Julie is pregnant but is not receiving prenatal care. She has a poor diet consisting mostly of fast food. She drinks no milk, preferring colas instead. How would this situation affect Julie’s level of parathyroid hormone?

28. Sherry tells her physician that she has been restless and irritable lately. She has a hard time sleeping and complains of diarrhea and weight loss. During the examination, her physician notices a higher-than-normal heart rate and a fine tremor in her outstretched fingers. What tests could the physician suggest to make a positive diagnosis of Sherry’s condition?

29. What are two benefits of having a portal system connect the median eminence of the hypothalamus with the anterior pituitary gland?

30. Pamela and her teammates are considering testosterone supplements to enhance their competitive skills. What natural effects of this hormone are they hoping to gain? What additional side effects might these women expect should they begin an anabolic steroid regime?

TABLE 18–1 Mechanisms of Intercellular Communication

Mechanism	**Transmission**	**Chemical Mediators**	**Distribution of Effects**
Direct communication	Through gap junctions	Ions, small solutes, lipid-soluble materials	Usually limited to adjacent cells of the same type that are interconnected by

connexons

Paracrine communication Through extracellular Paracrine factors Primarily limited to local area, fluid where concentrations are relatively high. Target cells must have appropriate receptors

Endocrine communication Through the circulatory H
system tissues and organs
and must have
appropriate
receptors

Synaptic communication Across synaptic clefts Neurotransmitters Limited to very specific area.

Target cells must have
appropriate receptors

Endocrine System

Can you describe the chemical structures of hormones? Stop here to use your **InterActive Physiology CD-ROM** to review the structure of hormones and mechanisms of hormone action. Click on the *Endocrine System* module to see interactive exercises, quizzes, and study outlines on the following topics:

- Orientation
- Endocrine System Review
- Biochemistry, Secretion, and Transport of Hormones
- The Actions of Hormones on Target Cells
- The Hypothalamic–Pituitary Axis
- Response to Stress

At this point in the chapter, click on *Biochemistry, Secretion, and Transport of Hormones* and then on *The Actions of Hormones on Target Cells*. Use **IP** to review hormone structures and actions before you continue reading about the endocrine glands. A Study Outline consisting of notes, diagrams, and study questions for each topic can also be printed from **IP**. To help ensure your success in anatomy and physiology, review the remaining endocrine topics as they appear in your text and each time you see the CD icon.

| SUMMARY TABLE 18–2 | THE PITUITARY HORMONES

Hypothalamic

Region/Area Hormone(s) Target(s) Hormonal Effect(s) Regulatory Hormone

ANTERIOR LOBE (ADENOHYPOPHYSIS)

Pars distalis Thyroid-stimulating Thyroid gland Secretion of thyroid Thyrotropin-releasing

hormone (TSH) hormones hormone (TRH)

Adrenocorticotropic Adrenal cortex Secretion of glucocorticoids Corticotropin-releasing

hormone (ACTH) (zona fasciculata) (cortisol, corticosterone) hormone (CRH)

Gonadotropins:

Follicle-stimulating Follicle cells of

hormone (FSH) ovaries

The Cardiovascular System: An Introduction

Blood is the fluid component of the **cardiovascular system**, which also includes a pump (the heart) that circulates the fluid and a series of conducting hoses (the blood vessels) that carry it throughout the body. In Chapter 18, we noted the importance of this system as the transport medium for hormones, but that is only one of its many vital roles. In adults, circulating blood provides nutrients, oxygen, chemical instructions, and a way of removing wastes to each of the roughly 75 trillion cells in the body. The blood also transports specialized cells that defend peripheral tissues from infection and disease. These services are essential—so much so that a body region deprived of circulation dies in a matter of minutes. This chap ter takes a close look at the structure and functions of blood, a fluid connective tissue with remarkable properties.

Objective

• List the components of the cardiovascular system and explain the major functions of this system.

The Nature of Blood

Objectives

. • Describe the important components and major functions of blood.

. • Identify body sites used for blood collection and list the basic physical characteristics of the blood samples drawn from these locations.

In this chapter, we examine the structure and functions of **blood**, a specialized fluid connective tissue that contains cells suspended in a fluid matrix. As you may recall, Chapter 4 introduced the components and properties of this connective tissue. l**p. 123**

The functions of blood include the following:

. • **The Transportation of Dissolved Gases, Nutrients, Hormones, and Metabolic Wastes.** Blood carries oxygen from the lungs to peripheral tissues, and carbon dioxide from those tissues to the lungs. Blood distributes nutrients absorbed at the digestive tract or released from storage in adipose tissue or in the liver. It carries hormones from endocrine glands toward their target cells, and it absorbs and carries the wastes produced by tissue cells to the kidneys for excretion.

. • **The Regulation of the pH and Ion Composition of Interstitial Fluids.** Diffusion between interstitial fluids and blood eliminates local deficiencies or excesses of ions such as calcium or potassium. Blood also absorbs and neutralizes acids generated by active tissues, such as lactic acid produced by skeletal muscles.

. • **The Restriction of Fluid Losses at Injury Sites.** Blood contains enzymes and other substances that respond to breaks in vessel walls by initiating the process of *clotting*. A blood clot acts as a temporary patch that prevents further blood loss.

. • **Defense against Toxins and Pathogens.** Blood transports *white blood cells*, specialized cells that migrate into peripheral tissues to fight infections or remove debris. Blood also delivers *antibodies*, proteins that specifically attack invading organisms or foreign compounds.

. • **The Stabilization of Body Temperature.** Blood absorbs the heat generated by active skeletal muscles and redistributes it to other tissues. If body temperature is already high, that heat will be lost across the surface of the skin. If body temperature is too low, the warm blood is directed to the brain and to other temperature-sensitive organs.

Blood has a unique composition (Figure 19–1•). It is a fluid connective tissue with a matrix called **plasma** (PLAZ-muh). Plasma proteins are in solution rather than forming insoluble fibers like those in other connective tissues, such as loose connective tissue or cartilage. Because these proteins are in solution, plasma is slightly denser than water. Plasma is similar to interstitial fluid, although it contains a unique assortment of suspended proteins. A continuous exchange of fluid between the tissues and the blood is driven by a combination of hydrostatic pressure, concentration gradients, and osmosis. These relationships will be considered further in Chapter 21.

Formed elements are blood cells and cell fragments that are suspended in plasma. Three types of formed elements exist: red

–

ı are the most abundant blood cells. These specialized cells are essential for the transport of oxygen in the blood. The less numer

blood cells, white blood cells, and platelets. **Red blood cells (RBCs)**, or **erythrocytes** (e-RITH-r

¯o

ts; *erythros*, red *cyte*, cell),

+

-s

ous **white blood cells (WBCs)**, or **leukocytes** (LOO-k

‾

ı anisms. There are five classes of leukocytes, each with slightly different functions. **Platelets** are small, membrane-bound cell fragments that contain enzymes and other substances important to the process of clotting.

‾o

ts; *leukos*, white -*cyte*, cell), participate in the body’s defense mech

+

-s

Formed elements are produced through the process of **hemopoiesis** (h

‾e

m-

‾o

-poy-E‾

-sis), or *hematopoiesis*. Two populations

of stem cells—*myeloid stem cells* and *lymphoid stem cells*—are responsible for the production of all the kinds of formed elements. We will consider the fates of the myeloid and lymphoid stem cells as we discuss the formation of each type of formed element.

Together, the plasma and the formed elements constitute **whole blood**. The components of whole blood can be **fractionated**, or separated, for analytical or clinical purposes. We will encounter examples of uses for fractionated blood later in the chapter.

Whole blood from any source—venous blood, blood from peripheral capillaries, or arterial blood—has the same basic physical characteristics:

- Blood temperature is roughly 38°C (100.4°F), slightly above normal body temperature.
- Blood is five times as viscous as water—that is, five times as sticky, five times as cohesive, and five times as resistant to flow as water. The high viscosity results from interactions among dissolved proteins, formed elements, and water molecules in

plasma.

. • Blood is slightly alkaline, with a pH between 7.35 and 7.45 (average: 7.4).

The cardiovascular system of an adult male contains 5–6 liters (5.3–6.4 quarts) of whole blood; that of an adult female contains 4–5 liters (4.2–5.3 quarts). The sex differences in blood volume primarily reflect differences in average body size. Blood volume in liters can be estimated for an individual of either sex by calculating 7 percent of the body weight in kilograms. For example, a 75-kg (165-lb) individual would have a blood volume of approximately 5.25 liters (5.4 quarts).

Clinical Note

Fresh whole blood is generally collected from a superficial vein, such as the *median cubital vein* on the anterior surface of the elbow

(see Figure 19–1a•). The procedure is called **venipuncture** (V E N-i-punk-chur; *vena*, vein + punctura, a piercing). It is a common

sampling technique because (1) superficial veins are easy to locate, (2) the walls of veins are thinner than those of comparably

sized arteries, and (3) blood pressure in the venous system is relatively low, so the puncture wound seals quickly. The most common

clinical procedures examine venous blood.

Blood from peripheral capillaries can be obtained by puncturing the tip of a finger, an earlobe, or (in infants) the great toe or heel. A small drop of capillary blood can be used to prepare a *blood smear*, a thin film of blood on a microscope slide. The blood smear is then stained with special dyes to show each type of formed element. Capillary blood can also be used to monitor glucose, cholesterol, and hemoglobin levels, as well as to check the clotting system.

An **arterial puncture**, or “arterial stick,” can be used for checking the efficiency of gas exchange at the lungs. Samples are generally drawn from the *radial artery* at the wrist or the *brachial artery* at the elbow.

Plasma

Objective

- Specify the composition and functions of plasma.

As shown in Figure 19–1a•, plasma makes up 46–63 percent of the volume of whole blood. Water accounts for 92 percent of the plasma volume (Figure 19–1b•). Together, plasma and interstitial fluid account for most of the volume of extracellular fluid (ECF) in the body.

In many respects, the composition of plasma resembles that of interstitial fluid. The concentrations of the major plasma ions, for example, are similar to those of interstitial fluid and differ markedly from those inside cells. This similarity is understandable, as water, ions, and small solutes are continuously exchanged between plasma and interstitial fluids across the walls of capillaries. Normally, the capillaries deliver more liquid and solutes to a tissue than they remove. The excess fluid flows through the tissue, into vessels of the lymphatic system, and eventually back to the bloodstream. The primary differences between plasma and interstitial fluid involve (1) the levels of respiratory gases (oxygen and carbon dioxide, due to the respiratory activities of tissue cells), and (2) the concentrations and types of dissolved proteins (because plasma proteins cannot cross capillary walls).

Plasma Proteins

Plasma contains significant quantities of dissolved proteins. On average, each 100 ml of plasma contains 7.6 g (0.3 oz) of protein, almost five times the concentration in interstitial fluid. The large size and globular shapes of most blood proteins prevent them from crossing capillary walls, so they remain trapped within the circulatory system. Three primary classes of plasma proteins exist:

¯U

albumins (al-B

–

-linz), and *fibrinogen* (f -BRIN-

ı the plasma proteins. The remainder consists of circulating enzymes, hormones, and prohormones.

Albumins

Albumins constitute roughly 60 percent of the plasma proteins. As the most abundant plasma proteins, they are major contributors to the osmotic pressure of plasma. Albumins are also important in the transport of fatty acids, thyroid hormones, some steroid hormones, and other substances.

Globulins

Globulins account for approximately 35 percent of the proteins in plasma. Important plasma globulins include antibodies and

-minz), *globulins* (GLOB-

-jen). These three classes make up more than 99% of

¯u ¯o

transport globulins. **Antibodies**, also called **immunoglobulins** (i-m

¯u

-n

¯o

-GLOB-

¯u

-linz), attack foreign proteins and pathogens.

We will examine several classes of immunoglobulins in Chapter 22. **Transport globulins** bind small ions, hormones, and compounds that might otherwise be lost at the kidneys or that have very low solubility in water. Important examples of transport globulins include the following:

. • *Hormone-binding proteins*, which provide a reserve of hormones in the bloodstream. Examples include *thyroid-binding globulin* and *transthyretin*, which transport thyroid hormones and *transcortin*, which transports ACTH. l**pp. 609, 613**

. • *Metalloproteins*, which transport metal ions. *Transferrin*, for example, is a metalloprotein that transports iron (Fe^{2+}).

¯A

¯O

Apolipoproteins (
-l
-PR
nz), which carry triglycerides and other lipids in blood. When bound to lipids, an
¯

ı apolipoprotein becomes a **lipoprotein** (L -p I¯
¯o¯o¯e
-t
•
-p
-p
¯o
-pr
¯o
-t
¯e
n).

- *Steroid-binding proteins*, which transport steroid hormones in blood. For example, *testosterone-binding globulin* (*TeBG*) binds and transports testosterone.

Fibrinogen

The third type of plasma protein, **fibrinogen**, functions in clotting. Fibrinogen normally accounts for roughly 4 percent of plasma
¯I
proteins. Under certain conditions, fibrinogen molecules interact, forming large, insoluble strands of **fibrin** (F -brin). These fibers provide the basic framework for a blood clot. If steps are not taken to prevent clotting in a blood sample, the conversion of fibrinogen to

fibrin will occur. This conversion removes the clotting proteins, leaving a fluid known as **serum**. The clotting process also removes calcium ions and other materials from solution, so plasma and serum differ in several significant ways. (See Appendix IV.) Thus, the results of a blood test generally indicate whether the sample was plasma or serum.

Other Plasma Proteins

The remaining 1 percent of plasma proteins is composed of specialized proteins whose levels vary widely. Peptide hormones— including insulin, prolactin (PRL), and the glycoproteins thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH)—are normally present in circulating blood. Their plasma concentrations rise and fall from day to day or even hour to hour.

Origins of the Plasma Proteins

The liver synthesizes and releases more than 90 percent of the plasma proteins, including all albumins and fibrinogen, most globulins, and various prohormones. Antibodies are produced by *plasma cells*. Plasma cells are derived from *lymphocytes,* the primary cells of the lymphatic system. Peptide hormones are produced in a variety of endocrine organs.

Because the liver is the primary source of plasma proteins, liver disorders can alter the composition and functional properties of blood. For example, some forms of liver disease can lead to uncontrolled bleeding due to the inadequate synthesis of fibrinogen and other proteins involved in clotting.

100 Keys | Your total blood volume, in liters, is roughly equal to 7 percent of your body weight in kilograms. Approximately half the volume of whole blood consists of cells and cell products. Plasma resembles interstitial fluid, but it contains a unique mixture of proteins not found in other extracellular fluids.

Clinical Note

Plasma expanders can be used to increase the blood volume temporarily, over a period of hours. They are often used to buy time for lab work to determine a person's blood type. (Transfusion of the wrong blood type can kill the recipient.) Isotonic electrolyte solutions such as normal (physiological) saline can be used as a plasma expander, but their effects are short-lived due to diffusion into interstitial fluid and cells. This fluid loss is slowed by the addition of solutes that cannot freely diffuse across cell membranes. One example is *Ringer’s solution*, isotonic saline containing lactate ions. The effects of Ringer’s solution fade gradually as the liver, skeletal muscles, and other tissues absorb and metabolize the lactate ions. Another option is the administration of isotonic saline solution containing purified human albumin. However, the plasma expanders in clinical use often contain large carbohydrate molecules, rather than proteins, to maintain proper osmotic concentration. (The emergency use of the carbohydrate dextran in sodium chloride solutions was noted in Chapter 3. l**p. 89**) Although these carbohydrates are not metabolized, they are gradually removed from the bloodstream by phagocytes, and blood volume slowly declines. Plasma expanders are easily stored, and their sterile preparation avoids viral or bacterial contamination, which can be a problem with donated plasma. Note that although they provide a temporary solution to low blood volume, plasma expanders do not increase the amount of oxygen carried by the blood; that function is performed by red blood cells.

Concept Check

Why is venipuncture a common technique for obtaining a blood sample?

What would be the effects of a decrease in the amount of plasma proteins?

Which plasma protein would you expect to be elevated during a viral infection?

Answers begin on p. A–1

Red Blood Cells

Objectives

- List the characteristics and functions of red blood cells.
- Describe the structure of hemoglobin and indicate its functions.
- Describe how the components of aged or damaged red blood cells are recycled.

. • Define erythropoiesis, identify the stages involved in red blood cell maturation, and describe the homeostatic regulation of red blood cell production.

. • Explain the importance of blood typing and the basis for ABO and Rh incompatibilities.

The most abundant blood cells are the red blood cells (RBCs), which account for 99.9 percent of the formed elements. These cells give whole blood its deep red color because they contain the red pigment *hemoglobin* (H¯E-m¯o-gl¯o-bin), which binds and transports oxygen and carbon dioxide.

Abundance of RBCs

A standard blood test reports the number of RBCs per microliter (ml) of whole blood as the *red blood cell count*. In adult males, 1 microliter, or 1 *cubic millimeter* (mm^3), of whole blood contains 4.5–6.3 million RBCs; in adult females, 1 microliter contains 4.2–5.5 million. A single drop of whole blood contains approximately 260 million RBCs, and the blood of an average adult has 25 trillion RBCs. RBCs thus account for roughly one-third of all cells in the human body.

The **hematocrit** (he-MAT-¯o-krit) is the percentage of whole blood volume contributed by formed elements, 99.9% of which are red blood cells (see Figure 19–1a•). The normal hematocrit in adult males averages 46 (range: 40–54); the average for adult females is 42 (range: 37–47). The sex difference in hematocrit primarily reflects the fact that androgens (male hormones) stimulate red blood cell production, whereas estrogens (female hormones) do not.

The hematocrit is determined by centrifuging a blood sample so that all the formed elements come out of suspension. Whole blood contains roughly 1000 red blood cells for each white blood cell. After centrifugation, the white blood cells and platelets form a very thin *buffy coat* above a thick layer of RBCs. Because the hematocrit value is due almost entirely to the volume of RBCs, hematocrit is commonly reported as the *volume of packed red cells* (*VPRC*), or simply the *packed cell volume* (*PCV*).

Many conditions can affect the hematocrit. For example, the hematocrit increases during dehydration, owing to a reduction in plasma volume, or after *erythropoietin* (*EPO*) stimulation. l**p. 621** The hematocrit can decrease as a result of internal bleeding or problems with RBC formation. As a result, the hematocrit alone does not provide specific diagnostic information. Still, an abnormal hematocrit is an indication that other, more specific tests are needed. (We will consider some of those tests later in the chapter.) AM: Polycythemia

Structure of RBCs

Red blood cells (Figure 19–2•) are among the most specialized cells of the body. A red blood cell is very different from the “typical cell” we discussed in Chapter 3. Each RBC is a biconcave disc with a thin central region and a thicker outer margin (Figure 19–2•). An average RBC has a diameter of 7.8 mm and a maximum thickness of 2.6 mm, although the center narrows to about 0.8 mm.

This unusual shape has three important effects on RBC function:

1. **1.** *It Gives Each RBC a Large Surface Area-to-Volume Ratio.* Each RBC carries oxygen bound to intracellular proteins. That oxygen must be absorbed or released quickly as the RBC passes through the capillaries of the lungs or peripheral tissues. The greater the surface area per unit volume, the faster the exchange between the RBC’s interior and the surrounding plasma. The total surface area of all the RBCs in the blood of a typical adult is about 3800 square meters, roughly 2000 times the total surface area of the body.

2. **2.** *It Enables RBCs to Form Stacks, Like Dinner Plates, That Smooth the Flow* *through Narrow Blood Vessels.* These stacks form and dissociate repeatedly without affecting the cells involved. An entire stack can pass along a blood vessel only slightly larger than the diameter of a single RBC, whereas individual cells would bump the walls, bang together, and form logjams that could restrict or prevent blood flow. Such stacks are shown in Figure 19–2b•.

3. **3.** *It Enables RBCs to Bend and Flex When Entering Small Capillaries and Branches.* Red blood cells are very flexible. By changing shape, individual RBCs can squeeze through capillaries as narrow as 4 mm.

During their differentiation, the RBCs of humans and other mammals lose most of their organelles, including nuclei; the cells retain only the cytoskeleton. (The RBCs of vertebrates other than mammals have nuclei.) Because they lack nuclei and ribosomes, circulating mammalian RBCs cannot divide or synthesize structural proteins or enzymes. As a result, the RBCs cannot perform repairs, so their life span is relatively short—normally less than 120 days. With few organelles and no ability to synthesize proteins, their energy demands are low. In the absence of mitochondria, they obtain the energy they need through the anaerobic metabolism of glucose absorbed from the surrounding plasma. The absence of mitochondria ensures that absorbed oxygen will be carried to peripheral tissues, not “stolen” by mitochondria in the RBC.

Hemoglobin

In effect, a developing red blood cell loses any organelle not directly associated with the cell’s primary function: the transport of respiratory gases. Molecules of **hemoglobin (Hb)** account for more than 95 percent of intracellular proteins. The hemoglobin content of whole blood is reported in grams of Hb per deciliter (100 ml) of whole blood (g dl). Normal ranges are 14–18 g > dl in

> males and 12–16 g > dl in females. Hemoglobin is responsible for the cell’s ability to transport oxygen and carbon dioxide.

Hemoglobin Structure

Hb molecules have complex quaternary structures. l**p. 50** Each Hb molecule has two *alpha*

() *chains* and two *beta* () *chains*

abof polypeptides (Figure 19–3•). Each chain is a globular protein subunit that resembles the myoglobin in skeletal and cardiac muscle cells. Like myoglobin, each Hb chain contains a single molecule of **heme**, a pigment complex. Each heme unit holds an iron ion in such a way that the iron can interact with an oxygen molecule, forming **oxyhemoglobin**, HbO2. Blood containing RBCs filled with oxyhemoglobin is bright red. The iron–oxygen interaction is very weak; the two can easily dissociate without damaging the heme unit or the oxygen molecule. The binding of an oxygen molecule to the iron in a heme unit is therefore completely reversible. A hemoglobin molecule whose iron is not bound to oxygen is called **deoxyhemoglobin**. Blood containing RBCs filled with deoxyhemoglobin is dark red—almost burgundy.

The RBCs of an embryo or a fetus contain a different form of hemoglobin, known as *fetal hemoglobin*, which binds oxygen more readily than does the hemoglobin of adults. For this reason, a developing fetus can "steal" oxygen from the maternal bloodstream at the placenta. The conversion from fetal hemoglobin to the adult form begins shortly before birth and continues over the next year. The production of fetal hemoglobin can be stimulated in adults by the administration of drugs such as *hydroxyurea* or *butyrate*. This is one method of treatment for conditions, such as *sickle cell anemia* or *thalassemia*, that result from the production of abnormal forms of adult hemoglobin.

Hemoglobin Function

Each red blood cell contains about 280 million Hb molecules. Because a Hb molecule contains four heme units, each RBC can potentially carry more than a billion molecules of oxygen at a time. Roughly 98.5 percent of the oxygen carried by the blood travels through the bloodstream bound to Hb molecules inside RBCs.

The amount of oxygen bound to hemoglobin depends primarily on the oxygen content of the plasma. When plasma oxygen levels are low, hemoglobin releases oxygen. Under these conditions, typical of peripheral capillaries, plasma carbon dioxide levels are elevated. The alpha and beta chains of hemoglobin then bind carbon dioxide, forming **carbaminohemoglobin**. In the capillaries of the lungs, plasma oxygen levels are high and carbon dioxide levels are low. Upon reaching these capillaries, RBCs absorb oxygen (which is then bound to hemoglobin) and release carbon dioxide. We will revisit these processes in Chapter 23.

Normal activity levels can be sustained only when tissue oxygen levels are kept within normal limits. If the hematocrit is low or the Hb content of the RBCs is reduced, the condition called **anemia** exists. Anemia interferes with oxygen delivery to peripheral tissues. Every system is affected as organ function deteriorates owing to oxygen starvation. Anemic individuals become weak, lethargic, and often confused, because the brain is affected as well. Anemia occurs in many forms; we will consider specific examples both in this chapter and in the *Applications Manual*. AM: Abnormal Hemoglobin

RBC Formation and Turnover

A red blood cell is exposed to severe mechanical stresses. A single round trip from the heart, through the peripheral tissues, and back to the heart usually takes less than a minute. In that time, an RBC gets pumped out of the heart and forced along vessels, where it bounces off the walls and collides with other RBCs. It forms stacks, contorts and squeezes through tiny capillaries, and then is rushed back to the heart to make yet another round trip.

With all this wear and tear and no repair mechanisms, a typical RBC has a relatively short life span. After it travels about 700 miles in 120 days, either its cell membrane ruptures or some other damage is detected by phagocytes, which engulf the RBC. The continuous elimination of RBCs usually goes unnoticed, because new ones enter the bloodstream at a comparable rate. About 1 percent of the circulating RBCs are replaced each day, and in the process approximately 3 million new RBCs enter the bloodstream *each second*!

Hemoglobin Conservation and Recycling

Macrophages of the liver, spleen, and bone marrow monitor the condition of circulating RBCs, generally recognizing and engulfing them before they **hemolyze**, or rupture. These phagocytes also detect and remove Hb molecules and cell fragments from the relatively small proportion of RBCs that hemolyze in the bloodstream (about 10 percent of the total recycled each day).

If the Hb released by hemolysis is not phagocytized, its components will not be recycled.

Hemoglobin remains intact only under the conditions inside RBCs. When hemolysis occurs, the Hb breaks down, and the alpha and beta chains are filtered by the kidneys and eliminated in urine. When abnormally large numbers of RBCs break down in the bloodstream, urine may turn red or

brown. This condition is called **hemoglobinuria**. The presence of intact RBCs in urine—a sign called **hematuria** (h

¯e

-ma-TOO-

r

¯e

-uh)—occurs only after kidney damage or damage to vessels along the urinary tract.

Once an RBC has been engulfed and broken down by a phagocytic cell, each component of the Hb molecule has a different fate (Figure 19–4•). The globular proteins are disassembled into their component amino acids, which are then either metabolized by the cell or released into the bloodstream for use by other cells. Each heme unit is stripped of its iron and converted to **biliverdin** (bil-i-VER-din), an organic compound with a green color. (Bad bruises commonly develop a greenish tint due to biliverdin formation in the blood-filled tissues.) Biliverdin is then converted to **bilirubin** (bil-i-ROO-bin), an orange-yellow pigment, and released into the bloodstream. There, the bilirubin binds to albumin and is transported to the liver for excretion in bile.

If the bile ducts are blocked or the liver cannot absorb or excrete bilirubin, circulating levels of the compound climb rapidly. Bilirubin then diffuses into peripheral tissues, giving them a yellow color that is most apparent in the skin and over the sclera of the eyes. This combination of signs (yellow skin and eyes) is called **jaundice** (JAWN-dis). AM: Bilirubin Tests and Jaundice

In the large intestine, bacteria convert bilirubin to related pigments called *urobilinogens (*

¯

ı -jens). Some of the urobilinogens are absorbed into the bloodstream and are subsequently excreted -b -LIN-

¯u ¯o ¯o

-jens) and *sterco*-r

*bilinogens (*ster-k

ı into urine. On exposure to oxygen, some of the urobilinogens and stercobilinogens are converted to **urobilins** *(* -b -LIN-

¯o ¯o

¯

¯

I -B -lins). Urine is usually yellow because it contains urobilins; feces are yellow-brown or brown owing to -B -lins) and

I the presence of urobilins and stercobilins in varying proportions.

Iron

Large quantities of free iron are toxic to cells, so in the body iron is generally bound to transport or storage proteins. Iron extracted from heme molecules may be bound and stored in a phagocytic cell or released into the bloodstream, where it binds to **transferrin** (trans-FER-in), a plasma protein. Red blood cells developing in the bone marrow absorb the amino acids and transferrins from the bloodstream and use them to synthesize new Hb molecules. Excess transferrins are removed in the liver and spleen, and the

¯u ¯o

r

stercobilins *(*ster-k

¯o

iron is stored in two special protein–iron complexes: **ferritin** (FER-i-tin) and **hemosiderin**

(h

¯e

-m

¯o

-SID-e-rin).

This recycling system is remarkably efficient. Although roughly 26 mg of iron is incorporated into Hb molecules each day, a dietary supply of 1–2 mg can keep pace with the incidental losses that occur at the kidneys and digestive tract.

Any impairment in iron uptake or metabolism can cause serious clinical problems, because RBC formation will be affected. -*Iron-deficiency anemia*, which results from a lack of iron in the diet or from problems with iron absorption, is one example. Too much iron can also cause problems, owing to excessive buildup in secondary storage sites, such as the liver and cardiac muscle tissue. Excessive iron deposition in cardiac muscle cells has been linked to heart disease. AM: Iron Deficiences and Excesses

RBC Production

Embryonic blood cells appear in the bloodstream during the third week of development. These cells divide repeatedly, rapidly increasing in number. The vessels of the embryonic *yolk sac* are the primary site of blood formation for the first eight weeks of development. As other organ systems appear, some of the embryonic blood cells move out of the bloodstream and into the liver, spleen, thymus, and bone marrow. These embryonic cells differentiate into stem cells whose divisions produce blood cells.

The liver and spleen are the primary sites of hemopoiesis from the second to fifth months of development, but as the skeleton enlarges, the bone marrow becomes increasingly important. In adults, red bone marrow is the only site of red blood cell production, as well as the primary site of white blood cell formation.

¯I

-sis), occurs only in *red bone marrow*, or **myeloid** (M -e-loyd)

tissue (*myelos*, marrow). This tissue is located in portions of the vertebrae, sternum, ribs, skull, scapulae, pelvis, and proximal limb bones. Other marrow areas contain a fatty tissue known as *yellow bone marrow*. l**p. 187** Under extreme stimulation, such as severe and sustained blood loss, areas of yellow marrow can convert to red marrow, increasing the rate of RBC formation.

Stages in RBC Maturation

¯E

Red blood cell formation, or **erythropoiesis** (e-rith-r

¯o

-poy-

¯e

During its maturation, a red blood cell passes through a series of stages. **Hematologists** (h -ma-TOL-o-jists), specialists in blood formation and function, have given specific names to key stages. Divisions of **hemocytoblasts** (*hemo-*, blood + *-cyte*, cell + *blastos*, precursor), or *pluripotent stem cells*, in bone marrow produce (1) **myeloid stem cells**, which in turn divide to produce red blood cells and several classes of white blood cells, and (2) **lymphoid stem cells**, which divide to produce the various classes of lymphocytes. Cells destined to become RBCs first differentiate into **proerythroblasts** and then proceed through various **erythroblast** stages (Figure 19–5•). Erythroblasts, which actively synthesize hemoglobin, are named based on total size, amount of hemoglobin present, and size and appearance of the nucleus.

After roughly four days of differentiation, the erythroblast, now called a *normoblast*, sheds its nucleus and becomes a **reticul-**

ı days. During this period, while the cells are synthesizing hemoglobin and other proteins, their cytoplasm still contains RNA which can be seen under the microscope with certain stains. After two days in the bone marrow, reticulocytes enter the bloodstream. At this time, reticulocytes normally account for about 0.8 percent of the RBC population in the blood and can still be detected by staining. After 24 hours in circulation, the reticulocytes complete their maturation and become indistinguishable from other mature RBCs.

Regulation of Erythropoiesis

For erythropoiesis to proceed normally, the red bone marrow must receive adequate supplies of amino acids, iron, and vitamins (including B12, B6, and folic acid) required for protein synthesis. We obtain **vitamin B12** from dairy products and meat, and its absorption requires the presence of *intrinsic factor* produced in the stomach. If vitamin B12 is not obtained from the diet, normal stem cell divisions cannot occur and *pernicious anemia* results. Thus, pernicious anemia is caused by either a vitamin B12 deficiency, a problem with the production of intrinsic factor, or a problem with the absorption of vitamin B_{12} bound to intrinsic factor.

Erythropoiesis is stimulated directly by the peptide hormone erythropoietin (l**p. 621**) and indirectly by several hormones, including thyroxine, androgens, and growth hormone. As previously noted, estrogens do not stimulate erythropoiesis, a fact that accounts for the differences in hematocrit values between males and females.

Erythropoietin (EPO), also called **erythropoiesis-stimulating hormone**, is a glycoprotein that appears in the plasma when peripheral tissues, especially the kidneys, are exposed to low oxygen concentrations. The state of low tissue oxygen levels is called **ocyte**

(re-TIK-

¯u

-l

¯o

t), which contains 80 percent of the Hb of a mature RBC. Hb synthesis then continues for two to three more -s

–

hypoxia (h -POKS-

ı flow to the kidneys declines, (3) when the oxygen content of air in the lungs declines, owing to disease or high altitude, and

(4) when the respiratory surfaces of the lungs are damaged. Once in the bloodstream, EPO travels to areas of red bone marrow, where it stimulates stem cells and developing RBCs.

Erythropoietin has two major effects: (1) It stimulates increased cell division rates in erythroblasts and in the stem cells that produce erythroblasts, and (2) it speeds up the maturation of RBCs, mainly by accelerating the rate of Hb synthesis. Under maximum EPO stimulation, bone marrow can increase the rate of RBC formation tenfold, to about 30 million cells per second.

The ability to increase the rate of blood formation quickly and dramatically is important to a person recovering from a severe blood loss. But if EPO is administered to a healthy individual, as in the case of the cyclists and Olympic competitors mentioned in Chapter 18, the hematocrit may rise to 65 or more. l**p. 629** Such an increase can place an intolerable strain on the heart. Comparable problems can occur after **blood doping**, a practice in which athletes attempt to elevate their hematocrits by reinfusing packed RBCs that were removed and stored at an earlier date. The goal is to improve oxygen delivery to muscles, thereby enhancing performance. The strategy can be dangerous, however, because by elevating blood viscosity it increases the workload on the heart. AM: Erythrocytosis and Blood

Doping

Blood tests provide information about the general health of an individual, usually with a minimum of trouble and expense. Several common blood tests focus on red blood cells, the most abundant formed elements. These *RBC tests* assess the number, size, shape, and maturity of circulating RBCs, providing an indication of the erythropoietic activities under way. The tests can also be useful in detecting problems, such as internal bleeding, that may not produce other obvious signs or symptoms. Table 19–1 lists examples of important blood tests and related terms. (See the *Applications Manual* for sample calculations.) AM: Blood Tests and RBCs

¯e

-uh; *hypo*-, below *ox*-, presence of oxygen). Erythropoietin is released (1) during anemia, (2) when blood

+

100 Keys | Red blood cells (RBCs) are the most numerous cells in the body. They remain in circulation for approximately

4 months before being recycled; several million are produced each second. The hemoglobin inside RBCs transports oxygen

from the lungs to peripheral tissues; it also carries carbon dioxide from those tissues to the lungs.

Concept Check

How would the hematocrit change after an individual suffered a significant blood loss?

Dave develops a blockage in his renal arteries that restricts blood flow to the kidneys. Will his hematocrit change?

How would the level of bilirubin in the blood be affected by a disease that causes damage to the liver?

Answers begin on p. A–1

Blood Types

Antigens are substances that can trigger a protective defense mechanism called an *immune* *response* Most antigens are proteins, although some other types of organic molecules are antigens as well. Your cell membranes contain **surface antigens**, substances that your immune system recognizes as “normal.” In other words, your immune system ignores these substances rather than attacking them as “foreign.”

Your **blood type** is a classification determined by the presence or absence of specific surface antigens in RBC cell membranes. The surface antigens involved are integral membrane glycoproteins or glycolipids whose characteristics are genetically determined. Although red blood cells have at least 50 kinds of surface antigens, three surface antigens are of particular importance: **A**, **B**, and **Rh** (or **D**).

Based on RBC surface antigens, there are four blood types (Figure 19–6a•): **Type A** blood has surface antigen A only, **Type B** has surface antigen B only, **Type AB** has both A and B, and **Type O** has neither A nor B. Individuals with these blood types are not evenly distributed throughout the population. The average values for the U.S. population are as follows: Type O, 46 percent; Type A, 40 percent; Type B, 10 percent; and Type AB, 4 percent (Table 19–2).

The term **Rh positive** (Rh^+) indicates the presence of the Rh surface antigen, sometimes called the *Rh factor*. The absence of this antigen is indicated as **Rh negative** (Rh^-). When the complete blood type is recorded, the term *Rh* is usually omitted and the data are reported as O negative (O^-), A positive (A^+), and so on. As in the distribution of A and B surface antigens, Rh type differs by ethnic group and by region (see Table 19–2).

Your immune system ignores the surface antigens—called **agglutinogens** (a-gloo-TIN-o¯-jenz)—on your own RBCs. However, your plasma contains antibodies, sometimes called *agglutinins* (a-GLOO-ti-ninz), that will attack the antigens on “foreign” RBCs. When these antibodies attack, the foreign cells **agglutinate**, or clump together; this process is called **agglutination**. If you have Type A blood, your plasma contains anti-B antibodies, which will attack Type B surface antigens. If you have Type B blood, your plasma contains anti-A antibodies. The RBCs of an individual with Type O blood have neither A nor B surface antigens, and that person’s plasma contains both anti-A and anti-B antibodies. A Type AB individual has RBCs with both A and B surface antigens, and the plasma does not contain anti-A or anti-B antibodies. The presence of anti-A and/or anti-B antibodies is genetically determined and they are present throughout life, regardless of whether the individual has ever been exposed to foreign RBCs.

In contrast, the plasma of an Rh-negative individual does not necessarily contain anti-Rh antibodies. These antibodies are present only if the individual has been **sensitized** by previous exposure to Rh-positive RBCs. Such exposure can occur accidentally during a transfusion, but it can also accompany a seemingly normal pregnancy involving an Rh-negative mother and an Rh-positive fetus. (See the Clinical Note "Hemolytic Disease of the Newborn" on pages 653–654.)

Cross-Reactions

When an antibody meets its specific surface antigen, the RBCs agglutinate and may also hemolyze. This reaction is called a **cross-reaction** (Figure 19–6b•). For instance, an anti-A antibody that encounters A surface antigens will cause the RBCs bearing the surface antigens to clump or even break up. Clumps and fragments of RBCs under attack form drifting masses that can plug small blood vessels in the kidneys, lungs, heart, or brain, damaging or destroying dependent tissues. Such cross-reactions, or *transfusion reactions*, can be prevented by ensuring that the blood types of the donor and the recipient are **compatible**—that is, that the donor's blood cells and the recipient's plasma will not cross-react.

In practice, the surface antigens on the donor's cells are more important in determining compatibility than are the antibodies in the donor's plasma. Unless large volumes of whole blood or plasma are transferred, cross-reactions between the donor's plasma and the recipient's blood cells will fail to produce significant agglutination. This is because the donated plasma is diluted quickly through mixing with the relatively large plasma volume of the recipient. (One unit of whole blood, 500 ml, contains roughly 275 ml of plasma, only about 10 percent of normal plasma volume.) Nonetheless, when increasing the blood's oxygen-carrying capacity rather than its plasma volume is the primary goal, packed RBCs, with a minimal amount of plasma, are often transfused. This practice minimizes the risk of a reaction between the donated plasma and the blood cells of the recipient.

Testing For Compatibility Extra care must be taken to avoid potentially life-threatening cross-reactions between the donor’s cells and the recipient’s plasma. As a result, a compatibility test is usually performed in advance. This process normally involves two steps: (1) a determination of blood type and (2) a cross-match test.

The standard test for blood type considers only the three surface antigens most likely to produce dangerous cross-reactions: A, B, and Rh (Figure 19–7•). The test involves taking drops of blood and mixing them separately with solutions containing anti-A, anti-B, and anti-Rh (anti-D) antibodies. Any cross-reactions are then recorded. For example, if an individual’s RBCs clump together when exposed to anti-A and to anti-B antibodies, the individual has Type AB blood. If no reactions occur after exposure, that person must have Type O blood. The presence or absence of the Rh surface antigen is also noted, and the individual is classified as Rh positive or Rh negative on that basis. Type O^+ is the most common blood type. The RBCs of Type O^+ individuals lack surface antigens A and B but have the Rh antigen.

Standard blood-typing of both donor and recipient can be completed in a matter of minutes. However, in an emergency, there may not be time for preliminary testing. For example, a person with a severe gunshot wound may require 5 *liters* or more of blood before the damage can be repaired. Under these circumstances, Type O blood (preferably O^-) will be administered. Because the donated RBCs lack both A and B surface antigens, the recipient’s blood can have anti-A antibodies, anti-B antibodies, or both and still not cross-react with the donor’s blood. Because cross-reactions with Type O blood are very unlikely, Type O individuals are sometimes called *universal donors*. Type AB individuals were once called *universal recipients*, because they lack anti-A or anti-B antibodies that would attack donated RBCs, and so can safely receive blood of any type. However, now that blood supplies are adequate and compatibility testing is regularly performed, the term has largely been dropped. If the recipient’s blood type is known to be AB, Type AB blood will be administered.
