twenty-second edition

WILLIAMS OBSTETRICS - 22nd Ed. (2005)

FRONT MATTER

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Williams Obstetrics 22ND EDITION

F. Gary Cunningham, MD

*Professor and Chairman, Department of Obstetrics & Gynecology
Beatrice & Miguel Elias Distinguished Chair in Obstetrics & Gynecology
The University of Texas Southwestern Medical Center at Dallas
Chief of Obstetrics & Gynecology
Parkland Memorial Hospital
Dallas, Texas*

John C. Hauth, MD

*Professor and Chairman, Department of Obstetrics & Gynecology
J. Marion Sims Chair in Obstetrics & Gynecology
University of Alabama at Birmingham
Birmingham, Alabama*

Kenneth J. Leveno, MD

*Jack A. Pritchard Distinguished Professor of Obstetrics & Gynecology
Vice-Chair for Maternal-Fetal Medicine
The University of Texas Southwestern Medical Center at Dallas
Chief of Obstetrics
Parkland Memorial Hospital
Dallas, Texas*

Larry Gilstrap III, MD

*Professor and Chairman, Department of Obstetrics & Gynecology, and Reproductive Sciences
Emma Sue Hightower Professor of Obstetrics & Gynecology
The University of Texas-Houston Medical School
Houston, Texas*

Steven L. Bloom, MD

*Associate Professor, Department of Obstetrics & Gynecology
The University of Texas Southwestern Medical Center at Dallas
Associate Director of Obstetrics
Parkland Memorial Hospital
Dallas, Texas*

Katharine D. Wenstrom, MD

*Professor, Department of Obstetrics & Gynecology
Director, Division of Maternal-Fetal Medicine
University of Alabama at Birmingham
Birmingham, Alabama*

Dedication

This 22nd edition of Williams Obstetrics is dedicated to those who work tirelessly to provide and improve health care for women and their unborn children. We especially applaud our faculty, residents, nurses, nurse practitioners, and nurse midwives, as well as the frequently unlauded but vital supporting team members who give selflessly to provide the best possible care for indigent women with the least possible resources. We are fortunate to have many such individuals working at the institutions with which we are proudly associated. We also recognize the efforts of many health-care administrators as well

as elected and appointed officials who strive to provide these less fortunate women with good obstetrical care and with contraceptive options. At the same time, it is our fervent hope that those who actively impede this progress will eventually come to understand the societal benefits that accrue from fulfilling these lofty goals.

Contents

Preface ix

SECTION I. Overview 1

1. Obstetrics in Broad Perspective 3

SECTION II. Anatomy and Physiology 13

- 2. Maternal Anatomy 15
- 3. Implantation, Embryogenesis, and Placental Development 39
- 4. Fetal Growth and Development 91
- 5. Maternal Physiology 121
- 6. Parturition 151

SECTION III. Antepartum 187

- 7. Preconceptional Counseling 189
- 8. Prenatal Care 201
- 9. Abortion 231
- 10. Ectopic Pregnancy 253
- 11. Gestational Trophoblastic Disease 273
- 12. Genetics 285
- 13. Prenatal Diagnosis and Fetal Therapy 313
- 14. Teratology, Drugs, and Other Medications 341
- 15. Antepartum Assessment 373
- 16. Ultrasonography and Doppler 389

SECTION IV. Labor and Delivery 407

- 17. Normal Labor and Delivery 409
- 18. Intrapartum Assessment 443
- 19. Obstetrical Anesthesia 473
- 20. Dystocia ☞—Abnormal Labor 495
- 21. Disorders of Amniotic Fluid Volume 525
- 22. Induction of Labor 535
- 23. Forceps Delivery and Vacuum Extraction 547
- 24. Breech Presentation and Delivery 565
- 25. Cesarean Delivery and Peripartum Hysterectomy 587
- 26. Prior Cesarean Delivery 607
- 27. Abnormalities of the Placenta, Umbilical Cord, and Membranes 619

SECTION V. Fetus and Newborn 631

- 28. The Newborn Infant 633
- 29. Diseases and Injuries of the Fetus and Newborn 649

SECTION VI. The Puerperium 693

- 30. The Puerperium 695
- 31. Puerperal Infection 711
- 32. Contraception 725
- 33. Sterilization 751

SECTION VII. Obstetrical Complications 759

- 34. Hypertensive Disorders in Pregnancy 761
- 35. Obstetrical Hemorrhage 809
- 36. Preterm Birth 855
- 37. Postterm Pregnancy 881
- 38. Fetal Growth Disorders 893
- 39. Multifetal Gestation 911
- 40. Abnormalities of the Reproductive Tract 949

SECTION VIII. Medical and Surgical Complications 971

- 41. General Considerations and Maternal Evaluation 973
- 42. Critical Care and Trauma 987
- 43. Obesity 1007
- 44. Cardiovascular Disease 1017
- 45. Chronic Hypertension 1043
- 46. Pulmonary Disorders 1055
- 47. Thromboembolic Disorders 1073
- 48. Renal and Urinary Tract Disorders 1093
- 49. Gastrointestinal Disorders 1111
- 50. Hepatic, Biliary Tract, and Pancreatic Disorders 1125
- 51. Hematological Disorders 1143
- 52. Diabetes 1169
- 53. Thyroid and Other Endocrine Disorders 1189
- 54. Connective Tissue Disorders 1209

55. Neurological and Psychiatric Disorders	1229
56. Dermatological Disorders	1249
57. Neoplastic Diseases	1257
58. Infections	1275
59. Sexually Transmitted Diseases	1301

Index 1327

Preface

In previous editions of *Williams Obstetrics*, we have emphasized that obstetrics, originally born as a technical specialty, began to accrue scientific-based underpinnings during the last half of the 20th century. And over the past three decades, evidence-based medicine became embraced and is now firmly inculcated into clinical obstetrics. Accordingly, we again acknowledge the many fruitful efforts of the National Institute of Child Health and Human Development (NICHD) to encourage and support basic science and clinical research in obstetrical specialties. In updating this text, we relied heavily on investigations performed by members of the Maternal-Fetal Medicine Units Network. We also applaud the efforts of the American Gynecological and Obstetrical Society, the Society for Maternal-Fetal Medicine, the Society for Gynecological Investigation, and the American Board of Obstetrics and Gynecology to support the scientific and fiscal health of young clinical investigators.

Evidence-based medicine can be a two-edged sword. How does the busy practitioner keep up with many innovations that seemingly appear daily into our clinical literature? Who is the arbiter of their incorporation into clinical obstetrics? Should observations that satisfy the mathematical definition of statistical significance, but that have limited clinical significance, be employed nationwide as the "standard of care"? To us, the obvious answer is "no." And so we applaud our professional organizations such as the American College of Obstetricians and Gynecologists for their pragmatism and wisdom in recommendation of protocols for clinical management that inevitably do become the "standard." For our part, in this book we have attempted to perform a balanced review of the literature to present readers with pros and cons of different management methods so that they may select options that are best suited to their available resources. We have also tried to avoid dogmatism which unfortunately dominated the practice of obstetrics for several decades of the 20th century. At the same time, we are proud to be associated with academic teaching services that are disciplined examples of evidence-based obstetrics. Although none of these services is perfect in any sense of the definition, we draw heavily on our combined clinical observations when recommending management options. We do however emphasize that these recommendations do not necessarily represent a sole method of management.

We have added new editors to further balance the breadth of obstetrics with a depth to ensure our self-imposed mandate of citing scientific underpinning of evidence-based clinical medicine. One imperative was a suitable replacement(s) for Dr. Norman Gant who needed more time as Executive Director of the American Board of Obstetrics and Gynecology. Joining us from the University of Texas Southwestern Medical Center is Dr. Steve Bloom who is director of Labor & Delivery at Parkland Hospital and who is responsible for overseeing the welfare of the more than 15,000 women who are delivered there annually. Dr. Bill Rainey is a nationally recognized scientist in reproductive and developmental biology who has made many valuable contributions to our knowledge of fetal physiology and labor initiation. Dr. George Wendel is director of the largest residency program in the country and he has also accrued an enviable reputation in the fields of obstetrical and perinatal infections, especially sexually transmitted diseases. Joining us from the University of Alabama at Birmingham, Dr. Dwight Rouse is an accomplished perinatal epidemiologist who provides depth to our myriad analyses of evidence-based outcomes. We are also fortunate to be joined by Dr. Cathy Spong from the National Institute of Child Health and Human Development who brings substantive dimension drawn from her extensive experiences accrued with the Maternal Fetal Medicine Units Network.

As in the past, we have relied heavily on the expertise of many of our colleagues and hopefully we cite all of them for their scholarly contributions. Drs. Judith Head and Khurram Rehman added insight into basic science principles of fetal and placental development, perinatal physiology, and the initiation of parturition. Dr. Marlene Corton provided new illustrations for pelvic anatomy and physiology. Dr. Beverly Rogers helped with a scholarly update of the placenta and its pathology. Considerable advice for obstetrical anesthesia was given by our colleagues Drs. Don Wallace, Shiv Sharma, and Elaine Sidawi. Dr. John Schorge lent substantive insight into gestational trophoblastic disease and Drs. David Hemsell and Chuck Rolle helped to review ectopic pregnancy. Dr. Jodi Dashe was inexhaustible in her efforts to continually update citations concerning all matters genetic. And she along with Drs. Diane Twickler and Rigoberto Santos lent their considerable knowledge and experiences with ultrasonography and Doppler technology as well as with many beautiful photographs. Dr. Jim Alexander provided useful suggestions concerning the conduct of normal and abnormal labor as well as analgesia for labor. Review of information concerning contraception and sterilization was provided by Drs. Gretchen Stuart, Barry Schwarz, and Stephen Heartwell. Help with the topics of obstetrical critical care as well as imaging techniques and cerebral blood flow measurement in eclamptic women came from Dr. Gerda Zeeman who is now at the University of Groningen in The Netherlands. Dr. Nicole Yost provided insight into gastrointestinal disorders as well as preterm birth. Dr. Brian Casey shared his considerable clinical and research expertise with diabetes and thyroid disorders complicating pregnancy. Dr. Jeanne Sheffield was immensely helpful with constant updating of recommendations from the Centers for Disease Control and Prevention for treatment of sexually transmitted diseases and other infections.

It would be impossible to put together a 5000-page typed manuscript without a dedicated team to bring these efforts together. We are deeply indebted to Ms. Connie Utterback for her untiring efforts as Production Coordinator. With the help of Ms. Minnie Tregaskis, Ms. Cynthia Allen, Ms. Marsha Congleton, Ms. Kym Morris, Ms. Dina Trujillano, Ms. Ellen Watkins, as well as the late Ms. Jeanette Cogburn, who we miss greatly, the Dallas group kept the lights burning late into many nights. They were aided by Ms. Belinda Rials and Ms. Rhonda Scott in Birmingham, and Ms. Gerri Lopez in Houston. Expert artistic help was provided by Mr. Scott Bodell who had lent his talents on previous editions. Finally, we were fortunate and privileged to have the expert help of Dr. Barbara Hoffman who served as copy and rewrite editor, English and grammar tutor, and eagle-eyed proofreader who helped to keep us honest with hundreds of randomized controlled trials.

These past few years have been most challenging for those of us dedicated to academic obstetrics; medical student, resident, and fellow training; and contributions to clinical and basic research. Imposition of pounds and mounds of forms and paperwork for Medicare, Medicaid, HIPAA, RRC, billing compliance, and managed care, along with major cuts in funding for health care in general, and indigent health care specifically, have required new dimensions of time taken away from clinical duties. We thus

are indebted to all of those who took up the slack to allow us more time to devote to this edition. We especially cite the efforts of Drs. Barry Schwarz, Karen Bradshaw, Morris Bryant, and Robert Coleman as well as Ms. Judy Wagers and Ms. Janice Walton.

This is the second edition of Williams Obstetrics for which we have been privileged to work closely with the excellent team at McGraw-Hill. Led by Ms. Andrea Seils, we thoroughly enjoyed our interactions with Ms. Karen Davis and Mr. John Williams who have been immensely helpful.

Finally, we thank our families and friends for allowing us to impinge on their time to perform "book duties." We appreciate their patience and encouragement.

FRONT MATTER

SECTION I - OVERVIEW

1. Obstetrics in Broad Perspective

INTRODUCTION

In the 10th edition of *Williams Obstetrics*, Eastman described the word *obstetrics* as being derived from the Latin *obstetrix*, meaning *midwife*. The word also is connected with the verb *obstare*— to *stand by or in front of*. The rationale for this derivation is that the midwife stood by or in front of the parturient. It is intriguing to consider that the derivation of *obstetrics* may have its origins in the evolution of the human species. To do so, we examine the thought-provoking observations of Rosenberg and Trevathan (2002). Their hypothesis dwells on two characteristics that set humans apart from other mammals, that is, that humans are the only mammals that walk on two legs, and that for body size, we have the largest brains. Also, unlike the females of other mammalian species, including other primates, women routinely seek assistance when they give birth.

Rosenberg and Trevathan (2002) propose that women's need for birthing assistance may be the result of this evolved bipedalism and large brain. The challenge of birth for many primates, and especially for humans, is that the size of the newborn's head is very close to the size of the passage through which it must travel. The series of rotations described in [Chapter 17](#) that the human fetus must undergo during childbirth are thought to be related to the evolution of upright locomotion as well as the larger brain. Because of pelvic changes necessary to accommodate bipedalism, the human fetus must negotiate a birth canal that is not constant in cross-section. The pelvic inlet, where the fetus begins its transit, is widest from side to side. Midway through the pelvis, however, the orientation shifts 90 degrees and the widest dimension of the pelvis is from anterior to posterior. This change in pelvic dimensions means that the fetus must negotiate a series of turns as it passes through the birth canal so that its largest dimensions— the head and shoulders— are always aligned with the widest dimension of the birth canal. As a consequence of this rotation, human fetuses predominantly assume the occiput anterior position at delivery. In contrast, occiput posterior delivery is characteristic for nonhuman primates with smaller brains and correspondingly smaller head size. For example, in monkeys, the neonate is born looking up into its mother's face, which makes it possible for the mother to reach down and guide the newborn out of the birth canal. She can also wipe mucus from the baby's face to assist its breathing.

Thus, Rosenberg and Trevathan (2002) propose that human parturients require assistance because they cannot mechanically manage delivery of the occiput anterior vertex without help. They suggest that the triple challenge of a big-brained neonate, a maternal pelvis designed for walking upright, and a rotational delivery in which the infant emerges facing backward were natural selection pressures that favored humans seeking assistance— hence, *obstetrics*.

In the broader sense, obstetrics is concerned with reproduction of the society of humans. The specialty aims to promote health and well-being as the branch of medicine that is concerned with pregnancy, labor, and the puerperium in both normal and abnormal circumstances. The importance of obstetrics is attested to by the observation that maternal and neonatal outcomes are universally used as an index of the quality of health and life in human society. With this in mind, we provide a synopsis of the current state of maternal and newborn health in the United States. Following this is a perspective on some of the forces affecting obstetrics in these early years of the 21st century.

VITAL STATISTICS

The vital statistics of the United States are collected and published through a decentralized, cooperative system (Tolson and colleagues, 1991). Responsibility for the registration of births, deaths, fetal deaths, marriages, divorces, annulments, and induced terminations of pregnancy is vested in the individual states and certain separate governmental entities. The system comprises 57 registration areas: each state, the District of Columbia, New York City, American Samoa, Guam, the Northern Mariana Islands, Puerto Rico, and the Virgin Islands.

The first standard certificates for the registration of live births and deaths were developed in 1900. An act of Congress in 1902 established the Bureau of the Census to develop a system for the annual collection of vital statistics. The overall objective was to develop and maintain a system for registration that is uniform in such matters as forms, procedures, and statistical methodology. The Bureau retained the authority for producing national vital statistics until 1946, when the function was transferred to the United States Public Health Service. It is presently assigned to the Division of Vital Statistics of the National Center for Health Statistics (NCHS). The standard certificate of live birth was substantially revised in 1989 to include much more information on medical and lifestyle risk factors and also obstetrical care practices. Currently, more than 99 percent of births in the United States are registered.

The NCHS is part of the Centers for Disease Control and Prevention (CDC). Its function is to collaborate with colleagues in state vital statistics offices to revise the certificates of live birth and fetal death. This process generally is carried out every 10 to 15 years. Revisions were initiated in some states in 2003, and full implementation in all states will begin in phases over several years. The 2003 revision focuses on fundamental changes in the way the data are collected to accomplish greater accuracy. Changes also include a format conducive to electronic processing, to collect more explicit parental demographic data, and to improve selection of information regarding antepartum and intrapartum complications. Some examples of new data to be collected include that related to uterine rupture, blood transfusion, and pregnancy resulting from infertility treatment.

DEFINITIONS. The uniform use of standard definitions is encouraged by the World Health Organization as well as the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002). Such uniformity allows comparison of data not only between states or regions of the country, but also between countries. It is recommended that United States statistics include all fetuses and neonates born weighing at least 500 g, whether alive or dead. It must be clarified, however, that the states are not uniform in their definition of fetal death. For example, 28 states stipulate that fetal deaths beginning at 20 weeks' gestation should be recorded, eight states report all products of conception as fetal deaths, and still others use birthweights of 350 g, 400 g, or 500 g or greater to identify fetal deaths.

Definitions recommended by the NCHS and the CDC are as follows:

- ✎ • **Perinatal period.** The period after birth of an infant weighing 500 g or more and ending at 28 completed days after birth. When perinatal rates are based on gestational age, rather than birthweight, it is recommended that the perinatal period be defined as commencing at 20 weeks.
- ✎ • **Birth.** The complete expulsion or extraction from the mother of a fetus, irrespective of whether the umbilical cord has been cut or the placenta is attached. Fetuses weighing less than 500 g are usually not considered as births, but rather are termed abortuses for purposes of vital statistics.
- ✎ • **Birthweight.** The weight of a neonate determined immediately after delivery or as soon thereafter as feasible. It should be expressed to the nearest gram.
- ✎ • **Birth rate.** The number of live births per 1000 population.
- ✎ • **Fertility rate.** The number of live births per 1000 females aged 15 through 44 years.
- ✎ • **Live birth.** The term used to record a birth whenever the newborn at or sometime after birth breathes spontaneously, or shows any other sign of life such as a heartbeat or definite spontaneous movement of voluntary muscles. Heartbeats are to be distinguished from transient cardiac contractions, and respirations are to be distinguished from fleeting respiratory efforts or gasps.
- ✎ • **Stillbirth or fetal death.** The absence of signs of life at or after birth.
- ✎ • **Neonatal death.** *Early* neonatal death refers to death of a liveborn neonate during the first 7 days after birth. *Late* neonatal death refers to death after 7 days but before 29 days.
- ✎ • **Stillbirth rate or fetal death rate.** The number of stillborn neonates per 1000 neonates born, including live births and stillbirths.
- ✎ • **Neonatal mortality rate.** The number of neonatal deaths per 1000 live births.
- ✎ • **Perinatal mortality rate.** The number of stillbirths plus neonatal deaths per 1000 total births.
- ✎ • **Infant death.** All deaths of liveborn infants from birth through 12 months of age.
- ✎ • **Infant mortality rate.** The number of infant deaths per 1000 live births.
- ✎ • **Low-birthweight.** A newborn whose weight is less than 2500 g.
- ✎ • **Very-low-birthweight.** A newborn whose weight is less than 1500 g.
- ✎ • **Extremely-low-birthweight.** A newborn whose weight is less than 1000 g.
- ✎ • **Term neonate.** A neonate born anytime after 37 completed weeks of gestation and up until 42 completed weeks of gestation (260 to 294 days).
- ✎ • **Preterm neonate.** A neonate born before 37 completed weeks (the 259th day).
- ✎ • **Postterm neonate.** A neonate born anytime after completion of the 42nd week, beginning with day 295.
- ✎ • **Abortus.** A fetus or embryo removed or expelled from the uterus during the first half of gestation ✎— 20 weeks or less ✎— and weighing less than 500 g.
- ✎ • **Induced termination of pregnancy.** The purposeful interruption of an intrauterine pregnancy with the intention other than to produce a liveborn neonate, and which does not result in a live birth. This definition excludes retention of products of conception following fetal death.
- ✎ • **Direct maternal death.** The death of the mother resulting from obstetrical complications of pregnancy, labor, or the puerperium, and from interventions, omissions, incorrect treatment, or a chain of events resulting from any of these factors. An example is maternal death from exsanguination after uterine rupture.
- ✎ • **Indirect maternal death.** A maternal death not directly due to an obstetrical cause, but resulting from previously existing disease, or a disease that developed during pregnancy, labor, or the puerperium, but which was aggravated by maternal physiological adaptation to pregnancy. An example is maternal death from complications of mitral valve stenosis.
- ✎ • **Nonmaternal death.** Death of the mother resulting from accidental or incidental causes not related to pregnancy. An example is death from an automobile accident or concurrent malignancy.
- ✎ • **Maternal mortality ratio.** The number of maternal deaths that result from the reproductive process per 100,000 live births. Used more commonly, but less accurately, are the terms *maternal mortality rate* or *maternal death rate*. The term *ratio* is more accurate because it includes in the numerator the number of deaths regardless of pregnancy outcome ✎— for example, live births, stillbirths, ectopic pregnancies ✎— while the denominator includes the number of live births.

In 1987, the CDC collaborated with the Maternal Mortality Special Interest Group of the American College of Obstetricians and Gynecologists, the Association of Vital Records and Health Statistics, and state and local health departments to initiate the National Pregnancy Mortality Surveillance System. Two new terms were introduced:

☛ **Pregnancy-associated death.** The death of any woman, from any cause, while pregnant or within 1 calendar year of termination of pregnancy, regardless of the duration and the site of pregnancy.

☛ **Pregnancy-related death.** A pregnancy-associated death resulting from (1) complications of the pregnancy itself, (2) the chain of events initiated by the pregnancy that led to death, or (3) aggravation of an unrelated condition by the physiological or pharmacological effects of the pregnancy that subsequently caused death.

PREGNANCY IN THE UNITED STATES

Data from diverse sources have been used to provide the following snapshot of pregnancy during the early years of the 21st century in the United States.

In 2002, the fertility rate of women aged 15 to 44 years was 64.8 live births per 1000 women (Sutton and colleagues, 2004). The fertility rate has been trending downward for Caucasian, African-American, and Hispanic women since 1990, when the rate was 70.9 per 1000. The rates of reproduction since 1990 were below replacement births, indicating a population decline (Hamilton, 2004). This decline, however, has been compensated by considerable net migration into the United States. For example, there were more than 1 million migrants each year from 2000 to 2002.

There were 4,021,726 live births in 2002, which when offset by 2,447,864 deaths, resulted in a net population increase of 1.6 million people (Kochanek and colleagues, 2004; Martin and colleagues, 2003). The 2002 birth rate for the United States fell to the lowest rate ever recorded at 13.9 per 1000 population. Hispanic women accounted for more than 1 in 5 births. American women average 3.2 pregnancies over their lifetimes, and 1.8 of these are considered wanted pregnancies (Ventura and colleagues, 1999). After exclusion of fetal losses and induced terminations, American women on average deliver 2.0 live births in a lifetime. Using 1996 as an example, there were 6.24 million pregnancies in the United States; 62 percent ended with live births, 22 percent ended by induced terminations, and 16 percent were spontaneous abortions ([Fig. 1-1](#)).

Prenatal care is a major component of the U.S. health care scene. In 2001, delivery was the second leading cause of hospitalization behind heart disease (Hall and DeFrances, 2003). The average length of hospital stay for all deliveries was 2.5 days. Prenatal care was the fourth leading reason for office visits to physicians and accounted for nearly 20 million visits in 2001 (Cherry and co-authors, 2003). Nondelivery hospitalizations have decreased substantially since the late 1980s due to efforts to minimize expenditures. The leading indication for hospitalization unrelated to delivery was preterm labor. Nicholson and co-workers (2000) estimated that the total national cost of hospitalization for preterm labor that did not eventuate in delivery was \$360 million in 1996 dollars. This sum increased to \$820 million when women with preterm labor who actually delivered early were added.

Figure 1-1. Results of 6,240,000 pregnancies in the United States, 1996. (Data from Ventura and colleagues, 1999.)

HEALTHY PEOPLE 2010

In 1991, the U.S. Department of Health and Human Services issued a report titled *Healthy People 2000*. In this report, 17 goals were proposed to improve the health of mothers and infants by the year 2000. Unfortunately, progress was made in only eight of these areas. Notable gains were made in the areas of infant death, fetal death, cesarean delivery (particularly repeat cesareans), breast feeding, prenatal care, hospitalization for pregnancy complications, tobacco abstinence during pregnancy, and screening for fetal abnormalities and genetic disorders. Although no progress was made toward four other goals, there also was no regression in these areas, which included maternal deaths, fetal alcohol syndrome, and low-birthweight neonates. For the remaining five objectives, unfortunately, movement was away from the target.

New objectives for maternal and infant health have been promulgated for the current decade as *Healthy People 2010*. Some of these goals are shown in [Table 1-1](#). One other goal is a new indicator of maternal health: maternal morbidity during labor and delivery (Danel and colleagues, 2003).

INFANT DEATHS. There were 27,523 infant deaths in 2001, and as shown in [Figure 1-2](#), two thirds of these were neonatal deaths within the first 28 days of life. When analyzed by birthweight, two thirds of infant deaths were in low-birthweight neonates ([Fig. 1-3](#)). Of particular interest are those births less than 500 g, for which neonatal intensive care can now be offered. In 2001, there were 6450 liveborn infants weighing less than 500 g; 86 percent of these infants died during the first 28 days of life. Of the 1044 who survived the first 28 days of life, 934 ☛— 11 percent of all births less than 500 g ☛—survived infancy.

There were 27,977 infant deaths in 2002 for a rate of 7.0 per 1000 live births compared with 6.8 in 2001 (Kochanek and Smith, 2004). This slight increase in infant mortality between 2001 and 2002 is the first numerical increase since the period that included 1957 through 1978. The increase was concentrated in the neonatal period, particularly the first week of life. The percentage of neonates born preterm and low birthweight rose in 2002, continuing a long-term upward trend. St. John and associates (2000) have estimated the total cost of initial care in the United States for all newborns as \$10.2 billion annually. Almost 60 percent of this expenditure is attributed to preterm births before 37 weeks, and 12 percent is spent on neonates born between 24 and 26 weeks.

Figure 1-2. Infant deaths from birth through 12 months — United States, 2001. (Data from Matthews and colleagues, 2003.)

Figure 1-3. Infant deaths from birth through 12 months according to birthweight — United States, 2001. (Data from Matthews and co-workers, 2003.)

MATERNAL DEATHS. The health of pregnant women also is an important indicator of national health care. In 2002, a total of 336 maternal deaths were identified by vital statistics (Kochanek and Smith, 2004). Importantly and unfortunately, it is estimated that more than half of maternal deaths are not recorded as such (Koonin and colleagues, 1997). One major accomplishment of obstetrical care was that the risk of death from pregnancy complications decreased almost 99 percent during the 20th century. The ratio of approximately 850 maternal deaths per 100,000 live births in 1900 decreased to 7.5 in 1982 (Chang and colleagues, 2003). Since 1982, however, maternal mortality in the United States has not decreased further.

As shown in [Figure 1-4](#), maternal mortality is related to age and race. Shown in [Table 1-2](#) are the causes of pregnancy-related maternal deaths. Hemorrhage and infection are prominent causes of death in ectopic pregnancies and abortions, whereas hypertension, embolism, hemorrhage, and infection are the leading causes of maternal death in women delivered after midpregnancy. There continues to be significant disparity with increased maternal deaths in minority and indigent populations (Anachebe and Sutton, 2003).

Figure 1-4. Pregnancy-related maternal mortality ratios by age and race — United States, 1991-1999. Deaths per 100,000 live births. (From Chang and colleagues, 2003, with permission.)

PERSPECTIVES ON OBSTETRICS

There are a number of areas in obstetrics in which societal factors — whether within society at large or within the profession of obstetrics — are influencing reproduction in the United States. Many of these are stimulated or influenced by economics, politics, and religion. There is very much *right* with obstetrics. Three examples were cited by Dr. John Gibbons (2003) in his presidential address to the American College of Obstetricians and Gynecologists: advances in basic science, clinical practice, and social dynamics of women's health care. At the same time, he also cited three serious problems, among them recruitment of medical students, changes in residency training, and the new face of private and academic practice. Frigoletto and Greene (2002) have also provided a thoughtful review of those changes, and we now include some of these that currently have an impact on obstetrics as a specialty.

RISING CESAREAN DELIVERY RATE. In 2002, the cesarean delivery rate climbed to the highest level ever reported in the United States — 26.1 percent (Martin and colleagues, 2003). The escalation in the total cesarean delivery rate was fueled by both a rise in the primary cesarean delivery rate and a steep decline in the rate of vaginal birth after cesarean (VBAC) delivery. The forces involved in these changes in cesarean delivery rates are multifactorial and complex. For example, as discussed in [Chapter 17](#), the major indication for primary cesarean delivery is dystocia, and there is evidence that this diagnosis has increased. This increase, at least in part, is due to greater maternal size, lower parity, and more advanced age. The sharp decline in VBAC deliveries is likely related to the uterine rupture risk associated with VBAC and attendant legal pressures (see [Chap. 26](#)). In defense of cesarean delivery, Matthews and co-authors (2003) have reported a consistent association between increasing cesarean delivery rates and falling perinatal death rates ([Fig. 1-5](#)).

Other forces undoubtedly involved in the record rate of cesarean deliveries include routine cesarean delivery for breech presentation (see [Chap. 24](#)) and increased induction of labor (see [Chap. 22](#)). An emerging factor is patient choice — or cesarean delivery on request. An emerging impetus for such requests is the desire to prevent pelvic floor injury, thus reducing the incidence of incontinence of stool, flatus, and urine, as well as pelvic organ prolapse (Minkoff and Chervenak, 2003).

Figure 1-5. Scatter plot of cesarean delivery rate versus perinatal death rate in three Dublin hospitals, 1979-2000. (From Matthews and co-authors, 2003, with permission.)

WOMEN IN OBSTETRICS. The gender of the obstetrical workforce in the United States has undergone a rapid transformation in the past 20 years (Benedetti and colleagues, 2004). The proportion of women practitioners has increased from 12 percent in 1980 to 32 percent in 2000 and is expected to increase to 50 percent by 2014 (American College of Obstetricians and Gynecologists, 1999). Currently, more than 70 percent of obstetrical residents are women (Association of American Medical Colleges, 2003). Good things undoubtedly will accrue from these changes. Frigoletto and Greene (2002) have identified some of these benefits, which include (1) meeting the preferences of many patients for female obstetricians, (2) heightened sensitivity to the need to balance the demands of work and raising a family, and (3) safer patient care by decreasing often inhumanly long work hours. As described so aptly by Dr. Vivian Dickerson (2004) in her presidential address

to the American College of Obstetricians and Gynecologists: "... who we are transcends gender."

That said, there are also concerns about these changes (Chan and Willett, 2004). For example, female obstetricians-gynecologists are less likely to continue to practice obstetrics because of concerns about balance between work and family life. One potential consequence of this phenomenon is that the increasing proportion of women in the obstetrical workforce will ultimately lead to a decline in the availability of obstetricians as early as 2010 (Pearse and colleagues, 2001a).

MEDICAL STUDENTS AND OBSTETRICAL RESIDENCIES. The declining number of medical school graduates for residency training in obstetrics and gynecology is of concern. This decline has been attributed to multiple reasons identified in the survey by Pearse and co-workers (2001b). The most commonly cited reason was lifestyle and family issues (45 percent), followed closely by malpractice issues (41 percent), and low reimbursement (35 percent).

According to Zuger (2004) the entire profession of medicine has been similarly affected. Dissatisfaction with the practice of medicine increased from 15 percent in 1973 to as high as 40 percent by 1995. And in a follow-up survey in 2001, 58 percent of physicians described "declining enthusiasm" and 87 percent felt that the overall morale of physicians had declined since the first survey in 1981 (Kaiser Family Foundation, 2003). Cited as the major reason for physician dissatisfaction was the deleterious effect on the quality of medical practice by managed care. The malpractice crisis — more accurately, the *liability crisis* — also was frequently cited. In their recent survey, Bettes and co-workers (2004) cited pressures from liability insurance costs as having a more negative impact on satisfaction than managed care. According to Zuger (2004), even those physicians who were not financially burdened cited defensive medicine to thwart potential litigation as being "widely deplored as a growing blight on medical practice."

We conclude, as did Gibbons (2003), that our specialty has not done an adequate job of emphasizing the positive and satisfying aspects to our students. We need to remind them that obstetricians practice in groups that provide reasonable call schedules. The mandate for 80-hour workweeks for residents intersects with the increasing emphasis on lifestyle and patient safety issues (Gaba and Howard, 2002).

PROFESSIONALISM AND MARKET FORCES. Swick (2001), delivering the President's Program at the 2000 Annual Meeting of the American College of Obstetricians and Gynecologists, observed that "Medicine today is under siege from market forces in the new corporate age and that its professional values, indeed, its very identity as a profession, are under threat." Shown in [Table 1-3](#) is the juxtaposition of business versus professional values. Swick concluded that the profession of medicine, viz., obstetrics, must exercise professionalism by advocating the interests of our patients. We are in complete accord.

MEDICAL LIABILITY. Lockwood (2002) has reviewed the professional liability crisis in American obstetrics. The average obstetrician is sued 2.5 times during his or her career and about 75 percent of obstetricians have been sued at least once. Almost 50 percent of obstetrical claims were for neurologically impaired infants or stillbirths. About half of the claims are dropped by the plaintiff attorney or found to be without merit. There has been a steady escalation, however, in the value of awards, with the median award now nearly 1 million dollars. As shown in [Table 1-4](#), professional liability insurance premiums have continued to escalate after a brief respite in the mid-1990s. According to Lockwood (2002), the cost of malpractice coverage passed on to patients added \$350 to annual health care premiums for the average American family!

The furor raised by the most outrageous payouts has caused a grassroots tort reform that has been successful in limiting noneconomical damages in some states. Despite this, the American Medical Association recently identified 18 states in which availability of affordable liability insurance was a grave concern (Mello and colleagues, 2003). Contrary to what is alleged by the relatively small number of plaintiff attorneys who personally profit from huge settlements, the crisis has resulted in sparse or no medical care in some areas. Could it be possible that this has caused more morbidity, mortality, and pain and suffering than bad medical outcomes, with or without errors in judgment? Some physicians may take solace in knowing that a 1999 study identified increasing rates of unhappiness among lawyers over the past decade, and that many were planning to leave their profession (Schlitz and associates, 1999). Hopefully this will include the most avaricious plaintiff attorneys!

TECHNOLOGY. Since 1983, when the first infant was conceived from in vitro fertilization (IVF) in the United States, the use of IVF and related procedures — assisted reproductive technology — has increased substantially (Schieve and colleagues, 2002). This technology has resulted in record numbers of multiple births, especially higher-order multiples involving three or more fetuses, with all of the attendant complications. Starting about 1998, the rate of higher-order multiple births began to decline slightly (Martin and colleagues, 2003). This decline likely can be attributed to national guidelines published in 1997 recommending transfer of fewer embryos (Jain and colleagues, 2004). Another effect of technology is the rapid evolution in the maternal-fetal relationship due to advances in imaging, prenatal diagnostics, genetic screening, and fetal surgery (van Dis, 2003).

BIRTHS TO IMMIGRANTS. Persons born outside the United States comprised an estimated 11 percent of the population in 2000, and approximately 20 percent of all U.S. births in 2000 were to women in this population (Sappenfield and colleagues, 2002). Hispanic women, particularly immigrants from Mexico, accounted for most of the births to persons born outside the United States. Women born outside the United States had better birth outcomes than their state-born racial or ethnic counterparts. The reasons for the improved outcomes are unclear. One theory is that women who immigrate are healthier than those who do not. Surgeon General Richard Carmona has called for an end to health care delivery inequalities for Hispanics and African-Americans (*Dallas Morning News*, August 17, 2002).

UNINSURED PEOPLE. The number of people in the United States without health insurance and the consequent strain on the entire health care system constitute a major public policy issue (McLellan, 2003). It is estimated that nearly one third of the nonelderly population, or about 7 million people, lacked health insurance for some part of 2001 and 2002. Hispanics and African-Americans were most likely to be uninsured. Approximately 80 percent of the uninsured were in working families. Factors implicated in this public health crisis include the economic revolution in medicine, whereby the pressure for profitability is closing the doors on the uninsured and concentrating them in public facilities (Ferrer, 2001). This phenomenon

already has had a significant impact on pregnant women. For example, 40 percent of the births in Dallas County, Texas, occur at Parkland Hospital, which is the only public facility for the uninsured. Unfortunately, current attitudes about taxes have decimated the budgets of many of these public hospitals.

ABORTION. Even before President George W. Bush had a chance to sign the Partial Birth Abortion Act of 2003, opponents had filed court challenges to block its implementation. Indeed, as of June 2004, at least one court has ruled this act to be unconstitutional. The editorial board of *The Lancet* (2003) has suggested that the Partial Birth Abortion Act will only serve to further divide the United States over the issue of abortion. It is important to recognize that abortion can have a significant effect on infant mortality. Liu and colleagues (2002) analyzed the impact of prenatal diagnosis and resultant pregnancy terminations in Canada between 1991 and 1998. A large decrease in infant deaths due to congenital anomalies was associated with a decline in the overall infant mortality in Canada.

BIRTH CONTROL. In its legislative agenda, the Bush administration has taken aim at the recent innovation in birth control consisting of over-the-counter availability of the *morning-after pill*. Barr Pharmaceuticals applied to the Food and Drug Administration for nonprescription sales of *Plan B*, which is described in [Chapter 32](#) (see p. 745). During a joint session, the Nonprescription Drug Advisory Committee and the Committee for Reproductive Health Drugs approved the application for over-the-counter sales by a vote of 23 to 4. Presumably concerned about "teenager abuse," and presumably with political pressure from within the Bush administration, the application was denied. Appropriate umbrage has been expressed by Dickerson (2004), Drazen and colleagues (2004), Lockwood and Greene (2004), and Steinbrook (2004).

Governmental interference with women's reproductive rights is not new, of course. In 1998, Congress considered the Title X Parental Notification Act, which would mandate parental notification for minors seeking contraception at federally funded clinics. In the study by Reddy and colleagues (2002), this would have dissuaded almost half of girls younger than 17 years of age from seeking testing or treatment for human immunodeficiency virus (HIV) infection or other sexually transmitted disease. As usual, poor women would suffer disparately.

THE FUTURE. Early into the 21st century, our specialty finds itself faced not only with the many complicated social issues just discussed, but also with many of the same fundamental clinical questions that puzzled our predecessors. What initiates labor at term? What initiates labor prematurely? What causes preeclampsia, and can it be prevented?

As discussed throughout this 22nd edition of *Williams Obstetrics*, much has been accomplished to begin to answer these and other important questions. That said, however, a massive amount of work remains. In our view, the future of obstetrics relies on our continued ability to attract talented individuals to the specialty. And although there are several reasons to question whether one should dedicate one's life to obstetrics, we agree with the description chosen by Dr. John Gibbons (2003). In his previously cited presidential address to the American College of Obstetricians and Gynecologists, he described obstetrics as "vital," "fascinating," and "satisfying." We would add that it is also "incredibly fun." Thus, our hope for the future is that we will continue to attract individuals who will dedicate themselves to this special field and join in the quest to help women safely through pregnancy, thus guaranteeing the best possible beginning for the children of the next generation.

SECTION II - ANATOMY AND PHYSIOLOGY

2. Maternal Anatomy

INTRODUCTION

The organs of reproduction of women are classified as either external or internal. There may be marked variation in anatomical structures in a given woman, and this is especially true for major blood vessels and nerves.

EXTERNAL GENERATIVE ORGANS

The *pubenda* — commonly designated the *vulva* — includes all structures visible externally from the pubis to the perineum, that is, the mons pubis, labia majora and minora, clitoris, hymen, vestibule, urethral opening, and various glandular and vascular structures ([Fig. 2-1](#)). The embryology of the external genitalia is discussed in [Chapter 4](#) (see [Fig. 4-17](#), p. 113).

Figure 2-1. External female reproductive organs. The lower anterior vaginal wall is visible through the labia minora. In nulliparous women, the vaginal orifice is not so readily visible (*inset*) because of the close apposition of the labia minora.

Figure 4-17. Gender differentiation. Genetic sex is established at the time of fertilization. At a time thereafter, the primordial gonad differentiates to testis if the *SRY* gene is expressed. The fetal testicular secretions effect male phenotypic gender differentiation.

MONS PUBIS. The mons pubis, or mons veneris, is the fat-filled cushion that lies over the symphysis pubis. After puberty, the skin of the mons pubis is covered by curly hair that forms the escutcheon. In women, it is distributed in a triangular area, the base of which is formed by the upper margin of the symphysis. In men, the escutcheon is not so well circumscribed.

LABIA MAJORA. These structures vary somewhat in appearance, principally according to the amount of fat that is contained within the tissues. Embryologically, the labia majora are homologous with the male scrotum. The round ligaments terminate at the upper borders. After repeated childbearing, the labia majora are less prominent. They are 7 to 8 cm in length, 2 to 3 cm in width, and 1 to 1.5 cm in thickness, and are somewhat tapered at the lower extremities. In children and nulliparous women (see [Fig. 2-1](#)), the labia majora usually lie in close apposition, whereas in multiparous women, they may gape widely. They are continuous directly with the mons pubis above and merge into the perineum posteriorly at a site where they are joined medially to form the *posterior commissure*.

Before puberty, the outer surface of the labia is similar to that of the adjacent skin, but after puberty the labia are covered with hair. In nulliparous women, the inner surface is moist and resembles a mucous membrane, whereas in multiparous women, the inner surface becomes more skinlike. The labia majora are richly supplied with sebaceous glands. Beneath the skin, there is a layer of dense connective tissue that is rich in elastic fibers and adipose tissue but is nearly void of muscular elements. Unlike the squamous epithelium of the vagina and cervix, there are epithelial appendages in parts of the vulvar skin. A mass of fat beneath the skin provides the bulk of the volume of the labium, and this tissue is supplied with a rich plexus of veins.

LABIA MINORA. The labia minora vary greatly in size and shape. In nulliparous women, they usually are not visible behind the nonseparated labia majora. In multiparas, it is common for the labia minora to project beyond the labia majora.

Each labium minus is a thin fold of tissue that is moist and reddish, similar in appearance to a mucous membrane. The labia minora are covered by stratified squamous epithelium. Although there are no hair follicles in the labia minora, there are many sebaceous follicles and, occasionally, a few sweat glands. The interior of the labial folds is composed of connective tissue with many vessels and some smooth muscular fibers. They are supplied with a variety of nerve endings and are extremely sensitive. The tissues of the labia minora converge superiorly, where each is divided into two lamellae; the lower pair fuse to form the *frenulum of the clitoris*, and the upper pair merge to form the *prepuce*. Inferiorly, the labia minora extend to approach the midline as low ridges of tissue that fuse to form the *fourchette*.

CLITORIS. The clitoris is the principal female erogenous organ. It is the homologue of the penis and is located near the superior extremity of the vulva. This erectile organ projects downward between the branched extremities of the labia minora. The clitoris is composed of a glans, a corpus, and two crura. The glans is made up of spindle-shaped cells, and in the body there are two corpora cavernosa, in the walls of which are smooth muscle fibers. The long, narrow crura arise from the inferior surface of the ischiopubic rami and fuse just below the middle of the pubic arch to form the corpus.

The clitoris rarely exceeds 2 cm in length. Its free end is pointed downward and inward toward the vaginal opening. The glans is usually less than 0.5 cm in diameter and is covered by stratified squamous epithelium that is richly supplied with nerve

endings. The vessels of the erectile clitoris are connected with the vestibular bulbs.

There is a delicate network of free nerve endings in the labia majora, labia minora, and clitoris (Krantz, 1958). Tactile discs are found in abundance in these areas. Genital corpuscles, which are mediators of erotic sensation, vary considerably in number. These structures are abundant in the labia minora and in the skin that overlies the glans clitoris.

VESTIBULE. The vestibule is an almond-shaped area that is enclosed by the labia minora laterally and extends from the clitoris to the fourchette. The vestibule is the functionally mature female structure of the urogenital sinus of the embryo. In the mature state, the vestibule usually is perforated by six openings: the urethra, the vagina, the two ducts of the Bartholin glands, and, at times, the two ducts of the paraurethral glands, also called the *Skene ducts and glands* (Fig. 2-2). The posterior portion of the vestibule between the fourchette and the vaginal opening is called the *fossa navicularis*, and it is usually observed only in nulliparous women.

The pair of *Bartholin glands* (see Fig. 2-2) are about 0.5 to 1 cm in diameter, and each is situated beneath the vestibule on either side of the vaginal opening. They are the *major vestibular glands*, and the ducts are 1.5 to 2 cm long and open on the sides of the vestibule just outside the lateral margin of the vaginal orifice. At times of sexual arousal, they secrete mucoid material. These glands may harbor *Neisseria gonorrhoeae* or other bacteria, which in turn may cause infection and a Bartholin gland abscess.

Urethral Opening. The lower two thirds of the urethra lies immediately above the anterior vaginal wall. The urethral opening or meatus is in the midline of the vestibule, 1 to 1.5 cm below the pubic arch, and a short distance above the vaginal opening. Ordinarily, the *paraurethral ducts*, also known as the *Skene ducts*, open onto the vestibule on either side of the urethra (see Fig. 2-2). The ducts occasionally open on the posterior wall of the urethra just inside the meatus.

Vestibular Bulbs. Embryologically, the vestibular bulbs correspond to the anlage of the corpus spongiosum of the penis. These are almond-shaped aggregations of veins, 3 to 4 cm long, 1 to 2 cm wide, and 0.5 to 1 cm thick, that lie beneath the mucous membrane on either side of the vestibule. They are in close apposition to the ischiopubic rami and are partially covered by the ischiocavernosus and constrictor vaginae muscles. The vestibular bulbs terminate interiorly at about the middle of the vaginal opening and extend upward toward the clitoris. During childbirth, they may be injured and may even rupture to form a vulvar hematoma.

Vaginal Opening and Hymen. In most virginal women, the vaginal opening most often is hidden by the overlapping labia minora. There are marked differences in shape and consistency of the hymen, which is composed mainly of elastic and collagenous connective tissue. Both the outer and inner surfaces are covered by stratified squamous epithelium. The hymen has no glandular or muscular elements, and it is not richly supplied with nerve fibers.

In the newborn, the hymen is very vascular and redundant. In pregnant women, its epithelium is thick, and the tissue is rich in glycogen. After menopause, the epithelium is thin, and focal cornification may develop. In adult women, the hymen is a membrane of various thickness that surrounds the vaginal opening more or less completely. Its aperture varies in diameter from pinpoint size to one that admits the tip of one or even two fingers.

The appearance of the hymen cannot be used to determine whether a woman has begun sexual activity. A fimbriated type of hymen in virginal women may be indistinguishable from one that has been penetrated during intercourse. As a rule, however, it is torn at several sites during first coitus, usually in the posterior portion. Identical tears may occur by other penetration, for example, tampons used during menstruation. The edges of the torn tissue soon cicatrize, and the hymen becomes divided permanently into two or more portions that are separated by narrow sulci. Occasionally with hymenal rupture, there may be profuse bleeding.

Changes produced in the hymen by childbirth are usually readily recognizable. Over time, the hymen consists of several cicatrized nodules of various sizes. *Imperforate hymen* is a rare lesion in which the vaginal orifice is occluded completely, causing retention of menstrual blood (see Chap. 40, p. 950).

Figure 2-2. The external genitalia with the skin and subcutaneous tissue removed from the right side.

VAGINA. This musculomembranous structure extends from the vulva to the uterus and is interposed anteriorly and posteriorly between the urinary bladder and the rectum (Fig. 2-3). The upper portion of the vagina arises from the mullerian ducts, and the lower portion is formed from the urogenital sinus. Anteriorly, the vagina is separated from the bladder and urethra by connective tissue, often referred to as the *vesicovaginal septum*. Posteriorly, between the lower portion of the vagina and the rectum, there are similar tissues that together form the *rectovaginal septum*. The upper fourth of the vagina is separated from the rectum by the *rectouterine pouch*, also called the *cul-de-sac of Douglas*.

Normally, the anterior and posterior vaginal walls lie in contact, with only a slight space intervening between the lateral margins. Vaginal length varies considerably, but commonly, the anterior and posterior vaginal walls are, respectively, 6 to 8 cm and 7 to 10 cm in length. The upper end of the vaginal vault is subdivided into the anterior, posterior, and two lateral fornices by the uterine cervix. These are of considerable clinical importance because the internal pelvic organs usually can be palpated through their thin walls. Moreover, the posterior fornix provides surgical access to the peritoneal cavity.

Prominent midline longitudinal ridges project into the vaginal lumen from the anterior and posterior walls. In nulliparous

women, numerous transverse ridges, or *rugae*, extend outward from and almost at right angles to the longitudinal ridges. In postmenopausal multiparous women, the vaginal walls often are smooth.

The vaginal mucosa is composed of noncornified stratified squamous epithelium. Beneath the epithelium is a thin fibromuscular coat, usually consisting of an inner circular layer and an outer longitudinal layer of smooth muscle. A thin layer of connective tissue beneath the mucosa and the muscularis is rich in blood vessels. It is controversial whether this connective tissue—often referred to as *perivaginal endopelvic fascia*—is a definite fascial plane in the strict anatomical sense.

There are no vaginal glands. After giving birth, fragments of stratified epithelium occasionally are embedded in the vaginal connective tissue. They may form *vaginal inclusion cysts*, which are not true glands. In the absence of glands, the vagina is kept moist by a small amount of secretion from the cervix. During pregnancy, there is copious, acidic vaginal secretion, which normally consists of a curdlike product of exfoliated epithelium and bacteria. *Lactobacillus* species are also recovered in higher concentrations than in nonpregnant women (Larsen and Galask, 1980; McGregor and French, 2000).

The vagina has an abundant vascular supply. The upper third is supplied by the cervicovaginal branches of the uterine arteries, the middle third by the inferior vesical arteries, and the lower third by the middle rectal and internal pudendal arteries. The vaginal artery may branch directly from the internal iliac artery. An extensive venous plexus immediately surrounds the vagina and follows the course of the arteries. Lymphatics from the lower third of the vagina, along with those of the vulva, drain primarily into the inguinal lymph nodes. Those from the middle third drain into the internal iliac nodes, and those from the upper third drain into the iliac nodes.

Figure 2-3. Sagittal section of the pelvis of an adult woman showing relations of pelvic viscera.

PERINEUM. The many structures that make up the perineum are illustrated in [Figure 2-4](#). Most of the support of the perineum is provided by the pelvic and urogenital diaphragms. The *pelvic diaphragm* consists of the levator ani muscles plus the coccygeus muscles posteriorly. The levator ani muscles form a broad muscular sling that originates from the posterior surface of the superior pubic rami, from the inner surface of the ischial spine, and between these two sites, from the obturator fascia. Some of these muscle fibers are inserted around the vagina and rectum to form efficient functional sphincters. In a recent study utilizing magnetic resonance imaging, Tunn (2003) and Hoyte (2004) and their colleagues used magnetic-resonance imaging and reported significant variation in the levator ani muscle, endopelvic fascia, and urethral support in nulliparous women. The *urogenital diaphragm* is external to the pelvic diaphragm and includes the triangular area between the ischial tuberosities and the symphysis. The urogenital diaphragm is made up of the deep transverse perineal muscles, the constrictor of the urethra, and the internal and external fascial coverings.

The external anal sphincter is shown in [Figure 2-4](#), where its proximity to the posterior vaginal fourchette is apparent. The relationship of the internal and external sphincter is shown in [Figure 2-5](#). Damage to either sphincter increases the likelihood of rectal incontinence following vaginal delivery (Delancey and co-workers, 1997). Repair of the disrupted sphincter is shown in [Figure 17-36](#) (see p. 438).

The major blood supply to the perineum is via the internal pudendal artery and its branches. These include the inferior rectal artery and posterior labial artery. The innervation of the perineum is primarily via the pudendal nerve and its branches. The pudendal nerve originates from the S2, S3, and S4 level of the spinal cord.

Perineal Body. The median raphe of the levator ani, between the anus and the vagina, is reinforced by the central tendon of the perineum. The bulbocavernosus, superficial transverse perineal, and external anal sphincter muscles also converge on the central tendon. Thus, these structures contribute to the perineal body, which provides much of the support for the perineum.

Figure 2-4. The perineum. The more superficial components are illustrated above and the deeper structures below. (a. = artery; Ext. = external; Int. = internal; lig. = ligament; m. = muscle; Post. = posterior; Sup. = superior; transv. = transverse; v = vein.)

Figure 2-5. Anatomy of the anorectum, drawn to show relations of the internal anal sphincter, the external anal sphincter, and the levator ani muscles.

Figure 17-36. Layered repair of a fourth-degree perineal laceration. **A.** Approximation of the anorectal mucosa and submucosa in a running or interrupted fashion using fine absorbable suture such as 3-0 or 4-0 chromic or Vicryl. The superior extent of the anterior anal laceration is identified and the sutures are placed through the submucosa of the anorectum approximately 0.5 cm apart down

to the anal verge. **B.** A second layer is placed through the rectal muscularis using 3-0 Vicryl suture in a running or interrupted fashion. This "reinforcing layer" should incorporate the torn ends of the internal anal sphincter, which is identified as the thickening of the circular smooth muscle layer at the distal 2 to 3 cm of the anal canal. It can be identified as the glistening white fibrous structure lying between the anal canal submucosa and the fibers of the external anal sphincter (EAS). In many cases, the internal sphincter retracts laterally and must be sought and retrieved for repair. **C.** The disrupted ends of the striated EAS muscle and capsule are then identified and grasped with Allis clamps. The torn ends of the EAS often retract laterally in an asymmetrical fashion as shown. **D.** Traditional end-to-end approximation of the EAS. Four to six simple interrupted 2-0 or 3-0 Vicryl sutures are placed at the 3, 6, 9, and 12 o'clock positions through the EAS muscle and its connective tissue capsule. The sutures through the inferior and posterior portions of the sphincter should be placed first and tied last to facilitate this part of the repair. The remainder of the repair is similar to that described for a midline episiotomy in [Figure 17-35](#).

INTERNAL GENERATIVE ORGANS

UTERUS. The nonpregnant uterus is situated in the pelvic cavity between the bladder anteriorly and the rectum posteriorly. Almost the entire posterior wall of the uterus is covered by serosa, or peritoneum, the lower portion of which forms the anterior boundary of the *recto-uterine cul-de-sac*, or pouch of Douglas. Only the upper portion of the anterior wall of the uterus is so covered ([Fig. 2-6](#)). The lower portion is united to the posterior wall of the bladder by a well-defined loose layer of connective tissue (see [Fig. 2-3](#)).

Size and Shape. The uterus resembles a flattened pear in shape (see [Fig. 2-6](#)). It consists of two major but unequal parts: an upper triangular portion, the *body*, or corpus; and a lower, cylindrical, or fusiform portion, the *cervix*, which projects into the vagina. The *isthmus* is that portion of the uterus between the internal cervical os and the endometrial cavity. It is of special obstetrical significance because it forms the lower uterine segment during pregnancy. The oviducts, or fallopian tubes, emerge from the *cornua* of the uterus at the junction of the superior and lateral margins. The convex upper segment between the points of insertion of the fallopian tubes is called the *fundus*. The round ligaments insert below the tubes on the anterior side. They are covered by a fold of peritoneum that extends to the pelvic sidewall. These folds are called the *broad ligaments*, however, they do not constitute the anatomical definition of a ligament.

The prepubertal uterus varies in length from 2.5 to 3.5 cm (Orsini and colleagues, 1984). The uterus of adult nulliparous women is from 6 to 8 cm in length as compared with 9 to 10 cm in multiparous women. Uteri of nonparous women average 50 to 70 g, and those of parous women average 80 g or more (Langlois, 1970). In the premenarchal girl, the body of the uterus is only half as long as the cervix. In nulliparous women, the two are about equal in length. In multiparous women, the cervix is only a little more than a third of the total length of the organ. After menopause, uterine size decreases as a consequence of atrophy of both myometrium and endometrium.

The bulk of the body of the uterus, but not the cervix, is composed of muscle. The inner surfaces of the anterior and posterior walls lie almost in contact, and the cavity between these walls forms a mere slit. The cervical canal is fusiform and is open at each end by small apertures, the *internal os* and the *external os*.

Congenital Anomalies. Abnormal mullerian fusion may give rise to a number of uterine anomalies that are discussed in [Chapter 40](#) (see p. 950).

Pregnancy-Induced Uterine Changes. Pregnancy stimulates remarkable uterine growth due to hypertrophy of muscle fibers. The weight of the uterus increases from 70 g to about 1100 g at term. Its total volume averages about 5 L. The uterine fundus, a previously flattened convexity between tubal insertions, now becomes dome shaped ([Fig. 2-7](#)). The round ligaments now appear to insert at the junction of the middle and upper thirds of the organ. The fallopian tubes elongate, but the ovaries grossly appear unchanged.

Cervix. Anteriorly, the upper boundary of the cervix is the internal os, which corresponds to the level at which the peritoneum is reflected upon the bladder. The supravaginal segment is covered by peritoneum on its posterior surface. This segment is attached to the cardinal ligaments anteriorly, and it is separated from the overlying bladder by loose connective tissue. The other segment is the lower vaginal portion of the cervix, also called the *portio vaginalis*.

Before childbirth, the external cervical os is a small, regular, oval opening. After childbirth, the orifice is converted into a transverse slit that is divided such that there are the so-called anterior and posterior lips of the cervix. If torn deeply during delivery, it might heal in such a manner that it appears to be irregular, nodular, or stellate ([Fig. 2-8](#)). These changes are sufficiently characteristic to permit an examiner to ascertain with some certainty whether a given woman has borne children by vaginal delivery.

The mucosa of the cervical canal is composed of a single layer of very high ciliated columnar epithelium that rests on a thin basement membrane. Numerous cervical glands extend from the surface of the endocervical mucosa directly into the subjacent connective tissue. These glands furnish the thick, tenacious cervical secretions. If the ducts of the cervical glands are occluded, retention cysts, known as *nabothian cysts*, are formed.

Body of the Uterus. The wall of the body of the uterus is composed of serosal, muscular, and mucosal layers. The serosal

layer is formed by the peritoneum that covers the uterus. It is firmly adherent except at sites just above the bladder and at the lateral margins, where the peritoneum is deflected to form the broad ligaments.

ENDOMETRIUM. This mucosal layer lines the uterine cavity in nonpregnant women. It is a thin, pink, velvet-like membrane that on close examination is found to be perforated by a large number of minute ostia of the uterine glands. The endometrium normally varies greatly in thickness, and measures from 0.5 mm to as much as 5 mm. It is composed of surface epithelium, glands, and interglandular mesenchymal tissue in which there are numerous blood vessels.

The epithelium of the endometrial surface is made up of a single layer of closely packed, high columnar, ciliated cells. The tubular *uterine glands* are invaginations of the epithelium. The glands extend through the entire thickness of the endometrium to the myometrium, which is occasionally penetrated for a short distance. Histologically, the inner glands resemble the epithelium of the surface and are lined by a single layer of columnar, partially ciliated epithelium that rests on a thin basement membrane. The glands secrete a thin, alkaline fluid. The connective tissue of the endometrium, between the surface epithelium and the myometrium, is a mesenchymal stroma. Histologically, the stroma varies remarkably throughout the ovarian cycle.

After menopause, the endometrium is atrophic and the epithelium flattens. The glands gradually disappear, and the interglandular tissue becomes more fibrous.

The vascular architecture of the uterus and the endometrium is of signal importance in pregnancy. The uterine and ovarian arteries branch and penetrate the uterine wall obliquely inward and reach its middle third. They then ramify in a plane that is parallel to the surface and are therefore named the *arcuate arteries* (DuBose and colleagues, 1985). Radial branches extend from the arcuate arteries at right angles and enter the endometrium to become *coiled or spiral arteries*. Also from the radial arteries, *basal arteries* branch at a sharp angle (Fig. 2-9). The coiled arteries supply most of the midportion and all of the superficial third of the endometrium. The walls of these vessels are responsive (sensitive) to the action of a number of hormones, especially by vasoconstriction, and thus probably serve an important role in the mechanism(s) of menstruation. The straight basal endometrial arteries extend only into the basal layer of the endometrium and are not responsive to hormonal action.

MYOMETRIUM. The myometrium makes up the major portion of the uterus. It is composed of bundles of smooth muscle united by connective tissue in which there are many elastic fibers. According to Schwalm and Dubrausky (1966), the number of muscle fibers of the uterus progressively diminishes caudally such that, in the cervix, muscle comprises only 10 percent of the tissue mass. In the inner wall of the body of the uterus, there is relatively more muscle than in the outer layers; and in the anterior and posterior walls, there is more muscle than in the lateral walls. During pregnancy, the upper myometrium undergoes marked hypertrophy, but there is no significant change in cervical muscle content.

LIGAMENTS. The *broad ligaments* are made up of two winglike structures that extend from the lateral margins of the uterus to the pelvic walls. They divide the pelvic cavity into anterior and posterior compartments. Each broad ligament consists of a fold of peritoneum. The inner two thirds of the superior margin form the *mesosalpinx*, to which the fallopian tubes are attached. The outer third of the superior margin, which extends from the fimbriated end of the oviduct to the pelvic wall, forms the *infundibulopelvic ligament* or *suspensory ligament of the ovary*, through which the ovarian vessels traverse.

At the lateral margin of each broad ligament, the peritoneum is reflected onto the side of the pelvis. The thick base of the broad ligament is continuous with the connective tissue of the pelvic floor. The densest portion is usually referred to as the *cardinal ligament* ♀— also called the *transverse cervical ligament* or the *Mackenrodt ligament* ♂— and is composed of connective tissue that medially is united firmly to the supravaginal portion of the cervix.

A vertical section through the uterine end of the broad ligament is triangular, and the uterine vessels and ureter are found within its broad base (Fig. 2-10). In its lower part, it is widely attached to the connective tissues that are adjacent to the cervix, that is, the *parametrium*. The upper part is made up of three folds that nearly cover the oviduct, the utero-ovarian ligament, and the round ligament.

The *round ligaments* extend from the lateral portion of the uterus, arising somewhat below and anterior to the origin of the oviducts. Each round ligament is located in a fold of peritoneum that is continuous with the broad ligament and extends outward and downward to the inguinal canal, through which it passes to terminate in the upper portion of the labium majus. In nonpregnant women, the round ligament varies from 3 to 5 mm in diameter, and is composed of smooth muscle cells. The round ligament corresponds embryologically to the gubernaculum testis of men. During pregnancy, the round ligaments undergo considerable hypertrophy and increase appreciably in both length and diameter.

Each *uterosacral ligament* extends from an attachment posterolaterally to the supravaginal portion of the cervix to encircle the rectum and inserts into the fascia over the sacrum. Umek and colleagues (2004) used MR-imaging to describe anatomical variations of these ligaments. The ligaments are composed of connective tissue and some smooth muscle and are covered by peritoneum. They form the lateral boundaries of the pouch of Douglas.

BLOOD VESSELS. The vascular supply of the uterus is derived principally from the uterine and ovarian arteries. The uterine artery, a main branch of the internal iliac artery ♀— referred to in the past as the hypogastric artery ♂— enters the base of the broad ligament and makes its way medially to the side of the uterus. Immediately adjacent to the supravaginal portion of the cervix, the uterine artery divides. The smaller cervicovaginal artery supplies blood to the lower cervix and upper vagina. The main branch turns abruptly upward and extends as a highly convoluted vessel that traverses along the margin of the uterus. A branch of considerable size extends to the upper portion of the cervix, and numerous other branches penetrate the body of the uterus. Just before the main branch of the uterine artery reaches the oviduct, it divides into three terminal branches. The ovarian branch of the uterine artery anastomoses with the terminal branch of the ovarian artery; the tubal branch makes its way through the mesosalpinx and supplies part of the oviduct; and the fundal branch is distributed to the uppermost uterus.

About 2 cm lateral to the cervix, the uterine artery crosses over the ureter (Figs. 2-6 and 2-11). The proximity of the uterine artery and vein to the ureter at this point is of great surgical significance. Because of their close proximity, the ureter may be injured or ligated during a hysterectomy when the vessels are clamped and ligated.

A major portion of the blood supply to the pelvis is via the branches of the internal iliac artery, as shown in the arteriogram in

Figure 2-12. In addition to the uterine artery, other branches of the anterior and posterior divisions of the internal iliac artery include those listed in [Table 2-1](#).

The *ovarian artery* is a direct branch of the aorta. It enters the broad ligament through the infundibulopelvic ligament. At the ovarian hilum, it divides into a number of smaller branches that enter the ovary. Its main stem, however, traverses the entire length of the broad ligament very near the mesosalpinx and makes its way to the upper lateral portion of the uterus. Here it anastomoses with the ovarian branch of the uterine artery. There are numerous additional communications among the arteries on both sides of the uterus.

When the uterus is in a contracted state, its numerous venous lumens are collapsed, however, in injected specimens the greater part of the uterine wall appears to be occupied by dilated venous sinuses. On either side, the arcuate veins unite to form the *uterine vein*, which empties into the internal iliac vein and thence into the common iliac vein. Some of the blood from the upper uterus, the ovary, and the upper part of the broad ligament is collected by several veins. Within the broad ligament, these veins form the large *pampiniform plexus* that terminates in the ovarian vein. The right ovarian vein empties into the vena cava, whereas the left ovarian vein empties into the left renal vein. During pregnancy, there is marked hypertrophy of the blood supply to the uterus, as shown in [Figure 2-7](#).

LYMPHATICS. The endometrium is abundantly supplied with true lymphatic vessels that are confined largely to the basal layer. The lymphatics of the underlying myometrium are increased in number toward the serosal surface and form an abundant lymphatic plexus just beneath it. Lymphatics from the cervix terminate mainly in the hypogastric nodes, which are situated near the bifurcation of the common iliac vessels. The lymphatics from the body of the uterus are distributed to two groups of nodes. One set of vessels drains into the internal iliac nodes. The other set, after joining certain lymphatics from the ovarian region, terminates in the periaortic lymph nodes.

INNERVATION. The nerve supply to the pelvic area is derived principally from the sympathetic nervous system, but also partly from the cerebrospinal and parasympathetic systems. The parasympathetic system is represented on either side by the pelvic nerve, which is made up of a few fibers that are derived from the second, third, and fourth sacral nerves. It loses its identity in the *cervical ganglion of Frankenhauser*. The sympathetic system enters the pelvis by way of the internal iliac plexus that arises from the aortic plexus just below the promontory of the sacrum. After descending on either side, it also enters the uterovaginal plexus of Frankenhauser, which is made up of ganglia of various sizes, but particularly of a large ganglionic plate that is situated on either side of the cervix and just above the posterior fornix in front of the rectum.

Branches from these plexuses supply the uterus, bladder, and upper vagina. In the 11th and 12th thoracic nerve roots, there are sensory fibers from the uterus that transmit the painful stimuli of contractions to the central nervous system. The sensory nerves from the cervix and upper part of the birth canal pass through the pelvic nerves to the second, third, and fourth sacral nerves, whereas those from the lower portion of the birth canal pass primarily through the pudendal nerve. Knowledge of the innervation of dermatomes and its clinical application to providing epidural or spinal analgesia for labor and vaginal or cesarean delivery is illustrated in [Figures 19-1](#) and [19-3](#) (see pp. 477 and 480).

Figure 2-9. Stereographic representation of myometrial and endometrial arteries in the macaque. Above, parts of myometrial arcuate arteries from which myometrial radial arteries course toward the endometrium. Below, the larger endometrial coiled arteries and the smaller endometrial basal arteries. (From Okkels and Engle, 1938.)

Figure 2-10. Vertical section through the uterine end of the right broad ligament.

Figure 2-11. Blood supply to the left ovary, left oviduct, and left side of the uterus. The ovarian and uterine vessels anastomose freely. Note the uterine artery and vein

crossing over the ureter that lies immediately adjacent to the cervix.

Figure 2-12. Iliac arteriogram. It can be seen that the bifurcation of the aorta (1) into the two common iliac arteries (2) occurs at the lower border of the body of the L4 vertebra. The common iliac vessels branch into external (3) and internal (4) iliac arteries. The internal iliac artery (4) on each side serves a number of branches to the pelvis, perineum, and gluteal region, whereas the external iliac artery (3), after giving off the inferior epigastric (15) and deep circumflex iliac (16) arteries, becomes the femoral artery below the inguinal ligament. (Also shown: 5 = femoral artery; 6 = lumbar arteries; 7 = iliolumbar artery; 8 = median sacral artery; 9 = uterine artery; 10 = uterus; 11 = lateral sacral artery; 12 = obturator artery; 13 = internal pudendal artery; 14 = superior gluteal artery; 17 = deep femoral artery; L4 = fourth lumbar vertebra; SP = symphysis pubis.) (From Wicke, 1982.)

Figure 19-3. Dermatome distribution. (Redrawn from Keegan and Garrett, 1948, with permission.)

OVIDUCTS. More commonly called the *fallopian tubes*, the oviducts vary in length from 8 to 14 cm. They are covered by peritoneum, and their lumen is lined by mucous membrane. Each tube is divided into an *interstitial portion*, *isthmus*, *ampulla*, and *infundibulum*. The interstitial portion is embodied within the muscular wall of the uterus. The isthmus, or the narrow portion of the tube that adjoins the uterus, passes gradually into the wider, lateral portion, or *ampulla*. The *infundibulum*, or fimbriated extremity, is the funnel-shaped opening of the distal end of the fallopian tube (Fig. 2-13). The oviduct varies considerably in thickness; the narrowest portion of the isthmus measures from 2 to 3 mm in diameter, and the widest portion of the ampulla measures from 5 to 8 mm. The fimbriated end of the infundibulum opens into the abdominal cavity. One projection, the *fimbria ovarica*, which is considerably longer than the other fimbriae, forms a shallow gutter that approaches or reaches the ovary.

The musculature of the fallopian tube is arranged in an inner circular and an outer longitudinal layer. In the distal portion, the two layers are less distinct and, near the fimbriated extremity, are replaced by an interlacing network of muscular fibers. The tubal musculature undergoes rhythmic contractions constantly, the rate of which varies with the hormonal changes of the ovarian cycle. The greatest frequency and intensity of contractions is reached during transport of ova.

The oviducts are lined by a single layer of columnar cells, some of them ciliated and others secretory. The ciliated cells are most abundant at the fimbriated extremity, elsewhere, they are found in discrete patches. There are differences in the proportions of these two types of cells in different phases of the ovarian cycle. Because there is no submucosa, the epithelium is in close contact with the underlying muscle. In the tubal mucosa, there are cyclical histological changes similar to those of the endometrium, but much less striking. The mucosa is arranged in longitudinal folds that are more complex toward the fimbriated end. On cross sections through the uterine portion, four simple folds are found that form a figure that resembles a Maltese cross. The isthmus has a more complex pattern. In the ampulla, the lumen is occupied almost completely by the arborescent mucosa, which consists of very complicated folds (see Fig. 2-13). The current produced by the tubal cilia is such that the direction of flow is toward the uterine cavity. Tubal peristalsis is believed to be an extraordinarily important factor in transport of the ovum.

The tubes are supplied richly with elastic tissue, blood vessels, and lymphatics. Sympathetic innervation of the tubes is extensive, in contrast to their parasympathetic innervation.

Diverticula may extend occasionally from the lumen of the tube for a variable distance into the muscular wall and reach almost to the serosa. These diverticula may play a role in the development of ectopic pregnancy (see Chap. 10, p. 256).

Embryological Development of the Uterus and Oviducts. The uterus and tubes arise from the mullerian ducts, which first appear near the upper pole of the urogenital ridge in the fifth week of embryonic development (Fig. 2-14). This ridge is composed of the mesonephros, gonad, and associated ducts. The first indication of the development of the mullerian duct is a thickening of the coelomic epithelium at about the level of the fourth thoracic segment. This thickening becomes the fimbriated extremity of the fallopian tube, which invaginates and grows caudally to form a slender tube at the lateral edge of the urogenital ridge. In the sixth week of embryonic life, the growing tips of the two mullerian ducts approach each other in the midline; they reach the urogenital sinus 1 week later. At that time, a fusion of the two mullerian ducts to form a single canal is begun at the level of the inguinal crest, that is, the gubernaculum (primordium of the round ligament). Thus, the upper ends of the mullerian ducts produce the oviducts and the fused parts give rise to the uterus. The vaginal canal is not patent throughout

its entire length until the sixth month of fetal life (Koff, 1933). Because of the clinical importance of anomalies that arise from abnormal fusion and dysgenesis of these structures, their embryogenesis is discussed in detail in [Chapter 40](#) (see [Fig. 40-1](#), p. 951).

Figure 2-13. The oviduct of an adult woman with cross-sectioned illustrations of the gross structure of the epithelium in several portions: **(A)** isthmus, **(B)** ampulla, and **(C)** infundibulum.

Figure 2-14. A. Cross section of an embryo at 4 to 6 weeks. **B.** Large ameboid primordial germ cells migrate (*arrows*) from the yolk sac to the area of germinal epithelium, within the genital ridge. **C.** Migration of sympathetic cells from the spinal ganglia to a region above the developing kidney. (After Moore and colleagues, 2000.)

Figure 40-1. Development of the female reproductive systems from the genital ducts and urogenital sinus. Vestigial structures are also shown. **A.** Reproductive system at 6 weeks before differentiation. **B.** In the female, the mullerian (paramesonephric) ducts extend and enter the urogenital sinus and become fused. **C.** Uterine cavitation occurs at site of fused mullerian ducts and the uterus grows downward. **D.** Cavitation is complete and the lower segment and cervix, along with the upper vagina, are formed.

OVARIES. Compared with each other, as well as between women, the ovaries vary considerably in size. During childbearing years, they are from 2.5 to 5 cm in length, 1.5 to 3 cm in breadth, and 0.6 to 1.5 cm in thickness. After menopause, ovarian size diminishes remarkably. The position of the ovaries also varies, but they usually are situated in the upper part of the pelvic cavity and rest in a slight depression on the lateral wall of the pelvis between the divergent external and internal iliac vessels—the *ovarian fossa of Waldeyer*. The ovary is attached to the broad ligament by the *mesovarium*. The *utero-ovarian ligament* extends from the lateral and posterior portion of the uterus, just beneath the tubal insertion, to the uterine pole of the ovary. Usually, it is several centimeters long and 3 to 4 mm in diameter. It is covered by peritoneum and is made up of muscle and connective tissue fibers. The *infundibulopelvic* or *suspensory ligament of the ovary* extends from the upper or tubal pole to the pelvic wall; through its course the ovarian vessels and nerves.

In young women, the exterior surface of the ovary is smooth, with a dull white surface through which glisten several small, clear follicles. As the woman ages, the ovaries become more corrugated, and in elderly women, the exterior surfaces may be convoluted markedly.

The ovary consists of two portions, the cortex and medulla. The cortex is the outer layer, which varies in thickness with age and becomes thinner with advancing years. It is in this layer that the ova and graafian follicles are located. The cortex is composed of spindle-shaped connective tissue cells and fibers, among which are scattered primordial and graafian follicles in various stages of development. As the woman ages, the follicles become less numerous. The outermost portion of the cortex, which is dull and whitish, is designated the *tunica albuginea*. On its surface, there is a single layer of cuboidal epithelium, the *germinal epithelium of Waldeyer*.

The medulla is the central portion, which is composed of loose connective tissue that is continuous with that of the mesovarium. There are a large number of arteries and veins in the medulla and a small number of smooth muscle fibers that are continuous with those in the suspensory ligament.

The ovaries are supplied with both sympathetic and parasympathetic nerves. The sympathetic nerves are derived primarily from the ovarian plexus that accompanies the ovarian vessels. Others are derived from the plexus that surrounds the ovarian branch of the uterine artery. The ovary is richly supplied with nonmyelinated nerve fibers, which for the most part accompany the blood vessels. These are merely vascular nerves, whereas others form wreaths around normal and atretic follicles, and these give off many minute branches that have been traced up to, but not through, the *membrana granulosa*.

Embryology. The earliest sign of a gonad is one that appears on the ventral surface of the embryonic kidney at a site between the eighth thoracic and fourth lumbar segments at about 4 weeks. The coelomic epithelium is thickened, and clumps of cells are seen to bud off into the underlying mesenchyme. This circumscribed area of the coelomic epithelium is called the *germinal epithelium*. By the fourth to sixth week, however, there are many large ameboid cells in this region that have migrated into the body of the embryo from the yolk sac (see [Fig. 2-14](#)). These *primordial germ cells* are distinguishable by their large size and certain morphological and cytochemical features.

When the primordial germ cells reach the genital area, some enter the germinal epithelium and others mingle with the groups of cells that proliferate from it or lie in the mesenchyme. By the end of the fifth week, rapid division of all these types of cells results in development of a prominent *genital ridge*. The ridge projects into the body cavity medially to a fold in which there are the mesonephric (wolffian) and the mullerian ducts ([Fig. 2-15](#)). By the seventh week, it is separated from the mesonephros except at the narrow central zone, the future hilum, where the blood vessels enter. At this time, the sexes can be distinguished, because the testes can be recognized by well-defined radiating strands of cells (sex cords). These cords are separated from the germinal epithelium by mesenchyme that is to become the *tunica albuginea*. The sex cords, which consist of large germ cells and smaller epithelioid cells derived from the germinal epithelium, develop into the seminiferous tubules and tubuli rete. The latter establishes connection with the mesonephric tubules that develop into the epididymis. The

mesonephric ducts become the vas deferens.

In the female embryo, the germinal epithelium continues to proliferate for a much longer time. The groups of cells thus formed lie at first in the region of the hilum. As connective tissue develops between them, these appear as sex cords. These cords give rise to the medullary cords and persist for variable times (Forbes, 1942). By the third month, medulla and cortex are defined (see [Fig. 2-15](#)). The bulk of the organ is made up of cortex, a mass of crowded germ and epithelioid cells that show some signs of grouping, but there are no distinct cords as in the testis. Strands of cells extend from the germinal epithelium into the cortical mass, and mitoses are numerous. The rapid succession of mitoses soon reduces the size of the germ cells to the extent that these no longer are differentiated clearly from the neighboring cells. These germ cells are now called *oogonia*.

By the fourth month, some germ cells in the medullary region begin to enlarge. These are called *primary oocytes* at the beginning of the phase of growth that continues until maturity is reached. During this period of cell growth, many oocytes undergo degeneration, both before and after birth. A single layer of flattened follicular cells that were derived originally from the germinal epithelium soon surrounds the primary oocytes. These structures are now called *primordial follicles* and are seen first in the medulla and later in the cortex. Some follicles begin to grow even before birth, and some are believed to persist in the cortex almost unchanged until menopause.

By 8 months, the ovary has become a long, narrow, lobulated structure that is attached to the body wall along the line of the hilum by the *mesovarium*, in which lies the *epoophoron*. The germinal epithelium has been separated for the most part from the cortex by a band of connective tissue—the *tunica albuginea*—which is absent in many small areas where strands of cells, usually referred to as *cords of Pfluger*, are in contact with the germinal epithelium. Among these cords are cells believed by many investigators to be oogonia that have come to resemble the other epithelial cells as a result of repeated mitoses. In the underlying cortex, there are two distinct zones. Superficially, there are nests of germ cells in synapsis, interspersed with Pfluger cords and strands of connective tissue. In the deeper zone, there are many groups of germ cells in synapsis, as well as primary oocytes, prospective follicular cells, and a few primordial follicles.

At term, the various types of ovarian cells in the human female fetus may still be found.

Histology. From the first stages of its development until after the menopause, the ovary undergoes constant change. The number of oocytes at the onset of puberty has been estimated variously at 200,000 to 400,000. Because only one ovum ordinarily is cast off during each ovarian cycle, it is evident that a few hundred ova suffice for purposes of reproduction.

The glandular elements of ovaries of adult women include interstitial, thecal, and luteal cells. The interstitial glandular elements are formed from cells of the theca interna of degenerating or atretic follicles; the thecal glandular cells are formed from the theca interna of ripening follicles; and the true luteal cells are derived from the granulosa cells of ovulated follicles and from the undifferentiated stroma that surround them.

The huge store of primordial follicles at birth is exhausted gradually after sexual maturation and through the reproductive span. Block (1952) found that there is a gradual decline from a mean of 439,000 oocytes in girls younger than 15 years to a mean of 34,000 in women older than 36 years. In young girls, the greater portion of the ovary is composed of the cortex, which is filled with large numbers of closely packed primordial follicles. In young women, the cortex is relatively thinner but still contains a large number of primordial follicles. Each primordial follicle is made up of an oocyte and its surrounding single layer of epithelial cells, which are small and flattened, spindle-shaped, and somewhat sharply differentiated from the still smaller and spindly cells of the surrounding stroma.

The oocyte is a large, spherical cell in which there is clear cytoplasm and a relatively large nucleus located near the center of the ovum. In the nucleus, there are one large and several smaller nucleoli, and numerous masses of chromatin. In adult women, the diameter of the smallest oocytes averages 33 μm , and that of the nuclei, 20 μm .

Figure 2-15. Continuation of sexual differentiation of the embryo. See text for explanation. (After Moore and colleagues, 2000.)

EMBRYOLOGICAL REMNANTS. There are a number of vestigial wolffian structures that are identified after embryogenesis of the female reproductive system. Some of these occasionally cause clinical concerns. The *parovarium* can be found in the scant loose connective tissue within the broad ligament in the vicinity of the mesosalpinx. It comprises a number of narrow vertical tubules that are lined by ciliated epithelium. These tubules connect at the upper ends with a longitudinal duct that extends just below the oviduct to the lateral margin of the uterus, where it ends blindly near the internal os. This canal is the remnant of the wolffian (mesonephric) duct in women and is called the *Gartner duct*. The parovarium, also a remnant of the wolffian duct, is homologous embryologically with the caput epididymis in men. The cranial portion of the parovarium is the *epoophoron*, or *organ of Rosenmüller*; the caudal portion, or *paroophoron*, is a group of vestigial mesonephric tubules that lie in or around the broad ligament. It is homologous embryologically with the paradidymis of men. The paroophoron in adult women usually disappears.

SURGICAL ANATOMY. Shown in [Figure 2-16](#) are illustrations of female pelvic surgical anatomy. The figure depicts a nonpregnant uterus, and details of a peripartum hysterectomy are discussed in [Chapter 25](#) (see p. 599).

Figure 2-16. Pelvic retroperitoneal anatomy. **A.** Dissected right retroperitoneal space illustrating the course of the pelvic ureter. The right uterine adnexa have

been transected adjacent to the uterus, the ovarian vessels have been severed just distal to the pelvic brim, and the peritoneum has been removed from the right pelvic sidewall and the right portion of the bladder. The ureter (1) enters the pelvis by crossing over the bifurcation of the common iliac artery just medial to the ovarian vessels (2). It then descends medial to the branches of the internal iliac artery (3). The ureter then courses through the cardinal ligament and passes under the uterine artery (4, "water under the bridge") approximately 1 to 2 cm lateral to the cervix at the level of the internal cervical os. The origin of the uterine artery from the internal iliac artery (3) is shown. The ureter then courses medially toward the base of the bladder. The distal part of the ureter is associated with the upper portion of the anterior vaginal wall. **B.** The retroperitoneal space has been entered and the peritoneum is retracted medially to show the ureter (1) crossing over the external and internal iliac artery bifurcation. Note that the ureter remains attached to the peritoneum of the pelvic sidewall and the medial leaf of the broad ligament. **C.** The ovarian vessels (2) are clamped and transected after visualization of the ureter. **D.** The uterine artery (4) is being clamped and transected. Note the ureter (1) crossing under this vessel lateral to the cervix. (Figs. B, C, and D from Nelson, 1977, with permission.)

THE BONY PELVIS

In both women and men, the pelvis forms the bony ring through which body weight is transmitted to the lower extremities, but in women it has a special form that adapts it to childbearing (Fig. 2-17). The pelvis is composed of four bones: the sacrum, coccyx, and two innominate bones. Each innominate bone is formed by the fusion of the ilium, ischium, and pubis. The innominate bones are joined to the sacrum at the sacroiliac synchondroses and to one another at the symphysis pubis.

Figure 2-17. Normal female pelvis with the false and true pelves identified.

PELVIC ANATOMY. The false pelvis lies above the linea terminalis and the true pelvis below this anatomical boundary (see Fig. 2-17). The false pelvis is bounded posteriorly by the lumbar vertebra and laterally by the iliac fossa. In front, the boundary is formed by the lower portion of the anterior abdominal wall.

The true pelvis is the portion important in childbearing. It is bounded above by the promontory and alae of the sacrum, the linea terminalis, and the upper margins of the pubic bones, and below by the pelvic outlet. The cavity of the true pelvis can be described as an obliquely truncated, bent cylinder with its greatest height posteriorly. Its anterior wall at the symphysis pubis measures about 5 cm, and its posterior wall, about 10 cm (Figs. 2-18 and 2-19).

The walls of the true pelvis are partly bony and partly ligamentous. The posterior boundary is the anterior surface of the sacrum, and the lateral limits are formed by the inner surface of the ischial bones and the sacrosciatic notches and ligaments. In front, the true pelvis is bounded by the pubic bones, the ascending superior rami of the ischial bones, and the obturator foramen.

The sidewalls of the true pelvis of an adult woman converge somewhat. Extending from the middle of the posterior margin of each ischium are the ischial spines. These are of great obstetrical importance because the distance between them usually represents the shortest diameter of the pelvic cavity. They also serve as valuable landmarks in assessing the level to which the presenting part of the fetus has descended into the true pelvis. The sacrum forms the posterior wall of the pelvic cavity. Its upper anterior margin corresponds to the promontory that may be felt during bimanual pelvic examination in women with a small pelvis. It can provide a landmark for clinical pelvimetry. Normally the sacrum has a marked vertical and a less pronounced horizontal concavity, which in abnormal pelves may undergo important variations. A straight line drawn from the promontory to the tip of the sacrum usually measures 10 cm, whereas the distance along the concavity averages 12 cm.

The descending inferior rami of the pubic bones unite at an angle of 90 to 100 degrees to form a rounded arch under which the fetal head must pass.

Figure 2-18. The cavity of the true pelvis is comparable to an obliquely truncated, bent cylinder with its greatest height posteriorly. Note the curvature of the pelvic axis.

Figure 2-19. Adult female pelvis. Anteroposterior (AP) and transverse (T)

diameters of the pelvic inlet are illustrated, as well as the posterior sagittal diameter of the inlet.

PELVIC JOINTS

Symphysis Pubis. Anteriorly, the pelvic bones are joined together by the symphysis pubis. This structure consists of fibrocartilage and the superior and inferior pubic ligaments; the latter are frequently designated the *arcuate ligament of the pubis* (Fig. 2-20).

Sacroiliac Joints. Posteriorly, the pelvic bones are joined by the articulations between the sacrum and the iliac portion of the innominate bones to form the sacroiliac joints. These joints also have a certain degree of mobility.

Relaxation of the Pelvic Joints. During pregnancy, relaxation of these joints likely results from hormonal changes. Abramson and co-workers (1934) observed that relaxation of the symphysis pubis commenced in women in the first half of pregnancy and increased during the last 3 months. They also observed that this laxity began to regress immediately after parturition and that regression was completed within 3 to 5 months. The symphysis pubis also increases in width during pregnancy—more so in multiparas than in primigravidas—and returns to normal soon after delivery.

There are important changes in sacroiliac joint mobility. Borell and Fernstrom (1957) demonstrated that the rather marked mobility of the pelvis at term was caused by an upward gliding movement of the sacroiliac joint. The displacement, which is greatest in the dorsal lithotomy position, may increase the diameter of the outlet by 1.5 to 2.0 cm. **This is the main justification for placing a woman in this position for a vaginal delivery.** The increase in the diameter of the pelvic outlet, however, occurs only if the sacrum is allowed to rotate posteriorly, that is, only if the sacrum is not forced anteriorly by the weight of the maternal pelvis against the delivery table or bed (Russell, 1969, 1982). Sacroiliac joint mobility is also the likely reason that the McRoberts maneuver often is successful in releasing an obstructed shoulder in a case of shoulder dystocia (see Chap. 20, p. 513). These changes have also been attributed to the success of the modified squatting position to hasten second-stage labor (Gardosi and co-workers, 1989). The squatting position may increase the interspinous diameter and the diameter of the pelvic outlet (Russell, 1969, 1982). These latter observations are unconfirmed, but this position is assumed for birth in many primitive societies.

Figure 2-20. Frontal section through the symphysis pubis. (lig. = ligament.) (Redrawn from Spalteholz, 1933.)

PLANES AND DIAMETERS OF THE PELVIS. The pelvis is described as having four imaginary planes:

1. The plane of the pelvic inlet— the superior strait.
2. The plane of the pelvic outlet— the inferior strait.
3. The plane of the midpelvis— the least pelvic dimensions.
4. The plane of greatest pelvic dimension— of no obstetrical significance.

Pelvic Inlet. The pelvic inlet (superior strait) is bounded posteriorly by the promontory and alae of the sacrum, laterally by the linea terminalis, and anteriorly by the horizontal pubic rami and the symphysis pubis (Figs. 2-21 and 2-22; see also Figs. 2-18 and 2-19). The inlet of the female pelvis typically is more nearly round than ovoid. Caldwell and co-workers (1934) identified radiographically a nearly round or *gynecoid* pelvic inlet in approximately 50 percent of white women.

Four diameters of the pelvic inlet are usually described: anteroposterior, transverse, and two obliques. The obstetrically important anteroposterior diameter is the shortest distance between the promontory of the sacrum and the symphysis pubis, and is designated the *obstetrical conjugate* (see Figs. 2-18, 2-19, and 2-21). Normally, this measures 10 cm or more.

The transverse diameter is constructed at right angles to the obstetrical conjugate and represents the greatest distance between the linea terminalis on either side. It usually intersects the obstetrical conjugate at a point about 4 cm in front of the promontory (Fig. 2-19). The segment of the obstetrical conjugate from the intersection of these two lines to the promontory is designated the *posterior sagittal diameter* of the inlet.

Each of the two oblique diameters extends from one of the sacroiliac synchondroses to the iliopectineal eminence on the opposite side. They average less than 13 cm.

The anteroposterior diameter of the pelvic inlet that has been identified as the *true conjugate* does not represent the shortest distance between the promontory of the sacrum and the symphysis pubis (see Fig. 2-21). The shortest distance is the obstetrical conjugate, which is the shortest anteroposterior diameter through which the head must pass in descending through the pelvic inlet (see Figs. 2-18, 2-19, and 2-21). The obstetrical conjugate cannot be measured directly with the examining fingers. For clinical purposes, the obstetrical conjugate is estimated indirectly by subtracting 1.5 to 2 cm from the diagonal

conjugate. The latter is determined by measuring the distance from the lower margin of the symphysis to the promontory of the sacrum (see [Fig. 2-21](#)).

Midpelvis. The midpelvis is measured at the level of the ischial spines \aleph — the midplane, or plane of least pelvic dimensions. It is of particular importance following engagement of the fetal head in obstructed labor. The interspinous diameter, 10 cm or somewhat more, is usually the smallest diameter of the pelvis. The anteroposterior diameter through the level of the ischial spines normally measures at least 11.5 cm. Its posterior component (posterior sagittal diameter), between the sacrum and the line created by the interspinous diameter, is usually at least 4.5 cm ([Fig. 2-22](#)).

Pelvic Outlet. The pelvic outlet consists of two approximately triangular areas that are not in the same plane. They have a common base, which is a line drawn between the two ischial tuberosities ([Fig. 2-23](#)). The apex of the posterior triangle is at the tip of the sacrum, and the lateral boundaries are the sacrosiatic ligaments and the ischial tuberosities. The anterior triangle is formed by the area under the pubic arch. Three diameters of the pelvic outlet usually are described: the anteroposterior, transverse, and posterior sagittal.

Figure 2-21. Three anteroposterior diameters of the pelvic inlet are illustrated: the true conjugate, the more important obstetrical conjugate, and the clinically measurable diagonal conjugate. The anteroposterior diameter of the midpelvis is also shown. (P = sacral promontory; Sym = symphysis pubis.)

Figure 2-22. Adult female pelvis demonstrating anteroposterior and transverse diameters of the pelvic inlet and transverse (interspinous) diameter of the midpelvis. The obstetrical conjugate is normally greater than 10 cm.

Figure 2-23. Pelvic outlet with diameters marked. Note that the anteroposterior diameter may be divided into anterior and posterior sagittal diameters.

PELVIC SHAPES. In the past, x-ray pelvimetry was used frequently in women with suspected cephalopelvic disproportion or fetal malpresentation. Caldwell and Moloy (1933, 1934) developed a classification of the pelvis that is still used. The classification is based on the shape of the pelvis, and its familiarity helps the clinician understand better the mechanisms of labor.

The *Caldwell-Moloy classification* is based on measurement of the greatest transverse diameter of the inlet and its division into anterior and posterior segments. The shapes of these are used to classify the pelvis as gynecoid, anthropoid, android, or platypelloid ([Fig. 2-24](#)). The character of the posterior segment determines the type of pelvis, and the character of the anterior segment determines the tendency. These are both determined because many pelvises are not pure but are mixed types; for example, a gynecoid pelvis with an android tendency means that the posterior pelvis is gynecoid and the anterior pelvis is android in shape.

From viewing the four basic types in [Figure 2-24](#), the configuration of the gynecoid pelvis would intuitively seem suited for delivery of most fetuses. Indeed, Caldwell and co-workers (1939) reported that the gynecoid pelvis was found in almost 50 percent of women. In contrast, in the android pelvis, the posterior sagittal diameter at the inlet is much shorter than the anterior sagittal diameter, limiting the use of the posterior space by the fetal head. Moreover, the anterior portion is narrow and triangular. The extreme android pelvis presages a poor prognosis for vaginal delivery. In the anthropoid pelvis, the anteroposterior diameter of the inlet is greater than the transverse. This results in an oval anteroposteriorly, with the anterior segment somewhat narrow and pointed. Variations of anthropoid-type pelvises are found in about one third of women. The *platypelloid pelvis* has a flattened gynecoid shape with short anteroposterior and wide transverse diameters. Pure varieties are found in fewer than 3 percent of women.

Figure 2-24. The four parent pelvic types of the Caldwell-Moloy classification. A line passing through the widest transverse diameter divides the inlets into posterior (P) and anterior (A) segments.

PELVIC SIZE AND ITS CLINICAL ESTIMATION

Pelvic Inlet Measurements. In many abnormal pelvises, the anteroposterior diameter of the pelvic inlet \aleph — the obstetrical conjugate \aleph — is considerably shortened. The diagonal conjugate is clinically estimated by measuring the distance from the sacral promontory to the lower margin of the symphysis pubis ([Figs. 2-25](#) and [2-26](#)). Two fingers of the dominant hand are introduced into the vagina. The mobility of the coccyx is first evaluated. The anterior surface of the sacrum is next palpated from below upward and its vertical and lateral curvatures noted. In normal pelvises, only the last three sacral vertebrae can be felt without indenting the perineum. Conversely, in markedly contracted pelvises, the entire anterior surface of the sacrum

usually is readily palpable. Next, in order to reach the sacral promontory, the examiner's elbow must be flexed and the perineum forcibly indented by the knuckles of the third and fourth fingers. The index and the second fingers are carried up and over the anterior surface of the sacrum. By deeply inserting the wrist, the promontory may be felt by the tip of the second finger as a projecting bony margin. With the finger closely applied to the most prominent portion of the upper sacrum, the vaginal hand is elevated until it contacts the pubic arch. The immediately adjacent point on the index finger is marked, as shown in [Figure 2-25](#). The distance between the mark and the tip of the second finger is the diagonal conjugate. The obstetrical conjugate is computed by subtracting 1.5 to 2.0 cm, depending on the height and inclination of the symphysis pubis, as illustrated in [Figure 2-26](#). If the diagonal conjugate is greater than 11.5 cm, it is justifiable to assume that the pelvic inlet is of adequate size for vaginal delivery of a normal-sized fetus.

Transverse contraction of the inlet can be measured only by imaging pelvimetry. Pelvic contraction is possible even if the anteroposterior diameter is adequate.

Engagement. Descent of the biparietal plane of the fetal head to a level below that of the pelvic inlet is termed *engagement* ([Fig. 2-27](#)). When the biparietal ⌀ —the largest ⌀ —diameter of the normally flexed fetal head has passed through the inlet, the head is engaged. Although engagement usually is regarded as a phenomenon of labor, in nulliparas it may occur during the last few weeks of pregnancy. When it does so, it is confirmatory evidence that the pelvic inlet is adequate for that fetal head. **With engagement, the fetal head serves as an internal pelvimeter to demonstrate that the pelvic inlet is ample for that fetus.**

Engagement is ascertained by vaginal examination or by abdominal palpation. With vaginal examination, the station of the lowermost part of the fetal head in relation to the level of the ischial spines is determined. If the lowest part of the occiput is at or below the level of the spines, the head usually, but not always, is engaged. The distance from the plane of the pelvic inlet to the level of the ischial spines is approximately 5 cm in most pelvises. Although the distance from the biparietal plane of the unmolded fetal head to the vertex is usually only 3 to 4 cm, accurate determination of engagement may be difficult if there is considerable elongation of the fetal head from molding or formation of a *caput succedaneum*.

Abdominal examination is a less satisfactory method to determine engagement. If the biparietal plane of a term-sized infant has descended through the inlet, the examining fingers cannot reach the lowermost part of the head. Thus, when pushed downward over the lower abdomen, the examining fingers will slide over that portion of the head proximal to the biparietal plane (nape of the neck) and diverge. Conversely, if the head is not engaged, the examining fingers can easily palpate the lower part of the head and will converge.

Fixation of the fetal head occurs when descent proceeds to a depth that prevents its free movement when pushed right and then left by both hands placed over the lower abdomen. Fixation is not necessarily synonymous with engagement. Although a head that is freely movable on abdominal examination cannot be engaged, fixation of the head is sometimes seen when the biparietal plane is still 1 cm or more above the pelvic inlet, especially if the head is molded appreciably.

Pelvic Outlet Measurements. An important dimension of the pelvic outlet that is accessible for clinical measurement is the diameter between the ischial tuberosities, variously called the *bischial diameter*, *intertuberous diameter*, and *transverse diameter of the outlet*. A measurement of more than 8 cm is considered normal. The measurement of the transverse diameter of the outlet can be estimated by placing a closed fist against the perineum between the ischial tuberosities. Usually the closed fist is wider than 8 cm. The shape of the subpubic arch also can be evaluated at the same time by palpating the pubic rami from the subpubic region toward the ischial tuberosities.

Midpelvis Estimation. Clinical estimation of midpelvic capacity by any direct form of measurement is not possible. If the ischial spines are quite prominent, the sidewalls are felt to converge, and the concavity of the sacrum is very shallow, then suspicion of a contraction is aroused.

Figure 2-25. Vaginal examination to determine the diagonal conjugate. (P = sacral promontory; S = symphysis pubis.)

Figure 2-26. Variations in length of the diagonal conjugate dependent on height and inclination of the symphysis pubis. (P. = sacral promontory; Sym. = symphysis pubis.)

Figure 2-27. When the lowermost portion of the fetal head is at or below the ischial spines, it is usually engaged. Exceptions occur when there is considerable molding, caput formation, or both. (P = sacral promontory; S = ischial spine; Sym = symphysis pubis.)

3. Implantation, Embryogenesis, and Placental Development

INTRODUCTION

All obstetricians should be aware of the basic reproductive biological processes that are required for women to successfully achieve ovulation, fertilization, and implantation. A number of abnormalities can affect each of these processes and lead to infertility or pregnancy loss. In most women, spontaneous, cyclical ovulation at 25- to 35-day intervals continues throughout almost 40 years between the time of menarche and menopause. For women who never use contraception, there are approximately 400 opportunities for pregnancy, which may occur with sexual intercourse on any of 1200 days (the day of ovulation and the 2 preceding days). This narrow window available for fertilization is controlled by tightly regulated production of ovarian steroids that cause the optimal regeneration of endometrium that begins with the ending of menstruation.

Should fertilization occur, the events that unfold after the initial implantation of the blastocyst onto the surface of the endometrium through to parturition result from a unique interaction between the trophoblasts of the fetus and the endometrium-decidua of the mother. The ability of mother and fetus to coexist as two distinct immunological systems results from endocrine, paracrine, and immunological modification of fetal and maternal tissues in a manner not seen elsewhere. The placenta mediates a unique fetal-maternal communication system, which creates a hormonal environment that helps initially to maintain pregnancy and eventually initiates the events leading to parturition. The following sections address the physiology of the ovarian-endometrial cycle, implantation, the placenta and fetal membranes, and the specialized endocrine arrangements between fetus and mother.

THE OVARIAN-ENDOMETRIAL CYCLE

The endometrium-decidua is the anatomical site of blastocyst apposition, implantation, and placental development. From an evolutionary perspective, the human endometrium is highly developed to accommodate interstitial implantation and a hemochorial type of placentation. Endometrial development of a magnitude similar to that observed in women—that is, with special spiral (or coiling) arteries—is restricted to only a few primates, such as humans, great apes, and Old World monkeys. Trophoblasts of the blastocyst invade these endometrial arteries during implantation and placentation to establish uteroplacental vessels.

These primates are the only mammals that menstruate, which is a process of endometrial tissue shedding with hemorrhage that is dependent on sex steroid hormone-directed changes in blood flow in the spiral arteries. With nonfertile, but ovulatory, ovarian cycles, menstruation effects desquamation of the endometrium. New endometrial growth and development must be initiated with each cycle, so that endometrial maturation corresponds rather precisely with the next pregnancy (implantation) opportunity. There seems to be a very narrow window of endometrial receptivity to blastocyst implantation in the human that corresponds approximately to menstrual cycle days 20 to 24.

To place repetitive menstruation in perspective, the lifetime cumulative blood loss associated with normal endometrial shedding is 10 to 20 liters or more, an amount of blood that contains at least three times the total body iron content of the average adult woman. The approximately 38-year reproductive lifetime cumulative production of progesterone by corpora lutea and placenta in the woman who has two pregnancies and 450 nonfertile ovarian cycles is about 150,000 mg (150 g), which is similar to the cumulative amount of cortisol secreted by the adrenal cortices during the same 38 years. This incredible investment in endometrial tissue growth provides for regular renewal of the functional portion of this tissue in preparation for the next pregnancy opportunity.

THE OVARIAN CYCLE. The development of predictable, regular, cyclical, and spontaneous ovulatory menstrual cycles is regulated by complex interactions of the hypothalamic-pituitary axis, the ovaries, and the genital tract ([Fig. 3-1](#)). The average duration of the cycle in women of reproductive age is approximately 28 days, with a range of 25 to 32 days. The sequence of hormonal events leading to ovulation dictates the menstrual cycle. The cyclical changes in endometrial histology are faithfully reproduced during each ovulatory ovarian cycle.

In 1937, Rock and Bartlett suggested that the histological features of the endometrium were sufficiently characteristic to permit "dating" of the ovarian cycle of the woman from whom the endometrial tissue was obtained. The histological changes that occur in the endometrium during the nonfertile (but ovulatory) menstrual cycle are summarized in [Figure 3-2](#). The follicular (proliferative) phase and the postovulatory (luteal or secretory) phase of the ovarian-endometrial cycle are customarily divided into early and late stages.

Follicular (Preovulatory) Ovarian Phase. In the human ovary, 2 million oocytes are found at birth, and about 400,000 follicles are present at the onset of puberty (Baker, 1963). The remaining follicles are depleted at a rate of approximately 1000 follicles per month until 35 years of age, when this rate accelerates (Faddy and colleagues, 1992). Only 400 follicles are normally ovulated during female reproductive life. Therefore, more than 99.9 percent of follicles undergo the degenerative process known as atresia through a process of cell death termed *apoptosis* (Gougeon, 1996; Hsueh and colleagues, 1994; Kaipia and Hsueh, 1997). Human follicular development consists of several stages, which include the gonadotropin-independent recruitment of primordial follicles from the resting pool and growth of these follicles to the antral stage. This process appears to be under the control of locally produced growth factors. The production of two members of the transforming growth factor- β family, viz., growth differentiation factors 9 and 10, regulates the proliferation and differentiation of the granulosa cells as the primary follicles grow (Aaltonen and colleagues, 1999; Hreinsson and colleagues, 2002). These factors are produced by the oocytes, suggesting that the early steps in follicular development are in part oocyte controlled. As the antral follicles develop, the surrounding stromal cells are recruited in a yet-to-be-defined mechanism to become thecal cells.

Although not required for early stages of follicular development, follicle-stimulating hormone (FSH) is required for further development of large antral follicles (Hillier, 2001). During each ovarian cycle, a group of antral follicles, known as a *cohort*, begins a phase of semisynchronous growth as a result of their state of maturation at the time of the FSH rise during the late luteal phase of the previous cycle. This FSH rise leading to the development of follicles is called the *selection window* of the

ovarian cycle (Macklon and Fauser, 2001). Only the follicles progressing to this stage develop the capacity to produce estrogen.

During the follicular phase, estrogen levels rise in parallel to the growth of the dominant follicle and the increase in its number of granulosa cells (see [Fig. 3-1](#)). The granulosa cells are the exclusive site of FSH receptor expression. The increase in circulating FSH during the late luteal phase of the previous cycle stimulates an increase in FSH receptors and, subsequently, the ability to aromatize thecal cell-derived androstenedione into estradiol. The requirement for thecal cells that respond to luteinizing hormone (LH) and granulosa cells that respond to FSH represents the *two-gonadotropin, two-cell hypothesis* for estrogen biosynthesis described by Short (1962) and shown in [Figure 3-2](#). FSH induces the enzyme aromatase and expansion of the antrum of the growing follicles. The follicle within the cohort that is most responsive to FSH is likely to be the first to produce estradiol and initiate expression of LH receptors.

After the appearance of LH receptors, the preovulatory granulosa cells begin to secrete small quantities of progesterone. The preovulatory secretion of progesterone, although somewhat limited, is believed to exert positive feedback on the estrogen-primed pituitary to either cause or help augment release of LH. In addition, during the late follicular phase, LH stimulates thecal cell production of androgens, particularly androstenedione, which are then transferred to the adjacent follicles where they are metabolized to estradiol. During the early follicular phase, the granulosa cells also produce inhibin B, which can feed back on the pituitary to inhibit FSH release (Groome and colleagues, 1996). As the dominant follicle begins to grow, the production of estradiol and the inhibins increases, resulting in a decline of follicular-phase FSH. This drop in FSH is responsible for the failure of other follicles to reach preovulatory status — *the Graafian follicle stage* — during any one cycle. Thus, 95 percent of plasma estradiol produced at this time is secreted by the dominant follicle, which is destined to ovulate. The contralateral ovary is relatively inactive.

Ovulation. The onset of the gonadotropin surge resulting from increasing secretion of estrogen by preovulatory follicles is a relatively precise predictor of the time of ovulation, occurring some 34 to 36 hours before the release of the ovum from the follicle (see [Fig. 3-1](#)). The peak of LH secretion occurs 10 to 12 hours before ovulation and stimulates the resumption of the meiosis process in the ovum with the release of the first polar body. At this time a protrusion of the follicular wall (the stigma) develops, which then ruptures, allowing release of the oocyte-cumulus complex. It has long been suggested that the actual rupture of the follicle is controlled by the plasminogen activator group of proteases (Beers, 1975). Current studies suggest that in response to LH, increased production of progesterone and prostaglandins activates members of both the plasminogen activator and matrix metalloproteinases. Activation of these proteases is likely to play a pivotal role in the weakening of the follicular basement membrane and ovulation (Ny and colleagues, 2002).

Luteal (Postovulatory) Phase of the Ovary. Following ovulation, the corpus luteum develops from the remains of the dominant or *Graafian follicle* in a process referred to as *luteinization*. Rupture of the follicle initiates a series of morphological and chemical changes leading to transformation into the corpus luteum (Browning, 1973). The basement membrane separating the granulosa-lutein and theca-lutein cells breaks down, and by day 2 postovulation, blood vessels and capillaries invade the granulosa cell layer. The rapid neovascularization of the once avascular granulosa may be due to a variety of angiogenic factors. These include vascular endothelial growth factor and others produced in response to LH by the theca-lutein and granulosa-lutein cells (Albrecht and Pepe, 2003; Fraser and Wulff, 2001). During luteinization, these cells undergo hypertrophy and increase their capacity to synthesize hormones (see [Figs. 3-1](#) and [3-2](#)).

That LH is the primary luteotropic factor was well established in studies of hypophysectomized women (Vande Wiele and colleagues, 1970). In these women, the life span of the corpus luteum is dependent on repeated injections of LH or human chorionic gonadotropin (hCG). In addition, LH injections can extend the life span of the corpus luteum in normal women by 2 weeks (Segaloff and colleagues, 1951). In normal cycling women, the corpus luteum is maintained by low-frequency, high-amplitude pulses of LH secreted by gonadotropes in the anterior pituitary (Filicori and colleagues, 1986).

The pattern of hormone secretion by the corpus luteum is different from that of the follicle (see [Fig. 3-1](#)). The increased capacity of the granulosa-lutein cells to produce progesterone is the result of increased access to considerably more steroidogenic precursors through blood-borne low-density lipoprotein (LDL)-derived cholesterol (Carr and colleagues, 1981b). It is due as well to changes in the level of steroidogenic acute regulatory protein, which allows rapid use of this cholesterol for progesterone biosynthesis (Devoto and colleagues, 2002). The important role for LDL in progesterone biosynthesis is supported by the observation that women with extremely low levels of LDL cholesterol exhibit low progesterone secretion during the luteal phase (Illingworth and colleagues, 1982). In addition, high-density lipoprotein (HDL) may contribute to progesterone production in granulosa-lutein cells (Ragoobir and colleagues, 2002).

Estrogen levels follow a more complex pattern of secretion. Specifically, just after ovulation, estrogen levels decrease followed by a secondary rise that reaches a peak production of 0.25 mg/day of 17 β -estradiol at the midluteal phase. Toward the end of the luteal phase there is a secondary decrease in estradiol production. Ovarian production of progesterone peaks at 25 to 50 mg/day during the midluteal phase. If pregnancy occurs, the corpus luteum continues production of progesterone in response to embryonic hCG, which will bind and activate luteal cell LH receptors (see [Fig. 3-2](#)).

The human corpus luteum is a transient endocrine organ that, in the absence of pregnancy, will rapidly regress 9 to 11 days after ovulation. The mechanisms that control luteolysis of the human corpus luteum remain unclear. In part luteolysis results from the combination of decreased levels of circulating LH in the late luteal phase and decreased LH sensitivity of luteal cells (Duncan and colleagues, 1996; Filicori and colleagues, 1986). The role of other luteotropic factors in women is less clear, however, prostaglandin F_{2 α} (PGF_{2 α}) appears to be luteolytic in nonhuman primates as well as in women (Auletta, 1987; Wentz and Jones, 1973). Within the corpus luteum, luteolysis is characterized by a loss of luteal cells due to an increase in apoptotic cell death (Vaskivuo and colleagues, 2002). The endocrine effects, consisting of a dramatic drop in circulating levels of estradiol and progesterone, are critical to allow the follicular development and ovulation of the next ovarian cycle. In addition, the regression of the corpus luteum and drop in circulating steroids signal the endometrium to initiate the molecular events that will lead to menstruation.

Figure 3-1. Gonadotropin control of the ovarian and endometrial cycles. The ovarian-endometrial cycle has been structured as a 28-day cycle. The follicular

phase (days 1 to 14) is characterized by rising levels of estrogen, thickening of the endometrium, and selection of the dominant "ovulatory" follicle. During the luteal phase (days 14 to 28), the corpus luteum produces estrogen and progesterone, which prepare the endometrium for implantation. If implantation occurs, the developing blastocysts will begin to produce human chorionic gonadotropin (hCG) and rescue the corpus luteum, thus maintaining progesterone production. (FSH = follicle-stimulating hormone; LH = luteinizing hormone.)

Figure 3-2. The two-cell-two-gonadotropin principle of ovarian steroid hormone production. During the follicular phase (*left panel*), luteinizing hormone (LH) controls theca cell production of androstenedione, which diffuses into the adjacent granulosa cells and acts as precursor for estradiol biosynthesis. The capacity for the granulosa cell to convert androstenedione to estradiol is controlled by follicle-stimulating hormone (FSH). After ovulation, the corpus luteum forms and both theca-lutein and granulosa-lutein cells respond to LH. The theca-lutein cells continue to produce androstenedione, while granulosa-lutein cells greatly increase the capacity to produce progesterone as well as to convert androstenedione to estradiol. If pregnancy occurs, the production of human chorionic gonadotropin (hCG) by the placenta rescues the corpus luteum through the LH receptor. (cAMP = cyclic adenosine monophosphate.)

ESTROGEN AND PROGESTERONE ACTION. The fluctuating levels of ovarian steroids are the direct cause of the endometrial cycle. Recent advances in the molecular biology of receptors for estrogen and progesterone have greatly improved our understanding of how sex steroids regulate the endometrium. 17β -Estradiol, the most biologically potent naturally occurring estrogen, is secreted by the granulosa cells of the dominant ovarian follicle and luteinized granulosa cells of the corpus luteum (see [Figs. 3-1](#) and [3-2](#)). Estrogen is the essential hormonal signal on which most events in the normal menstrual cycle depend. Estradiol action is complex and appears to involve two classical nuclear hormone receptors, which have been designated estrogen receptor α (ER α) and estrogen receptor β (ER β) (Katzenellenbogen and colleagues, 2001). These isoforms are the product of separate genes and can exhibit distinct tissue differences in relative expression. Both estradiol-receptor complexes act as transcriptional factors that become associated with the estrogen response element of specific genes. Both share a robust activation by estradiol, but there are differences in the binding of other estrogens, making these receptors targets for selective estrogen receptor modulators.

The interaction with steroid ligands brings about estrogen receptor-specific initiation of gene transcription, which promotes the synthesis of specific messenger RNAs, and thereafter the synthesis of specific proteins. Among the many proteins synthesized in most estrogen-responsive cells are additional estrogen receptors and progesterone receptors. In addition, estradiol has been proposed to act at the cell surface to stimulate nitric oxide production in endothelial cells, leading to the rapid vasoactive properties of estradiol (Shaul, 2002). The ability of estradiol to work in the cell nucleus through classical ligand-regulated nuclear hormone receptors and at the cell surface to cause rapid changes in cell signaling molecules is one explanation for the complex responses seen as a result of estrogen therapies.

It is likely that estradiol and other bioactive estrogens cause replication of the endometrium indirectly (through actions on stromal cells). The expression pattern of ER α and ER β in the various cellular components of the endometrium has been examined using immunohistochemistry (Lecce and colleagues, 2001). ER β is expressed in glands, stroma, and vascular cells of the endometrium. ER β levels are highest during the proliferative phase of the cycle. With the development and widespread use of selective estrogen receptor modulators, the differential expression and roles of the two isoforms of estrogen receptor within the endometrium will need careful study.

The majority of effects of progesterone on the female reproductive tract are mediated through nuclear hormone receptors. Progesterone enters cells by diffusion and in responsive tissues becomes associated with progesterone receptors (Conneely and colleagues, 2002). There are two distinct isoforms of the human progesterone receptor, viz., the progesterone receptor type A (PR-A) and type B (PR-B). Both arise from a single gene, are members of the steroid receptor superfamily of transcription factors, and regulate transcription of target genes. These receptors may have unique actions within cells. When the PR-A and PR-B receptors are co-expressed, it appears that the PR-A can act as an inhibitor of PR-B gene regulation. The repressor effect of PR-A may extend to actions on other steroid receptors, including estrogen receptors. In addition, progesterone may act by receptor-independent nongenomic mechanisms. Membrane receptors for progesterone have been best characterized in human spermatozoa, but their role in other human tissues is not currently clear (Luconi and colleagues, 2002).

The expression patterns of PR-A and PR-B receptors in the human endometrium have been examined using immunohistochemistry (Mote and colleagues, 1999). The endometrial glands and stroma appear to have different expression patterns for PR-A and PR-B, which vary over the menstrual cycle. The glands express both receptors in the proliferative phase, suggesting that both receptors are involved with subnuclear vacuole formation. After ovulation the glands continue to express PR-B through the midluteal phase, suggesting that glandular secretion seen during the luteal phase is PR-B regulated. In contrast, the stroma and predecidual cells express only PR-A throughout the menstrual cycle, suggesting that progesterone-stimulated events within the stroma are mediated by this receptor. Progesterone receptor expression has not been observed in inflammatory cells or in endothelial cells of the endometrial vessels. Dissecting the role of these two receptor isoforms in the regulation of human menstruation may be difficult, however, studies in animal models have given evidence that the PR-A receptor regulates the antiproliferative effects of progesterone seen in the secretory phase. Specifically, ablation of PR-A expression in mice blocks decidualization and implantation. These observations imply that the two progesterone receptor

isoforms play distinct roles in the endometrium during the menstrual cycle. In addition, distinct roles for PR-A and PR-B have been proposed for the regulation of the myometrium during the initiation of labor (Mesiano and colleagues, 2002).

THE ENDOMETRIAL CYCLE

Proliferative (Preovulatory) Phase of the Endometrium.

Fluctuations in estrogen and progesterone levels produce striking effects on the reproductive tract, particularly the endometrium (Fig. 3-3). Characteristic changes occur in the endometrium during the menstrual cycle, which makes dating of the endometrium possible (Rock and Bartlett, 1937). The growth and functional characteristics of the human endometrium are unique. The epithelial (glandular) cells, the stromal (mesenchymal) cells, and the blood vessels of the endometrium replicate cyclically in reproductive-aged women at a rapid rate. The endometrium is regenerated during each ovarian-endometrial cycle. The superficial endometrium is shed and regenerated almost 400 times during the reproductive lifetime of most women. There is no other example in humans of the cyclical shedding and regrowth of an entire tissue.

Follicular-phase production of estradiol is the most important factor in recovery of the endometrium following menstruation. About two thirds of the functional endometrium is fragmented and shed during menstruation; but reepithelialization is in progress even before menstrual bleeding has ceased. By the fifth day of the endometrial cycle (first day of menses equals day 1), the epithelial surface of the endometrium has been restored and revascularization of the endometrium is in progress. The preovulatory endometrium is characterized by proliferation of vascular endothelial, stromal, and glandular cells (see Fig. 3-3). During the early part of the proliferative phase, the endometrium is thin, usually less than 2 mm in thickness. The glands at this stage are narrow, tubular structures that pursue almost a straight and parallel course from the basal layer toward the surface of the endometrial cavity. Mitotic figures, especially in the glandular epithelium, are identified by the fifth cycle day, and mitotic activity in both epithelium and stroma persists until day 16 to 17 (2 to 3 days after ovulation). Although blood vessels are numerous and prominent, there is no extravascular blood or leukocyte infiltration in the endometrium at this stage.

Clearly, reepithelialization and angiogenesis are important to the cessation of endometrial bleeding at the end of menstruation, and these processes are dependent on tissue regrowth. Estradiol appears to act by inducing growth factor gene expression in stromal cells. Stromal cell proliferation appears to increase through paracrine and autocrine action of estrogen and increased local levels of fibroblast growth factor-9 (Tsai and colleagues, 2002). Estrogens also increase local production of vascular endothelial growth factor (Bausero and colleagues, 1998; Sugino and colleagues, 2002), which causes angiogenesis through the elongation of vessels in the basalis (Gargett and Rogers, 2001).

By the late proliferative phase, the endometrium thickens, the result of both glandular hyperplasia and an increase in stromal ground substance (edema and proteinaceous material). The loose stroma is especially prominent, and the glands in the superficial portions of the endometrium (the functionalis layer) are widely separated compared with those of the deeper zone (the basalis layer), where the glands are more crowded and the stroma is denser. At midcycle, as the time of ovulation is approached, the glandular epithelium has become taller and pseudostratified. The surface epithelial cells acquire numerous microvilli, which increase epithelial surface area, and cilia, which aid in the movement of endometrial secretions in the secretory phase (Ferenczy, 1976).

Day-by-day dating of the endometrium by histological criteria is difficult during the proliferative phase because of the considerable variation among women in the length of this phase of the cycle. In apparently normal, fertile women the follicular phase may be as short as 5 to 7 days or as long as 21 to 30 days. However, the luteal or secretory (postovulatory) phase of the cycle among women is remarkably constant in duration (12 to 14 days).

Secretory (Postovulatory) Phase of the Endometrium. During the early secretory phase, the dating of the endometrium is based on the histology of the glandular epithelium. After ovulation the estrogen-primed endometrium responds to rising levels of progesterone in a highly predictable manner (see Fig. 3-3). By day 17, glycogen accumulates in the basal portion of the glandular epithelium, creating subnuclear vacuoles and pseudostratification. This is the first sign of ovulation that is reflected in histological changes, and it is likely the result of direct progesterone action through progesterone receptors expressed in the glandular cells (Mote and colleagues, 2000). On day 18, the vacuoles move to the apical portion of the secretory nonciliated cells, and by day 19, these cells begin to release their glycoprotein and mucopolysaccharide contents into the lumen through an apocrine method of secretion (Hafez and colleagues, 1975). Glandular cell mitosis ceases with the start of secretory activity on day 19 due to the rising levels of progesterone, which antagonize the mitotic effects of estrogen. Estradiol action is also decreased because of glandular expression of the type 2 form of 17β -hydroxysteroid dehydrogenase, which converts estradiol to the less active estrogen, estrone (Casey and MacDonald, 1996).

The dating of the cycle in the mid- to late-secretory phase relies on changes seen in the endometrial stroma (see Fig. 3-3). On cycle days 21 to 24, the stroma becomes edematous. On days 22 to 25, stromal cells surrounding the spiral arterioles begin to enlarge, and stromal mitosis becomes apparent. Days 23 to 28 are characterized by the presence of predecidual cells, which surround the spiral arterioles. An important characteristic of the secretory-phase endometrium occurring between days 22 and 25 is the striking change associated with the predecidual transformation of the upper two thirds of the functionalis layer. The glands exhibit extensive coiling and secretions become visible within the lumen. Changes within the endometrium also can mark the so-called window of implantation seen on days 20 to 24. Close examination of the surface epithelial cells during this time has shown a decrease in microvilli and cilia on cell surfaces as well as protrusions of the apical cell surface into the lumen (Nikas, 2003). These protrusions, termed *pinopods*, are an important event in preparation for blastocyst implantation and coincide with changes in the surface glycocalyx that allow acceptance of a blastocyst (Aplin, 2003).

In addition, this secretory phase is highlighted by the continuing growth and development of the spiral arteries. Boyd and Hamilton (1970) emphasized the extraordinary importance of the spiraling or coiled arteries of the human endometrium, pointing out that the British gynecologist William Hunter in 1774 referred to these vessels as the "curling" arteries. The endometrial spiral arteries arise from the arcuate arteries, which are branches of the uterine vessels that lie in the myometrium (see Fig. 2-9; p. 23). The morphological and functional properties of the spiral arteries are unique and essential for establishing the changes in blood flow that permit menstruation or, should fertilization occur, implantation. During the phase of endometrial growth, the spiral arteries lengthen at a rate that is appreciably greater than the rate of increase in endometrial tissue height or thickness (Fig. 3-4). This discordance in growth between the two tissues obliges even greater

coiling of the already spiraling vessels. The development of the spiral arteries represents an extraordinary induction of angiogenesis, consisting of widespread sprouting and extension of blood vessels. Perrot-Applanat and associates (1988) described progesterone and estrogen receptors in the smooth muscle cells of the uterine arteries, including the spiral arteries. These investigators further demonstrated that this rapid angiogenesis is regulated in part through estrogen- and progesterone-regulated synthesis of vascular endothelial growth factor (Ancelin and colleagues, 2002). This protein is secreted by cells within the stroma and glandular epithelium and stimulates endothelial cell proliferation and increases vascular permeability. Thus, steroid hormone influences on growth and vasculature are directed to a large degree through the local production of growth factors.

Figure 2-9. Stereographic representation of myometrial and endometrial arteries in the macaque. Above, parts of myometrial arcuate arteries from which myometrial radial arteries course toward the endometrium. Below, the larger endometrial coiled arteries and the smaller endometrial basal arteries. (From Okkels and Engle, 1938.)

Figure 3-3. Dating of the endometrium according to the day of the menstrual cycle during a hypothetical 28-day ovarian cycle. Correlation with the extent of typical morphological findings. (From Noyes and colleagues, 1950.)

Figure 3-4. Modifications in the spiral arteries of the human endometrium during the ovulatory cycle. Changes in blood flow through these vessels facilitate endometrial growth (blue band). Excessive coiling and stasis in blood flow coincides with regression of corpus luteum function, and leads to a decline in endometrial tissue volume. Just prior to the commencement of endometrial bleeding, intense spiral artery vasospasm serves to limit blood loss with menstruation.

MENSTRUATION. In the catarrhine primates, the midluteal-secretory phase of the endometrial cycle is a critical branch point in the development and differentiation of the endometrium. With rescue of the corpus luteum and continued progesterone secretion, the process of decidualization continues. If, however, the corpus luteum production of progesterone drops as a result of *luteolysis*, the events leading to menstruation will be initiated. Many of the molecular mechanisms involving endometrial progesterone withdrawal, as well as the subsequent inflammatory response that causes the sloughing of the endometrium, have been defined (Critchley and colleagues, 2001).

A notable histological characteristic of the late premenstrual-phase endometrium is the infiltration of the stroma by polymorphonuclear leukocytes, giving a pseudoinflammatory appearance to the tissue (see Fig. 3-3). The infiltration of neutrophils occurs primarily on the day or two immediately preceding the onset of menstruation. The endometrial stromal and epithelial cells produce interleukin-8 (IL-8), a chemotactic-activating factor for neutrophils (Arici and colleagues, 1993). IL-8 may be one of the agents that serve to recruit neutrophils to the endometrium just prior to the onset of menstruation. Similarly, the endometrium is capable of synthesizing monocyte chemoattractant protein-1 (MCP-1), a potent chemoattractant for monocytes (Arici and colleagues, 1995). The rates of synthesis of IL-8 and MCP-1 in endometrial stromal cells appear to be modulated, in part, by circulating sex steroid hormones and local production of transforming growth factor- β (Arici and colleagues, 1996a, 1996b).

The infiltration of leukocytes is considered key to initiation of extracellular matrix breakdown of the functionalis layer. The invading leukocytes secrete enzymes that are members of the matrix metalloproteinase family of proteins. These metalloproteinases add to the proteases already produced by the endometrial stromal cells. The rising level of metalloproteinases tips the balance between proteases and protease inhibitors, effectively initiating degradation of the matrix. This phenomenon has been proposed to initiate the events leading to menstruation (Dong and colleagues, 2002).

A classical study by Markee (1940) described the tissue and vascular changes that occur in endometrium before menstruation. He observed 432 separate cyclical alterations in endometrial tissue explants that he had transplanted to the anterior chamber of the eye of rhesus monkeys. There were marked changes in blood flow to the endometrium during the time of growth regression, which are essential for menstruation. As the regression of the endometrium occurs, the coiling of the spiral arteries becomes sufficiently severe that the resistance to blood flow in these vessels is increased strikingly, causing hypoxia of the endometrium. The resultant stasis is the primary cause of endometrial ischemia and then tissue degeneration. A period of vasoconstriction precedes the onset of menstruation and is the most striking and constant event observed in the menstrual cycle. The intense vasoconstriction of the spiral arteries serves to limit blood loss during menstruation. Blood flow in the spiral arteries appears to be regulated in an endocrine manner by sex steroid hormone-induced modifications of a local (paracrine-mediated) vasoactive peptide system.

Prostaglandins and Menstruation. Prostaglandins are most often synthesized within the same tissue in which they act through autocrine or paracrine mechanisms, or both. Prostaglandins act through a host of separate but specific plasma membrane G-protein-linked receptors that can activate diverse cellular signaling cascades and thus provide an additional level of specificity to the various prostaglandins. Prostaglandins can be degraded rapidly in the tissues of origin, for example, endometrium, in nearby tissues, or in more remote sites such as the lungs in a reaction catalyzed by prostaglandin dehydrogenase (Casey and colleagues, 1980, 1989).

A role for prostaglandins, especially prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), which is a vasoconstrictor, in the initiation of menstruation has

been suggested (Abel, 2002). Large amounts of prostaglandins are present in menstrual blood. The administration of $\text{PGF}_{2\alpha}$ to women gives rise to symptoms that mimic dysmenorrhea, which is commonly associated with normal menses and likely is caused by myometrial contractions and uterine ischemia. The administration of $\text{PGF}_{2\alpha}$ to nonpregnant women also will cause menstruation. This response is believed to be mediated by $\text{PGF}_{2\alpha}$ -induced vasoconstriction of the endometrial spiral arteries.

Vasoactive Peptides and Menstruation. The actions of a number of peptides may comprise a hormone-responsive paracrine system in the endometrium to regulate spiral artery blood flow. One is the endothelin-enkephalinase system (Casey and MacDonald, 1996). The endothelins are—ET-1, ET-2, and ET-3—are small, 21-amino acid peptides. Endothelin-1 (ET-1) is a potent vasoconstrictor that was first identified as a product of vascular endothelial cells (Yanagisawa and colleagues, 1988). The endothelins are degraded by the enzyme enkephalinase. Enkephalinase is localized in endometrial stromal cells, and its specific activity in these cells increases strikingly and in parallel with the increase in blood levels of progesterone after ovulation. The specific activity of enkephalinase in endometrium is highest during the midluteal phase of the ovarian cycle and declines steadily thereafter as the plasma levels of progesterone decrease with regression of the corpus luteum (Casey and colleagues, 1991).

Origin of Menstrual Blood. Menstrual bleeding is of both arterial and venous origin, but arterial bleeding is, quantitatively, appreciably greater than venous. Endometrial bleeding appears to begin by rupture of an arteriole of a coiled artery, with consequent formation of a hematoma. On occasion, however, bleeding takes place by leakage through a spiral artery. When a hematoma forms, the superficial endometrium is distended and then ruptures. Subsequently, fissures develop in the adjacent functionalis layers and blood, as well as fragments of tissue of various sizes, is detached. Although some tissue autolysis occurs, as a rule, fragments of endometrium can be identified in menstrual discharge collected from the vagina. Hemorrhage stops when the arterioles are again constricted. The changes that accompany partial tissue necrosis also serve to seal off the tips of the vessels. Often only the endothelium remains in the superficial portion.

The surface of the endometrium is restored, by growth of the flanges, or collars, that form the everted free ends of the uterine glands (Markee, 1940). These flanges increase in diameter very rapidly, and the continuity of the epithelium is reestablished by the fusion of the edges of these sheets of migrating thin cells.

Interval Between Menses. The modal interval at which menstruation recurs is considered to be 28 days, but there is considerable variation among women in general, as well as in the cycle lengths of a given woman. Marked variation in the intervals between menstrual cycles is not necessarily indicative of infertility. Arey (1939) analyzed the findings of 12 studies comprising about 20,000 calendar records from 1500 women and concluded that there is no evidence of perfect menstrual cycle regularity. He found that among average adult women, one third of menstrual cycles departed by more than 2 days from the mean of the lengths of all cycles. In Arey's analysis of 5322 cycles in 485 normal women, an average interval of 28.4 days was estimated; his finding for the average cycle length in pubertal girls was longer, 33.9 days. Haman (1942) surveyed 2460 cycles in 150 women who attended a clinic where special attention was directed to recording accurately the length of the menstrual cycles. The distribution curve for menstrual cycle length, computed from averages from both the Haman and Arey studies, is shown in [Figure 3-5](#).

Figure 3-5. Duration of menstrual cycle. (Based on distribution data of Arey, 1939, and Haman, 1942.)

THE DECIDUA OF THE ENDOMETRIUM. The decidua is a specialized, highly modified endometrium of pregnancy and is a function of hemochorial placentation. This form of placentation has in common the process of trophoblast invasion, and therefore considerable research has focused on the interaction between the cells within the decidua and the invading trophoblasts. Decidualization, the transformation of secretory endometrium to decidua, is dependent on the action of estrogen and progesterone and factors secreted by the implanting blastocyst during trophoblast invasion. The special relationship that exists between the decidua and the invading trophoblast seemingly defies the laws of transplantation immunology (Beer and Billingham, 1971). The success of this unique semiallograft not only is of great scientific interest but may involve processes that harbor insights leading to more successful transplantation surgery and perhaps even immunological treatment of neoplasia (Billingham and Head, 1986; Lala and colleagues, 2002).

Decidual Structure. William Hunter, the 18th-century British gynecologist, provided the first scientific description of the *membrana decidua*. According to Damjanov (1985), the term *membrana* denoted its gross anatomical appearance, while *decidua* was added with analogy to deciduous leaves to indicate an ephemeral nature and the fact that it is shed from the rest of the uterus after childbirth. The decidua of pregnancy is composed of three parts based on its anatomical location. The portion of the decidua directly beneath the site of blastocyst implantation is modified by trophoblast invasion and becomes the *decidua basalis*. That portion overlying the enlarging blastocyst, and initially separating it from the rest of the uterine cavity, is the *decidua capsularis* ([Fig. 3-6](#)). The decidua capsularis is most prominent during the second month of pregnancy, consisting of decidual cells covered by a single layer of flattened epithelial cells without traces of glands. Internally, this portion of the decidua contacts the avascular, extraembryonic fetal membrane, the *chorion laeve*. The remainder of the uterus is lined by *decidua parietalis*, sometimes called the *decidua vera* at the point in development when decidua capsularis and decidua parietalis are joined.

During the early weeks of pregnancy, there is a space between the decidua capsularis and decidua parietalis because the gestational sac does not fill the entire uterine cavity. By 14 to 16 weeks, the expanding sac has enlarged enough to fill the uterine cavity. With fusion of the decidua capsularis and parietalis, the uterine cavity is functionally obliterated. In early pregnancy, the decidua begins to thicken, eventually attaining a depth of 5 to 10 mm. With magnification, furrows and numerous small openings, representing the mouths of uterine glands, can be detected. Later in pregnancy, as the fetus grows and the amniotic fluid expands, the thickness of the decidua decreases, presumably because of the pressure exerted by the

expanding uterine contents.

The decidua parietalis and the decidua basalis, like the secretory endometrium, each are composed of three layers: a surface, or compact zone (zona compacta); a middle portion, or spongy zone (zona spongiosa), with remnants of glands and numerous small blood vessels; and a basal zone (zona basalis). The zona compacta and spongiosa together form the functional zone (zona functionalis). The basal zone remains after delivery and gives rise to new endometrium.

The Decidual Reaction. In human pregnancy, the decidual reaction is completed only with blastocyst implantation. Predecidual changes, however, commence first during the midluteal phase in endometrial stromal cells adjacent to the spiral arteries and arterioles, spreading thereafter in waves throughout the mucosa of the uterus and then from the site of implantation. The endometrial stromal cells enlarge to form polygonal or round decidual cells. The nuclei become round and vesicular, and the cytoplasm becomes clear, slightly basophilic, and surrounded by a translucent membrane. Each mature decidual cell becomes surrounded by a pericellular membrane. Thus, the human decidual cells clearly build walls around themselves and possibly around the fetus. The pericellular matrix surrounding the decidual cells may provide for attachment of cytotrophoblasts through cellular adhesion molecules. The pericellular decidual cell membrane also may provide for protection of the decidual cell against selected proteases of the cytotrophoblasts.

Decidual Blood Supply. This supply is changed as a consequence of implantation. The blood supply to the decidua capsularis is lost as the embryo-fetus grows and expands into the uterine cavity. The blood supply to the decidua parietalis through the spiral arteries persists, as in the endometrium during the luteal phase of the cycle. The spiral arteries in the decidua parietalis retain a smooth muscle wall and endothelium and thereby remain responsive to vasoactive agents that act on the smooth muscle or the endothelial cells of these vessels.

The spiral arterial system supplying the decidua basalis directly beneath the implanting blastocyst, and ultimately the intervillous space surrounding the syncytiotrophoblast of the placenta, is altered remarkably. These spiral arterioles and arteries are invaded by the cytotrophoblasts, and during this process the walls of the vessels in the basalis are destroyed, leaving only a shell without smooth muscle or endothelial cells. As a consequence, these vascular conduits of maternal blood — which become the uteroplacental vessels — are not responsive to vasoactive agents. By contrast, the fetal chorionic vessels, which transport blood between the placenta and the fetus, contain smooth muscle and do respond to vasoactive agents.

Decidual Histology. The decidua is composed of a variety of cell types, which varies with the stage of gestation (Loke and King, 1995). The primary cellular components of the decidua are the true decidual cells that differentiated from the endometrial stromal cells and numerous bone marrow-derived cells. The compact layer of the decidua consists of large, closely packed, epithelioid, polygonal, lightly staining cells with round nuclei. Many stromal cells appear stellate, with long protoplasmic processes that anastomose with those of adjacent cells. This is particularly so when the decidua is edematous. Numerous small round cells, which contain very little cytoplasm, are scattered among the decidual cells, especially in early pregnancy. Most of these are a particular type of natural killer lymphocyte and are referred to as *endometrial large granular lymphocytes (LGLs)*, in which a special and unusual phenotype has been defined (Vince and Johnson, 2000). These are bone marrow-derived cells that at one time entered endometrium from peripheral blood. But thereafter, these large granular lymphocytes arise primarily by replication in the endometrium in situ at specific times in the menstrual cycle and during the first trimester.

Early in pregnancy, the spongy layer of the decidua consists of large distended glands, often exhibiting marked hyperplasia and separated by minimal stroma. At first, the glands are lined by typical cylindrical uterine epithelium. They have abundant secretory activity that contributes to the nourishment of the blastocyst. As pregnancy progresses, the epithelium gradually becomes cuboidal or even flattened, later degenerating and sloughing to a greater extent into the lumens of the glands. Later in pregnancy the glandular elements of the decidua largely disappear. In comparing the decidua parietalis at 16 weeks with the early proliferative endometrium of a nonpregnant woman, it is clear that there is marked hypertrophy but only slight hyperplasia of the endometrial stroma during decidual transformation.

The decidua basalis contributes to the formation of the basal plate of the placenta, and differs histologically from the decidua parietalis in two important respects (Fig. 3-7). First, the spongy zone of the decidua basalis consists mainly of arteries and widely dilated veins, but by term, the glands have virtually disappeared. Second, the decidua basalis is invaded by large numbers of interstitial trophoblast cells and trophoblastic giant cells. Although most abundant in the decidua, the giant cells commonly penetrate the upper myometrium. Their number and invasiveness may be so extensive as to be confused with choriocarcinoma by the inexperienced observer.

Where invading trophoblasts meet the decidua, there is a zone of fibrinoid degeneration, the *Nitabuch layer*. Whenever the decidua is defective, as in placenta accreta, the Nitabuch layer is usually absent (see Chap. 35, p. 830). There is also a more superficial, but inconsistent deposition of fibrin — *Rohr stria* — at the bottom of the intervillous space and surrounding the anchoring villi. McCombs and Craig (1964) found that decidual necrosis is a normal phenomenon in the first and probably the second trimester. Thus, necrotic decidua obtained through curettage after spontaneous abortion in the first trimester should not necessarily be interpreted as either a cause or an effect of the pregnancy loss.

Decidual Prolactin Production. Convincing evidence has been presented that the decidua is the source of the prolactin that is present in enormous amounts in amniotic fluid during human pregnancy (Golander and colleagues, 1978; Riddick and colleagues, 1979). Decidual prolactin is not to be confused with placental lactogen (hPL), which is produced only by the syncytiotrophoblast. Rather, decidual prolactin is a product of the same gene that encodes for prolactin that is secreted by the anterior pituitary, and the amino acid sequence of prolactin in both tissues is identical. In decidua, however, an alternative promoter is used within the prolactin gene to initiate transcription (Telgmann and Gellersen, 1998). This alternative prolactin promoter through novel transcription factors is thought to explain the different mechanisms that regulate expression in the decidua versus pituitary (Christian and colleagues, 2002a, 2000b).

The levels of prolactin in amniotic fluid may reach 10,000 nq/mL during the 20th to 24th weeks (Tyson and colleagues, 1972). This is extraordinarily high compared with the 350 ng/mL seen in the fetus or 150 to 200 ng/mL seen in maternal plasma. Prolactin produced in decidua preferentially enters amniotic fluid, and little or none enters maternal blood. This is a classical example of paracrine function between maternal and fetal tissues.

The factors that regulate prolactin production in decidua are not clearly defined. Most of the agents known to inhibit or stimulate anterior pituitary prolactin secretion, including dopamine, dopamine agonists, and thyrotropin-releasing hormone, do not alter the rate of decidual prolactin secretion either in vivo or in vitro. Brosens and colleagues (2000) demonstrated that progestins act synergistically with cyclic adenosine monophosphate on human endometrial stromal cells in culture to increase the expression of prolactin. These findings suggest that the level of progesterone receptor expression may determine the decidualization process, as marked by prolactin production. It has been reported that arachidonic acid, but not PGF_{2α} or PGE₂, attenuates the rate of decidual prolactin secretion (Handwerger and colleagues, 1981). In addition, a variety of cytokines and growth factors, including ET-1, IL-1, IL-2, and epidermal growth factor, act to decrease decidual prolactin secretion (Chao and colleagues, 1994; Frank and colleagues, 1995).

The exact physiological roles of prolactin produced in decidua are still unknown. Prolactin action is mediated by the relative expression of two unique prolactin receptors as well as the amount of intact (full-length) prolactin protein versus the truncated (16-kDa) form (Jabbour and Critchley, 2001). Receptor expression has been demonstrated in decidua, chorionic cytotrophoblasts, amnionic epithelium, and placental syncytiotrophoblast (Maaskant and colleagues, 1996). Because all (or most) of the prolactin produced in decidua enters amniotic fluid, it has been speculated that there may be a role for this hormone in solute and water transport across the amniochorion, and thus in the maintenance of amniotic fluid volume homeostasis. It also has been shown, however, that prolactin receptors are present in a number of bone marrow-derived immune cells, and that prolactin may act on human T cells in an autocrine or paracrine manner (Pellegrini and colleagues, 1992). Therefore, prolactin produced in decidua may act in regulating immunological functions in this tissue during pregnancy. Prolactin also may play a role in the regulation of angiogenesis that occurs during implantation. In this regard, the intact (full-length) prolactin protein can enhance angiogenesis while the proteolytic fragment (16-kDa) form can inhibit angiogenesis. Thus, the role of prolactin may vary dramatically at different periods of gestation based on the type of receptors expressed and the relative form of prolactin present.

Figure 3-6. Decidualized endometrium covers the early embryo. Three portions of the decidua (basalis, capsularis, and vera or parietalis) also are illustrated.

Figure 3-7. Section through junction of chorion and decidua basalis at fourth month of gestation. (CV = chorionic villi; DB = decidua basalis; FD = fibrinoid degeneration; GC = giant cell; IS = intervillous space containing maternal blood; P = fastening villus; PT = proliferating trophoblast.)

IMPLANTATION AND FORMATION OF THE PLACENTA AND FETAL MEMBRANES

The development of the human placenta is as uniquely intriguing as the embryology of the fetus. During its brief intrauterine existence, the fetus is dependent on the placenta for pulmonary, hepatic, and renal functions. The placenta accomplishes these functions through its unique anatomical association with the mother. The placenta links the mother and fetus by indirect interaction with the maternal blood that spurts out of the uteroplacental vessels. This blood bathes the outer syncytiotrophoblast, allowing exchange of gases and nutrients with fetal capillary blood within the connective tissue at the villous core. Fetal and maternal blood are not mixed in this hemochorial type of placenta. There is also a paracrine system that links the mother and fetus through the anatomical and biochemical juxtaposition of extraembryonic chorion laeve of fetal origin and maternal uterine decidua parietalis tissue. This is an extraordinarily important arrangement for communication between fetus and mother, for maternal immunological acceptance of the conceptus, and possibly for controlling the timing of parturition.

FERTILIZATION AND IMPLANTATION

Ovum Fertilization and Zygote Cleavage. The union of egg and sperm at fertilization represents one of the most important processes in biology. Ovulation frees the secondary oocyte and the adhering cells of the cumulus oophorus from the ovary. Although technically this mass of cells is released into the peritoneal cavity, the oocyte is quickly engulfed by the infundibulum of the fallopian tube. Transport of the oocyte through the fallopian tube toward the uterus is accomplished by directional movement of ciliary action as well as peristalsis. Fertilization occurs in the fallopian tube, and it is generally agreed that fertilization of the ovum must occur a few hours and no more than a day after ovulation. Consequently, spermatozoa must be present in the fallopian tube at the time of oocyte arrival. Almost all pregnancies occur when intercourse occurs during the 2 days preceding or on the day of ovulation. Thus the postovulatory and postfertilization developmental ages are similar. The steps involved to achieve fertilization are highly complex and have been the topic of much research. The molecular mechanisms that allow passage of spermatozoa between the follicular cells, through the zona pellucida, and into the oocyte cytoplasm leading to the formation of the zygote continue to be unraveled and recently have been reviewed (Primakoff and Myles, 2002).

In this chapter, the timing of events in early human development is described as days or weeks postfertilization, viz., postconceptional, rather than using the clinical pregnancy dating convention of weeks from the start of the last menstrual period. As discussed on page 46, the length of the follicular phase of the menstrual cycle is subject to more variability than that of the luteal phase. Thus, 1 week postfertilization corresponds to approximately 3 weeks from the last menstrual period in

women with regular 28-day cycles.

After fertilization in the fallopian tube, the mature ovum becomes a zygote—a diploid cell with 46 chromosomes—that then undergoes cleavage into blastomeres (Fig. 3-8). In the two-cell zygote, the blastomeres and the polar body are free in the perivitelline fluid and are surrounded by a thick zona pellucida. The zygote undergoes slow cleavage for 3 days while still within the fallopian tube. As the blastomeres continue to divide, a solid mulberry-like ball of cells, referred to as the *morula*, is produced (Fig. 3-8D). The morula enters the uterine cavity about 3 days after fertilization. The gradual accumulation of fluid between the cells of the morula results in the formation of the early blastocyst.

In a 58-cell blastocyst, the outer cells, called the *trophectoderm*, can be distinguished from the inner cell mass that forms the embryo (Fig. 3-8E). In the earliest stages of the human blastocyst, the wall of the primitive blastodermic vesicle is characterized as consisting of a single layer of ectoderm. As early as 4 to 5 days after fertilization, the 58-cell blastula differentiates into five embryo-producing cells known as the *inner cell mass*, and 53 cells destined to form trophoblasts (Hertig, 1962).

Interestingly, the 107-cell blastocyst is found to be no larger than the earlier cleavage stages, despite the accumulated fluid (Fig. 3-8F). It measured 0.155 mm in diameter, which is similar to the size of the initial postfertilization zygote. At this stage the eight formative, or embryo-producing, cells are surrounded by 99 trophoblastic cells. It is at this stage that the blastocyst is released from the zona pellucida as a result of secretion of specific proteases from the secretory-phase endometrial glands (O'Sullivan and colleagues, 2002).

Release from the zona pellucida allows blastocyst-produced cytokines and hormones to directly influence the receptivity of the endometrium (Lindhard and colleagues, 2002). Evidence has accumulated that IL-1 α and IL-1 β are secreted by the blastocyst and that these cytokines can directly influence the endometrium. Embryos also have been shown to secrete human chorionic gonadotropin (hCG), which may influence endometrial receptivity (Licht and colleagues, 2001; Lobo and colleagues, 2001). The receptive endometrium is thought to respond by producing leukemia inhibitory factor and colony-stimulating factor-1, which increase trophoblast production of proteases that degrade selected endometrial extracellular matrix proteins and allow trophoblast invasion. Thus, embryo "hatching" is a critical step toward successful pregnancy as it allows association of the trophoblasts with the epithelial cells of the endometrium and the release of trophoblast-produced hormones into the uterine cavity.

Implantation of the Blastocyst. Implantation of the embryo into the wall of the uterus is a common feature of all mammals and in humans occurs six or seven days after fertilization. Successful implantation requires a receptive endometrium that has been appropriately primed with estrogen and progesterone. As shown in Figure 3-1, uterine receptivity toward the blastocyst is limited to days 20 to 24 of the ovarian-endometrial cycle (Bergh and Navot, 1992). The ability of the blastocyst to adhere to the epithelium is mediated by cell surface receptors at the implantation site that interact with receptors on the blastocyst (Carson, 2002; Lessey and Castelbaum, 2002; Lindhard and colleagues, 2002; Paria and colleagues, 2002). The development of the receptive epithelia results from the postovulatory production of estrogen and progesterone by the corpus luteum. If the blastocyst approaches the endometrium after cycle day 24, the potential for adhesion is diminished because of the synthesis of antiadhesive glycoproteins, which prevent receptor interactions (Navot and Bergh, 1991).

At the time of its interaction with the endometrium, the blastocyst is composed of 100 to 250 cells. The blastocyst loosely adheres to the endometrial epithelium, a process called *apposition*, which most commonly occurs on the endometrium of the upper posterior wall of the uterus. Although as subsequently discussed, syncytiotrophoblast has not been distinguished prior to human blastocyst implantation, syncytiotrophoblast has been observed in the earliest implanted blastocyst of the macaque monkey (Boyd and Hamilton, 1970). The attachment of the trophoblast of the blastocyst to the endometrial surface by apposition and adherence appears to be closely regulated by paracrine interactions between these two tissues.

Successful adhesion of the blastocyst to the endometrium also involves modification in the expression of cellular adhesion molecules. The integrins, one of four families of cell adhesion molecules, are cell-surface receptors that mediate the adhesion of cells to extracellular matrix proteins (Lessey and Castelbaum, 2002). Great diversity of cell binding to a host of different extracellular matrix proteins is possible by differential regulation of the integrin system of receptors. An alteration of integrin subunit expression on the endometrial epithelial cells is considered a marker of receptivity for blastocyst attachment.

Figure 3-8. Cleavage of the zygote and formation of the blastocyst. **A** through **D** show various stages of cleavage. The period of the morula begins at the 12- to 16-cell stage and ends when the blastocyst forms, which occurs when there are 50 to 60 blastomeres present. **E** and **F** are sections of blastocysts. The zona pellucida has disappeared by the late blastocyst stage (5 days). The polar bodies shown in **A** are small, nonfunctional cells that soon degenerate. (From Moore, 1988.)

BIOLOGY OF THE TROPHOBLAST. The formation of the human placenta begins with the trophoblast, which is the first tissue to differentiate at the morula stage of development, giving rise to a layer of trophoblast cells encircling the blastocyst. From the early blastocyst to term placenta, the trophoblast plays critical roles at the fetal-maternal interface. The trophoblast exhibits the most variable structure, function, and developmental pattern of all placental components. Its invasiveness provides for attachment of the blastocyst to the decidua; its role in nutrition of the conceptus is reflected in its name; and its function as an endocrine organ in human pregnancy is essential to maternal physiological adaptations and to the maintenance of pregnancy.

Trophoblast Differentiation. By the eighth day postfertilization, after initial implantation of the blastocyst, the trophoblast has differentiated into an outer multinucleated syncytium, the primitive *syncytiotrophoblast*, and an inner layer of primitive mononuclear *cytotrophoblasts*. The cytotrophoblasts are the germinal cells for the syncytium; the latter acts as the primary secretory component within the placenta. Although the ability to undergo DNA synthesis and mitosis, a well-demarcated cell border, and a single nucleus characterize each cytotrophoblast, these characteristics are lacking in the syncytium covering the

chorionic villi (Arnholdt and colleagues, 1991). The syncytium has no individual cells, only a continuous syncytial lining. Therefore, the cellular term used is *syncytiotrophoblast*, in which the cytoplasm is amorphous, without cell borders, and the nuclei are multiple and diverse in size and shape. The absence of cell borders facilitates transport across the syncytiotrophoblast, because the control of transport is not dependent on the participation of individual cells.

After implantation is complete, *the trophoblast further differentiates along two main pathways, giving rise to villous and extravillous trophoblast*. Both pathways give rise to populations of trophoblast cells with distinct functions, which come into contact with maternal tissues (Loke and King, 1995). The villous trophoblast, as its name suggests, gives rise to the chorionic villi of the placenta, and primarily functions in the transport of oxygen and nutrients between the fetus and mother. The extravillous trophoblast migrates into the decidua and myometrium and also penetrates maternal vasculature, thus coming into contact with a variety of maternal cell types (Pijnenborg, 1994). The extravillous trophoblast is thus further classified as interstitial trophoblast and endovascular trophoblast. The interstitial trophoblast both invades the maternal decidua, eventually penetrating the myometrium to form placental bed giant cells, and surrounds the maternal spiral arteries. The endovascular trophoblast penetrates the lumen of the spiral arteries (Pijnenborg and colleagues, 1983). Both the formation of chorionic villi and the remarkable process of invasion of maternal tissues by extravillous trophoblast are discussed separately in greater detail in the sections that follow.

EMBRYONIC DEVELOPMENT AFTER BREAK IMPLANTATION

Early Trophoblast Invasion. After gentle erosion between epithelial cells of the surface endometrium, the invading trophoblasts burrow deeper into the endometrium, and by the 10th day the blastocyst becomes totally encased within the endometrium. This process of erosion and invasion into the endometrium is carried out actively by the trophoblast cells. *The mechanisms leading to trophoblast invasion into the endometrium are similar to the characteristics of metastasizing malignant cells.* These mechanisms are discussed in more detail on page 58.

One of the earliest implanting blastocysts discovered by Hertig and Rock (1945) is shown in [Figure 3-9](#). It measured only 0.36 by 0.31 mm, and it was believed to have been in the process of penetrating the endometrium, with the thin outer wall of the blastocyst still within the uterine cavity. An implanting blastocyst at a similar stage of development, 9 days after fertilization, is shown in [Figure 3-10](#). It appears to have been flattened in the process of penetrating the uterine epithelium; the enlargement and multiplication of the trophoblasts in contact with the endometrium are alone responsible for the increase in size of the implanted blastocyst as compared with that of the free blastocyst.

At 9 days of development (see [Figs. 3-9](#) and [3-10](#)), the wall of the blastocyst that faces toward the uterine lumen is a single layer of flattened cells. The opposite, thicker wall comprises two zones, the trophoblasts and the embryo-forming inner cell mass. As early as 7 1/2 days after fertilization, the inner cell mass, referred to as the embryonic disc, is differentiated into a thick plate of primitive ectoderm and an underlying layer of endoderm. Some small cells appear between the embryonic disc and the trophoblast, enclosing a space that will become the amniotic cavity.

The embryonic mesenchyme first appears as isolated cells within the cavity of the blastocyst. When the cavity is completely lined with mesoderm, it is termed the *chorionic vesicle*, and its membrane, now called the *chorion*, is composed of trophoblasts and mesenchyme. The amnion and yolk sac, with both epithelial and mesenchymal components, are illustrated in [Figures 3-11](#) and [3-12](#). The mesenchymal cells within the cavity are the most numerous and eventually will condense to form the body stalk, which serves to join the embryo to the nutrient chorion and later develops into the umbilical cord. The body stalk can be recognized at an early stage, as shown in [Figure 3-12](#), at the caudal end of the embryonic disc.

Lacunae Formation Within the Syncytiotrophoblast. About 12 days after conception, the syncytiotrophoblast of the trophoblast shell is permeated by a system of intercommunicating channels of trophoblastic lacunae, or small cavities. As the embryo enlarges, more maternal tissue (decidua basalis) is invaded by the basal syncytiotrophoblast, including the walls of the superficial decidual capillaries, and these lacunae become filled with maternal blood (see [Fig. 3-11](#)). At the same time, the decidual reaction intensifies in the surrounding stroma, which is characterized by enlargement of the decidual stromal cells and glycogen storage.

Development of Primary Villous Stalks. With deeper blastocyst invasion into the decidua, the extravillous cytotrophoblasts give rise to the solid primary villi composed of a cytotrophoblast core covered by syncytium. As the lacunae join, a complicated labyrinth is formed that is partitioned by solid cytotrophoblastic columns, which arise from buds of cytotrophoblast that begin to protrude into the primitive syncytium before 12 days postfertilization. The trophoblast-lined labyrinthine channels and the solid cellular columns form the intervillous space and the primary villous stalks, respectively. The villi initially are located over the entire blastocyst surface, but later disappear except over the most deeply implanted portion, the site destined to form the placenta.

Figure 3-9. Low- and high-power photomicrographs of a surface view of an early implanted blastocyst obtained on day 22 of the endometrial cycle, less than 8 days after conception. The site was slightly elevated and measured 0.36 \times 0.31 mm. Mouths of uterine glands appear as dark spots surrounded by halos. (From Hertig and Rock, 1945.)

Figure 3-10. Section through middle of an implanting embryo at about 9 days. Regeneration of the endometrial epithelium is taking place. Lacunae appear as clear spaces in the large mass of syncytiotrophoblast. The bilaminar embryonic disc is seen. (Carnegie Collection no. 8225.) (From Hertig and Rock, 1944.)

Figure 3-11. Drawing of sections through implanted blastocysts. **A.** At 10 days. **B.**

At 12 days after fertilization. The stage of development is characterized by the intercommunication of the lacunae filled with maternal blood. Note in **B** that large cavities have appeared in the extraembryonic mesoderm, forming the beginning of the extraembryonic coelom. Also note that extraembryonic endodermal cells have begun to form on the inside of the primitive yolk sac. (From Moore, 1988.)

Figure 3-12. Median view of a drawing of a wax reconstruction of an 18-day-old Mateer-Streeter embryo, showing the amniotic cavity and its relations to chorionic membrane and yolk sac ($\times 500$). (After Streeter, 1920.)

ORGANIZATION OF THE PLACENTA. The term *hemochorial* and the older term *hemochorioendothelial* are used to describe human placentation. The terms are derived as follows: *hemo* refers to maternal blood, which directly bathes the syncytiotrophoblast; *chorio* is for chorion-placenta, which in turn is separated from fetal blood by the *endothelial* wall of the fetal capillaries that traverse the villous core (hence the older term *hemochorioendothelial*). The characteristics of this type of placentation are illustrated in [Figures 3-11](#) and [3-12](#).

CHORIONIC VILLI. Chorionic villi can first be distinguished in the human placenta on about the 12th day after fertilization. Mesenchymal cords, derived from extraembryonic mesoderm, invade the solid trophoblast columns, forming the secondary villi. After angiogenesis occurs from the mesenchymal cores, the resulting villi are termed *tertiary*. Maternal venous sinuses are tapped early in the implantation process, but until the 14th or 15th day after fertilization, maternal arterial blood does not enter the intervillous space. By about the 17th day, fetal blood vessels are functional, and a placental circulation is established. The fetal-placental circulation is completed when the blood vessels of the embryo are connected with the chorionic blood vessels. Some villi, in which failure of angiogenesis results in a lack of circulation, become distended with fluid and form vesicles. A striking exaggeration of this process is characteristic of the development of hydatidiform mole (see [Chap. 11](#), p. 274).

The trophoblasts of the villus consist of the outer layer of syncytium and an inner layer of cytotrophoblasts, also known as *Langhans cells*. Proliferation of the cytotrophoblasts at the tips of the villi produces the trophoblastic cell columns or anchoring villi. These structures are not invaded by fetal mesenchyme but are anchored to the decidua at the basal plate. Thus, the base of the intervillous space, the maternal-facing side, consists of cytotrophoblasts from the cell columns (trabeculae), the covering syncytium of the trophoblast shell, and decidua of the basal plate. The base of the chorionic plate forms the roof of the intervillous space and consists of two layers of trophoblasts externally and fibrous mesoderm internally. The "definitive" chorionic plate is formed by 8 to 10 weeks as the amniotic and primary chorionic plate mesenchyme fuse together. This formation is accomplished by expansion of the amniotic sac, which also surrounds the connective stalk and the allantois and joins these structures to form the umbilical cord (Kaufmann and Scheffen, 1992).

Villus Ultrastructure. The electron microscopic studies of Wislocki and Dempsey (1955) permitted a functional interpretation of the fine structure of the placenta. There are prominent microvilli on the syncytial surface, corresponding to the so-called brush border described by light microscopy ([Fig. 3-13](#)). Associated pinocytotic vacuoles and vesicles are related to the absorptive and secretory placental functions. The microvilli act to increase the surface area that will have direct contact with maternal blood. It is the contact between the trophoblastic surface and maternal blood that is the defining characteristic of the hemochorial type of placenta. Depending on the number of trophoblastic epithelial layers, the human hemochorial placenta can be subdivided into hemodichorial or hemomonochorial (Enders, 1965). The inner layer of the villi—the cytotrophoblasts and the associated basal lamina—is more prominent during the first trimester of gestation ([Fig. 3-14](#)). Later in gestation, however, the layer of cytotrophoblasts inside the syncytium is no longer continuous, with only scattered cells present at term, creating a narrower hemomonochorial barrier that facilitates transport of nutrients and oxygen to the fetus.

Figure 3-13. Electron micrograph of first-trimester human placenta showing well-differentiated syncytiotrophoblast (S) with numerous mitochondria (*black arrows*) and Golgi complexes (*white arrow*). Cytotrophoblast (C) has large mitochondria (M) but few other organelles. At the top, there is a prominent border of microvilli arising from the syncytium.

Figure 3-14. Term human placenta showing electron-dense syncytium (S), Langhans cells (cytotrophoblasts) (L), transitional cytotrophoblast (T), and capillary endothelium (E). Arrow points to desmosome. (Courtesy of Dr. Ralph M. Wynn.)

PLACENTAL DEVELOPMENT

Development of the Chorion and Decidua. In early pregnancy, the villi are distributed over the entire periphery of the chorionic membrane. A blastocyst dislodged from the endometrium at this stage of development appears shaggy ([Fig. 3-15](#)). As the blastocyst with its surrounding trophoblasts grows and expands into the decidua, one pole of this mass extends outward toward the endometrial cavity. The opposite, innermost pole enters into the formation of the placenta, that is, the villous

trophoblasts and the anchoring cytotrophoblasts. Here the chorionic villi, in contact with the decidua basalis, proliferate to form the chorion frondosum or so-called leafy chorion, the fetal component of the placenta. As the growth of embryonic and extraembryonic tissues continues, the blood supply of the chorion facing the endometrial cavity is restricted, and consequently the villi in contact with the decidua capsularis cease to grow and degenerate. This portion of the chorion becomes the avascular fetal membrane that touches the decidua parietalis, viz., the chorion laeve or so-called smooth chorion. The chorion laeve is generally more nearly translucent than the amnion and rarely exceeds 1 mm thickness. It is composed of cytotrophoblasts and fetal mesodermal (mesenchymal) cells that survive in a relatively low-oxygen atmosphere.

Until near the end of the third month, the chorion laeve is separated from the amnion by the exocoelomic cavity. Thereafter, the amnion and chorion are in intimate contact. In the human, the chorion laeve and amnion form an avascular amniochorion, but these two structures are important sites of molecular transfer and metabolic activity. They constitute an important paracrine arm of the fetal-maternal communication system.

With continued expansion of the embryo-fetus, the uterine lumen is obliterated and the chorion laeve becomes contiguous with the entire maternal decidua parietalis that is not occupied by the placenta. As the fetus grows, the decidua capsularis merges with the decidua parietalis. The decidua capsularis, however, is largely lost by pressure and the attendant loss of blood supply. The area of decidua where decidua capsularis and decidua parietalis merge is referred to as the *decidua vera* (see [Fig. 3-6](#)).

Trophoblast Invasion of the Endometrium. The extravillous trophoblast cells of the first-trimester placenta are highly invasive. They form columns of cells that extend from the endometrium to the inner third of the myometrium. Development of the hemochorial placenta requires the invasion of the endometrium and the spiral arteries. The invasive ability of these cells results from their ability to secrete numerous proteolytic enzymes capable of digesting the extracellular matrix of the endometrium as well as activating proteinases that are already present in the endometrium. Trophoblasts produce urokinase-type plasminogen activator, which converts plasminogen into the broadly acting serine protease plasmin, which in turn is able to both degrade matrix proteins and activate matrix metalloproteinases. The matrix metalloproteinases are a family of structurally similar enzymes that are secreted as inactive proenzymes. One member of the family, matrix metalloproteinase-9, appears to be critical for human trophoblast invasion, and its production is increased by factors produced by the trophoblasts such as IL-1 and hCG as well as paracrine factors produced by the uterus such as leukemia inhibiting factor and colony-stimulating factor-1 (Bischof and colleagues, 2002; Librach and colleagues, 1991).

The relative ability to invade maternal tissue in the first trimester versus the limited invasiveness seen in the last trimester is controlled by autocrine and paracrine trophoblastic and endometrial factors. Trophoblasts secrete insulin-like growth factor II, which acts in an autocrine manner to promote invasion into the endometrium, whereas decidual cells secrete insulin-like growth factor binding protein type 4, which is able to block this autocrine loop. Thus, the degree of trophoblast invasion is kept under tight control through the regulation of matrix degradation as well as by factors that cause migration of the trophoblasts.

Integrin subunit expression also appears to be important in the control of trophoblast invasion of the endometrium-decidua. Recall that the decidual cell becomes completely encased by a pericellular extracellular matrix membrane. This "wall" around the decidual cell provides the scaffolding for the attachment of the cytotrophoblasts of the anchoring villi described earlier, which are a subset of extravillous trophoblasts. These cells first elaborate selected proteinases that degrade the extracellular matrix of decidua. Thereafter, the expression of a specific group of integrins enables the docking of these cells. The trophoblasts are further secured by the production of fetal fibronectin (Feinberg and colleagues, 1991). This oncofetal fibronectin, or fetal-specific fibronectin (f FN), is a unique glycopeptide of the fibronectin molecule. fFN has been called *trophoblast glue* to suggest a critical role for this protein in the migration and attachment of trophoblasts to maternal decidua. Indeed, the presence of fFN in cervical or vaginal fluid can be used as a prognostic indicator for preterm labor, as discussed in [Chapter 36](#) (see p. 862).

Decidual Spiral Artery Invasion. One of the most remarkable features of human placental development is the extensive modification of the maternal vasculature by trophoblast cells, which are, by definition, of fetal origin. These events occur in the first half of pregnancy and are considered in detail because of their importance in the understanding of uteroplacental blood flow in both normal pregnancy and labor. They are also important in pathological conditions such as preeclampsia and intrauterine growth restriction (see [Chap. 34](#), p. 763 and [Chap. 38](#), p. 895). These modifications are carried out by two populations of extravillous trophoblast, viz., the interstitial trophoblast surrounding the maternal spiral arteries and the endovascular trophoblast, which penetrates the lumen of the spiral arteries. Early investigators focused on the role of the endovascular trophoblast, however, the function of the interstitial trophoblast has more recently been investigated (Benirschke and Kaufmann, 2000). These cells are now recognized to constitute a major portion of the placental bed, penetrating the decidua and adjacent myometrium (Pijnenborg and colleagues, 1981). They aggregate around the maternal spiral arteries, where their functions may include preparation of the vessels to facilitate invasion by the endovascular trophoblast (Pijnenborg and colleagues, 1983).

The endovascular trophoblast enters the lumen of the maternal spiral arteries, initially forming cellular plugs within the lumen. It then proceeds to destroy the vascular endothelium, and invade and modify the vascular media, where fibrinoid material replaces the smooth muscle and connective tissue of this layer. The spiral arteries later regenerate their endothelium. Hamilton and Boyd (1966) give credit to Friedlander who in 1870 first described the structural changes occurring in the spiral arteries. They noted that the invading endovascular trophoblast can pass several centimeters along the vessel lumen, migrating against arterial flow and pressure. They also found that these vascular changes are not observed in the decidua parietalis, that is, in decidual sites removed from the invading cytotrophoblasts. Of note, the invasion of maternal vascular tissues by trophoblasts involves only the decidual spiral arteries, and not the decidual veins.

Ramsey and Donner (1980) presented a summary of their anatomical studies of the uteroplacental vasculature. The timing of the development of these uteroplacental vessels has been described in waves, or stages, over the course of gestation. The first wave occurs before 12 weeks postfertilization and consists of invasion and modification of the spiral arteries of the decidua, reaching its border with the myometrium. Between 12 to 16 weeks postfertilization, the second wave occurs. This involves invasion of the intramyometrial parts of the spiral arteries, converting narrow-lumen, muscular spiral arteries into dilated, low-resistance uteroplacental vessels. The molecular mechanisms of these crucial events, and their significance in the pathogenesis of preeclampsia and fetal growth restriction, have recently been reviewed by Kaufmann and associates (2003).

Establishment of Maternal Blood Flow. At approximately 1 month after conception, maternal blood enters the intervillous

space from the spiral arteries in fountain-like bursts. Thus, maternal blood that is propelled outside of the maternal vessels sweeps over and directly bathes the syncytiotrophoblast. The apical surface of the syncytiotrophoblast consists of a complex microvillous structure that undergoes continual shedding and reformation during pregnancy.

Villus Branching. Certain villi of the chorion frondosum extend from the chorionic plate to the decidua and serve as *anchoring villi*. Most chorionic villi, however, arborize and end freely in the intervillous space without reaching the decidua (Fig. 3-16). As the placenta develops, the short, thick, early stem villi branch repeatedly, forming progressively finer subdivisions and greater numbers of increasingly small villi (Fig. 3-17). Each of the truncal or main stem villi and their ramifications (rami) constitute a placental *lobule*, or cotyledon. Each lobule is supplied with a single truncal branch of the chorionic artery; and for each lobule, there is a single vein; thus, these lobules constitute the functional units of the placental architecture.

Figure 3-15. Human chorionic vesicle at ovulatory age of 40 days. (Carnegie Collection No. 8537.)

Figure 3-16. Scanning electron micrograph of placental villi at 10 to 14 weeks' gestation. Note the larger stem villi and the small syncytial sprouts at various stages of formation. Furrows or creases on the surface also are evident, especially at the bases of larger villi ($\times 289$). (From King and Menton, 1975.)

Figure 3-17. Comparison of chorionic villi in early and late pregnancy. **A.** About 8 weeks' gestation. Note inner Langhans cells (cytotrophoblasts) and outer syncytial layer. **B.** Term placenta. Syncytial layer is obvious, but Langhans cells (cytotrophoblasts) are difficult to recognize at low magnification in light micrographs.

PLACENTAL GROWTH AND MATURATION

PLACENTAL GROWTH. In the first trimester, growth of the placenta is more rapid than that of the fetus, but by approximately 17 weeks postmenstruation (from the last menstrual period), placental and fetal weights are approximately equal. At term, the placental weight may be roughly one sixth that of fetal weight. According to Boyd and Hamilton (1970), the average placenta at term is 185 mm in diameter and 23 mm in thickness, with a volume of 497 mL and a weight of 508 g. These measurements vary widely, and there are multiple variant forms of the human placenta and several types of umbilical cord insertions, which are discussed in [Chapter 27](#).

Viewed from the maternal surface, the number of slightly elevated convex areas, called *lobes*, varies from 10 to 38. These lobes are incompletely separated by grooves of variable depth, overlying the *placental septa*, which arise from folding of the basal plate. These grossly visible lobes have also been referred to as "cotyledons", however, this use should be avoided, because they bear no relation to the functional units supplied by each primary villus, which are termed either *lobules* or *cotyledons*.

The total number of lobes remains the same throughout gestation, and individual lobes continue to grow, although less actively in the final weeks (Crawford, 1959). Placental weights vary considerably, depending on how the placenta is prepared. If the fetal membranes and most of the cord are left attached and the adherent maternal blood clot is not removed, the weight may be greater by nearly 50 percent (Thomson and colleagues, 1969).

PLACENTAL MATURATION. As the villi continue to branch and the terminal ramifications become more numerous and smaller, the volume and prominence of cytotrophoblasts decrease. As the syncytium thins, the fetal vessels become more prominent and lie closer to the surface. The stroma of the villi also exhibits changes as gestation progresses. In placentas of early pregnancy, the branching connective tissue cells are separated by an abundant loose intercellular matrix. Later, the stroma becomes denser and the cells more spindle and more closely packed.

Another change in the stroma involves the infiltration of *Hofbauer cells*, which represent fetal macrophages. These cells are nearly round with vesicular, often eccentric nuclei and very granular or vacuolated cytoplasm. Hofbauer cells are characterized histochemically by intracytoplasmic lipid and by phenotypic markers specific for macrophages. They increase in numbers and maturation state as pregnancy progresses. Although phagocytic, they have an immunosuppressive phenotype (Vince and Johnson, 1996). In addition, they can produce a variety of cytokines and are capable of paracrine regulation of trophoblast functions (Cervar and colleagues, 1999).

Some of the histological changes that accompany placental growth and maturation provide an increased efficiency of transport and exchange to meet increasing fetal metabolic requirements. Among these changes are a decrease in thickness of the syncytium, a significant reduction of cytotrophoblast cells, a decrease in the stroma, an increase in the number of capillaries, and an approximation of these vessels to the syncytial surface. By 4 months, the apparent continuity of the cytotrophoblasts is broken, and at term, the covering of the villi may be focally reduced to a thin layer of syncytium with minimal connective tissue where the fetal capillaries appear to abut the trophoblast. The villi become dominated by thin-walled capillaries.

Other changes in placental architecture, however, can cause a decrease in the efficiency of placental exchange if they include a

substantial portion of the exchange area. These changes include thickening of the basal lamina of the trophoblast or capillaries, obliteration of certain fetal vessels, and fibrin deposition on the surface of the villi in the basal and chorionic plates as well as elsewhere in the intervillous space.

FETAL AND MATERNAL BLOOD CIRCULATION IN THE MATURE PLACENTA.

Because the placenta functionally represents an intimate approximation of the fetal capillary bed to maternal blood, its gross anatomy primarily concerns vascular relations. The fetal surface of the placenta is covered by the transparent amnion, beneath which the fetal chorionic vessels course. A section through the placenta includes amnion, chorion, chorionic villi and intervillous spaces, decidua (basal) plate, and myometrium ([Figs. 3-18, 3-19, and 3-20](#)). The maternal surface of the placenta shown in [Figure 3-21](#) is divided into irregular lobes by furrows produced by septa, which consist of fibrous tissue with sparse vessels confined mainly to their bases. The broad-based septa ordinarily do not reach the chorionic plate, thus providing only incomplete partitions.

Fetal Circulation. Deoxygenated, or "venous-like," fetal blood flows to the placenta through the two umbilical arteries. Where the umbilical cord joins the placenta, the umbilical vessels branch repeatedly beneath the amnion and again within the dividing villi, finally forming capillary networks in the terminal divisions ([Fig. 3-22](#)). Blood with significantly higher oxygen content returns from the placenta to the fetus through a single umbilical vein.

The branches of the umbilical vessels that traverse along the fetal surface of the placenta in the chorionic plate are referred to as the *placental surface* or *chorionic vessels*. These vessels are responsive to vasoactive substances, but anatomically, morphologically, histologically, and functionally, they are unique. The chorionic arteries always cross over the chorionic veins. Identification of chorionic artery and vein is most readily recognized by this interesting relationship, but they are difficult to distinguish by histological criteria. In 65 percent of placentas, the chorionic arteries form a fine network supplying the cotyledons—a pattern of disperse-type branching. The remaining 35 percent of arteries radiate to the edge of the placenta without narrowing. Both are end arteries, supplying one cotyledon as each branch turns downward to pierce the chorionic plate.

The truncal arteries are the perforating branches of the surface arteries that pass through the chorionic plate. Each truncal artery supplies one cotyledon. There is a decrease in smooth muscle of the vessel wall and an increase in the caliber of the vessel as it penetrates through the chorionic plate. The loss in smooth muscle continues as the truncal arteries branch into the rami, and the same is true of the vein walls.

Before 10 weeks, there is no end-diastolic flow pattern within the umbilical artery at the end of the fetal cardiac cycle (Cole and colleagues, 1991a; Fisk and colleagues, 1988; Loquet and colleagues, 1988). At 10 weeks, however, end-diastolic flow appears and is maintained throughout normal pregnancies (Maulik, 1996). Clinically, these are recorded with Doppler ultrasonography as an assessment of fetal well-being (see [Chap. 16](#), p. 401).

Maternal Circulation. Fetal homeostasis is dependent on an efficient maternal-placental circulation. Consequently, investigators have sought to define the factors that regulate the flow of blood into and from the intervillous space. An adequate theory must explain how blood can (1) leave the maternal circulation; (2) flow into an amorphous space lined by syncytiotrophoblast, rather than capillary endothelium; and (3) return through maternal veins without producing arteriovenous-like shunts that would prevent maternal blood from remaining in contact with the villi long enough for adequate exchange. It was not until the studies of Ramsey with Davis (Ramsey and Davis, 1963; Ramsey and Harris, 1966) that a physiological explanation of the placental circulation was available (see [Fig. 3-22](#)). These investigators demonstrated, by careful, low-pressure injections of radiocontrast material, that the arterial entrances as well as the venous exits are scattered randomly over the entire base of the placenta.

The physiological maternal-placental circulation is as follows: Maternal blood enters through the basal plate and is driven high up toward the chorionic plate by maternal arterial pressure before lateral dispersion occurs (see [Fig. 3-22](#)). After bathing the external microvillous surface of chorionic villi, the maternal blood drains back through venous orifices in the basal plate and enters the uterine veins. Therefore, maternal blood traverses the placenta randomly without preformed channels, propelled by maternal arterial pressure. The previously described processes of trophoblast invasion of the spiral arteries create low-resistance uteroplacental vessels, which can accommodate the massive increase in uterine perfusion over the course of gestation. Generally, the spiral arteries are perpendicular to, but the veins are parallel to, the uterine wall, an arrangement that facilitates closure of the veins during a uterine contraction and prevents squeezing of essential maternal blood from the intervillous space. The number of arterial openings into the intervillous space becomes gradually reduced by cytotrophoblast invasion. According to Brosens and Dixon (1963), there are about 120 spiral arterial entries into the intervillous space at term. These discharge blood in spurts that bathes the adjacent villi (Borell and co-workers, 1958). After the 30th week, a prominent venous plexus, shown in [Figure 3-22](#), separates the decidua basalis from the myometrium, thus participating in providing a plane of cleavage for placental separation.

During uterine contractions, both inflow and outflow are curtailed. Bleker and associates (1975) used serial sonography during normal labor and found that the length, thickness, and surface of the placenta increased during contractions. They attributed these changes to distention of the intervillous spaces by blood as the consequence of relatively greater impairment of venous outflow compared with arterial inflow. During contractions, therefore, a somewhat larger volume of blood is available for exchange even though the rate of flow is decreased. Subsequently, by use of Doppler velocimetry, it was shown that diastolic flow velocity in spiral arteries is diminished during uterine contractions. Therefore, the principal factors regulating blood flow in the intervillous space are arterial blood pressure, intrauterine pressure, the pattern of uterine contractions, and factors that act specifically on the arterial walls.

Breaks in the Placental "Barrier." The placenta does not maintain absolute integrity of the fetal and maternal circulations. This conclusion is evidenced by numerous findings of the passage of cells between mother and fetus in both directions. This situation is best exemplified clinically by erythrocyte D-antigen isoimmunization and the occurrence of *erythroblastosis fetalis*, discussed in [Chapter 29](#) (see p. 663). Typically, a few fetal blood cells are found in maternal blood, but on extremely rare occasions, the fetus exsanguinates into the maternal circulation. Desai and Creger (1963) found that, even under normal conditions, labeled maternal leukocytes and platelets crossed the placenta from mother to fetus. Fetal leukocytes may replicate in the mother, and leukocytes bearing a Y chromosome have been identified in women many years after giving birth to a son

(Bianchi and co-workers, 1996; Ciaranfi and colleagues, 1977). These observations have led to the concept of "microchimerism," whereby a variety of fetal cell types may persist in the mother's body for years to decades after a pregnancy. The clinical consequences of fetal cells in the mother are still under debate, however, they may cause maternal autoimmune diseases such as scleroderma, thyroiditis and thyroid failure, and maternal cutaneous eruptions (Aractingi and colleagues, 1998; Lambert and colleagues, 2000; Nelson and colleagues, 1998).

Figure 3-21. Maternal surface of a term placenta. Variably discrete, irregularly shaped adjacent lobes are evident plus a large separate (succenturiate) lobe.

Figure 3-22. Schematic drawing of a section through a full-term placenta: **1.** The relation of the villous chorion (C) to the decidua basalis (D) and the fetal-placental circulation. **2.** The maternal blood flows into the intervillous spaces in funnel-shaped spurts, and exchanges occur with the fetal blood as the maternal blood flows around the villi. **3.** The in-flowing arterial blood pushes venous blood into the endometrial veins, which are scattered over the entire surface of the decidua basalis. Note also that the umbilical arteries carry deoxygenated fetal blood to the placenta and that the umbilical vein carries oxygenated blood to the fetus. The cotyledons are separated from each other by placental (decidual) septa. Each cotyledon consists of two or more mainstem villi and their many branches. (Based on Moore, 1988.)

IMMUNOLOGICAL CONSIDERATIONS OF THE FETAL-MATERNAL INTERFACE.

Over the past half-century, many attempts to explain the survival of the semiallogenic fetal graft have been proposed. One of the earliest explanations was based on the theory of antigenic immaturity of the embryo-fetus. This explanation was disproved by Billingham (1964), who showed that transplantation (HLA) antigens are demonstrable very early in embryonic life. Another explanation was based on diminished immunological responsiveness of the pregnant woman. There is, however, no evidence for this to be other than an ancillary factor. In a third explanation, the uterus (decidua) is proposed as an immunologically privileged tissue site. This would preclude well-documented advanced ectopic pregnancies, discussed in [Chapter 10](#).

Clearly, the lack of transplantation immunity manifest in the uterus is unique compared with that of other tissues. Therefore, the acceptance and the survival of the conceptus in the maternal uterus must be attributed to an immunological peculiarity of the trophoblasts, not the decidua. The trophoblasts are the only cells of the conceptus in direct contact with maternal tissues or blood, and these tissues are genetically identical with fetal tissues. Several features of trophoblast cells likely contribute to the survival of these cells in an immunologically hostile environment (Thellin and colleagues, 2000). The most important may be the novel aspects of the expression of the HLA system in trophoblasts, coupled with a unique set of uterine lymphocytes.

Immunogenicity of the Trophoblasts. Over 50 years ago, Sir Peter Medawar (1953) suggested that the solution to the riddle of the fetal semiallograft might be explained by *immunological neutrality*. The placenta was considered immunologically inert and therefore unable to cause a maternal immune response. Subsequently, many researchers focused on defining the expression of the *major histocompatibility complex (MHC)* antigens on trophoblasts. *Human leukocyte antigens (HLA)* are the human analogue of the major histocompatibility complex. MHC class I and II antigens are absent from villous trophoblasts at

all stages of gestation (Weetman, 1999). Thus, these cells do appear to be immunologically inert with regard to fetal-maternal interactions. However, the invasive cytotrophoblasts do express MHC class I molecules and these have been the focus of considerable study.

Trophoblast HLA (MHC) Class I Expression. The HLA genes are the products of multiple genetic loci of the MHC located within the short arm of chromosome 6 (Hunt and Orr, 1992). There are 17 HLA class I genes, including three classical genes, HLA-A, -B, and -C, that encode the major class I (class Ia) transplantation antigens. Three other class I genes, designated HLA-E, -F, and -G, encode class Ib HLA antigens. The remaining DNA sequences appear to be pseudogenes or partial gene fragments.

Moffett-King (2002) reasoned that normal implantation is dependent on controlled trophoblastic invasion of maternal endometrium-decidua and the spiral arteries. Trophoblast invasion must proceed far enough to provide for normal fetal growth and development, and a mechanism for regulating the depth of trophoblast invasion must exist. She suggested that the uterine large granular lymphocytes (LGLs) and the unique expression of three specific HLA class I genes in extravillous cytotrophoblasts act to permit and subsequently to limit the process of trophoblast invasion.

Class I antigens in extravillous cytotrophoblasts are accounted for by the expression of the classical HLA-C and the nonclassical class Ib molecules of HLA-E and HLA-G. To elucidate the importance of HLA-C, HLA-E and HLA-G expression, it is important to understand the nature of the unusual lymphocyte population of the human decidua.

Uterine Large Granular Lymphocytes (LGLs). These distinctive lymphocytes are believed to originate in bone marrow and belong to the natural killer cell lineage. They are by far the predominant population of leukocytes present in midluteal phase endometrium at the expected time of implantation (Johnson and colleagues, 1999). These LGLs have a distinct phenotype characterized by a high surface density of CD56 or neural cell adhesion molecule (Loke and King, 1995; Moffett-King, 2002). The infiltration of LGLs is increased by progesterone as well as stromal cell production of IL-15 and prolactin (Dunn and colleagues, 2002; Gubbay and colleagues, 2002).

Near the end of the luteal phase of nonfertile ovulatory cycles, the nuclei of the uterine LGL begin to disintegrate. With blastocyst implantation, however, these cells persist in large numbers in the decidua during the early weeks of pregnancy. At term, however, there are relatively few LGLs in the decidua. In first-trimester decidua, many LGLs are in close proximity to the extravillous trophoblast. It is speculated that LGLs are involved in the regulation of trophoblast invasion. They secrete large amounts of granulocyte-macrophage-colony-stimulating factor (GM-CSF), suggestive that the LGLs in first-trimester decidua are in an activated state. This has led Jokhi and co-workers (1999) to speculate that GM-CSF may function primarily not to promote trophoblast replication but rather to forestall trophoblast apoptosis. Moreover, expression of angiogenic factors by uterine natural killer cells is suggestive of a potential role for these cells in decidual vascular remodeling (Li and colleagues, 2001). According to this theory, LGLs rather than the T lymphocytes, would bear the primary responsibility for immunosurveillance in decidua.

HLA-G Expression in Human Trophoblasts. HLA-G is expressed only in humans and is distinguished from the HLA class Ia products by a highly restricted tissue distribution. Indeed, HLA-G antigen expression is identified only in extravillous cytotrophoblasts in the decidua basalis and in the chorion laeve (McMaster and colleagues, 1995). HLA-G is not present in villous trophoblasts, either in the syncytium or in the cytotrophoblasts. HLA-G is expressed, however, in cytotrophoblasts that are contiguous with maternal tissues, viz., decidual cells and LGLs. Interestingly the HLA-G gene produces several mRNA transcripts as a result of alternative splicing to yield at least seven isoforms, some soluble and some membrane bound (Carosella and colleagues, 2000). There are few individual DNA variations or polymorphisms in the HLA-G gene sequence, further suggesting an important role for this factor. It has been shown that a soluble major isoform, HLA-G2, is increased during pregnancy (Hunt and colleagues, 2000a, 2000b). Additionally, a recent study of embryos being used for in vitro fertilization showed that pregnancy did not occur in any of the embryos that did not produce the soluble form of HLA-G (Fuzzi and colleagues, 2002). It may be that HLA-G is immunologically permissive of the antigen mismatch between mother and fetus (LeBouteiller and colleagues, 1999). One hypothesis is that its expression may be stimulated by hypoxia, leading to developmental modifications in HLA-G class I antigen expression on trophoblasts (Kilburn and colleagues, 2000). In that regard, Goldman-Wohl and associates (2000) have provided evidence for abnormal HLA-G expression in extravillous trophoblasts from women with preeclampsia.

AMNION. The amnion at term is a tough and tenacious but pliable membrane. It is the innermost fetal membrane and is contiguous with amniotic fluid. This particular avascular structure occupies a role of incredible importance in human pregnancy. In many obstetrical populations, preterm prematurely ruptured fetal membranes are the single most common antecedent of preterm delivery (see [Chap. 6](#), p. 177, and [Chap. 36](#), p. 864). The amnion is the tissue that provides almost all of the tensile strength of the fetal membranes. Therefore, the development of the components of the amnion that protect against its rupture or tearing is vitally important to successful pregnancy outcome.

Amnion Structure. Bourne (1962) described five separate layers of amnion tissue. The inner surface, which is bathed by amniotic fluid, is an uninterrupted, single layer of cuboidal epithelial cells, believed to be derived from embryonic ectoderm. This epithelium is attached firmly to a distinct basement membrane that is connected to the acellular compact layer, which is composed primarily of interstitial collagens. On the outer side of the compact layer, there is a row of fibroblast-like mesenchymal cells, which are widely dispersed at term. These are probably derived from mesoderm of the embryonic disc. There also are a few fetal macrophages in the amnion. The outermost layer of amnion is the relatively acellular zona spongiosa, which is contiguous with the second fetal membrane, the chorion laeve. The human amnion lacks smooth muscle cells, nerves, lymphatics, and importantly, blood vessels.

Amnion Development. Early in the process of implantation, a space develops between the embryonic cell mass and adjacent trophoblasts (see [Fig. 3-11](#)). Small cells that line this inner surface of trophoblasts have been called *amniogenic cells*, the precursors of amniotic epithelium. The human amnion is first identifiable about the seventh or eighth day of embryo development. Initially a minute vesicle (see [Fig. 3-11](#)), the amnion develops into a small sac that covers the dorsal surface of the embryo. As the amnion enlarges, it gradually engulfs the growing embryo, which prolapses into its cavity (Benirschke and Kaufmann, 2000).

Distention of the amniotic sac eventually brings it into contact with the interior surface of the chorion laeve. Apposition of the mesoblasts of chorion laeve and amnion near the end of the first trimester then causes an obliteration of the extraembryonic coelom. The amnion and chorion laeve, although slightly adherent, are never intimately connected and usually can be separated easily, even at term.

Amnion Cell Histogenesis. It is now generally accepted that the epithelial cells of the amnion are derived from fetal ectoderm of the embryonic disc. They do not arise by delamination from trophoblasts. This is an important consideration from both embryological and functional perspectives. For example, HLA class I gene expression in amnion is more akin to that in cells of the embryo than that in trophoblasts.

In addition to the epithelial cells that line the amniotic cavity, there is a layer of fibroblast-like (i.e., mesenchymal) cells that are likely derived from embryonic mesoderm. Early in human embryogenesis, the amniotic mesenchymal cells of the amnion lie immediately adjacent to the basal surface of the epithelium. At this time, the amnion surface is a two-cell-layer structure with approximately equal numbers of epithelial and mesenchymal cells. Simultaneously with growth and development, interstitial collagens are deposited between these two layers of cells. This marks the commencement of the formation of the compact layer of the amnion, which also brings about a distinct separation of the two layers of amnion cells.

As the amniotic sac expands to envelop the placenta and then the chorion frondosum at about 10 to 14 weeks, there is a progressive reduction in the compactness of the mesenchymal cells. These cells continue to separate and in the process become rather sparsely distributed. It appears that early in pregnancy the epithelial cells of the amnion replicate at a rate appreciably faster than the mesenchymal cells. At term, the epithelial cells form a continuous uninterrupted epithelium on the fetal surface of the amnion. The mesenchymal cells, however, are widely dispersed, being connected by a fine lattice network of extracellular matrix with the appearance of long slender fibrils.

Amnion Epithelial Cells. The epithelial cells lining the entire amniotic cavity are the cells most commonly studied in investigations of amnion function. The apical surface of the epithelial cells is replete with highly developed microvilli, consistent with a major site of transfer between amniotic fluid and amnion (Fig. 3-23). They also are active metabolically; for example, these epithelial cells are the site of tissue inhibitor of metalloproteinase-1 synthesis, and produce PGE₂ and fetal fibronectin (Rowe and colleagues, 1997). In term pregnancies, the expression of prostaglandin endoperoxide H synthase in amnion has been shown to correlate with elevated fetal fibronectin (Mijovic and co-workers, 2000). As a site of prostaglandin production, the amniotic epithelium participates in the so-called final common pathway of initiation of labor. The epithelial cells may respond to signals derived from the fetus or the mother, and they have been shown to be responsive to a variety of potential endocrine or paracrine modulators. These include oxytocin and vasopressin, which increase PGE₂ production in vitro (Moore and associates, 1988). They may also produce cytokines during the initiation of labor, such as IL-8 (Elliott and colleagues, 2001).

The amniotic epithelium also synthesizes vasoactive peptides, including the vasoconstrictor endothelin as well as the vasodilator parathyroid hormone-related protein (Economos and colleagues, 1992; Germain and colleagues, 1992). Amniotic epithelium also produces brain natriuretic peptide and corticotropin-releasing hormone (CRH), which are peptides that are smooth muscle relaxants (Riley and colleagues, 1991; Warren and Silverman, 1995). Thus, the vasoactive peptides produced in amnion may gain access to the adventitial surface of the chorionic vessels. These findings suggest that the placental amnion could be involved in modulating chorionic vessel tone and blood flow. These amnion-derived vasoactive peptides also function in other tissues in diverse physiological processes, including the promotion of cell replication and calcium metabolism. After secretion from the amnion, these bioactive agents can enter amniotic fluid and thereby are available to the fetus by swallowing and fetal thoracic movements.

Amnion Mesenchymal Cells. The mesenchymal cells of the fibroblast layer of amnion are also responsible for major amnion functions. The synthesis of interstitial collagens that make up the compact layer of the amnion, the source of the majority of tensile strength of this membrane, takes place in mesenchymal cells (Casey and MacDonald, 1996). These cells also are highly capable of synthesizing cytokines that include IL-6, IL-8, and monocyte chemoattractant protein-1 (MCP-1). Their synthesis is increased in response to bacterial toxins and IL-1. This functional capacity of amnion mesenchymal cells is an important consideration in the study of amniotic fluid for evidence of labor-associated accumulation of inflammatory mediators (Garcia-Velasco and Arici, 1999). Studies in which isolation of amnion mesenchymal cells from epithelial cells was used demonstrated that the mesenchymal cells may be a far greater source of PGE₂ than epithelial cells (Whittle and colleagues, 2000).

Amnion Anatomy. Reflected amnion is fused to the chorion laeve. Placental amnion covers the fetal surface of the placenta, and thereby is in contact with the adventitial surface of the chorionic vessels. Umbilical amnion covers the umbilical cord. In the conjoined portion of the membranes of diamniotic-dichorionic twin placentas, the fused amnions are separated by fused chorion laeve. Thus, aside from the small area of the membranes immediately over the cervical os, this is the only site at which the reflected chorion laeve is not contiguous with decidua. With diamniotic-monochorionic placentas, there is no intervening tissue between the fused amnions of each twin.

Amnion Tensile Strength. Over 135 years ago, Matthew Duncan examined the nature of the forces involved in fetal membrane rupture. During tests of tensile strength—resistance to tearing and rupture—he found that the decidua and then the chorion laeve gave way long before the amnion ruptured. Indeed, the membranes are quite elastic and can expand to twice normal size during pregnancy (Benirschke and Kaufmann, 2000). The amnion provides the major strength of the membranes. Moreover, the tensile strength of amnion resides almost exclusively in the compact layer, which is composed of cross-linked interstitial collagens I and III and lesser amounts of collagens V and VI.

Interstitial Collagens. Collagens are the major macromolecules of most connective tissues and the most abundant proteins in the body. Collagen I is the major interstitial collagen in tissues characterized by great tensile strength, such as bone and tendon. In other tissues, collagen III is believed to make a unique contribution to tissue integrity, serving to increase tissue extensibility and tensile strength. For example, the ratio of collagen III to collagen I in the walls of a number of highly extensible tissues—amnion, blood vessels, urinary bladder, bile ducts, intestine, and gravid uterus—is greater than that in nonelastic tissues. Although collagen III provides some of the extensibility of this membrane, elastin microfibrils have been identified (Bryant-Greenwood, 1998). Another unique structural feature of interstitial collagens important to amnion integrity is resistance to proteolytic degradation (Jeffrey, 1991).

Metabolic Functions. The amnion is clearly more than a simple avascular membrane that functions to contain amniotic fluid. It is metabolically active, involved in solute and water transport to maintain amniotic fluid homeostasis, and produces a variety of bioactive compounds, including vasoactive peptides, growth factors, and cytokines. The amnion is responsive both acutely and chronically to mechanical stretch, which alters amniotic gene expression (Nemeth and colleagues, 2000). This in turn potentially triggers both autocrine and paracrine responses, such as increased production of matrix metalloproteinases, IL-8 production, and collagenase activity (Bryant-Greenwood, 1998; Maradny and colleagues, 1996). Such factors may modulate changes in the membrane properties during term or preterm labor.

Amniotic Fluid. The normally clear fluid that collects within the amniotic cavity increases as pregnancy progresses until about 34 weeks, when there is a decrease in volume. An average volume of about 1000 mL is found at term, although this may vary widely from a few milliliters to many liters in abnormal conditions. The origin, composition, circulation, and function of the amniotic fluid are discussed further in [Chapters 11](#) and [31](#).

Figure 3-23. Electron micrograph of human amnion at term. Epithelium (E) and mesenchyme (M) are shown. Thin arrow indicates intercellular space. Thick arrow points to specializations of basal plasma membranes. (Courtesy of Dr. Ralph M. Wynn.)

UMBILICAL CORD AND RELATED STRUCTURES

Cord Development. The yolk sac and the umbilical vesicle into which it develops are quite prominent early in pregnancy. At first, the embryo is a flattened disc interposed between amnion and yolk sac (see [Fig. 3-12](#)). Because the dorsal surface grows faster than the ventral surface, in association with the elongation of the neural tube, the embryo bulges into the amniotic sac and the dorsal part of the yolk sac is incorporated into the body of the embryo to form the gut. The allantois projects into the base of the body stalk from the caudal wall of the yolk sac or, later, from the anterior wall of the hindgut.

As pregnancy advances, the yolk sac becomes smaller and its pedicle relatively longer. By about the middle of the third month, the expanding amnion obliterates the exocoelom, fuses with the chorion laeve, and covers the bulging placental disc and the lateral surface of the body stalk. The latter is then called the *umbilical cord*, or *funis*. Remnants of the exocoelom in the anterior portion of the cord may contain loops of intestine, which continue to develop outside the embryo. Although the loops are later withdrawn into the peritoneal cavity, the apex of the midgut loop retains its connection with the attenuated vitelline duct.

The cord at term normally has two arteries and one vein. The right umbilical vein usually disappears early during fetal development, leaving only the original left vein. Sections of any portion of the cord frequently reveal, near the center, the small duct of the umbilical vesicle, lined by a single layer of flattened or cuboidal epithelial cells. In sections just beyond the umbilicus, but never at the placental end of the cord, another duct representing the allantoic remnant is occasionally found. The intra-abdominal portion of the duct of the umbilical vesicle, which extends from umbilicus to intestine, usually atrophies and disappears, but occasionally it remains patent, forming a Meckel diverticulum. The most common vascular anomaly is the absence of one umbilical artery (see [Chap. 27](#), p. 626).

Cord Structure and Function. The umbilical cord, or funis, extends from the fetal umbilicus to the fetal surface of the placenta or chorionic plate. Its exterior is dull white, moist, and covered by amnion, through which three umbilical vessels may be seen. Its diameter is 0.8 to 2.0 cm, with an average length of 55 cm and a range of 30 to 100 cm. Generally, cord length less than 30 cm is considered abnormally short (Benirschke and Kaufmann, 2000). Folding and tortuosity of the vessels, which are longer than the cord itself, frequently create nodulations on the surface, or false knots, which are essentially varices. The extracellular matrix is a specialized connective tissue referred to as *Wharton jelly* ([Fig. 3-24A](#)). After fixation, the umbilical vessels appear empty, but [Figure 3-24B](#) more accurately is representative of the situation in vivo, when the vessels are not emptied of blood. The two arteries are smaller in diameter than the vein. The mesoderm of the cord, which is of allantoic origin, fuses with that of the amnion.

Blood flows from the umbilical vein by two routes \mathfrak{R} —the ductus venosus, which empties directly into the inferior vena cava, and numerous smaller openings into the fetal hepatic circulation \mathfrak{R} —and then into the inferior vena cava by the hepatic vein. The blood takes the path of least resistance through these alternate routes. Resistance in the ductus venosus is controlled by a sphincter situated at the origin of the ductus at the umbilical recess and innervated by a branch of the vagus nerve.

Anatomically, the umbilical cord can be regarded as a component of the fetal membranes. The vessels contained in the cord are characterized by spiraling or twisting. The spiraling may occur in a clockwise (dextral) or anticlockwise (sinistral) direction. The anticlockwise spiral is present in 50 to 90 percent of cases. It is believed that the spiraling serves to prevent clamping, which occurs in all hollow cylinders subjected to torsion. Boyd and Hamilton (1970) note that these twists are not truly spirals, but rather they are cylindrical helices in which a constant curvature is maintained equidistant from the central axis. Benirschke and Kaufmann (2000) reported that 11 is the average number of helices in the cord.

Figure 3-24. A. Cross-section of umbilical cord fixed after blood vessels had been emptied. The umbilical vein, carrying oxygenated blood to the fetus, is in the center; on either side are two umbilical arteries carrying deoxygenated blood from the fetus to the placenta. **B.** Cross-section of the same umbilical cord shown in **A**, but through a segment from which the blood vessels had not been emptied. This photograph represents more accurately the conditions in utero. (From Reynolds, 1954.)

PLACENTAL HORMONES

The production of steroid and protein hormones by human trophoblasts is greater in amount and diversity than that of any single endocrine tissue in all of mammalian physiology. A compendium of the average production rates for various steroid hormones in nonpregnant and in near-term pregnant women is given in [Table 3-1](#). It is apparent that the alterations in steroid hormone production that accompany normal human pregnancy are incredible. The human placenta also synthesizes an enormous amount of protein and peptide hormones: as much as 1 gram of placental lactogen (hPL) every 24 hours, massive quantities of chorionic gonadotropin (hCG), adrenocorticotropin (ACTH), growth hormone variant (hGH-V), parathyroid hormone-related protein (PTH-rP), calcitonin, relaxin, inhibins, activins, and atrial natriuretic peptide, as well as a variety of hypothalamic-like releasing and inhibiting hormones such as thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), somatostatin, and growth hormone-releasing hormone (GHRH).

It is understandable, therefore, that yet another remarkable feature of human pregnancy is the success of the physiological adaptations of pregnant women to the unique endocrine milieu (see [Chap. 6](#)). The anatomical parts of the placental arm of the fetal-maternal endocrine communication system are illustrated in [Figure 3-25](#).

Figure 3-25. Anatomical parts of the endocrine component of the placental arm of the fetal-maternal communication system. Adrenocorticotropin hormone from the fetal pituitary gland stimulates fetal adrenal steroidogenesis. Fetal adrenal dehydroepiandrosterone sulfate and 16α -hydroxydehydroepiandrosterone sulfate are transported to the placenta and converted to 17β -estradiol and estriol, respectively. Fetal liver is the major site of production of low-density lipoprotein (LDL) cholesterol, the principal precursor for fetal adrenal steroidogenesis. Cholesterol, derived from LDL in maternal plasma, serves as the precursor for progesterone biosynthesis in the placenta.

HUMAN CHORIONIC GONADOTROPIN (hCG). The so-called pregnancy hormone is a glycoprotein with biological activity very similar to luteinizing hormone (LH), both of which act via the plasma membrane LH-hCG receptor. hCG is produced almost exclusively in the placenta but also is synthesized in fetal kidney, and a number of fetal tissues may produce the β -subunit or intact hCG molecule (McGregor and associates, 1981, 1983).

Various malignant tumors also produce hCG, sometimes in large amounts—especially trophoblastic neoplasms. Chorionic gonadotropin is produced in very small amounts in tissues of men and nonpregnant women, perhaps primarily in the anterior pituitary gland. Nonetheless, the detection of hCG in blood or urine is almost always indicative of pregnancy (see [Chap. 8](#), p. 206).

Chemical Characteristics. Chorionic gonadotropin is a glycoprotein (molecular weight 36,000 to 40,000 d) with the highest carbohydrate (30 percent) content of any human hormone. The carbohydrate component, and especially the terminal sialic acid, protects the molecule from catabolism. The 36-hour plasma half-life of intact hCG is much longer than the 2 hours for LH. The hCG molecule is composed of two dissimilar subunits, designated α (92 amino acids) and β (145 amino acids), which are noncovalently linked. They are held together by electrostatic and hydrophobic forces that can be separated in vitro. Isolated subunits are unable to bind the LH receptor and thus lack biological activity.

This hormone is structurally related to three other glycoprotein hormones—LH, FSH, and TSH. The amino-acid sequence of the α -subunits of all four glycoproteins is identical. The β -subunits, although sharing certain similarities, are characterized by distinctly different amino-acid sequences. Recombination of an α - and a β -subunit of the four glycoprotein hormones gives a molecule with biological activity characteristic of the hormone from which the β -subunit was derived.

Biosynthesis. The synthesis of the α - and the β -chains of hCG is regulated separately. A single gene located on chromosome 6 encodes the α -subunit of all four glycoprotein hormones—hCG, LH, FSH, and TSH. There are seven separate genes on chromosome 19 for the β -hCG- β -LH family. Six of these genes code for β -hCG and one for β -LH, but only three of the β -hCG genes are expressed at significant levels (Miller-Lindholm and colleagues, 1997). Both the α - and β -subunits of hCG are synthesized as larger molecular weight precursors, which are cleaved by microsomal endopeptidases. Once intact hCG is assembled, the molecule is rapidly released from the cell through exocytosis of secretory granules (Morrish and colleagues, 1987).

Cellular Origin of hCG. The origin of hCG appears to vary depending on the time in gestation. At less than 5 weeks, hCG expression is observed in both syncytiotrophoblast and cytotrophoblast cells (Maruo and colleagues, 1992). Later in gestation, when maternal serum levels are at their peak, hCG is produced almost solely in the syncytiotrophoblast (Beck and colleagues, 1986; Kurman and colleagues, 1984). The amounts of hCG mRNA for both α - and β -subunits in syncytiotrophoblast from the first trimester are greater than at term, which may be an important consideration when used as a screening procedure to identify abnormal fetuses (Hoshina and co-workers, 1982).

Molecular Forms of hCG in Plasma and Urine. There are multiple forms of hCG in maternal plasma and urine. Some of these arise as the result of enzymatic degradation, and others are accounted for by modifications during the normal cellular sequence of synthesis and processing of the hCG molecule. The multiple forms of hCG vary enormously in bioactivity and immunoreactivity.

FREE SUBUNITS. The levels of circulating free β -subunit are low to undetectable throughout pregnancy. In part, this is the result of the rate-limiting synthesis of the β -subunit. Free α -subunits that do not combine with the β -subunit are found in the placenta and in maternal plasma. Plasma levels of free α -subunits increase gradually, but steadily, until about 36 weeks, when a plateau is maintained for the remainder of pregnancy. Thus, the secretion of α -hCG roughly corresponds to placental mass,

whereas the rate of secretion of the complete hCG molecule is maximal at 8 to 10 weeks' gestation. The plasma concentration of α -hCG, although a minor portion of intact hCG at 10 weeks, can represent 30 to 50 percent during the last trimester (Cole, 1997).

NICKS IN THE hCG molecule. A portion of hCG molecules in serum and urine, as well as purified standard preparations, has been shown to contain so-called nicks, or missing peptide linkages. These nicks occur primarily between β -subunit amino acids 44-45 and 47-48. The extent of nicking in standard preparations from pooled urine is 10 to 20 percent, but in individual samples it varies from 0 to 100 percent (Cole and colleagues, 1991a,b). Their origin is believed to be through enzymatic action on the molecule near the cellular site of β -subunit synthesis. Nicked forms of hCG predominate in cases of gestational trophoblastic neoplasia such as hydatidiform mole or choriocarcinoma (Cole and Butler, 2002). The biological importance of these nicked molecules is unknown but can be an issue of some concern as their detection by commercial immunoassays for hCG is variable (Cole, 1997).

Concentrations of hCG in Serum and Urine. The intact hCG molecule is detectable in plasma of pregnant women about 7 to 9 days after the midcycle surge of LH that precedes ovulation. Thus, it is likely that hCG enters maternal blood at the time of blastocyst implantation. Blood levels increase rapidly, doubling every 2 days, with maximal levels being attained at about 8 to 10 weeks' gestation (Fig. 3-26). Appreciable fluctuations in the levels of plasma hCG are observed on the same day, and evidence has accrued that the trophoblast secretion of protein hormones is episodic (Barnea and Kaplan, 1989; Diaz-Cueto and colleagues, 1994).

Because hCG circulates as multiple highly related isoforms with variable cross-reactivity between commercial assays, there is considerable variation in calculated serum hCG levels among the more than 100 assays. Peak levels reach about 100,000 mIU/mL between the 60th and 80th days after the last menses (see Fig. 3-26). Beginning at about 10 to 12 weeks' gestation, maternal plasma levels of hCG begin to decline, and a nadir is reached by about 20 weeks. Plasma levels are maintained at this lower level for the remainder of pregnancy.

The pattern of appearance of hCG in fetal blood is similar to that in the mother, however, fetal plasma levels are only about 3 percent of those in maternal plasma. The hCG concentration in amniotic fluid early in pregnancy is similar to that in maternal plasma. As pregnancy progresses, the hCG concentration in amniotic fluid declines, so that near term, the levels are only one fifth those in maternal plasma.

Maternal urine hCG also can be monitored and is composed of a variety of degradation products. The primary form of hCG in urine is the terminal degradation product of hCG, the β -core fragment. Its concentrations follow the same general pattern as that in maternal plasma, peaking at about 10 weeks. It is important, however, to recognize that the so-called β -subunit antibody used in most pregnancy tests reacts with both intact hCG, the major form in the plasma, and with fragments of hCG, the major forms found in urine.

Elevated or Depressed hCG Levels in Maternal Plasma or Urine. Significantly higher plasma levels of hCG are sometimes found in women pregnant with multiple fetuses or with a single erythroblastotic fetus resulting from maternal D-antigen isoimmunization. The levels of hCG in plasma and urine may be increased strikingly in women with hydatidiform mole or choriocarcinoma. Relatively higher levels of plasma hCG may be found at midtrimester in women carrying a fetus with Down syndrome, and this finding can be used in biochemical screening tests (see Chap. 13, p. 323). The reason for this is not clear, but it has been speculated that the placentas in these pregnancies are less mature compared with those associated with normal fetuses. Relatively lower levels of hCG in plasma are found with ectopic pregnancies and impending spontaneous abortion.

Regulation of hCG Synthesis. Placental GnRH is likely involved in the regulation of hCG formation. Both GnRH and its receptor are expressed on cytotrophoblasts and syncytiotrophoblast (Wolfahrt and colleagues, 1998). GnRH administration elevates circulating hCG levels, and cultured trophoblast cells respond to GnRH treatment with increased hCG secretion (Iwashita and colleagues, 1993; Siler-Khodr and Khodr, 1981). Pituitary production of GnRH also is regulated by levels of inhibin and activin. In cultured placental cells, activin stimulates and inhibin inhibits the production of GnRH and hCG production, supporting a role for these factors (Petraglia and colleagues, 1989; Steele and colleagues, 1993).

Metabolic Clearance of hCG. The renal clearance of hCG accounts for 30 percent of metabolic clearance and the remainder is cleared by other pathways, likely by metabolism in the liver and kidney (Wehmann and Nisula, 1980). Clearances of β -subunit and α -subunit are about 10-fold and 30-fold, respectively, greater than that of intact hCG. By contrast, renal clearance of these subunits is considerably lower than that of dimeric hCG.

Biological Functions of hCG. Both subunits of hCG are required for normal binding to the LH-hCG receptor in the corpus luteum and the testis. LH-hCG receptors are present in a variety of tissues, and their role there is less defined. The best-known biological function of hCG is the so-called *rescue and maintenance of function of the corpus luteum*—that is, continued progesterone production. Bradbury and colleagues (1950) found that the progesterone-producing life span of the corpus luteum of menstruation could be prolonged perhaps for 2 weeks by hCG administration. This action provides only an incomplete explanation for its physiological role in pregnancy. The maximum plasma hCG concentrations are attained well after hCG-stimulated corpus luteum secretion of progesterone has ceased. Specifically, progesterone luteal synthesis begins to decline at about 6 weeks despite continued and increasing hCG production.

Chorionic gonadotropin stimulates fetal testicular testosterone secretion that is maximum at approximately the same time that maximal levels of hCG are attained. Thus, at a critical time in sexual differentiation of the male fetus, hCG enters fetal plasma from the syncytiotrophoblast, acts as an LH surrogate, and stimulates replication of testicular Leydig cells and testosterone synthesis to *promote male sexual differentiation* (see Chap. 4, p. 113). Before about 110 days, there is no vascularization of the fetal anterior pituitary from the hypothalamus, and thus little LH secretion from the pituitary. HCG acts as LH before this time. Thereafter, as hCG levels fall, pituitary LH maintains a more modest level of fetal testicular stimulation.

There is hCG stimulation of the maternal thyroid gland. In some women with hydatidiform mole or choriocarcinoma, biochemical and clinical evidence of hyperthyroidism sometimes develops (see Chap. 11, p. 277). For a time, this was believed to be due to the formation of *chorionic thyrotropins* by neoplastic trophoblasts. Later, however, it was shown that some forms of hCG bind to the TSH receptors of thyroid cells (Hershman, 1999). Additionally, treatment of normal men with hCG increases

thyroid activity. The thyroid-stimulatory activity in plasma of first-trimester pregnant women varies appreciably from sample to sample. Modifications in the oligosaccharides of hCG seem to be important in establishing the capacity of hCG to stimulate thyroid function. Some of the acidic isoforms of hCG stimulate thyroid activity, and some more basic forms also stimulate iodine uptake (Kraiem and colleagues, 1994; Tsuruta and colleagues, 1995; Yoshimura and colleagues, 1994). There is also evidence that the LH-hCG receptor is expressed in the thyroid (Tomer and colleagues, 1992). Thus, the possibility exists that hCG stimulates thyroid activity via the LH-hCG receptor and by the TSH receptor as well.

Other functions include *promotion of relaxin secretion by the corpus luteum* (Duffy and co-workers, 1996). LH-hCG receptors are found in myometrium and in uterine vascular tissue, and it has been hypothesized that hCG may act to *promote uterine vascular vasodilatation and myometrial smooth muscle relaxation* (Kurtzman and colleagues, 2001).

Figure 3-26. Distinct profiles for the concentrations of human chorionic gonadotropin (hCG), human placental lactogen (hPL), and corticotropin-releasing hormone (CRH) in serum of women throughout normal pregnancy.

HUMAN PLACENTAL LACTOGEN (HPL). Prolactin-like activity in the human placenta was first described by Ehrhardt in 1936. The protein responsible for this activity was isolated from extracts of human placenta and retroplacental blood (Ito and Higashi, 1961; Josimovich and MacLaren, 1962). Because of the potent lactogenic and growth hormone-like bioactivity, as well as an immunochemical resemblance to human growth hormone, it was first called human placental lactogen or chorionic growth hormone. It also has been referred to as chorionic somatomammotropin. Recently, most authors have used the original name, human placental lactogen (hPL). Grumbach and Kaplan (1964) found, by immunofluorescence studies, that this hormone, like hCG, was concentrated in the syncytiotrophoblast. It is detected in the trophoblast as early as the second or third week after fertilization of the ovum. As with hCG, hPL also is identified in cytotrophoblasts from before 6 weeks (Maruo and associates, 1992).

Chemical Characteristics. Placental lactogen is a single nonglycosylated polypeptide chain with a molecular weight of 22,279 daltons. It is derived from a precursor of 25,000 daltons that contains a 26-amino-acid signal sequence. There are 191 amino-acid residues in placental lactogen, compared with 188 in human growth hormone (hGH). The amino acid sequence in each hormone is strikingly similar, with 96-percent homology. HPL also is structurally similar to human prolactin (hPRL), with an amino-acid sequence similarity of about 67 percent. For these reasons, it has been suggested that the genes for hPL, hPRL, and hGH evolved from a common ancestral gene—probably that of prolactin—by repeated gene duplication (Ogren and Talamantes, 1994).

Gene Structure and Expression. There are five genes in the growth hormone-placental lactogen gene cluster that are linked and located on chromosome 17. Two of these genes, *hPL2* and *hPL3*, both encode hPL, and the amount of mRNA in the term placenta is similar for each. In contrast, the prolactin gene is located on chromosome 6 (Owerbach and colleagues, 1980, 1981). *The production rate of hPL near term, about 1 g/day, is the greatest, by far, of any known hormone in humans.*

Serum Concentration. HPL is demonstrable in the placenta within 5 to 10 days after conception and can be detected in maternal serum as early as 3 weeks after fertilization. Maternal plasma concentration rises steadily until about 34 to 36 weeks and this rise is linked mainly to placental mass. The serum concentration reaches higher levels in late pregnancy (5 to 15 $\mu\text{g/mL}$) than those of any other known protein hormone (see Fig. 3-26). The half-life of hPL in maternal plasma is between 10 and 30 minutes (Walker and co-workers, 1991).

Very little hPL is detected in fetal blood or in the urine of the mother or newborn. Amniotic fluid levels are somewhat lower than in maternal plasma. Because hPL is secreted primarily into the maternal circulation, with only very small amounts in cord blood, it appears that the role of the hormone in pregnancy, if any, is mediated through actions in maternal rather than in fetal tissues. Nonetheless, there is continuing interest in the possibility that hPL serves select functions in fetal growth.

Regulation of hPL Biosynthesis. The levels of mRNA for hPL in syncytiotrophoblast remain relatively constant throughout pregnancy. This finding is supportive of the idea that the rate of hPL secretion is proportional to placental mass. There are very high plasma levels of hCG in women with trophoblastic neoplasms, but only low levels of hPL in these same women.

Prolonged maternal starvation in the first half of pregnancy leads to an increase in the plasma concentration of hPL. Short-term changes in plasma glucose or insulin, however, have relatively little effect on plasma levels of hPL. In vitro studies using human syncytiotrophoblast suggest that the synthesis of hPL is stimulated by insulin and insulin-like growth factor-1 and inhibited by PGE_2 and $\text{PGF}_{2\alpha}$ (Bhaumick and colleagues, 1987; Genbacev and colleagues, 1977).

Metabolic Actions. HPL has putative actions in a number of important metabolic processes. These include:

1. *Maternal lipolysis* and an increase in the levels of circulating free fatty acids, thereby providing a source of energy for maternal metabolism and fetal nutrition.
2. *An anti-insulin or "diabetogenic" action*, leading to an increase in maternal levels of insulin, which favors protein synthesis and provides a readily available source of amino acids for transport to the fetus.
3. *A potent angiogenic hormone*; it also may play an important role in the formation of fetal vasculature (Corbacho and co-workers, 2002).

OTHER PLACENTAL PROTEIN HORMONES

Chorionic Adrenocorticotropin. ACTH, lipotropin, and β -endorphin—all proteolytic products of proopiomelanocortin—are recovered in placental extracts (Genazzani and colleagues, 1975; Odagiri and colleagues, 1979). The physiological role of

placental ACTH is unclear. Although maternal plasma levels of ACTH increase during pregnancy, they remain lower than those in men and nonpregnant women, except during labor (Carr and colleagues, 1981a). The placental ACTH is secreted into the mother or fetus during pregnancy, however, maternal ACTH does not cross the placenta to the fetus. Importantly, ACTH produced within the placenta is not under feedback regulation by glucocorticoid, which has been proposed as the rationale for maternal partial resistance to dexamethasone suppression (Nolten and Rueckert, 1981). Corticotropin-releasing hormone (CRH), also produced within the placenta, stimulates the synthesis and release of chorionic ACTH, and placental production of CRH is positively regulated by cortisol, producing a novel positive feedback loop. As discussed later, this system may be important for controlling fetal lung maturation and the timing of parturition.

Relaxin. Expression of relaxin has been demonstrated in human corpus luteum, decidua, and placenta (Bogic and colleagues, 1995). This peptide is synthesized as a single 105 amino-acid preprorelaxin molecule that is cleaved to A and B molecules. Relaxin is structurally similar to insulin and insulin-like growth factor. There are three relaxin genes—H1, H2, and H3—but only H2 and H3 are transcribed in the corpus luteum (Bathgate and associates, 2002; Hudson and colleagues, 1983, 1984). Other tissues, including decidua, placenta, and fetal membranes, express H1 and H2 (Hansell and colleagues, 1991).

The rise in maternal circulating relaxin seen in early pregnancy is attributed to secretion by the corpus luteum, and levels parallel those seen for hCG. The uterine relaxin receptor was recently cloned, which should allow the role of relaxin gene family members to be defined (Hsu and colleagues, 2002). It has been proposed that relaxin along with rising progesterone levels acts on myometrial smooth muscle to promote uterine relaxation and the quiescence observed in early pregnancy (see [Chap. 6](#), p. 163). In addition, the production of relaxin and relaxin-like factors within the placenta and fetal membranes is believed to play an autocrine-paracrine role in regulation of extracellular matrix degradation in the puerperium (Qin and colleagues, 1997a, 1997b).

Parathyroid Hormone-Related Protein (PTH-rP). Circulating levels of PTH-rP are significantly elevated in pregnancy within the maternal but not fetal circulation (Bertelloni and colleagues, 1994; Saxe and colleagues, 1997). Although not clear, many potential functions of this hormone have been proposed. The synthesis of PTH-rP has been demonstrated in several normal adult tissues, especially in reproductive organs, including the myometrium, endometrium, corpus luteum, and lactating mammary tissue. PTH-rP is not produced in the parathyroid glands of normal adults. Placental-derived PTH-rP may have an important autocrine-paracrine role within the fetal-maternal unit as well as on the adjacent myometrium. In the placenta, it may activate receptors on the trophoblast to promote calcium transport for fetal bone growth and ossification.

Growth Hormone Variant (hGH-V). The placenta expresses a growth hormone variant that is not expressed in the pituitary. The gene encoding hGH-V is located in the hGH-hPL gene cluster on chromosome 17. Sometimes referred to as placental growth hormone, hGH-V is a 191-amino-acid protein that differs in 15 amino-acid positions from the sequence for hGH. Placental hGH-V presumably is synthesized in the syncytium, but its pattern of synthesis and secretion during gestation is not precisely known because antibodies against hGH-V cross-react with hGH. It is believed that hGH-V is present in maternal plasma by 21 to 26 weeks, increases in concentration to about 36 weeks, and remains relatively constant thereafter. There is a correlation between the levels of hGH-V in maternal plasma and those of insulin-like growth factor-1, and the secretion of hGH-V by trophoblasts in vitro is inhibited by glucose in a dose-dependent manner (Patel and colleagues, 1995). Overexpression of hGH-V in mice causes severe insulin resistance, and thus it is a likely candidate to mediate insulin resistance of pregnancy (Barbour and associates, 2002).

HYPOTHALAMIC-LIKE RELEASING HORMONES. For each of the known hypothalamic-releasing or -inhibiting hormones described—GnRH, TRH, CRH, GHRH, and somatostatin—there is an analogous hormone produced in human placenta (Petraglia and colleagues, 1992; Siler-Khodr, 1988). Many investigators have proposed that these substances in placental tissue are indicative of a hierarchy of control in the synthesis of chorionic trophic agents.

Gonadotropin-Releasing Hormone (GnRH). There is a reasonably large amount of immunoreactive GnRH in the placenta (Siler-Khodr, 1988; Siler-Khodr and Khodr, 1978). Interestingly, immunoreactive GnRH was present in cytotrophoblasts but not in the syncytiotrophoblast. Gibbons and co-workers (1975) and Khodr and Siler-Khodr (1980) demonstrated that the human placenta could synthesize both GnRH and TRH in vitro. Placental-derived GnRH functions to regulate trophoblast production of hCG, which is supported by the observation that GnRH levels are higher early in pregnancy. Placental-derived GnRH is also the likely cause of the elevation of maternal levels of circulating GnRH that are seen early in pregnancy (Siler-Khodr and colleagues, 1984).

Corticotropin-Releasing Hormone (CRH). This hormone is a member of a larger family of CRH-related peptides, which includes CRH, urocortin, urocortin II, and urocortin III (Dautzenberg and Hauger, 2002). CRH is produced in nonpregnant women and circulates at the relatively low level of 5 to 10 pmol/L. During pregnancy, levels are significantly elevated and increase to about 100 pmol/L in the early third trimester and to almost 500 pmol/L abruptly during the last 5 to 6 weeks (see [Fig. 3-26](#)) (Goland and associates, 1988). Urocortin also is produced by the placenta and secreted into the maternal circulation, but at much lower levels than seen for CRH (Florio and co-workers, 2002). After labor begins, maternal plasma CRH levels increase further by about two- to threefold (Petraglia and colleagues, 1989, 1990).

The biological function of CRH synthesized in the placenta, fetal membranes, and decidua is beginning to be defined. Receptors for CRH are present in many tissues: placenta, adrenal gland, sympathetic ganglia, lymphocytes, gastrointestinal tract, pancreas, gonads, and myometrium. Recent findings suggest that CRH can act through two major families—the type 1 and type 2 CRH receptors (CRH-R1 and CRH-R2). Trophoblast, amnion-chorion, and decidua express both CRH-R1 and CRH-R2 receptors, as well as several variant receptors (Florio and colleagues, 2000). Both CRH and urocortin can increase trophoblast ACTH secretion, supporting an autocrine-paracrine role for these hormones (Petraglia and co-workers, 1999). Large amounts of CRH from trophoblast enter the maternal blood, but there also is a large concentration of a specific CRH-binding protein in maternal plasma, and the bound CRH seems to be biologically inactive.

Other proposed biological roles include the induction of smooth muscle relaxation in vascular and myometrial tissue, and immunosuppression. The physiological reverse, however, induction of myometrial contractions, has been proposed for the rising levels of CRH seen near the end of gestation, leading to the hypothesis that CRH may be involved with the initiation of parturition (Wadhwa and colleagues, 1998). Prostaglandin formation in the placenta, amnion, chorion laeve, and decidua is increased by treatment with CRH (Jones and Challis, 1989), further supporting the potential role of CRH in the timing of

parturition.

Glucocorticoids act in the hypothalamus to *inhibit CRH release*, but in the trophoblast, glucocorticoids *stimulate* CRH gene expression. Studies using trophoblast cultures show two- to fivefold increases in CRH mRNA and protein after treatment with glucocorticoids (Jones and colleagues, 1989; Robinson and co-workers, 1988). Thus, a novel positive feedback loop has been considered in the placenta that involves placental CRH stimulation of placental ACTH formation, placental ACTH stimulation of adrenal glucocorticoid formation, and glucocorticoid stimulation of placental CRH expression (Nicholson and King, 2001; Riley and colleagues, 1991).

Growth Hormone-Releasing Hormone (GHRH). Although GHRH has been identified in human placenta, its exact function is not known (Berry and associates, 1992). Another regulator of hGH secretion called *ghrelin* recently was discovered (Horvath and colleagues, 2001). Ghrelin is expressed in the trophoblasts of first-trimester placenta and represents a potential regulator of placental growth hormone production or a paracrine regulator of differentiation (Gualillo and co-workers, 2001).

OTHER PLACENTAL PEPTIDE HORMONES

Leptin. This hormone is normally secreted by adipocytes and initially was believed to be an anti-obesity hormone that decreases food intake and body weight through its receptor in the hypothalamus. It is now known, however, that leptin also regulates bone growth and immune function (Cock and Auwerx, 2003; La Cava and colleagues, 2004). Leptin also is synthesized by both cytotrophoblast cells and syncytiotrophoblast, which explains the increase in circulating levels seen in pregnancy (Henson and Castracane, 2002). Fetal leptin levels are correlated positively with fetal birthweight and are likely to play an important role in fetal development and growth. Maternal serum levels are significantly higher than in nonpregnant women or those seen in the fetal circulation. Currently the relative contribution of leptin from maternal adipose tissue versus placenta is not well defined.

Neuropeptide Y. This small, 36-amino-acid peptide is widely distributed in brain. It also is found in sympathetic neurons innervating the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. Neuropeptide Y has been isolated from placenta and localized in cytotrophoblasts (Petraglia and colleagues, 1989). Receptors for neuropeptide Y have been demonstrated in the placenta, and treatment of placental cells with neuropeptide Y causes the release of CRH (Robidoux and colleagues, 2000).

Inhibin and Activin. Inhibin is a glycoprotein hormone that acts preferentially to inhibit pituitary FSH release. It is produced by human testis and by the granulosa cells of the ovary, including the corpus luteum. Inhibin is a heterodimer with dissimilar α - and β -subunits. The inhibin β -subunit is composed of one of two distinct peptides, βA or βB . The placenta produces inhibin α -, βA -, and βB -subunits with the greatest levels present at term (Petraglia and co-workers, 1991). Placental inhibin production may serve, in conjunction with the large amounts of sex steroid hormones produced in human pregnancy, to inhibit FSH secretion and thereby preclude ovulation during pregnancy. Inhibin may act via GnRH to regulate hCG synthesis and secretion in the placenta (Petraglia and colleagues, 1987).

Activin is closely related to inhibin and is formed by the combination of the two β -subunits. Petraglia and colleagues (1994) found that serum activin A levels decline rapidly after delivery. It is not detectable in fetal blood before labor but is present in umbilical cord blood after labor begins. The receptor for activin is expressed in the placenta and amnion. Chorionic activin and inhibin may serve functions in placental metabolic processes other than GnRH synthesis, but these possibilities continue to be investigated.

PLACENTAL PROGESTERONE PRODUCTION. After 6 to 7 weeks of gestation, very little progesterone is produced in the ovary (Diczfalusy and Troen, 1961). Surgical removal of the corpus luteum or even bilateral oophorectomy during the 7th to 10th week does not cause a decrease in the rate of excretion of urinary pregnanediol, the principal urinary metabolite of progesterone. Before this time, however, removal of the corpus luteum will result in miscarriage unless an exogenous progestin is given (see [Chap. 9](#), p. 234, and [Chap. 40](#), p. 965). After about 8 weeks, the placenta replaces the ovary as the source of progesterone and continues to increase production such that there is a gradual increase in the levels throughout the remainder of pregnancy ([Fig. 3-27](#)). By the end of pregnancy, maternal levels of progesterone are 10 to 5000 times those in nonpregnant women, depending on the stage of the ovarian cycle (see [Fig. 3-27](#)).

Progesterone Production Rates. Isotope dilution techniques for the measurement of the rates of endogenous hormone production in humans were first applied to the study of progesterone in pregnancy (Pearlman, 1957). The daily production rate of progesterone in late, normal, singleton pregnancies is about 250 mg. The findings of numerous studies using a variety of methodologies have agreed with this value. In some pregnancies with multiple fetuses, however, the daily progesterone production rate may exceed 600 mg/day.

Source of Cholesterol for Placental Progesterone Biosynthesis. Progesterone is synthesized from cholesterol in a two-step enzymatic reaction. First, cholesterol is converted to pregnenolone within the mitochondria, in a reaction catalyzed by cytochrome P450 cholesterol side-chain cleavage enzyme. Pregnenolone leaves the mitochondria and is converted to progesterone in the endoplasmic reticulum by 3β -hydroxysteroid dehydrogenase. Progesterone is not stored but is released immediately through a process of diffusion.

The placenta produces a prodigious amount of progesterone; nonetheless, there is a limited capacity for the biosynthesis of cholesterol in trophoblast. The incorporation of radiolabeled acetate into cholesterol by placental tissue proceeds at a very slow rate, and the activity of the rate-limiting enzyme in cholesterol biosynthesis, 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase, in placental tissue microsomes is low. Thus, the placenta must rely on exogenous cholesterol for progesterone formation. Bloch (1945) and Werbin and co-workers (1957) found that after the intravenous administration of radiolabeled cholesterol to pregnant women, the amount of radioactivity of urinary pregnanediol was similar to that of plasma cholesterol. Hellig and associates (1970) also found that maternal plasma cholesterol was the principal precursor (up to 90 percent) of progesterone biosynthesis in human pregnancy. The trophoblast preferentially uses LDL cholesterol for progesterone biosynthesis (Simpson and Burkhardt, 1980; Simpson and colleagues, 1979). This finding was supported by studies in pregnant baboons in which maternal levels of LDL were reduced, leading to a significant drop in placental progesterone production (Henson and associates, 1997). Thus, the formation of placental progesterone occurs through the uptake and use of a

maternal circulating precursor. This mechanism is unlike the placental production of estrogens, which relies principally on fetal adrenal precursors.

Progesterone Synthesis and Fetal Well-Being. Although there is a relationship between fetal well-being and placental production of estrogen, this is not the case for placental progesterone. Fetal demise, ligation of the umbilical cord with the fetus and placenta remaining in situ, and anencephaly are all conditions associated with very low maternal plasma levels and urinary excretion of estrogens. In these circumstances, there is not a concomitant decrease in progesterone until some indeterminate time after fetal death. Thus, placental endocrine function, including the formation of protein hormones such as hCG, and progesterone biosynthesis may persist for long periods (weeks) after fetal demise.

Progesterone Metabolism During Pregnancy. The metabolic clearance rate of progesterone in pregnant women is similar to that found in men and nonpregnant women. This is an important consideration in evaluating the role of progesterone in the initiation of parturition (see [Chap. 6](#), p. 168). During pregnancy, there is a disproportionate increase in the plasma concentration of 5α -dihydroprogesterone as a result of synthesis in syncytiotrophoblast from both placenta-produced progesterone and fetal-derived precursor (Dombroski and co-workers, 1997). Thus the ratio of the concentration of this progesterone metabolite to the concentration of progesterone is increased in pregnant women. The mechanisms for this are not defined completely, but may be relevant to the resistance to pressor agents that normally develops in pregnant women (Everett and colleagues, 1978). Progesterone also is converted to the potent mineralocorticoid deoxycorticosterone in pregnant women and in the fetus. The concentration of deoxycorticosterone is increased strikingly in both the maternal and fetal compartments. The extra-adrenal formation of deoxycorticosterone from circulating progesterone accounts for the vast majority of its production in human pregnancy (Casey and MacDonald, 1982a, 1982b).

Figure 3-27. Plasma levels of progesterone, estradiol, estrone, estetrol, and estriol in women during the course of gestation. (From Mesiano, 2001, with permission.)

PLACENTAL ESTROGEN PRODUCTION. The placenta produces huge amounts of estrogens using blood-borne steroidal precursors from the maternal and fetal adrenal glands. Near term, normal human pregnancy is a hyperestrogenic state of major proportions. The amount of estrogen produced each day by syncytiotrophoblast during the last few weeks of pregnancy is equivalent to that produced in 1 day by the ovaries of no fewer than 1000 ovulatory women. The hyperestrogenic state of human pregnancy is one of continually increasing magnitude as pregnancy progresses, terminating abruptly after delivery.

During the first 2 to 4 weeks of pregnancy, rising levels of hCG maintain production of estradiol in the maternal corpus luteum. The functional activity, viz., production of both progesterone and estrogens, of the maternal ovaries decreases significantly by the seventh week of pregnancy. At this time there is a luteal-placental transition such that, by the seventh week, more than 50 percent of estrogen entering the maternal circulation is produced in the placenta (MacDonald, 1965; Siiteri and MacDonald, 1963, 1966). These studies support the transition of a steroid milieu dependent on the maternal corpus luteum to one dependent on the developing placenta.

Placental Estrogen Biosynthesis. The pathways of estrogen synthesis in the human placenta differ from those in the ovary of nonpregnant women. Estrogen production in the ovary occurs in the follicular and luteal phase through the interaction of theca and granulosa cells. Specifically, androstenedione, synthesized in ovarian theca, is transferred to adjacent granulosa cells for estradiol synthesis. Estradiol production within the corpus luteum of nonpregnant women as well as in early pregnancy continues to require interaction between the luteinized theca and granulosa cells. In human trophoblast, neither cholesterol nor progesterone can serve as precursor for estrogen biosynthesis. A crucial enzyme necessary for sex steroid synthesis, steroid 17α -hydroxylase/ $17,20$ -lyase (CYP17), is not expressed in the human placenta. Consequently, the conversion of C_{21} -steroids to C_{19} -steroids, the latter being the immediate and obligatory precursors of estrogens, is not possible.

The C_{19} -steroids, dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S), often are called adrenal androgens, however, these steroids can also act as estrogen precursors ([Fig. 3-28](#)). Ryan (1959a) found that there was an exceptionally high capacity of placenta to convert appropriate C_{19} -steroids to estrone and estradiol. The conversion of DHEA-S to estradiol requires placental expression of four key enzymes. First, the placenta expresses high levels of steroid sulfatase (STS), which converts the conjugated DHEA-S to DHEA. DHEA is then acted upon by 3β -hydroxysteroid dehydrogenase type 1 (3β HSD) to produce androstenedione. Cytochrome P_{450} aromatase (CYP19) then converts androstenedione to estrone, which is converted to estradiol by the enzyme 17β -hydroxysteroid dehydrogenase type 1 (17β HSD1). The principal cellular location of STS, 3β HSD, CYP19, and 17β HSD1 is in the syncytiotrophoblast (Bonenfant and colleagues, 2000b; Salido and co-workers, 1990).

Plasma C_{19} -Steroids as Estrogen Precursors.

Frandsen and Stakemann (1961) found that levels of urinary estrogens in women pregnant with an anencephalic fetus were only about one tenth those in urine of pregnant women with a normal fetus. Because of the characteristic absence of the fetal zone of the adrenal cortex in anencephalic fetuses, they reasoned that the glands might provide one or more substances that serve to promote placental estrogen formation. The adrenal glands of anencephalic fetuses are atrophic because of the absence of hypothalamic-pituitary function, which precludes ACTH stimulation.

In subsequent studies, radiolabeled DHEA-S infused into pregnant women was converted to radioactive urinary estrogens in high yield (Baulieu and Dray, 1963; Siiteri and MacDonald, 1963). The large amounts of DHEA-S in plasma and its much longer half-life uniquely qualify it as the principal circulating precursor for placental estradiol synthesis. Gant and co-workers (1971)

found that there is a 10- to 20-fold increase in the metabolic clearance rate of plasma DHEA-S in normally pregnant women at term compared with that in men and nonpregnant women. As a consequence, there is a progressive decrease in plasma concentration of DHEA-S as pregnancy progresses (Milewich and co-workers, 1978; Siiteri and MacDonald, 1966). The increase in the metabolic clearance of plasma DHEA-S in pregnant women is attributable to rapid use as substrate for placental estrogens. Even so, the maternal adrenal glands do not produce sufficient amounts of DHEA-S during pregnancy to account for more than a fraction of total placental estrogen biosynthesis. *The fetal adrenal glands are quantitatively the most important source of placental estrogen precursors in human pregnancy.* A schematic representation of the pathways of estrogen formation in the placenta is presented in [Figure 3-28](#). The estrogen products released from the placenta are dependent on the nature of the substrate available. As discussed below, the nature of the estrogens produced during pregnancy reflects the unique interactions between the fetal adrenal, fetal liver, placenta, and maternal adrenal glands.

Figure 3-28. Schematic presentation of the biosynthesis of estrogens in the human placenta. Dehydroepiandrosterone sulfate (DHEA-S), secreted in prodigious amounts by the fetal adrenal glands, is converted to 16α -hydroxydehydroepiandrosterone sulfate (16α -OHDHEA-S) in the fetal liver. These steroids, DHEA-S and 16α -OHDHEA-S, are converted in the placenta to estrogens, viz., 17β -estradiol (E2) and estriol (E3). Near term, half of E2 is derived from fetal adrenal DHEA-S and half from maternal DHEA-S. On the other hand, 90 percent of E3 in the placenta arises from fetal 16α -OHDHEA-S and only 10 percent from all other sources.

FETAL ADRENAL GLANDS. Morphologically, functionally, and physiologically, the human fetal adrenal glands are remarkable organs. Compared with adult organs, the adrenal cortex is the largest organ of the fetus. At term, the fetal adrenal glands weigh the same as those of the adult ([Fig. 3-29](#)). More than 85 percent of the fetal gland is composed of a unique fetal zone, which is not found in adults. The daily production of steroids by the fetal adrenal glands near term is estimated to be 100 to 200 mg/day. This compares with steroid secretion in resting adults of 30 to 40 mg/day, demonstrating that the fetal adrenal gland is a truly prodigious steroidogenic tissue.

Contribution to Placental Estrogen Formation. As discussed earlier, women pregnant with an anencephalic fetus excrete little urinary estrogen. This fact, together with the finding of high levels of DHEA-S in cord blood of normal newborns, was suggestive that fetal adrenal cortex is the principal source of placental estrogen precursors. The finding that DHEA-S in maternal plasma is converted to estrogen in placenta established this concept. Confirmation was provided by Bolte and co-workers (1964a, 1964b), who demonstrated that radiolabeled DHEA-S perfused through the placenta was converted to estradiol. Near term, about half of the estradiol produced in the placenta arises from maternal and half from fetal plasma DHEA-S (Siiteri and MacDonald, 1966).

Placental Estriol Synthesis. The estrogen products released from the placenta are dependent on the nature of the substrate available. Estradiol is but one placental estrogen secretory product and is the primary estrogen circulating at term. In addition, significant levels of estriol and estetrol are found in the maternal circulation, and they increase, particularly late in gestation. These hydroxylated forms of estrogen are produced in the placenta using substrates formed by the combined efforts of the fetal adrenal gland and liver.

An important component of the fetal-maternal communication system is the fetal liver ([Fig. 3-25](#)). The fetal liver expresses high levels of the enzyme 16α -hydroxylase, which acts on adrenal derived steroids. Ryan (1959b) and MacDonald and Siiteri (1965) found that 16α -hydroxylated C_{19} -steroids, particularly 16α -hydroxydehydroepiandrosterone (16 -OHDHEA), were converted to estriol by placental tissue ([Fig. 3-28](#)). Thus, the disproportionate increase in estriol formation during pregnancy is accounted for by placental synthesis of estriol principally from plasma-borne 16 -OHDHEA-S. Near term, the fetus is the source of 90 percent of the placental estriol and estetrol precursor in normal human pregnancy.

Thus, the placenta secretes several estrogens, including estradiol, estrone, estriol, and estetrol. Because of its hemochorial nature, the majority of estrogen produced in the placenta is released into the maternal circulation. Maternal estriol and estetrol are produced by steroid precursors produced almost solely in the fetus, thus, the measure of these steroids can act as an indicator of fetal well-being. However, the low sensitivity and specificity of such tests have diminished their diagnostic value, and they have been supplanted other means of determining fetal well-being (see [Chap. 15](#), p. 373).

Fetal Adrenal Gland Development. The fetal adrenal cortex derives from a common adrenogonadal precursor lineage that also gives rise to the steroid-secreting cells of the gonads. These progenitor cells first appear in the fourth week of gestation within the coelomic epithelium. Soon after, they begin to migrate to the mesonephros, and by 6 to 8 weeks' gestation the cells form the primitive adrenal gland. The factors that control the formation of the primordial adrenal gland are not known. However, it appears that ACTH is not necessary for the early stages of adrenal formation. Specifically, the adrenal gland is formed in the anencephalic fetus as well as in fetuses with mutations in the ACTH receptor.

Fetal Adrenal Morphology. Nearly a century ago, Elliott and Armour (1911) described a histologically unique *fetal zone* in the adrenal cortex. The fetal zone accounts for the bulk of the fetal gland after the first trimester, and it is the source for steroid precursors that are used by the placenta to produce estrogens. The outer zone is called the *neocortex*, or the *definitive zone*, and it is this zone that gives rise to the adult adrenal glomerulosa. Recent studies using immunohistochemistry have been useful in identifying a third region between the neocortex and fetal zone, now called the *transitional zone* (Narasaka and colleagues, 2001). This zone is thought to give rise to the cortisol-producing zona fasciculata seen in the postnatal adrenal gland (Mesiano and co-workers, 1993). The fetal zone of the adrenal gland begins a process of involution commencing immediately after birth. The weight of the adrenal glands decreases strikingly during the first few weeks of life, and the size attained by the fetal glands just before birth is not achieved again until late in adolescence or early adult life.

Fetal Adrenal Gland Growth. The cortex continues to grow throughout gestation and, during the last 5 to 6 weeks of

pregnancy, there is a very rapid increase in adrenal size ([Fig. 3-29](#)). Relative to body weight, the fetal adrenal glands at term are 25 times larger than those of adults. Because of the enormous size and their very great capacity for steroid synthesis, many investigators have surmised that in addition to ACTH, there must be other growth stimuli for these glands. Indeed, there is a continual decrease in the concentration of immunoreactive ACTH in human fetal plasma as pregnancy progresses and as the fetal adrenal glands are growing at a rapid rate (Winters and associates, 1974). Generally, ACTH acts to promote hypertrophy, but not hyperplasia, of adrenal cells. Despite this, it has been shown that fetal adrenal cells respond to ACTH by secretion of growth factors that appear to stimulate hyperplasia of the fetal zone (Mesiano and colleagues, 1991). ACTH is necessary for the rapid growth of the adrenal gland during the latter part of pregnancy. This is supported by the observation that the adrenal glands in anencephalic fetuses are underdeveloped, indicating that a functional hypothalamic-pituitary system also is needed for normal fetal adrenal function. It also seems likely that the rate of growth of the fetal adrenal glands is influenced by factors secreted by the placenta. This supposition is supported by the continued growth of the fetal adrenal glands throughout gestation, but rapid involution immediately after birth when placenta-derived factors are lost.

Enzymatic Considerations. There is a severe deficiency in the expression of the microsomal enzyme 3α -hydroxysteroid dehydrogenase, Δ^{5-4} -isomerase (3β HSD) in adrenal fetal zone cells (Doody and co-workers, 1990; Rainey and colleagues, 2001). This limits the conversion of pregnenolone to progesterone and of 17α -hydroxypregnenolone to 17α -hydroxyprogesterone, an obligatory step in cortisol biosynthesis. There is, however, very active steroid sulfotransferase activity in the fetal adrenal glands. As a consequence, the principal secretory products of the fetal adrenal glands are pregnenolone sulfate and DHEA-S. Comparatively, cortisol, which likely arises primarily in the neocortex and transitional zone of the fetal adrenal glands and not in the fetal zone, is a minor secretory product of the fetal adrenal gland until late in gestation.

Fetal Adrenal Steroid Precursor. The precursor for fetal adrenal steroidogenesis is cholesterol. The rate of steroid biosynthesis in the fetal adrenal gland is so great that its steroidogenesis alone is equivalent to one fourth of the total daily LDL cholesterol turnover in adults. The fetal adrenal glands can synthesize cholesterol from two-carbon fragments, that is, acetate. All enzymes involved in cholesterol biosynthesis are elevated compared with that of the adult adrenal gland (Rainey and colleagues, 2001). Thus, the rate of de novo cholesterol synthesis by fetal adrenal tissue is extremely high, however, it is insufficient to account for the steroids produced by these glands. Therefore, cholesterol must be assimilated from the fetal circulation. Plasma cholesterol and its esters are present in the form of very-low-density lipoprotein (VLDL), LDL, and high-density lipoprotein (HDL).

Simpson and colleagues (1979) ascertained that fetal adrenal glands take up lipoproteins as a source of cholesterol for steroidogenesis. HDL was much less effective than LDL, and VLDL was devoid of stimulatory activity. These authors also evaluated the relative contribution of cholesterol synthesized de novo and that of cholesterol derived from LDL uptake. They confirmed that the fetal adrenal glands are highly dependent on circulating LDL as a source of cholesterol for optimum steroidogenesis (Carr and colleagues, 1980, 1982; Carr and Simpson, 1981). A model of cholesterol metabolism in the fetal adrenal glands is shown in [Figure 3-30](#).

The majority of fetal plasma cholesterol arises by de novo synthesis in the fetal liver (Carr and Simpson, 1984). The low level of LDL cholesterol in fetal plasma is not the consequence of impaired fetal LDL synthesis, but instead, it is the result of the rapid use of LDL by the fetal adrenal glands for steroidogenesis (Parker and colleagues, 1980, 1983). In the anencephalic newborn in whom the adrenal glands are atrophic, the levels of LDL cholesterol in umbilical cord plasma are high.

Figure 3-29. Size of the adrenal gland and its component parts in utero, during infancy, and during childhood. (Adapted from Bethune, 1974.)

Figure 3-30. A model proposed for the regulation of fetal adrenal steroidogenesis, low-density lipoprotein (LDL) use, and cholesterol (chol) metabolism in the human fetal adrenal gland. (DS = dehydroepiandrosterone sulfate; Preg = pregnenolone). DS is produced in the fetal zone and cortisol primarily in the neocortex of the fetal adrenal glands.

FETAL CONDITIONS THAT AFFECT ESTROGEN PRODUCTION.

Several conditions affecting the fetus may alter the availability of substrate for steroid synthesis in placenta. A schematic representation of the pathways of estrogen formation in the placenta is presented in [Figure 3-28](#).

Fetal Demise. It has been known for many decades that death of the human fetus is followed by a striking reduction in the levels of urinary estrogens. Moreover, it was demonstrated that after ligation of the umbilical cord with the fetus and placenta left in situ, there was an abrupt and striking decrease in the production of placental estrogens (Cassmer, 1959). The findings of this classical study were subject to at least two interpretations. The first was that maintenance of the fetal placental circulation is essential to the functional integrity of the placenta. This explanation was unlikely to be correct, however, because the placental production of progesterone was maintained after occlusion of the umbilical cord. A second explanation for the marked decrease in urinary estrogens was that after umbilical cord ligation, an important source of precursors of placental estrogen (but not progesterone) biosynthesis was eliminated — that is, the fetus.

Fetal Anencephaly. In the absence of the fetal zone of the adrenal cortex, as in anencephaly, the rate of formation of placental estrogens (especially estriol) is severely limited because of limited availability of C_{19} -steroid precursors. Verification of the diminished levels of precursors in anencephalic fetuses was provided by the finding of low levels of DHEA-S in cord blood

of such newborns (Nichols and colleagues, 1958). Therefore, almost all of the estrogens produced in women pregnant with an anencephalic fetus arise by the placental use of maternal plasma DHEA-S. Furthermore, in such pregnancies the production of estrogens can be increased by the maternal administration of ACTH, which stimulates the rate of DHEA-S secretion by the maternal adrenal. ACTH does not cross the placenta, and thus there is no fetal adrenal stimulation. Finally, placental estrogen production is decreased in women pregnant with an anencephalic fetus when a potent glucocorticoid is given to the mother. This suppresses ACTH secretion and thus decreases the rate of DHEA-S secretion from the maternal adrenal cortex (MacDonald, 1965; MacDonald and Siiteri, 1965). Estriol formation is disproportionately decreased in pregnancies with an anencephalic fetus because the fetal adrenal at term normally provides 90 percent of placental estriol precursor.

Fetal Adrenal Hypoplasia. Congenital adrenal cortical hypoplasia occurs in perhaps 1 in 12,500 births (McCabe, 2001). There appear to be two primary forms of adrenal hypoplasia. The *miniature adult form* is thus named because of the very small cortical zone seen in histological examination. The majority of these cases result from anencephaly or abnormal pituitary function. The *cytomegalic form* is so called because these adrenals, although without the normal fetal adrenal structure, have nodular formation of eosinophilic cells in the fetal zone. Estrogen formation, particularly estriol, in pregnancies with such a fetus is limited and suggests the absence of fetal adrenal C₁₉-precursors for placental estrogen formation. The cytomegalic form results from disruptive mutations in the gene known as the *dosage-sensitive sex reversal-adrenal hypoplasia congenita critical region on the X chromosome, gene 1 (DAX1)* (McCabe, 2001).

Fetal-Placental Sulfatase Deficiency. Placental estrogen formation is generally regulated by the availability of C₁₉-steroid prohormones in fetal and maternal plasma. Specifically, there is no rate-limiting enzymatic reaction in the placental pathway from C₁₉-steroids to estrogen biosynthesis. An exception to this generalization was found by France and Liggins (1969), who were the first to establish that placental sulfatase deficiency is a cause of very low estrogen levels in otherwise normal pregnancies. Sulfatase deficiency precludes the hydrolysis of C₁₉-steroid sulfates, the first enzymatic step in the placental use of these circulating prohormones for estrogen biosynthesis. This deficiency is an X-linked disorder, and all affected fetuses are male. It occurs in an estimated frequency of 1 in 2000 to 5000 births and is associated with delayed onset of labor. It also is associated with the development of ichthyosis, a scaling skin disorder, in the affected males later in life (Bradshaw and Carr, 1986).

Fetal-Placental Aromatase Deficiency. There are a few well-documented examples of aromatase deficiency (Simpson, 2000). Fetal adrenal DHEA-S, which is produced in large quantities, is converted in the placenta to androstenedione, but in cases of placental aromatase deficiency, androstenedione cannot be converted to estradiol. Rather, androgen metabolites of DHEA produced in the placenta, including androstenedione and some testosterone, are secreted into the maternal or fetal circulation, or both, causing virilization of the mother and the female fetus (Harada and colleagues, 1992; Shozu and associates, 1991). Although pregnancies with aromatase deficiency and a male fetus may be uneventful, these estrogen-deficient males have delayed epiphyseal closure during puberty, and as a consequence, the affected men continue to grow during adulthood, becoming very tall and displaying deficient bone mineralization (Morishima and colleagues, 1995).

Trisomy 21 (Down Syndrome). Second-trimester maternal serum screening for abnormal levels of hCG, alpha-fetoprotein, and other analytes has become universal (see [Chap. 13](#), p. 323). As experience accrued, it was discovered that serum unconjugated estriol levels were low in pregnancies with a Down syndrome fetus (Benn, 2002). The likely reason for this is inadequate formation of C₁₉-steroids in the adrenal glands of these trisomic fetuses. This supposition is supported by reduced DHEA-S levels in both amniotic fluid and maternal serum in Down syndrome pregnancies (Newby and colleagues, 2000).

Deficiency in Fetal LDL Cholesterol Biosynthesis. A successful pregnancy in a woman with beta-lipoprotein deficiency has been described (Parker and co-workers, 1986). The absence of LDL in the maternal serum restricted progesterone formation in both the corpus luteum and placenta. In addition, levels of estriol were lower than normal. Presumably, the diminished estrogen production was the result of decreased fetal LDL formation, which limited fetal adrenal production of estrogen precursor.

Fetal Erythroblastosis. In some cases of severe fetal D-antigen isoimmunization, the levels of estrogens in maternal plasma are elevated above normal for gestational age. This is likely due to an increased placental weight (hypertrophy), which occurs in such pregnancies (see [Chap. 29](#), p. 666).

MATERNAL CONDITIONS THAT AFFECT PLACENTAL ESTROGEN PRODUCTION

Glucocorticoid Treatment. The administration of glucocorticoids in moderate to high doses to pregnant women causes a striking reduction in placental estrogen formation. Glucocorticoids act to inhibit ACTH secretion by the maternal and fetal pituitary glands, resulting in decreased maternal and fetal adrenal secretion of the placental estrogen precursor, DHEA-S.

Maternal Adrenal Dysfunction. In pregnant women with Addison disease, maternal urinary estrogen levels are decreased (Baulieu and colleagues, 1956). The decrease principally affects estrone and estradiol, because the fetal adrenal contribution to the synthesis of estriol, particularly in the latter part of pregnancy, is quantitatively much more important.

Maternal Ovarian Androgen-Producing Tumors. The extraordinary efficiency of the placenta in the aromatization of C₁₉-steroids may be exemplified by two considerations. First, Edman and associates (1981) found that the placental clearance of maternal plasma androstenedione to estradiol was very similar to estimated placental blood flow. Thus, virtually all of the androstenedione entering the intervillous space is taken up by syncytium and converted to estradiol, and none of this C₁₉-steroid escapes into the fetus. Second, it is relatively rare that a female fetus is virilized in a pregnant woman who is known to have an androgen-secreting ovarian tumor. This finding also indicates that the placenta efficiently converts aromatizable C₁₉-steroids, including testosterone, to estrogens, thus precluding transplacental passage. Indeed, it may be that virilized female fetuses of women with an androgen-producing tumor are cases in which a nonaromatizable C₁₉-steroid androgen is produced by the tumor (e.g., 5 α -dihydrotestosterone). Another explanation is that testosterone is produced very early in pregnancy in amounts that exceed the capacity of placental aromatase.

Maternal Renal Disease. Lower levels of estriol in the urine of pregnant women with pyelonephritis may be observed. Presumably this is the consequence of diminished renal clearance, as the maternal serum levels of estrogen are normal in such pregnancies.

Gestational Trophoblastic Disease. In the case of complete hydatidiform mole or choriocarcinoma, there is no fetal adrenal source of C₁₉-steroid precursor for trophoblast estrogen biosynthesis. Consequently, placental estrogen formation is limited to the use of C₁₉-steroids in the maternal plasma, and therefore the estrogen produced is principally estradiol (MacDonald and Siiteri, 1964, 1966). Great variation is observed in the rates of both estradiol and progesterone formation in molar pregnancies. This, however, is not necessarily related to the volume of neoplastic tissue. There is variable disruption of large masses of molar tissue from the uterine wall by blood clots. Consequently, variable amounts of trophoblastic tissue are separated from the maternal blood supply of precursors for estradiol and progesterone formation.

DIRECTIONAL SECRETION OF STEROIDS FROM SYNCYTIOTROPHOBLAST.

Estrogens synthesized in the syncytium preferentially enter the maternal circulation. Gurpide and co-workers (1966) reported that more than 90 percent of estradiol and estriol formed in syncytiotrophoblast enters maternal plasma. Gurpide and co-workers (1972) later found that 85 percent or more of placental progesterone enters maternal plasma, and very little maternal plasma progesterone crosses the placenta to the fetus.

The placental estrogens that enter the maternal compartment are estradiol, estrone, and estriol. Estriol synthesized in trophoblasts enters both fetal and maternal plasma, but most (90 percent) enters the mother. There also appears to be preferential transfer of estradiol into the maternal compartment. The major reason for directional movement of newly formed steroid into the maternal circulation is the nature of the hemochorioendothelial form of placentation. In this system, steroids secreted from the syncytiotrophoblast can enter maternal blood directly. Steroids that leave the syncytium toward the fetal compartment, however, do not enter fetal blood directly. First, steroids traveling toward the fetus must traverse the cytotrophoblasts and then enter the connective tissue of the villous core. Steroids in this space can reenter the syncytium. Second, steroids that escape the villous core must then traverse the wall of the fetal capillaries to reach fetal blood. Steroids in the fetal capillaries of the villous core then can reenter the connective tissue of the villous core and then the syncytium. The net result of this hemochorial arrangement is that there is substantially greater entry of steroids into the maternal circulation compared with the amount that enters the fetal blood.

Somewhat surprisingly, there appears to be preferential entry of estrone rather than estradiol into the fetal plasma (Gurpide and colleagues, 1982). One explanation is that the fetal endothelial cells found within the placenta express high levels of 17 β -hydroxysteroid dehydrogenase type 2 (17 β HSD type 2), the enzyme that converts estradiol to estrone (Bonenfant and co-workers, 2000a; Moghrabi and colleagues, 1997). This enzyme would act as a partial barrier, converting estradiol to estrone as it enters the fetal circulation. In this way, fetal levels of estrone would be composed of the estrone made in the trophoblasts that makes it to the fetal circulation as well as the estradiol that reaches the fetal placental endothelial cells and is converted to estrone. The localization of the 17 β HSD type 2 enzyme at the site of fetal-maternal exchange likely serves to protect the fetus from high levels of active estrogens and androgens, principally estradiol and testosterone (Moghrabi and colleagues, 1997).

4. Fetal Growth and Development

INTRODUCTION

Contemporary obstetrical research focuses on the physiology and pathophysiology of the fetus, its development, and its environment. An important direct result of this research is that the status of the fetus has been elevated to that of a patient who, in large measure, can be given the same meticulous care that obstetricians provide for pregnant women. In the course of these studies it has become apparent that the conceptus is a dynamic force in the pregnancy unit. The contributions of the conceptus to implantation, maternal recognition of pregnancy, immunological acceptance, endocrine function, nutrition, and parturition are enormous, and absolutely essential for successful pregnancy as described in [Chapter 3](#). Normal fetal development is considered in this chapter. Anomalies, injuries, and diseases that affect the fetus and newborn are addressed in detail in [Chapter 29](#). Techniques used to evaluate fetal well-being, or fetal health, are presented in other chapters.

DETERMINATION OF GESTATIONAL AGE

Several different terms are used to define the duration of pregnancy, and thus fetal age, but these are somewhat confusing. They are shown schematically in [Figure 4-1](#). *Gestational age* or *menstrual age* is the time elapsed since the first day of the last menstrual period, a time that actually precedes conception. This starting time, which is usually about 2 weeks before ovulation and fertilization, and nearly 3 weeks before implantation of the blastocyst, has traditionally been used because most women know their last period. The increasing use of infertility therapy has changed this somewhat because ovulation may be known exactly. Embryologists describe embryo-fetal development in *ovulation age*, or the time in days or weeks from ovulation. Another term is *postconceptional age*, nearly identical to ovulation age.

Obstetricians customarily calculate gestational age as menstrual age. About 280 days, or 40 weeks, elapse on average between the first day of the last menstrual period and the birth of the fetus. This corresponds to 9 1/3 calendar months, or 10 units of 28 days each. The unit of 28 days has been referred to commonly, but imprecisely, as a *lunar month* of pregnancy. Actually, the time from one new moon to the next is 29 1/2 days. A quick estimate of the due date of a pregnancy based on menstrual cycle can be made as follows: add 7 days to the first day of the last menstrual period and subtract 3 months. For example, if the first day of the last menses was July 5th, the due date of this pregnancy is 07-05 + 7 (days) minus 3 (months) = 04-12, or April 12th of the following year. As discussed in [Chapter 16](#) (see p. 392), many women now undergo first- or early second-trimester ultrasound examination to confirm gestational age. In these cases, the sonographic estimate is usually a few days later than that determined by the last period. To rectify this inconsistency and to reduce the number of pregnancies diagnosed as postterm—some authorities suggest assuming that the average pregnancy is actually 283 days long instead of 280, and thus adding 10 days to the last menses instead of 7 (Olsen and Clausen, 1998).

The period of gestation can also be divided into three units of three calendar months (13 weeks) each, or three *trimesters*, because important obstetrical milestones can be designated conveniently by trimesters. The possibility of spontaneous abortion, for example, is limited principally to the first trimester, whereas the likelihood of infant survival is increased greatly in pregnancies that reach the third trimester.

Figure 4-1. Terminology used to describe the duration of pregnancy.

MORPHOLOGICAL GROWTH

OVUM, ZYGOTE, AND BLASTOCYST. During the first 2 weeks after ovulation, several successive phases of development can be identified: (1) fertilization, (2) formation of free blastocyst, and (3) implantation of the blastocyst. Primitive chorionic villi are formed soon after implantation. With the development of chorionic villi, it is conventional to refer to the products of conception not as a fertilized ovum, or zygote, but as an *embryo*. The early stages of preplacental development and formation of the placenta are described in [Chapter 3](#).

EMBRYO. The embryonic period commences at the beginning of the third week after ovulation and fertilization, which coincides in time with the expected day that the next menstruation would have started. Most pregnancy tests that measure human chorionic gonadotropin (hCG) are positive by this time (see [Chap. 8](#), p. 206), and the embryonic disc is well defined. The body stalk is differentiated; the chorionic sac is approximately 1 cm in diameter ([Figs. 4-2](#) and [4-3](#)). There is a true intervillous space that contains maternal blood and villous cores in which angioblastic chorionic mesoderm can be distinguished.

By the end of the fourth week after ovulation, the chorionic sac is 2 to 3 cm in diameter, and the embryo is about 4 to 5 mm in length ([Figs. 4-4](#), [4-5](#), and [4-6](#)). Partitioning of the primitive heart begins in the middle of the fourth week. Arm and leg buds are present, and the amnion is beginning to unsheath the body stalk, which thereafter becomes the umbilical cord.

At the end of the sixth week after fertilization, the embryo is 22 to 24 mm in length, and the head is quite large compared with the trunk. The heart is completely formed. Fingers and toes are present, and the arms bend at the elbows. The upper lip is complete, and the external ears form definitive elevations on either side of the head.

The end of the embryonic period and the beginning of the fetal period is arbitrarily designated by most embryologists to occur 8 weeks after fertilization, or 10 weeks after the onset of the last menstrual period. At this time, the embryo-fetus is nearly 4 cm long ([Fig. 4-7](#)). The major portion of lung development is yet to occur, but few other new major body structures are formed after this time.

Figure 4-2. Early human embryos. Only the chorion adjacent to the body stalk is shown. Small outline to the right of each embryo gives its actual size. Ovulation ages: **A.** 19 days (presomite). **B.** 21 days (7 somites). **C.** 22 days (17 somites). (After drawings and models in the Carnegie Institute, drawing identification number noted below each.)

FETUS. Development during the fetal period of gestation consists of growth and maturation of structures that were formed during the embryonic period.

12 Gestational Weeks. By the end of the 12th week of pregnancy, when the uterus usually is just palpable above the symphysis pubis, the crown-rump length of the fetus is 6 to 7 cm. Centers of ossification have appeared in most of the fetal bones, and the fingers and toes have become differentiated. Skin and nails have developed and scattered rudiments of hair appear. The external genitalia are beginning to show definitive signs of male or female gender. The fetus begins to make spontaneous movements.

16 Gestational Weeks. By the end of the 16th week, the crown-rump length of the fetus is 12 cm, and the weight is 110 g. Gender can be correctly determined by experienced observers by inspection of the external genitalia by 14 weeks.

20 Gestational Weeks. The end of the 20th week is the midpoint of pregnancy as estimated from the beginning of the last normal menstrual period. The fetus now weighs somewhat more than 300 g, and the weight begins to increase in a linear manner. The fetal skin has become less transparent, a downy lanugo covers its entire body, and some scalp hair has developed.

24 Gestational Weeks. By the end of the 24th week, the fetus weighs about 630 g. The skin is characteristically wrinkled, and fat deposition begins. The head is still comparatively large, and eyebrows and eyelashes are usually recognizable. The canalicular period of lung development, during which the bronchi and bronchioles enlarge and alveolar ducts develop, is nearly completed. A fetus born at this time will attempt to breathe, but most will die because the terminal sacs, required for gas exchange, have not yet formed.

28 Gestational Weeks. By the end of the 28th week, a crown-rump length of about 25 cm is attained and the fetus weighs about 1100 g. The thin skin is red and covered with vernix caseosa. The pupillary membrane has just disappeared from the eyes. An infant born at this time moves limbs energetically and cries weakly. The otherwise normal infant of this age has a 90-percent chance of survival without physical or neurological impairment.

32 Gestational Weeks. At the end of 32 gestational weeks, the fetus has attained a crown-rump length of about 28 cm and a weight of about 1800 g. The skin surface is still red and wrinkled. Barring other complications, infants born at this period also usually survive intact.

36 Gestational Weeks. At the end of 36 weeks of gestation, the average crown-rump length of the fetus is about 32 cm and the weight is about 2500 g. Because of the deposition of subcutaneous fat, the body has become more rotund, and the previous wrinkled appearance of the face has been lost. Infants born at this time have an excellent chance of survival with proper care.

40 Gestational Weeks. Term is reached at 40 weeks from the onset of the last menstrual period. At this time, the fetus is fully developed. The average crown-rump length of the fetus at term is about 36 cm, and the weight is approximately 3400 g.

Length of Fetus. Because of the variability in the length of the legs and the difficulty of maintaining them in extension, measurements corresponding to the sitting height (crown-to-rump) are more accurate than those corresponding to the standing height. The average sitting height and weight of the fetus at the end of each lunar month were determined by Streeter (1920) from 704 specimens. These values are similar to those shown in [Table 4-1](#). Such values are approximate, but generally, length is a more accurate criterion of gestational age than weight.

Fetal Head. From an obstetrical viewpoint, the size of the fetal head is important because an essential feature of labor is the adaptation between the fetal head and the maternal bony pelvis. Only a comparatively small part of the head at term is represented by the face. The rest of the head is composed of the firm skull, which is made up of two frontal, two parietal, and two temporal bones, along with the upper portion of the occipital bone and the wings of the sphenoid. These bones are separated by membranous spaces, or *sutures* ([Fig. 4-8](#)).

The most important sutures are the frontal, between the two frontal bones; the sagittal, between the two parietal bones; the two coronal, between the frontal and parietal bones; and the two lambdoid, between the posterior margins of the parietal bones and upper margin of the occipital bone. Where several sutures meet, an irregular space forms, which is enclosed by a membrane and designated as a *fontanel* (see [Fig. 4-8](#)). The greater, or anterior fontanel, is a lozenge-shaped space that is situated at the junction of the sagittal and the coronal sutures. The lesser, or posterior fontanel, is represented by a small triangular area at the intersection of the sagittal and lambdoid sutures. The localization of these fontanels gives important information concerning the presentation and position of the fetus. The temporal, or cassarian fontanels, have no diagnostic significance.

It is customary to measure certain critical diameters and circumferences of the newborn head ([Fig. 4-9](#)). The diameters most frequently used, and the average lengths thereof, are:

1. The *occipitofrontal* (11.5 cm), which follows a line extending from a point just above the root of the nose to the most prominent portion of the occipital bone.
2. The *biparietal* (9.5 cm), the greatest transverse diameter of the head, which extends from one parietal boss to the other.
3. The *bitemporal* (8.0 cm), the greatest distance between the two temporal sutures (see [Fig. 4-8](#)).
4. The *occipitomenal* (12.5 cm), from the chin to the most prominent portion of the occiput.
5. The *suboccipitobregmatic* (9.5 cm), which follows a line drawn from the middle of the large fontanel to the undersurface of the occipital bone just where it joins the neck.

The greatest circumference of the head, which corresponds to the plane of the occipitofrontal diameter, averages 34.5 cm, a size too large to fit through the pelvis without flexion. The smallest circumference, corresponding to the plane of the suboccipitobregmatic diameter, is 32 cm. The bones of the cranium are normally connected only by a thin layer of fibrous tissue that allows considerable shifting or sliding of each bone to accommodate the size and shape of the maternal pelvis. This intrapartum process is termed *molding*. The head position and degree of skull ossification result in a spectrum of cranial plasticity from minimal to great and, in some cases, undoubtedly contribute to fetopelvic disproportion, a leading indication for cesarean delivery (see [Chap. 25](#), p. 591).

Fetal Brain. There is a steady gestational age-related change in the appearance of the fetal brain ([Fig. 4-10](#)). It is therefore possible to identify fetal age rather precisely from its external appearance (Dolman, 1977). Myelination of the ventral roots of the cerebrospinal nerves and brainstem begins at approximately 6 months, but the major portion of myelination occurs after birth. The lack of myelin and the incomplete ossification of the fetal skull permit the structure of the brain to be seen with ultrasound throughout gestation.

Figure 4-9. Diameters of the fetal head at term.

Figure 4-10. Characteristic configuration of fetal brains from 22 to 40 weeks of gestation at 2-week intervals. (From Dolman, 1977, with permission.)

PLACENTAL ROLE IN FETAL GROWTH

The placenta is the organ of transfer between mother and fetus. At the maternal-fetal interface, there is transfer of oxygen and nutrients from the mother to the fetus. Conversely, there is transfer of carbon dioxide and other metabolic wastes from fetus to mother (see [Fig. 3-22](#), p. 65). There are no direct communications between the fetal blood, which is contained in the fetal capillaries in the intravillous space of the chorionic villi, and the maternal blood, which remains in the intervillous space. The one exception to this dictum is the occasional development of breaks in the chorionic villi, permitting the escape of fetal erythrocytes and leukocytes, in various numbers, into the maternal circulation. This leakage is the mechanism by which some D-negative women become sensitized by the erythrocytes of their D-positive fetus (see [Chap. 29](#), p. 663). Aside from these occasional leaks, however, there is no gross intermingling of the macromolecular constituents of the two circulations. Therefore, bidirectional transfer depends primarily on the processes that permit or facilitate the transport of such substances through the syncytiotrophoblast of the intact chorionic villi.

Figure 3-22. Schematic drawing of a section through a full-term placenta: **1.** The relation of the villous chorion (C) to the decidua basalis (D) and the fetal-placental circulation. **2.** The maternal blood flows into the intervillous spaces in funnel-shaped spurts, and exchanges occur with the fetal blood as the maternal blood flows around the villi. **3.** The in-flowing arterial blood pushes venous blood into the endometrial veins, which are scattered over the entire surface of the decidua basalis. Note also that the umbilical arteries carry deoxygenated fetal blood to the placenta and that the umbilical vein carries oxygenated blood to the fetus. The cotyledons are separated from each other by placental (decidual) septa. Each cotyledon consists of two or more mainstem villi and their many branches. (Based on Moore, 1988.)

THE INTERVILLOUS SPACE: MATERNAL BLOOD. The intervillous space is the primary biological compartment of maternal-fetal transfer. Maternal blood in this extravascular compartment directly bathes the trophoblasts. Substances transferred from mother to fetus first enter the intervillous space and are then transported to the syncytiotrophoblast. Substances transported from the fetus to the mother are transferred from the syncytium into the same space. Thus, the chorionic villi and the intervillous space, together, function for the fetus as lung, gastrointestinal tract, and kidney.

The circulation of maternal blood within the intervillous space is described in [Chapter 3](#) (see p. 63). The residual volume of the intervillous space of the term placenta measures about 140 mL. However, before delivery the normal volume of the intervillous space may be twice this value (Aherne and Dunnill, 1966). Uteroplacental blood flow near term has been estimated to be about 700 to 900 mL/min, with most of the blood apparently going to the intervillous space.

The forceful uterine contractions of active labor cause a reduction in blood flow into the intervillous space, the degree of reduction depending in large measure on the intensity of the contraction. Blood pressure within the intervillous space is significantly less than the uterine arterial pressure, but somewhat greater than uterine venous pressure. Uterine venous pressure, in turn, varies depending on several factors, including maternal position. When supine, for example, pressure in the lower part of the inferior vena cava is elevated, and consequently, pressure in the uterine and ovarian veins, and in turn in the intervillous space, is increased.

PLACENTAL TRANSFER

Chorionic Villus. Substances that pass from maternal blood to fetal blood must traverse (1) syncytiotrophoblast, (2) stroma of the intravillous space, and (3) fetal capillary wall. Although this histological barrier separates the blood in the maternal and fetal circulations, it does not behave in a uniform manner like a simple physical barrier. Throughout pregnancy, syncytiotrophoblast actively or passively permits, facilitates, and adjusts the amount and rate of transfer of a wide range of substances to the fetus. The walls of the villous capillaries likewise become thinner, and the relative number of fetal vessels increases in relation to the villous connective tissue. It is important to recall that the walls of the fetal placental surface vessels, after branching from the truncal arteries of the chorionic vessels, do not contain smooth muscle cells (see [Chap. 3](#), p. 63). Several attempts have been made to estimate the total surface area of chorionic villi in the human placenta at term. From the planimetric measurements made by Aherne and Dunnill (1966) of the villous surface area of the placenta, it is evident that there is a close correlation with fetal weight. The total surface area at term has been estimated to be approximately 10 m².

Regulation of Placental Transfer. The syncytiotrophoblast is the fetal tissue interface. The maternal-facing surface of this tissue is characterized by a complex microvillus structure. The fetal-facing (basal) cell membrane of the trophoblast is the site of transfer to the intravillous space through which the fetal capillaries traverse. The fetal capillaries are an additional site for transport from the intravillous space into fetal blood, or vice versa.

In determining the effectiveness of the human placenta as an organ of transfer, at least 10 variables are important:

1. The concentration of the substance under consideration in the maternal plasma, and in some instances, the extent to which it is bound to another compound, such as a carrier protein.
2. The rate of maternal blood flow through the intervillous space.
3. The area available for exchange across the villous trophoblast epithelium.
4. If the substance is transferred by diffusion, the physical properties of the tissue barrier interposed between blood in the intervillous space and in the fetal capillaries.
5. For any substance actively transported, the capacity of the biochemical machinery of the placenta for effecting active transfer, for example, specific receptors on the plasma membrane of the trophoblast.
6. The amount of the substance metabolized by the placenta during transfer.
7. The area for exchange across the fetal capillaries in the placenta.
8. The concentration of the substance in the fetal blood, exclusive of any that is bound.
9. Specific binding or carrier proteins in the fetal or maternal circulation.
10. The rate of fetal blood flow through the villous capillaries.

Mechanisms of Transfer. Most substances with a molecular mass less than 500 d diffuse readily through placental tissue. Molecular weight is clearly important in determining the rate of transfer by diffusion. Simple diffusion, however, is by no means the only mechanism of transfer of low-molecular-weight compounds. The syncytiotrophoblast actively facilitates the transfer of a variety of small compounds, especially those that are in low concentration in maternal plasma but are essential for normal fetal growth and development. Simple diffusion appears to be the mechanism involved in the transfer of oxygen, carbon dioxide, water, and most (but not all) electrolytes. Anesthetic gases also pass through the placenta rapidly by simple diffusion.

Insulin, steroid hormones, and thyroid hormones cross the placenta, but at very slow rates. The hormones synthesized in situ in the trophoblasts enter both the maternal and fetal circulations, but not equally (see [Chap. 3](#)). For example, concentrations of chorionic gonadotropin and placental lactogen in fetal plasma are much lower than in maternal plasma. Substances of high molecular weight usually do not traverse the placenta, but there are important exceptions, such as immunoglobulin G d —molecular weight 160,000 d d —which is transferred by way of a specific trophoblast receptor-mediated mechanism.

Transfer of Oxygen and Carbon Dioxide. In their excellent account of placental transport, Morriss and associates (1994) recall that in 1674, Mayow suggested that the placenta served as the fetal lung. In 1796, Erasmus Darwin, only 22 years after the discovery of oxygen, observed that the color of blood passing through lungs and gills became bright red. He deduced, from the structure as well as the position of the placenta, that it appeared to be a respiratory organ by which the fetus becomes oxygenated.

The transfer of oxygen across the placenta is blood-flow limited. The placenta supplies about 8 mL O_2 /min/kg of fetal weight, and because fetal blood oxygen stores are sufficient for only 1 to 2 minutes, this supply must be continuous (Longo, 1991). Normal values for oxygen, carbon dioxide, and pH in fetal blood are presented in [Figure 4-11](#). Because of the continuous passage of oxygen from maternal blood in the intervillous space to the fetus, its oxygen saturation resembles that in the maternal capillaries. The average oxygen saturation of intervillous blood is estimated to be 65 to 75 percent, with a partial pressure (P_{O_2}) of about 30 to 35 mm Hg. The oxygen saturation of umbilical vein blood is similar, but with a somewhat lower oxygen partial pressure.

In general, transfer of fetal carbon dioxide is accomplished by diffusion. The placenta is highly permeable to carbon dioxide, which traverses the chorionic villus more rapidly than oxygen. Near term, the partial pressure of carbon dioxide (P_{CO_2}) in the umbilical arteries is estimated to average about 48 mm Hg, or about 5 mm Hg more than in the maternal intervillous blood. Fetal blood has less affinity for carbon dioxide than does maternal blood, thereby favoring the transfer of carbon dioxide from the fetus to the mother. Also, mild hyperventilation by the pregnant woman results in a fall in P_{CO_2} , favoring a transfer of carbon dioxide from the fetal compartment to maternal blood.

Selective Transfer and Facilitated Diffusion. Although simple diffusion is an important method of placental transfer, the trophoblast and chorionic villus unit demonstrate enormous selectivity in transfer. This results in different concentrations of a variety of metabolites on the two sides of the villus. The concentrations of a number of substances that are not synthesized by the fetus are several times higher in fetal than in maternal blood. Ascorbic acid is a good example of this phenomenon. This relatively low-molecular-weight substance resembles the pentose and hexose sugars and might be expected to traverse the placenta by simple diffusion. The concentration of ascorbic acid, however, is two to four times higher in fetal plasma than in maternal plasma (Morriss and associates, 1994). The unidirectional transfer of iron across the placenta provides another example of transport and sequestration of selected agents. Typically, iron is present in the plasma of the pregnant woman at a lower concentration than in her fetus.

Figure 4-11. Umbilical venous oxygen pressure (P_{O_2}) (**a**), carbon dioxide pressure (P_{CO_2}) (**b**), and pH (**c**) from cordocentesis on 59 fetuses being evaluated for possible intrauterine infections or hemolysis, and who were found to be healthy at birth and appropriately grown. (From Ramsey, 1996, with permission.)

FETAL NUTRITION

During the first 2 months of pregnancy, the embryo consists almost entirely of water. Because of the small amount of yolk in the human ovum, growth of the embryo-fetus from an early stage of development is dependent on nutrients obtained from the mother. During the first few days after implantation, the nutrition of the blastocyst comes from the interstitial fluid of the endometrium and the surrounding maternal tissue. Within the next week, the forerunners of the intervillous space are formed. In the beginning, these are simply lacunae that are filled with maternal blood, but during the third week after fertilization, fetal blood vessels in the chorionic villi appear. During the fourth week, a cardiovascular system has formed, and thereby a true circulation is established both within the embryo and between the embryo and the chorionic villi.

Maternal adaptations to store and transfer nutrients to the fetus are discussed in [Chapter 5](#) and summarized here. The maternal diet is translated into storage forms that are made available to meet the demands for energy, tissue repair, and new growth, including maternal needs for pregnancy. Three major maternal storage depots—the liver, muscle, and adipose tissue—and the storage hormone insulin are intimately involved in the metabolism of the nutrients absorbed from the maternal gut.

Insulin secretion is sustained by increased serum levels of glucose and amino acids. The net effect is storage of glucose as glycogen primarily in liver and muscle, retention of some amino acids as protein, and storage of the excess as fat. Storage of maternal fat peaks in the second trimester, and then declines as fetal demands increase in late pregnancy (Pipe and colleagues, 1979).

During times of fasting, glucose is released from glycogen, but maternal glycogen stores cannot provide an adequate amount of glucose to meet requirements for maternal energy and fetal growth. However, cleavage of triacylglycerols, stored in adipose tissue, provides the mother with energy in the form of free fatty acids. Lipolysis is activated, directly or indirectly, by several hormones, including glucagon, norepinephrine, placental lactogen, glucocorticosteroids, and thyroxine.

GLUCOSE AND FETAL GROWTH. Although the fetus is dependent on the mother for nutrition, the fetus also actively participates in providing for its own nutrition. At midpregnancy, fetal glucose concentration is independent of and may exceed maternal levels (Bozzetti and colleagues, 1988). Glucose is a major nutrient for fetal growth and energy. It is thus logical that mechanisms exist during pregnancy to minimize maternal glucose use so that the limited maternal supply is available to the fetus. It is believed that placental lactogen (hPL), a hormone normally present in abundance in the mother but not the fetus, blocks the peripheral uptake and use of glucose while promoting the mobilization and use of free fatty acids by maternal tissues (see [Chap. 3](#), p. 73).

Glucose Transport. The transfer of d-glucose across cell membranes is accomplished by a carrier-mediated, stereospecific, nonconcentrating process of *facilitated diffusion*. Six separate glucose transport proteins (GLUT) have been discovered. They belong to the 12-transmembrane segment transporter superfamily and are characterized further by tissue-specific distribution (see [Chap. 38](#), p. 895). Transporter proteins for d-glucose—GLUT-1 and GLUT-3—are located in the plasma membrane of the microvilli of human syncytiotrophoblast. GLUT-1 expression is prominent in human placenta, it increases as pregnancy advances, and it is induced by almost all growth factors (Sakata and colleagues, 1995). GLUT-3 is also localized in human syncytiotrophoblast (Hahn and associates, 1995).

Glucose, Insulin, and Fetal Macrosomia. The precise biomolecular events in the pathophysiology of fetal macrosomia are not defined. Nonetheless, it seems clear that fetal hyperinsulinemia is one driving force (Schwartz and colleagues, 1994). As discussed in [Chapter 38](#) (see p. 895), insulin-like growth factor, as well as fibroblast growth factor, also are involved (Giudice and associates, 1995; Hill and colleagues, 1995). Therefore, a hyperinsulinemic state with increased levels of selected growth factors, together with increased expression of GLUT proteins in syncytiotrophoblast, may promote excessive fetal growth.

LACTATE. This substance also is transported across the placenta by facilitated diffusion. By way of co-transport with hydrogen ions, lactate is probably transported as lactic acid.

FREE FATTY ACIDS AND TRIGLYCERIDES. Among mammalian neonates, the human newborn has a large proportion of fat, on average 15 percent of body weight (Kimura, 1991). This finding is indicative that late in pregnancy, a substantial part of the substrate transferred to the human fetus is stored as fat. Neutral fat (triacylglycerols) does not cross the placenta, but glycerol does. It is likely that most fatty acids cross the placenta by simple diffusion. Moreover, fatty acids also are synthesized in the placenta. Lipoprotein lipase is present on the maternal but not on the fetal side of the placenta. This arrangement should favor hydrolysis of triacylglycerols in the maternal intervillous space while preserving these neutral lipids in fetal blood. Fatty acids transferred to the fetus can be converted to triacylglycerols in the fetal liver.

The placental uptake and use of low-density lipoprotein (LDL) was cited in [Chapter 3](#) (see p. 80) as an alternative mechanism for fetal assimilation of essential fatty acids and amino acids. The LDL particles from maternal plasma bind to specific LDL receptors in the coated-pit regions of the microvilli on the maternal-facing side of the syncytiotrophoblast. The large—about 250,000 d—LDL particle is taken up by a process of receptor-mediated endocytosis. The apoprotein and cholesterol esters of LDL are hydrolyzed by lysosomal enzymes in the syncytium to give (1) cholesterol for progesterone synthesis; (2) free amino acids, including essential amino acids; and (3) essential fatty acids, primarily linoleic acid. Indeed, the concentration of arachidonic acid, which is synthesized from linoleic acid in fetal plasma, is greater than that in maternal plasma. Linoleic acid or arachidonic acid, or both, must be assimilated from maternal dietary intake.

AMINO ACIDS. In addition to the hydrolysis of LDL, the placenta concentrates a large number of amino acids (Lemons, 1979). Neutral amino acids from maternal plasma are taken up by trophoblasts by at least three specific processes. Presumably, amino acids are concentrated in the syncytiotrophoblasts and thence transferred to the fetal side by diffusion. Based on data from cordocentesis blood samples, the concentration of amino acids in umbilical cord plasma is greater than in maternal venous or arterial plasma (Morriss and associates, 1994).

PROTEINS. Generally, there is very limited transfer of larger proteins across the placenta. There are important exceptions, for example, immunoglobulin G (IgG) crosses the placenta in large amounts. Another exception is retinol-binding protein. Near term, IgG is present in approximately the same concentrations in cord and maternal sera, but IgA and IgM of maternal origin are effectively excluded from the fetus (Gitlin and colleagues, 1972). Fc receptors are present on trophoblasts, and IgG transport is accomplished by way of these through endocytosis. Increased amounts of IgM are found in the fetus only after the fetal immune system has been provoked into antibody response by infection in the fetus.

IONS AND TRACE METALS. Iodide transport across the placenta is clearly attributable to a carrier-mediated, energy-requiring active process. And indeed, the placenta concentrates iodide. The concentrations of zinc in the fetal plasma also are greater than those in maternal plasma. Conversely, copper levels in fetal plasma are less than those in maternal plasma. This fact is of particular interest because important copper-requiring enzymes are necessary for fetal development.

Placental Sequestration of Heavy Metals. The heavy metal-binding protein, metallothionein-1, is expressed in human syncytiotrophoblast. This protein binds and sequesters a host of heavy metals, including zinc, copper, lead, and cadmium.

The most common source of cadmium in the environment is cigarette smoke. Cadmium levels in maternal blood and placenta are increased with maternal smoking, but there is no increase in cadmium transfer into the fetus. The cadmium concentration in cord blood is less than that in maternal blood, and there is little or no cadmium in fetal liver or kidney. Presumably, the low levels of cadmium in the fetus are attributable to the sequestration of cadmium by metallothionein(s) in trophoblast. This comes about because cadmium acts to increase the transcription of the metallothionein gene(s). Thus, cadmium-induced increases in trophoblast metallothionein levels result in placental cadmium accumulation by sequestration.

Metallothionein also binds and sequesters copper (Cu^{2+}) in placental tissue, thus accounting for the low levels of Cu^{2+} in cord blood (Iyengar and Rapp, 2001). A number of mammalian enzymes require Cu^{2+} , and its deficiency results in inadequate collagen cross-linking and, in turn, diminished tensile strength of tissues. This may be important because the concentration of cadmium in amniotic fluid is similar to that in maternal blood. The incidence of preterm membrane rupture is increased in women who smoke. It is possible that cadmium provokes metallothionein synthesis in amnion, causing sequestration of Cu^{2+} and a pseudocopper deficiency.

Calcium and Phosphorus. These minerals also are actively transported from mother to fetus. A calcium-binding protein is present in placenta. Parathyroid hormone-related protein (PTH-rP), as the name implies, acts as a surrogate PTH in many systems, including the activation of adenylate cyclase and the movement of calcium (Ca^{2+}) (see also [Chap. 3](#), p. 74, and [Chap. 6](#), p. 162). PTH-rP is produced not in normal adult parathyroid glands but rather in the fetal parathyroid and in the placenta and other fetal tissues, especially the fetal kidney. Moreover, PTH is not demonstrable in fetal plasma, but PTH-rP is present. For those reasons, some refer to PTH-rP as the fetal parathormone (Abbas and associates, 1990). There is a Ca^{2+} -sensing receptor in trophoblast, as there is in the parathyroid glands (Juhlin and colleagues, 1990). The expression of PTH-rP in cytotrophoblasts is modulated by the extracellular concentration of Ca^{2+} (Hellman and co-workers, 1992). It seems possible, therefore, that PTH-rP synthesized in decidua, placenta, and other fetal tissues is important in fetal Ca^{2+} transfer and homeostasis.

VITAMINS. The concentration of *vitamin A (retinol)* is greater in fetal than in maternal plasma. Vitamin A in fetal plasma is bound to retinol-binding protein and to prealbumin. Retinol-binding protein is transferred from the maternal compartment across the syncytium. The transport of *vitamin C (ascorbic acid)* across the placenta from mother to fetus is accomplished by an energy-dependent, carrier-mediated process. The levels of the principal *vitamin D (cholecalciferol)* metabolites, including 1,25-dihydroxycholecalciferol, are greater in maternal plasma than are those in fetal plasma. The 1β -hydroxylation of 25-hydroxyvitamin D_3 is known to take place in placenta and in decidua.

FETAL PHYSIOLOGY

AMNIONIC FLUID. In early pregnancy, amniotic fluid is an ultrafiltrate of maternal plasma. By the beginning of the second trimester, it consists largely of extracellular fluid that diffuses through the fetal skin, and thus reflects the composition of fetal plasma (Gilbert and Brace, 1993). After 20 weeks, however, the cornification of fetal skin prevents this diffusion, and amniotic fluid is composed largely of fetal urine. The fetal kidneys start producing urine at 12 weeks, and by 18 weeks they are producing 7 to 14 mL per day. Fetal urine contains more urea, creatinine, and uric acid than fetal plasma. It also contains desquamated fetal cells, vernix, lanugo, and various secretions. Because these are hypotonic, the net effect is decreasing amniotic fluid osmolality with advancing gestation. Pulmonary fluid contributes a small proportion of the amniotic volume, and fluid filtering through the placenta accounts for the rest.

The volume of amniotic fluid at each week of gestation is quite variable. In general, the volume increases by 10 mL per week at 8 weeks and increases up to 60 mL per week at 21 weeks, then declines gradually back to a steady state by 33 weeks (Brace and Wolf, 1989).

Amniotic fluid serves to cushion the fetus, allowing musculoskeletal development and protecting it from trauma. It also maintains temperature and has a minimal nutritive function. Epidermal growth factor (EGF) and EGF-like growth factors, such as transforming growth factor- β , are present in amniotic fluid. Ingestion of amniotic fluid into the gastrointestinal tract and inhalation into the lung may promote growth and differentiation of these tissues. Animal studies have shown that pulmonary hypoplasia can be produced by draining off amniotic fluid, by chronically draining pulmonary fluid through the trachea, and by physically preventing the prenatal chest excursions that mimic breathing (Adzick and associates, 1984; Alcorn and colleagues, 1977). Thus the formation of intrapulmonary fluid and, at least as important, the alternating egress and retention of fluid in the lungs by breathing movements are essential to normal pulmonary development. Clinical implications of oligohydramnios and pulmonary hypoplasia are discussed in [Chapter 21](#) (see p. 530).

FETAL CIRCULATION. The fetal circulation is substantially different from that of the adult and functions smoothly until the moment of birth, when it is required to change dramatically. For example, because fetal blood does not need to enter the pulmonary vasculature to be oxygenated, the major portion of the right ventricular output bypasses the lungs. In addition, the fetal heart chambers work in parallel, not in series, which effectively supplies the brain and heart with more highly oxygenated blood than the rest of the body.

Oxygen and nutrient materials required for fetal growth and maturation are delivered to the fetus from the placenta by the single umbilical vein (Fig. 4-12). The vein then divides into the ductus venosus and the portal sinus. The ductus venosus is the major branch of the umbilical vein and traverses the liver to enter the inferior vena cava directly. Because it does not supply oxygen to the intervening tissues, it carries well-oxygenated blood directly to the heart. In contrast, the portal sinus carries blood to the hepatic veins primarily on the left side of the liver, where oxygen is extracted. The relatively deoxygenated blood from the liver then flows back into the inferior vena cava, which also receives less oxygenated blood returning from the lower body. Blood flowing to the fetal heart from the inferior vena cava, therefore, consists of an admixture of arterial-like blood that passes directly through the ductus venosus and less well-oxygenated blood that returns from most of the veins below the level of the diaphragm. The oxygen content of blood delivered to the heart from the inferior vena cava is thus lower than that leaving the placenta.

In contrast to postnatal life, the ventricles of the fetal heart work in parallel, not in series. Well-oxygenated blood enters the left ventricle, which supplies the heart and brain, and less oxygenated blood enters the right ventricle, which supplies the rest of the body. The two separate circulations are maintained by the structure of the right atrium, which effectively directs entering blood to either the left atrium or the right ventricle, depending on its oxygen content. This separation of blood according to its oxygen content is facilitated by the pattern of blood flow in the inferior vena cava. The well-oxygenated blood tends to course along the medial aspect of the inferior vena cava and the less oxygenated blood stays along the lateral vessel wall, facilitating their shunting into opposite sides of the heart. Once this blood enters the atrium, the configuration of the upper interatrial septum, called the *crista dividens*, is such that it preferentially shunts the well-oxygenated blood from the medial side of the inferior vena cava and the ductus venosus through the foramen ovale into the left heart and then to the heart and brain (Dawes, 1962). After these tissues have extracted needed oxygen, the resulting less oxygenated blood returns to the right heart through the superior vena cava.

The less oxygenated blood coursing along the lateral wall of the inferior vena cava enters the right atrium and is deflected through the tricuspid valve to the right ventricle. The superior vena cava courses inferiorly and anteriorly as it enters the right atrium, ensuring that less well-oxygenated blood returning from the brain and upper body also will be shunted directly to the right ventricle. Similarly, the ostium of the coronary sinus lies just superior to the tricuspid valve so that less oxygenated blood from the heart also returns to the right ventricle. As a result of this blood flow pattern, blood in the right ventricle is 15 to 20 percent less saturated than blood in the left ventricle.

The major portion, almost 90 percent, of blood exiting the right ventricle is then shunted through the ductus arteriosus to the descending aorta. The high pulmonary vascular resistance and the comparatively lower resistance in the ductus arteriosus and the umbilical-placental vasculature ensure that only about 15 percent of right ventricular output (8 percent of the combined ventricular output) goes to the lungs (Teitel, 1992). Thus, one third of the blood passing through the ductus arteriosus is delivered to the body. The remaining right ventricular output returns to the placenta through the two hypogastric arteries, which distally become the umbilical arteries.

In the placenta, this blood picks up oxygen and other nutrients and is then recirculated back through the umbilical vein. After birth, the umbilical vessels, ductus arteriosus, foramen ovale, and ductus venosus normally constrict or collapse. With the functional closure of the ductus arteriosus and the expansion of the lungs, blood leaving the right ventricle preferentially enters the pulmonary vasculature to become oxygenated before it returns to the left heart. Virtually instantaneously, the ventricles, which had worked in parallel in fetal life, now effectively work in series. The more distal portions of the hypogastric arteries, which course from the level of the bladder along the abdominal wall to the umbilical ring and into the cord as the umbilical arteries, undergo atrophy and obliteration within 3 to 4 days after birth. These become the umbilical ligaments, while the intra-abdominal remnants of the umbilical vein form the ligamentum teres. The ductus venosus constricts by 10 to 96 hours after birth and is anatomically closed by 2 to 3 weeks, resulting in the formation of the ligamentum venosum (Clymann and Heymann, 1981).

Figure 4-12. The intricate nature of the fetal circulation is evident. The degree of oxygenation of blood in various vessels differs appreciably from that in the postnatal state as the consequences of oxygenation being provided by the placenta rather than the lungs and the presence of three major vascular shunts: **1.** Ductus venosus. **2.** Foramen ovale. **3.** Ductus arteriosus.

FETAL BLOOD

Hemopoiesis. In the very early embryo, hemopoiesis is demonstrable first in the yolk sac. The next major site is the liver, and finally the bone marrow. The contributions made by each site throughout the growth and development of the embryo and fetus are demonstrated graphically in [Figure 4-13](#).

The first erythrocytes released into the fetal circulation are nucleated and macrocytic. The mean cell volume is at least 180 fL in the embryo and normally decreases to 105 to 115 fL at term. The erythrocytes of aneuploid fetuses generally do not undergo this maturation and maintain high mean cell volumes, 130 fL on average (Sipes and associates, 1991). As fetal development progresses, more and more of the circulating erythrocytes are smaller and nonnucleated. As the fetus grows, not only does the volume of blood in the common fetoplacental circulation increase, but hemoglobin concentration rises as well.

Hemoglobin content of fetal blood rises to the level of about 12 g/dL at midpregnancy, and at term, it is about 18 g/dL (Walker and Turnbull, 1953). Fetal erythrocytes have a short life span, which progressively lengthens to approximately 90 days at term (Pearson, 1966). As a consequence, red blood cell production is increased. Reticulocytes are initially present at high levels, but decrease to about 4 to 5 percent of the total at term. The fetal erythrocytes differ structurally and metabolically from those of the adult. Fetal erythrocytes are more deformable, which serves to offset their higher viscosity, and contain several enzymes with appreciably different activities (Smith and co-workers, 1981).

Erythropoiesis. This process is controlled primarily by erythropoietin made by the fetus. Maternal erythropoietin does not cross the placenta. Fetal erythropoietin production is influenced by testosterone, estrogen, prostaglandins, thyroid hormone, and lipoproteins (Stockman and deAlarcon, 1992). Serum levels of erythropoietin increase with fetal maturity, as do the numbers of erythrocytes responsive to it. The exact site of erythropoietin production is disputed, but the fetal liver appears to be an important source until renal production begins. There is a close correlation between the concentration of erythropoietin in amniotic fluid and that in umbilical venous blood obtained by cordocentesis. After birth, erythropoietin normally may not be detectable for up to 3 months.

Fetal Blood Volume. Precise measurements of human fetoplacental volume are lacking. Usher and associates (1963), however, have measured blood volume of term normal infants very soon after birth and found an average of 78 mL/kg when immediate cord-clamping was conducted. Gruenwald (1967) found the volume of blood of fetal origin contained in the placenta after prompt cord clamping to average 45 mL/kg of fetus. Thus, fetoplacental blood volume at term is approximately 125 mL/kg of fetus.

Fetal Hemoglobin. This respiratory protein is a tetramer composed of two copies each of two different peptide chains. The type of chains determines the type of hemoglobin produced. For example, α and β chains make up normal adult hemoglobin A. During embryonic and fetal life, a variety of α and β chain precursors are produced, resulting in the serial production of several different embryonic hemoglobins. The genes that direct production of the various embryonic versions of these chains are arranged in the order in which they are temporally activated on chromosomes 11 (β -type chains) and 16 (α -type chains). This sequence is shown in [Figure 4-14](#). Each of these genes is turned on and then off during fetal life, until the α and β genes, which direct the production of hemoglobin A, are permanently activated.

Interestingly, the timing of the production of each of these early hemoglobin versions corresponds to changes in the site of hemoglobin production. As [Figure 4-13](#) illustrates, fetal blood is first produced in the yolk sac, where hemoglobins Gower 1, Gower 2, and Portland are made. Erythropoiesis then moves to the liver, where fetal hemoglobin F is produced. When hemopoiesis finally moves to the bone marrow at around 11 weeks, normal hemoglobin A appears in fetal red blood cells and is present in progressively greater amounts as the fetus matures (Pataryas and Stamatoyannopoulos, 1972).

The final adult version of the α chain is produced exclusively by 6 weeks after this there are no functional alternative versions. If an α -gene mutation or deletion occurs, there is no alternate α -type chain that could substitute to form functional hemoglobin. In contrast, at least two versions of the β chain— δ and γ —remain in production throughout fetal life and beyond. In the case of a β -gene mutation or deletion, these two other versions of the β chain often continue to be produced, resulting in hemoglobin A₂ or hemoglobin F, which substitute for the abnormal or missing hemoglobin.

The mechanism by which genes are turned off is methylation of the control region, which is discussed in greater detail in [Chapter 12](#) (see p. 305). Thus, the switch from the various embryonic hemoglobins to hemoglobin A likely is associated with methylation of the early globin genes. In some situations, methylation does not occur, and in newborns of diabetic women, there may be persistence of hemoglobin F from hypomethylation of the γ gene (Perrine and associates, 1988). With sickle cell anemia, the γ gene remains unmethylated, and large quantities of fetal hemoglobin continue to be produced (see also [Chap. 51](#), p. 1150).

There is a functional difference between hemoglobins A and F. At any given oxygen tension and at identical pH, fetal erythrocytes that contain mostly hemoglobin F bind more oxygen than do those that contain nearly all hemoglobin A (see [Fig. 42-3](#), p. 992). The major reason for this is that hemoglobin A binds 2,3-diphosphoglycerate (2,3-DPG) more avidly than does hemoglobin F, and this lowers the affinity of hemoglobin A for oxygen (De Verdier and Garby, 1969). The increased oxygen affinity of the fetal erythrocyte results from a lower concentration of 2,3-DPG compared with that of the maternal erythrocyte, in which the 2,3-DPG level is increased during pregnancy.

The amount of hemoglobin F in fetal erythrocytes falls somewhat during the latter weeks of pregnancy. At term, about three fourths of the total hemoglobin normally is hemoglobin F. During the first 6 to 12 months of life, the proportion of hemoglobin F continues to decrease, eventually to reach the low level found in adult erythrocytes. Glucocorticosteroids mediate the switch from fetal to adult hemoglobin, and the effect is irreversible (Zitnik and associates, 1995).

Fetal Coagulation Factors. There are no embryonic forms of the various hemostatic proteins. With the exception of fibrinogen, the fetus starts producing normal, adult-type, procoagulant, fibrinolytic and anticoagulant proteins by about 12 weeks, albeit at appreciably reduced levels. Even with higher levels of these proteins in maternal blood, they do not cross the placenta. The concentrations of several coagulation factors at birth are thus markedly below the levels that develop within a few weeks of life (Corrigan, 1992). Factors that are low in cord blood are II, VII, IX, X, XI, XII, XIII, and fibrinogen. Without prophylactic treatment, the vitamin K-dependent coagulation factors usually decrease even further during the first few days after birth. This decrease is amplified in breast-fed infants and may lead to hemorrhage in the newborn (see [Chap. 29](#), p. 676).

Fetal *fibrinogen*, which appears as early as 5 weeks, has the same amino acid composition as adult fibrinogen but has different properties (Klagsbrun, 1988). It forms a less compressible clot, and the fibrin monomer has a lower degree of aggregation (Heimark and Schwartz, 1988). For reasons unknown, the time for conversion of fibrinogen in plasma to fibrin clot when thrombin is added (thrombin time) is somewhat prolonged compared with that of adults. Fibrinogen levels at birth are somewhat less than those in nonpregnant adults.

Fetal functional *factor XIII (fibrin-stabilizing factor)* levels in plasma are significantly reduced compared with those in normal adults (Henriksson and co-workers, 1974). Severe deficiencies of *factors VIII, IX, XI, or XIII* are usually suspected after observing a continuous ooze from the umbilical stump. Nielsen (1969) described low levels of plasminogen and somewhat increased *fibrinolytic activity* in cord plasma compared with maternal plasma. *Platelet* counts in cord blood are in the normal

range for nonpregnant adults.

Despite this relative reduction in procoagulant, the fetus seems to be protected from hemorrhage, and fetal bleeding is a rare event. Excessive bleeding does not usually occur even after invasive fetal procedures such as cordocentesis. Ney and colleagues (1989) have shown that amniotic fluid thromboplastins and some factor in Wharton jelly combine to facilitate coagulation at the umbilical cord puncture site.

A variety of thrombophilias, such as protein C, S, or antithrombin III deficiency, or the factor V Leiden mutation may cause thromboses and pregnancy complications in adults (see [Chap. 47](#), p. 1074). If the fetus inherits one of these mutations, thrombosis and infarction can develop. Thorarensen and colleagues (1997) described three neonates with ischemic infarction or hemorrhagic stroke who were heterozygous for factor V Leiden mutation. One had multiple thromboses in the placental vasculature.

Fetal Plasma Proteins. Liver enzymes and other plasma proteins are produced by the fetus, and these levels do not correlate with maternal levels (Weiner and colleagues, 1992). Concentrations of plasma protein, albumin, lactic dehydrogenase, aspartate aminotransferase, γ -glutamyl transpeptidase, and alanine transferase all increase with gestational age. At birth, the mean total plasma protein and albumin concentrations in fetal blood are similar to maternal levels (Foley and associates, 1978).

Figure 4-13. Sites of hemopoiesis synthesized at various stages of fetal development. (From Brown, 1968, with permission.)

Figure 4-14. Schematic drawing of the arrangement of the α and β gene precursors on chromosomes 11 and 16, and the types of hemoglobin made from them. (From Thompson and colleagues, 1991, with permission.)

Figure 42-3. Oxyhemoglobin dissociation curve. With higher oxygen tension ($P_{a}O_2$) in the pulmonary alveoli, adult hemoglobin is maximally saturated compared with that at the lower oxygen tension at the tissue capillary level. At any given oxygen tension, fetal hemoglobin carries more oxygen than adult hemoglobin, as indicated by percent saturation.

ONTOGENY OF THE FETAL IMMUNE RESPONSE. Infections in utero have provided an opportunity to examine some of the mechanisms of the fetal immune response. Evidence of immunological competence has been reported as early as 13 weeks. Altshuler (1974) described infection of the placenta and fetus by cytomegalovirus with characteristic severe inflammatory cell proliferation as well as viral inclusions. Fetal synthesis of complement late in the first trimester has been demonstrated by Kohler (1973) and confirmed by Stabile and co-workers (1988). All components of complement are produced at an early stage of fetal development. In cord blood at or near term, the average level for most components is about half of the adult value (Adinolfi, 1977).

Fetal Immunocompetence. In the absence of a direct antigenic stimulus, such as infection, the immunoglobulins in the fetus consist almost totally of maternal immunoglobulin G (IgG) transferred across the placenta by receptor-mediated processes in syncytiotrophoblast. Therefore, antibodies in the fetus and the newborn infant are most often reflective of maternal immunological experiences.

Immunoglobulin G. Maternal IgG transport to the fetus begins at about 16 weeks and increases thereafter. The bulk of IgG is acquired during the last 4 weeks of pregnancy (Gitlin, 1971). Accordingly, preterm infants are endowed relatively poorly with maternal antibodies. Newborns begin to produce IgG, but slowly, and adult values are not attained until 3 years of age. In certain situations, the transfer of IgG antibodies from mother to fetus can be harmful rather than protective to the fetus. The classical example is hemolytic disease of the fetus and newborn resulting from D-antigen isoimmunization (see [Chap. 29](#), p. 663).

Immunoglobulin M. In the adult, production of immune globulin M (IgM) in response to an antigenic stimulus is superseded in 1 week or so predominantly by IgG production. In contrast, the IgM response is dominant in the fetus and remains so for weeks to months in the newborn. Because IgM is not transported from mother to fetus, any IgM in the fetus or newborn is that which it produced. Very little IgM is produced by normal, healthy fetuses, and that produced may include antibody to maternal T lymphocytes (Hayward, 1983). Increased levels of IgM are found in newborns with congenital infection such as rubella, cytomegalovirus, or toxoplasmosis. Serum IgM levels in umbilical cord blood and identification of specific antibodies may be useful in the diagnosis of intrauterine infection. Adult levels of IgM are normally attained by 9 months of age.

Immunoglobulin A. Differing from many animals, the human newborn does not acquire much in the way of passive immunity from the absorption of humoral antibodies ingested in colostrum. Nevertheless, immunoglobulin A (IgA) ingested in colostrum provides mucosal protection against enteric infections. This is likely also true for IgA ingested with amniotic fluid before delivery.

Lymphocytes. The immune system begins to mature early in fetal life. B lymphocytes appear in liver by 9 weeks and are

present in blood and spleen by 12 weeks. T lymphocytes begin to leave the thymus at about 14 weeks (Hayward, 1983). Despite this, the newborn responds poorly to immunization, and especially poorly to bacterial capsular polysaccharides. This immature response may be due to either deficient response of newborn B cells to polyclonal activators, or lack of T cells that proliferate in response to specific stimuli (Hayward, 1983).

Monocytes. In the newborn, monocytes are able to process and present antigen when tested with maternal antigen-specific T cells.

NERVOUS SYSTEM AND SENSORY ORGANS. The spinal cord extends along the entire length of the vertebral column in the embryo, but after that it grows more slowly. By 24 weeks, the spinal cord extends to S1, at birth to L3, and in the adult to L1. Myelination of the spinal cord begins in the middle of gestation and continues through the first year of life. Synaptic function is sufficiently developed by the eighth week to demonstrate flexion of the neck and trunk (Temiras and co-workers, 1968). At 10 weeks, local stimuli may evoke squinting, opening of the mouth, incomplete finger closure, and flexion of the toes. Swallowing begins at about 10 weeks, and respiration is evident at 14 to 16 weeks (Miller, 1982). Rudimentary taste buds are present at 7 weeks, and mature receptors are present by 12 weeks (Mistretta and Bradley, 1975). The ability to suck is not present until at least 24 weeks (Lebenthal and Lee, 1983). During the third trimester, integration of nervous and muscular function proceeds rapidly.

The internal, middle, and external components of the ear are well developed by midpregnancy. The fetus apparently hears some sounds in utero as early as 24 to 26 weeks. By 28 weeks, the eye is sensitive to light, but perception of form and color is not complete until long after birth.

GASTROINTESTINAL SYSTEM. Swallowing begins at 10 to 12 weeks, coincident with the ability of the small intestine to undergo peristalsis and transport glucose actively (Koldovsky and colleagues, 1965; Miller, 1982). Much of the water in swallowed fluid is absorbed, and unabsorbed matter is propelled as far as the lower colon (Fig. 4-15). In late pregnancy, swallowing serves to remove some of the insoluble debris that is normally shed into the amniotic sac and sometimes abnormally excreted into it. It is not clear what stimulates swallowing, but the fetal neural analogue of thirst, gastric emptying, and change in the amniotic fluid composition are potential factors (Boyle, 1992). The fetal taste buds may play a role because saccharin injected into amniotic fluid increases swallowing, whereas injection of a noxious chemical inhibits it (Liley, 1972). Fetal swallowing appears to have little effect on amniotic fluid volume early in pregnancy because the volume swallowed is small compared with the total volume. Late in pregnancy, however, the volume of amniotic fluid appears to be regulated substantially by fetal swallowing, for when swallowing is inhibited, hydramnios is common (see Chap. 21, p. 527). Term fetuses reportedly swallow between 200 and 760 mL per day—an amount comparable to that of the neonate (Pritchard, 1966).

Hydrochloric acid and some digestive enzymes are present in the stomach and small intestine in very small amounts in the early fetus. Intrinsic factor is detectable by 11 weeks, and pepsinogen by 16 weeks. The preterm infant, depending on the gestational age when born, may have transient deficiencies of these enzymes (Lebenthal and Lee, 1983).

Stomach emptying appears to be stimulated primarily by volume. Movement of amniotic fluid through the gastrointestinal system may enhance growth and development of the alimentary canal and condition the fetus for alimentionation after birth. Other regulatory factors may be involved, however, because anencephalic fetuses, in whom swallowing is limited, often have normal amniotic fluid volumes and normal-appearing gastrointestinal tracts. The undigested portions of the swallowed debris can be identified in meconium. Gitlin (1974) demonstrated that late in pregnancy, about 0.8 g of soluble protein, approximately half albumin, appears to be ingested by the fetus each day.

Several anomalies can affect normal fetal gastrointestinal function. *Hirschsprung disease*, or *congenital aganglionic megacolon*, prevents the bowel from undergoing parasympathetic-mediated relaxation and thus emptying normally (Watkins, 1992). It may be recognized prenatally by grossly enlarged bowel on sonography. Obstructions such as duodenal atresia, megacystis-microcolon syndrome, or imperforate anus can also prevent the bowel from emptying normally. Meconium ileus, commonly found with fetal cystic fibrosis, is bowel obstruction caused by thick, viscid meconium that blocks the distal ileum.

Meconium. The fetal bowel contents consist of various products of secretion, such as glycerophospholipids from the lung, desquamated fetal cells, lanugo, scalp hair, and vernix. It also contains undigested debris from swallowed amniotic fluid. The dark greenish-black appearance is caused by pigments, especially biliverdin. Meconium passage can result from normal bowel peristalsis in the mature fetus or from vagal stimulation. It can also occur when hypoxia stimulates arginine vasopressin (AVP) release from the fetal pituitary gland. AVP stimulates the smooth muscle of the colon to contract, resulting in intra-amniotic defecation (DeVane and co-workers, 1982; Rosenfeld and Porter, 1985). Small bowel obstruction may lead to vomiting in utero (Shrand, 1972). Fetuses who suffer from congenital chloride diarrhea may have diarrhea in utero, which leads to hydramnios and preterm delivery (Holmberg and associates, 1977).

Liver. Fetal liver enzyme levels increase with gestational age but are present in reduced amounts. The liver has a very limited capacity for converting free bilirubin to bilirubin diglucuronoside (see Chap. 29, p. 672). The more immature the fetus, the more deficient is the system for conjugating bilirubin. Because the life span of fetal erythrocytes is shorter than that of adult erythrocytes, relatively more bilirubin is produced. Most of the bilirubin is transferred to the maternal circulation through the placenta (Bashore and colleagues, 1969). The fetal liver conjugates only a small fraction, which is excreted into the intestine and ultimately oxidized to biliverdin. Unconjugated bilirubin is excreted into the amniotic fluid after 12 weeks and is then transferred across the placenta. Placental transfer, however, is bidirectional. Thus, a pregnant woman with severe hemolytic anemia will have maternal bilirubin that readily passes into the amniotic fluid. On the other hand, conjugated bilirubin is not exchanged to any significant degree between mother and fetus.

Most fetal cholesterol is produced in the fetal liver. Indeed, the large demand for LDL cholesterol by the fetal adrenal glands is met primarily by fetal hepatic synthesis. Glycogen is present in low concentration in the fetal liver during the second trimester, but near term there is a rapid and marked increase to levels two to three times those in the adult liver. After birth, glycogen content falls precipitously.

Pancreas. The discovery of insulin by Banting and Best (1922) came in response to its extraction from the fetal calf pancreas.

Insulin-containing granules can be identified in the human fetal pancreas by 9 to 10 weeks, and insulin in fetal plasma is detectable at 12 weeks (Adam and associates, 1969). The fetal pancreas responds to hyperglycemia by increasing plasma insulin (Obenshain and colleagues, 1970). Although the precise role of insulin of fetal origin is not clear, fetal growth must be determined to a considerable extent by the amounts of basic nutrients from the mother with anabolism through the action of fetal insulin. Serum insulin levels are high in newborns of diabetic mothers and in other large-for-gestational-age infants, but insulin levels are low in infants who are small for gestational age (Brinsmead and Liggins, 1979). This relationship is discussed further in [Chapter 38](#) (see p. 895).

Glucagon has been identified in the fetal pancreas at 8 weeks. In the rhesus monkey, hypoglycemia and infused alanine cause an increase in maternal glucagon levels, whereas similar stimuli to the fetus do not. Within 12 hours of birth, however, the infant is capable of responding (Chez and co-workers, 1975). Fetal pancreatic α cells are capable of responding to L-dopa (Epstein and associates, 1977). Therefore, nonresponsiveness to hypoglycemia is likely the consequence of failure of glucagon release rather than inadequate production. This is consistent with findings of the developmental expression of pancreatic genes in the fetus (Mally and associates, 1994).

Most pancreatic enzymes are present by 16 weeks. Trypsin, chymotrypsin, phospholipase A, and lipase are present in the 14-week fetus at low levels, and they increase with gestational age (Werlin, 1992). Amylase has been identified in amniotic fluid at 14 weeks (Davis and associates, 1986). The exocrine function of the fetal pancreas is limited. Physiologically important secretion occurs only after stimulation by a secretagogue such as acetylcholine, which is released locally after vagal stimulation (Werlin, 1992). Cholecystokinin normally is released only after ingestion of protein and thus ordinarily would not be found in the fetus. Its release, however, can be stimulated experimentally. Pritchard (1965) injected radioiodine-labeled albumin into the amniotic sac, where it was swallowed by the fetus, digested, and absorbed from the fetal intestine.

Figure 4-15. Radiograph of a 115-g fetus showing radiopaque dye present in the lungs, esophagus, stomach, and entire intestinal tract after injection into the amniotic cavity 26 hours before delivery. This is illustrative not only of intrauterine "respiration" by the fetus but also of active swallowing of amniotic fluid. (From Davis and Potter, 1946, with permission.)

URINARY SYSTEM. Two primitive urinary systems, the pronephros and the mesonephros, precede the development of the metanephros. The pronephros has involuted by 2 weeks, and the mesonephros is producing urine at 5 weeks and degenerates by 11 to 12 weeks. Failure of these two structures either to form or to regress may result in anomalous development of the definitive urinary system. Between 9 and 12 weeks, the ureteric bud and the nephrogenic blastema interact to produce the metanephros. The kidney and ureter develop from intermediate mesoderm. The bladder and urethra develop from the urogenital sinus. The bladder also develops in part from the allantois.

By week 14, the loop of Henle is functional and reabsorption occurs (Smith and associates, 1992). New nephrons continue to be formed until 36 weeks. In preterm infants, their formation continues after birth. Although the fetal kidneys produce urine, their ability to concentrate and modify the pH is quite limited even in the mature fetus. Fetal urine is hypotonic with respect to fetal plasma and has low concentrations of electrolytes. In the human fetus, the kidneys receive between 2 and 4 percent of the cardiac output compared with 15 to 18 percent in the newborn (Gilbert, 1980).

Renal vascular resistance is high and the filtration fraction is low compared with values in later life (Smith and colleagues, 1992). Fetal renal blood flow and thus urine production are controlled or influenced by the renin-angiotensin system, the sympathetic nervous system, prostaglandins, kallikrein, and atrial natriuretic peptide. The glomerular filtration rate increases with gestational age from less than 0.1 mL/min at 12 weeks to 0.3 mL/min at 20 weeks. In later gestation, the rate remains constant when corrected for fetal weight (Smith and colleagues, 1992). Hemorrhage or hypoxia generally results in a decrease in renal blood flow, glomerular filtration rate, and urine output.

Urine usually is found in the bladder even in small fetuses. The fetal kidneys start producing urine at 12 weeks. By 18 weeks they are producing 7 to 14 mL/day, and at term this increases to 27 mL/hr or 650 mL/day (Wladimiroff and Campbell, 1974). Maternally administered furosemide increases fetal urine formation, whereas uteroplacental insufficiency and other types of fetal stress decrease it. Kurjak and associates (1981) found that fetal glomerular filtration rates and tubular water reabsorption were decreased in 33 percent of growth-restricted infants and in 17 percent of infants of diabetic mothers. All values were normal in anencephalic infants and in those with polyhydramnios.

Obstruction of the urethra, bladder, ureters, or renal pelvis can damage renal parenchyma and distort fetal anatomy. With urethral obstruction, the bladder may become sufficiently distended that it ruptures or dystocia results. Kidneys are not essential for survival in utero, but are important in the control of the composition and volume of amniotic fluid. Furthermore, abnormalities that cause chronic anuria are usually accompanied by oligohydramnios and pulmonary hypoplasia. Pathological correlates and prenatal therapy of urinary tract obstruction are discussed in [Chapter 13](#) (see p. 332).

PULMONARY SYSTEM. The timetable of lung maturation and the identification of biochemical indices of functional fetal lung maturity are of considerable interest to the obstetrician. Morphological or functional immaturity of the lung at birth leads to the development of the *respiratory distress syndrome*, and complicates the course and treatment of other neonatal disorders (see [Chap. 29](#), p. 650).

The presence of a sufficient amount of surface-active materials, or *surfactant*, in the amniotic fluid is evidence of fetal lung maturity. As Liggins (1994) emphasized, however, the structural and morphological maturation of fetal lung also is extraordinarily important to proper lung function. It is important, as well, in choosing therapeutic agents used to hasten fetal lung maturation when preterm delivery is likely. Therefore, the two separate but complementary aspects to be considered are anatomical and morphological development of fetal lung as well as its capacity for surfactant formation.

Anatomical Maturation. Like the branching of a tree, lung development proceeds along an established timetable that apparently cannot be hastened by antenatal or neonatal therapy. The limits of viability, therefore, appear to be determined by the usual process of pulmonary growth. There are three essential stages of lung development as described by Moore (1983):

1. During the *pseudoglandular stage*, which entails the growth of the intrasegmental bronchial tree between the 5th and 17th weeks, the lung looks microscopically like a gland.
2. This period is followed by the *canalicular stage*, from 16 to 25 weeks, during which the bronchial cartilage plates extend peripherally. Each terminal bronchiole gives rise to several respiratory bronchioles, and each of these in turn divides into multiple saccular ducts.
3. The final stage is the *terminal sac stage*, during which the alveoli give rise to the primitive pulmonary alveoli, called the terminal sacs. Simultaneously, an extracellular matrix develops from proximal to distal lung segments until term. An extensive capillary network also develops, the lymph system forms, and type II cells begin to produce surfactant. At birth, only about 15 percent of the adult number of alveoli are present, and thus the lung continues to grow, adding more alveoli, from late fetal life up to about 8 years.

Various insults can upset this process, and the timing of the insult determines the outcome. With renal agenesis, for example, no amniotic fluid is present from the beginning of lung growth, and major defects occur in all three stages. The fetus with membrane rupture before 20 weeks and subsequent oligohydramnios usually exhibits nearly normal bronchial branching and cartilage development but has immature alveoli. Membrane rupture occurring after 24 weeks may have little long-term effect on pulmonary structure.

Surfactant. After birth, the terminal sacs must remain expanded despite the pressure imparted by the tissue-to-air interface, and surfactant keeps them from collapsing. There are more than 40 cell types in the lung, but surfactant is formed specifically in the type II pneumonocytes that line the alveoli. These cells are characterized by multivesicular bodies that produce the *lamellar bodies* in which surfactant is assembled. During late fetal life, at a time when the alveolus is characterized by a water-to-tissue interface, the intact lamellar bodies are secreted from the lung and swept into the amniotic fluid during fetal respiratory-like movements, that is, fetal breathing. At birth, with the first breath, an air-to-tissue interface is produced in the lung alveolus. Surfactant uncoils from the lamellar bodies, and it then spreads to line the alveolus to prevent alveolar collapse during expiration. Thus, it is the capacity for fetal lungs to produce surfactant, and not the actual laying down of this material in the lungs in utero, that establishes fetal lung maturity.

SURFACTANT COMPOSITION. Gluck and associates (1967, 1970, 1972) and Hallman and co-workers (1976) found that about 90 percent of surfactant mass (dry weight) is lipid. Proteins account for the other 10 percent. Approximately 80 percent of the glycerophospholipids are phosphatidylcholines (lecithins). The principal active component of surfactant is a specific lecithin PC —*dipalmitoylphosphatidylcholine (DPPC)*—which accounts for nearly 50 percent. *Phosphatidylglycerol (PG)*, the second most surface active component of surfactant, accounts for 8 to 15 percent (Keidel and Gluck, 1975). This component is capable of reducing surface tension in the alveolus, but its precise role is unclear. Infants born with a "mature" lecithin-sphingomyelin (L/S) ratio, but without phosphatidylglycerol, usually do well.

SURFACTANT SYNTHESIS. Biosynthesis takes place in the type II cells. The apoproteins are produced in the endoplasmic reticulum, and the glycerophospholipids are synthesized by cooperative interactions of several cellular organelles. Phospholipid is the primary surface tension-lowering component of surfactant, whereas the surfactant apoproteins serve to facilitate the forming and reforming of a surface film in the alveoli during respiration. The surface properties of the surfactant phospholipids are determined by the composition and degree of saturation of the long-chain fatty acids, the types and amounts of minor lipids and proteins, and the temperature. The regulation of phosphatidylglycerol synthesis is especially important. ([Fig. 4-16](#)).

The known surfactant-associated apoproteins are surfactant proteins A, B, and C (Whitsett, 1992). The major one is surfactant A (SP-A), which is a glycoprotein with a molecular weight of about 28,000 to 35,000 d. It is synthesized in the type II cells, and increased synthesis is related temporally to increased surfactant formation in maturing fetal lungs. The amniotic fluid content of SP-A increases as a function of gestational age and fetal lung maturity. Synthesis of SP-A is increased by treatment of fetal lung tissue with cyclic adenosine monophosphate (AMP) analogues, epidermal growth factors, and triiodothyronine. Increases in surfactant apoprotein synthesis precede the increase in surfactant glycerophospholipid synthesis (Mendelson and associates, 1986).

SP-A gene expression is not detectable at 16 to 20 weeks, but it is demonstrable at 29 weeks (Snyder and colleagues, 1988). More recently, it has been demonstrated that there are two separate SP-A genes on chromosome 10 (SP-A1 and SP-A2). The regulation of synthesis of these two genes is distinctive and different. McCormick and Mendelson (1994) found that the two SP-A genes are differentially regulated. Cyclic AMP is more important in SP-A2 expression (11-fold), whereas dexamethasone caused a decrease in SP-A2 expression.

There are also several smaller apoproteins of about 5000 to 18,000 d. SP-B and SP-C are believed to be important in optimizing the surface-active properties of surfactant. Deletions in the surfactant SP-B gene are not compatible with neonatal survival despite the production of large amounts of surfactant.

CORTICOSTEROIDS AND FETAL LUNG MATURATION. Liggins (1969) observed accelerated lung maturation in lambs that had been treated with glucocorticosteroids prior to preterm birth. Since that time, many investigators have suggested that fetal cortisol is the natural stimulus for lung maturation and augmented surfactant synthesis. Corticosteroids, however, may not be the only stimulus for augmented surfactant formation. For example, respiratory distress syndrome is not always observed in neonates in whom the capacity to secrete cortisol is limited. These situations include those with anencephaly, adrenal hypoplasia, or congenital adrenal hyperplasia. Nevertheless, there is now clinical evidence that glucocorticosteroids administered in large amounts to the woman at certain critical times during gestation effect an increase in the rate of fetal lung maturation. In addition, the advent of neonatal surfactant therapy, either alone or following prenatal corticosteroid treatment, has significantly reduced the incidence of respiratory disease. The use of betamethasone to accelerate fetal lung maturity as well as neonatal surfactant therapy is widely accepted (see [Chap. 36](#), p. 868, and [Chap. 29](#), p. 650).

Respiration. Within a very few minutes after birth, the respiratory system must be able to provide oxygen as well as eliminate carbon dioxide. Respiratory muscles develop early, and movements of the fetal chest wall have been detected by ultrasonic techniques as early as 11 weeks (Boddy and Dawes, 1975). From the beginning of the fourth month, the fetus is capable of respiratory movement sufficiently intense to move amniotic fluid in and out of the respiratory tract.

Figure 4-16. Relation between the levels of lecithin, or dipalmitoylphosphatidylcholine (PC), phosphatidylinositol (PI), and phosphatidylglycerol (PG) in amniotic fluid as a function of gestational age.

ENDOCRINE GLANDS

Pituitary Gland. The fetal endocrine system is functional for some time before the central nervous system reaches a state of maturity competent to perform many functions associated with homeostasis (Mulchahey and co-workers, 1987). The fetal endocrine system does not necessarily mimic that of the adult but nonetheless may be one of the first homeostatic systems to develop. The pituitary develops from two different sources. The adenohypophysis develops from the oral ectoderm (Rathke pouch) and the neurohypophysis develops from the neuroectoderm.

ANTERIOR PITUITARY. The adenohypophysis, or anterior pituitary, differentiates into five cell types that secrete six protein hormones: (1) lactotropes, producing prolactin (PRL); (2) somatotropes, producing growth hormone (GH); (3) corticotropes, producing corticotropin (ACTH); (4) thyrotropes, producing thyroid-stimulating hormone (TSH); and (5) gonadotropes, producing luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

ACTH is first detected in the fetal pituitary gland at 7 weeks, and before the end of the 17th week the fetal pituitary gland is able to synthesize and store all pituitary hormones. GH, ACTH, and LH have been identified by 13 weeks. Moreover, the fetal pituitary is responsive to hormones and is capable of secreting these hormones from early in gestation (Grumbach and Kaplan, 1974). Levels of immunoreactive GH are rather high in cord blood, although its role in fetal growth and development is not clear. Anencephalic fetuses, with little pituitary tissue, are not remarkably different in weight from normal fetuses. The fetal pituitary produces and releases β -endorphin in a manner separate from maternal plasma levels (Browning and colleagues, 1983). Furthermore, cord blood levels of β -endorphin and β -lipotropin increase with fetal P_{CO_2} .

NEUROHYPOPHYSIS. The posterior pituitary gland is well developed by 10 to 12 weeks when oxytocin and arginine vasopressin (AVP) are demonstrable. Oxytocin as well as AVP probably function in the fetus to conserve water by actions largely at the level of lung and placenta rather than kidney. Levels of AVP in umbilical cord plasma are increased strikingly compared with the maternal levels (Chard and associates, 1971; Polin and co-workers, 1977). AVP in fetal blood appears to be elevated with fetal stress (DeVane and Porter, 1980; DeVane and co-workers, 1982).

INTERMEDIATE PITUITARY GLAND. There is a well-developed intermediate lobe in the fetal pituitary gland. The cells of this structure begin to disappear before term and are absent from the adult pituitary. The principal secretory products of the intermediate lobe cells are α -melanocyte-stimulating hormone (α -MSH) and β -endorphin. The levels of fetal β -MSH decrease progressively with gestation.

Thyroid Gland. The pituitary-thyroid system is functional by the end of the first trimester. The thyroid gland is able to synthesize hormones by 10 to 12 weeks, and TSH, thyroxine, and thyroid-binding globulin (TBG) have been detected in fetal serum as early as 11 weeks (Ballabio and colleagues, 1989). The placenta actively concentrates iodide on the fetal side, and by 12 weeks and throughout pregnancy, the fetal thyroid concentrates iodide more avidly than does the maternal thyroid. Thus, maternal administration of either radioiodide or appreciable amounts of ordinary iodide is hazardous after this time. Normal fetal levels of free thyroxine (T_4), free triiodothyronine (T_3), and thyroxin-binding globulin increase steadily throughout gestation (Ballabio and associates, 1989). In comparison to adult levels, by 36 weeks, fetal serum concentrations of TSH are higher, total and free T_3 concentrations are lower, and T_4 is similar. This suggests that the fetal pituitary may not become sensitive to feedback until late in pregnancy (Thorpe-Beeston and co-workers, 1991; Wenstrom and colleagues, 1990).

Fetal thyroid hormone plays a role in the normal development of virtually all fetal tissues, but especially the brain. Its influence is illustrated by congenital hyperthyroidism, which occurs when maternal thyroid-stimulating antibody crosses the placenta to stimulate the fetal thyroid. These fetuses develop tachycardia, hepatosplenomegaly, hematological abnormalities, craniosynostosis, and growth restriction. As children they have perceptual motor difficulties, hyperactivity, and reduced growth (Wenstrom and colleagues, 1990). This relationship is discussed further in [Chapter 53](#) (see p. 1193).

Placental tissue and membranes appear to prevent substantial passage of maternal thyroid hormones to the fetus by rapidly deiodinating maternal T_4 and T_3 to reverse T_3 , a relatively inactive thyroid hormone (Vulsma and colleagues, 1989). A number of antithyroid antibodies, however, cross the placenta readily when present in high maternal serum concentrations. Those include the long-acting thyroid stimulators LATS and LATS-protector and thyroid-stimulating immunoglobulin (see [Chap. 53](#), p. 1190). Because maternal thyroid hormones cross the placenta to a very limited degree, congenital hypothyroidism can result in a variety of neonatal problems. These include neurological abnormalities, respiratory difficulties, dysmorphic facies, lethargy and hypotonia, and myxedema of the larynx and epiglottis. These problems typically develop only after birth and can be avoided with prompt thyroid replacement. It was previously believed that normal fetal growth and development that occurred despite fetal hypothyroidism provided evidence that T_4 was not essential for fetal growth. It is now known, however, that growth proceeds normally because small quantities of maternal T_4 prevent antenatal cretinism. Vulsma and colleagues (1989), who studied fetuses with thyroid agenesis, found that fetal T_4 levels were very low and actually represented maternal hormone.

Immediately after birth, there are major changes in thyroid function and metabolism. Atmospheric cooling evokes sudden and

marked increase in thyrotropin secretion, which in turn causes a progressive increase in serum T_4 levels that are maximal 24 to 36 hours after birth. There are nearly simultaneous elevations of serum T_3 levels. Failure of these changes to occur, for instance, when the fetus is congenitally hypothyroid, causes multiple problems, including cretinism, a form of mental retardation resulting from postnatal brain injury.

Adrenal Glands. These glands are much larger in relation to total body size in the fetus than in adults. The bulk is made up of the inner or so-called *fetal zone* of the adrenal cortex. The normally hypertrophied fetal zone involutes rapidly after birth. It is scant to absent in rare instances where the fetal pituitary gland is congenitally absent. The function of the fetal adrenal glands and the control of fetal adrenal steroidogenesis of dehydroepiandrosterone sulfate and cortisol are discussed in detail in [Chapter 3](#) (see p. 78).

The fetal adrenal glands also synthesize aldosterone. In one study, aldosterone levels in cord plasma near term exceeded those in maternal plasma, as did renin and renin substrate (Katz and colleagues, 1974). The renal tubules of the newborn, and presumably the fetus, appear relatively insensitive to aldosterone (Kaplan, 1972).

FETAL GENDER

The establishment of the primary gender ratio in humans is impractical, for it would require the recovery and assignment of gender to zygotes that fail to cleave, blastocysts that fail to implant, and early pregnancy losses. Carr (1963) suggested that the primary gender ratio in humans may be unity. However, the secondary ratio \aleph —that is, the gender ratio of fetuses that reach viability \aleph —usually is quoted as approximately 106 males to 100 females. Studies from industrialized nations more recently suggest that the proportion of male births is dropping. Davis and colleagues (1998) report a significant decline in male births since 1950 in Denmark, Sweden, the Netherlands, the United States, Germany, Norway, and Finland. Allan and co-workers (1997) reviewed the male-to-female ratio for all live births in Canada and found that since 1970, the proportion of males has dropped by 2.2 male births per 1000 live births. In the Atlantic region, the decline was 5.6 male births per 1000.

Theoretically, there should be as many Y-bearing as X-bearing sperm, and thus a primary gender ratio of 1:1 at the time of fertilization. Recent data dispute this, and many factors \aleph —among them, differential susceptibility to toxins and other environmental exposures and concomitant medical disorders \aleph —have been shown to contribute to gender ratios at conception. Parental age appears to influence the primary gender ratio. For example, Manning and associates (1997) reported that couples with a large age discrepancy more likely have a male offspring. James (1986) theorizes that this may be a result of high stress in urbanized society, which may increase corticotropin secretion, stimulating maternal adrenal androgen secretion that favors male conceptions. If this is not the case, the unbalanced secondary gender ratio can only be explained by the loss of more female than male embryo-fetuses during the early months of pregnancy.

GENDER ASSIGNMENT AT BIRTH. The first thing that parents in the delivery room want to know is the gender of their infant. If the external genitalia of the newborn are ambiguous, the obstetrician faces a profound dilemma. Griffin and Wilson (1986) state that it is no exaggeration to say that the detection of sexual ambiguity in the newborn constitutes a true medical emergency. An incorrect assignment of gender portends grave psychological and social problems for the infant and family. Furthermore, several endocrinological causes of genital ambiguity are associated with profound blood pressure instability and serious metabolic abnormalities.

It is no longer believed that the proper functional gender assignment for newborns with genital ambiguity can be made in the delivery room. Assignment requires knowledge of the karyotypic sex, gonadal sex, hormonal milieu to which the fetus was exposed, anatomy, and all possibilities for surgical correction. In the past, all infants with a small or likely insufficient phallus were often assigned to the female gender. Based on what is now known of the role of fetal exposure to hormones in establishing gender preference and behavior, it can be seen why such a policy may have caused *gender identity disorder* (Slijper and colleagues, 1998). Thus, it seems best to inform the parents that although their infant appears healthy, the gender will need to be determined by a series of tests. To develop a plan that can assist in determining the cause of ambiguous genitalia, the mechanisms of normal and abnormal sexual differentiation must be considered.

SEXUAL DIFFERENTIATION OF THE EMBRYO-FETUS. Phenotypic gender differentiation is determined by chromosomal makeup acting in conjunction with gonadal development.

Chromosomal Gender. Genetic gender \aleph —XX or XY \aleph —is established at the time of fertilization. For the first 6 weeks thereafter, however, the development of male and female embryos is morphologically indistinguishable. The differentiation of the primordial gonad into testis or ovary heralds the establishment of gonadal sex ([Fig. 4-17](#)).

Gonadal Gender. Primordial germ cells originate in the endoderm of the yolk sac and migrate to the genital ridge to form the indifferent gonad (Simpson, 1997). If a Y chromosome is present, at about 6 weeks after conception the gonad begins developing into a testis. Testes development is directed by a gene located on the short arm of Y, namely *testis-determining factor* (*TDF*), also called *sex-determining region* (*SRY*). This gene encodes a transcription factor that acts to modulate the rate of transcription of a number of genes involved in gonadal differentiation. The *SRY* gene is specific to the Y chromosome and is expressed in the human single-cell zygote immediately after ovum fertilization. It is not expressed in spermatozoa (Fiddler and co-workers, 1995; Gustafson and Donahoe, 1994). In addition, testis development requires a *dose-dependent sex reversal* (*DDS*) region on the X chromosome, as well as yet unidentified autosomal genes. It is not clear how these genes, or the Y chromosome, direct the biomolecular events involved in gonadal differentiation of the testis.

The contribution of chromosomal gender to gonadal gender is illustrated by several paradoxical conditions. The incidence of 46,XX phenotypic human males is estimated to be about 1 in 20,000 male births (Page and colleagues, 1985). These infants apparently result from translocation of the Y chromosome fragment containing *TDF* to the X chromosome during meiosis of male germ cells (George and Wilson, 1988). Similarly, individuals with XY chromosomes can appear phenotypically female if they carry a mutation in the *TDF* (*SRY*) gene. There is evidence that genes on Xp are capable of suppressing testicular development, despite the presence of the *SRY* gene. Indeed, this accounts for a form of X-linked recessive gonadal dysgenesis.

The existence of autosomal sex-determining genes is supported by several genetic syndromes in which disruption of an autosomal gene causes, among other things, gonadal dysgenesis. For example, *camptomelic dysplasia*, localized to chromosome 17, is associated with XY phenotypic sex reversal. Similarly, *male pseudohermaphroditism* has been associated with a mutation in the Wilms tumor suppressor gene on chromosome 11.

Phenotypic Gender. After establishment of gonadal gender, phenotypic gender develops very rapidly. It is clear that male phenotypic sexual differentiation is directed by the function of the fetal testis. In the absence of a testis, female differentiation ensues irrespective of the genetic gender. The development of urogenital tracts in both sexes of human embryos is indistinguishable before 8 weeks. Thereafter, development and differentiation of the internal and external genitalia to the male phenotype is dependent on testicular function. The fundamental experiments to determine the role of the testis in male sexual differentiation were conducted by the French anatomist Alfred Jost. Ultimately, he established that the induced phenotype is male and that secretions from the gonads are not necessary for female differentiation. Specifically, the fetal ovary is not required for female sexual differentiation.

Jost and associates (1973) found that if castration of rabbit fetuses was conducted before differentiation of the genital anlagen, all newborns were phenotypic females with female external and internal genitalia. Thus, the mullerian ducts developed into uterus, fallopian tubes, and upper vagina.

If fetal castration was conducted before differentiation of the genital anlagen, and thereafter a testis was implanted on one side in place of the removed gonad, the phenotype of all fetuses was male. Thus, the external genitalia of such fetuses were masculinized. On the side of the testicular implant, the wolffian duct developed into the epididymis, vas deferens, and seminal vesicle. With castration, on the side without the implant, the mullerian duct developed but the wolffian duct did not.

In another experiment, these investigators found that if an androgen pellet was implanted on only the side of the removed gonad, then the external genitalia masculinized. So did the wolffian duct on the side of the androgen pellet. The mullerian duct, however, did not regress. Specifically, the uterine horn and fallopian tube developed despite the androgen implant.

Wilson and Gloyna (1970) and Wilson and Lasnitzki (1971) demonstrated that testosterone action was amplified by conversion to 5α -dihydrotestosterone (5α -DHT). These investigators demonstrated convincingly that in most androgen-responsive tissues, testosterone is converted to 5α -DHT in a reaction catalyzed by the enzyme(s) 5α -reductase. This hormone acts primarily and almost exclusively in the genital tubercle and labioscrotal folds. All of these observations form the basic framework of our understanding of the mechanisms of sexual differentiation of the human embryo-fetus.

Physiological and Biomolecular Basis of Gender Differentiation. Based on these observations, the physiological basis of gender differentiation can be summarized as follows. Genetic gender is established at fertilization. Gonadal gender is determined primarily by factors encoded by genes on the Y chromosome, such as the *SRY* gene. In a manner not yet understood, differentiation of the primitive gonad into a testis is accomplished.

Fetal Testicular Contributions to Male Sexual Differentiation. The fetal testis secretes a proteinaceous substance called *mullerian-inhibiting substance*, a dimeric glycoprotein with a molecular weight of about 140,000 d. It acts locally as a paracrine factor to cause regression of the mullerian duct. Thus, it prevents the development of uterus, fallopian tube, and upper vagina. Fetal testes secrete testosterone, which acts to cause virilization of the external and internal genital anlagen. Mullerian-inhibiting substance is produced by the Sertoli cells of the seminiferous tubules. Importantly, these tubules appear in fetal gonads before differentiation of Leydig cells, which are the cellular site of testosterone synthesis. Thus, mullerian-inhibiting substance is produced by Sertoli cells even before differentiation of the seminiferous tubules, and is secreted as early as 7 weeks. Mullerian duct regression is completed by 9 to 10 weeks, which is before testosterone secretion has commenced. Because it acts locally near its site of formation, if a testis were absent on one side, the mullerian duct on that side would persist and the uterus and fallopian tube would develop on that side.

Fetal Testosterone Secretion. Apparently through stimulation initially by chorionic gonadotropin (hCG), and later by fetal pituitary LH, the fetal testes secrete testosterone. Some investigators are of the view that early embryo-fetal testosterone synthesis is gonadotropin independent. Testosterone acts directly on the wolffian duct to effect the development of the vas deferens, epididymis, and seminal vesicles. Testosterone also enters fetal blood and acts on the anlagen of the external genitalia. In these tissues, however, testosterone is converted to 5α -DHT, which amplifies the androgen action of testosterone to cause virilization of the external genitalia. Work in marsupials suggests that dihydrotestosterone may be converted to 5α -androstenediol for circulation to the external genitalia (Leihy and colleagues, 2002; Shaw and associates, 2000).

Figure 4-17. Gender differentiation. Genetic sex is established at the time of fertilization. At a time thereafter, the primordial gonad differentiates to testis if the *SRY* gene is expressed. The fetal testicular secretions effect male phenotypic gender differentiation.

GENITAL AMBIGUITY OF THE NEWBORN. Ambiguity of the neonatal genitalia is the result of either excessive androgen action in an embryo-fetus that was destined to be female, or inadequate androgen representation for one destined to be male. Rarely, genital ambiguity indicates true hermaphroditism. **If the neonate is a phenotypic male with bilateral cryptorchidism, or if the genitalia are completely ambiguous, congenital adrenal hyperplasia is diagnosed and the neonate treated until appropriate tests confirm it or rule it out.** This is because, of all the causes of genital ambiguity, only congenital adrenal hyperplasia can be life threatening. If not treated immediately, adrenal failure provokes nausea, vomiting, diarrhea, dehydration, and shock (Speroff and co-workers, 1994).

Abnormalities of gender differentiation causing genital ambiguity can be assigned to one of four clinically defined categories that include (1) female pseudohermaphroditism, (2) male pseudohermaphroditism, (3) dysgenetic gonads, including true hermaphroditism, and rarely (4) true hermaphroditism (Low and Hutson, 2003).

Category 1. Female Pseudohermaphroditism. In this condition:

1. Mullerian-inhibiting substance is not produced.
2. Androgen exposure of the embryo-fetus is excessive, but variable, for a fetus genetically predestined to be female.
3. The karyotype is 46,XX.
4. Ovaries are present.

Therefore, by genetic and gonadal gender, all subjects of this category are predestined to be female, and the basic abnormality is androgen excess. Because mullerian-inhibiting substance is not produced, the uterus, fallopian tubes, and upper vagina develop in these subjects.

If affected fetuses were exposed to a small amount of excess androgen reasonably late in fetal development, the only genital abnormality will be slight to modest clitoral hypertrophy, with an otherwise normal female phenotype.

With somewhat greater androgen exposure, clitoral hypertrophy will be more pronounced and posterior labial fusion will develop. With progressively increasing androgen excess occurring somewhat earlier in embryonic development, progressively more severe virilization can be seen. This includes formation of labioscrotal folds; development of a urogenital sinus, in which the vagina empties into the posterior urethra; and even development of a penile urethra with scrotal formation: the empty scrotum syndrome.

The androgenic excess in fetuses with female pseudohermaphroditism most commonly arises as the result of congenital adrenal hyperplasia. These defects in the steroidogenic enzymes that are required in the synthesis of cortisol from cholesterol cause increased secretion of androgenic prehormones by the fetal adrenal cortex. With impaired cortisol synthesis, pituitary ACTH secretion is increased, and excessive ACTH stimulation of the fetal adrenal glands leads to the secretion of large amounts of cortisol precursors, including androgenic prehormones. These prehormones, for example, androstenedione, are converted to testosterone in extra-adrenal fetal tissues. The enzyme deficiency may involve any of several enzymes, but the most common are steroid 21-hydroxylase, 11 β -hydroxylase, or 3 β -hydroxysteroid dehydrogenase. Deficiency of 3 β -hydroxysteroid dehydrogenase prevents synthesis of virtually all steroid hormones. Deficiency of either 17 β -hydroxylase or 11 β -hydroxylase results in the increased production of deoxycorticosterone, which causes hypertension and hypokalemic acidosis. These forms of congenital adrenal hyperplasia thus constitute medical emergencies.

Another cause of androgen excess in the female embryo-fetus is the transfer of androgen from the maternal compartment. Excess maternal androgen secretion may arise from the ovaries with hyperreactio luteinalis or theca-lutein cysts or tumors such as luteomas, arrhenoblastomas (Sertoli-Leydig cell tumors), or hilar cell tumors. In most of these conditions, however, the female fetus does not become virilized. This is because during most of pregnancy, the fetus is protected from excess maternal androgen by the extraordinary capacity of the syncytiotrophoblast to convert most C₁₉-steroids, including testosterone, to estradiol-17 β . The only exception to this generalization is fetal aromatase deficiency, which produces both maternal and fetal virilization (see [Chap. 3](#), p. 81). Drugs ingested in pregnancy also can cause female fetal androgen excess. Most commonly, the drugs implicated are synthetic progestins or anabolic steroids (see [Chap. 14](#), p. 352).

Importantly, all subjects with female pseudohermaphroditism, except those with aromatase deficiency, can be normal, fertile women if the proper diagnosis is made and appropriate and timely treatment is initiated.

Category 2. Male Pseudohermaphroditism. These subjects are characterized by:

1. Production of mullerian-inhibiting substance.
2. Incomplete but variable androgenic representation for a fetus predestined to be male.
3. A 46,XY karyotype.
4. The presence of testes or no gonads.

Incomplete masculinization of the fetus destined to be male is caused by inadequate production of testosterone by the fetal testis. It also may arise from diminished responsiveness of the genital anlagen to normal quantities of androgen, which includes failure of the in situ formation of 5 α -DHT in androgen-responsive tissue. Because testes were present, at least at some time in embryonic life, mullerian-inhibiting substance is produced during embryonic life. Thus, the uterus, fallopian tubes, and upper vagina do not develop.

Deficient fetal testicular testosterone production may occur if there is an enzymatic defect of steroidogenesis that involves any one of four enzymes in the biosynthetic pathway for testosterone synthesis. Impaired fetal testicular steroidogenesis can also be caused by an abnormality in the LH-hCG receptor and by Leydig cell hypoplasia.

With embryonic testicular regression, the testes regress during embryonic or fetal life, and there is no testosterone production thereafter (Edman and associates, 1977). These subjects have a spectrum of phenotypes that varies from a normal female with absent uterus, fallopian tubes, and upper vagina, to a normal male phenotype with anorchia.

Androgen resistance, or deficiencies in androgen responsiveness, are caused by an abnormal (or absent) androgen receptor protein, or else by failure of conversion of testosterone to 5 α -DHT in such tissues because of deficient enzyme activity (Wilson and MacDonald, 1978).

ANDROGEN INSENSITIVITY SYNDROME. Formerly called *testicular feminization*, this is the most extreme form of the androgen resistance syndrome. These individuals have no tissue responsiveness to androgen. Affected subjects have a female phenotype with a short, blind-ending vagina, no uterus or fallopian tubes, and no wolffian duct structures. At the expected time of puberty, testosterone levels in affected women increase to values similar to normal men. Nonetheless, virilization does

not occur, and even pubic and axillary hair do not develop because of end-organ resistance. Presumably, because of androgen resistance at the level of the brain and pituitary, LH levels also are elevated. In response to high concentrations of LH, there is increased testicular secretion of estradiol-17 β compared with that in normal men (MacDonald and colleagues, 1979). Increased estrogen secretion and absence of androgen responsiveness act in concert to cause feminization (breast development).

Individuals with *incomplete androgen insensitivity* are slightly responsive to androgen. Although they usually have modest clitoral hypertrophy at birth, at the expected time of puberty, pubic and axillary hair develop but virilization does not occur. These women also develop feminine breasts, presumably through the same endocrine mechanisms as in women with the complete form of the disorder (Madden and co-workers, 1975).

Another group has been referred to as *familial male pseudohermaphroditism, type I* (Walsh and colleagues, 1974). It also is commonly referred to as *Reifenstein syndrome*, but constitutes a spectrum of incomplete genital virilization that can vary from a phenotype similar to that of women with incomplete androgen insensitivity to that of a male phenotype with only a bifid scrotum, infertility, and gynecomastia. In these subjects, androgen resistance is demonstrated by demonstrating diminished 5 α -DHT-binding capacity in genital skin.

The gene encoding the androgen receptor protein is located on the X chromosome. More than 100 different mutations of this gene have been demonstrated. This accounts for the wide variability in androgen responsiveness among persons in whom the androgen receptor protein is absent or abnormal, and for the many different mutations associated with one disorder (McPhaul and associates, 1991; Patterson and co-workers, 1994).

An alternate form of androgen resistance is caused by 5 α -reductase deficiency in androgen-responsive tissues. Because androgen action in the external genitalia anlagen is mediated by 5 α -DHT, persons with this enzyme deficiency have external genitalia that are female but with modest clitoral hypertrophy. But because androgen action in the wolffian duct is mediated directly by testosterone, there are well-developed epididymides, seminal vesicles, and vas deferens, and the male ejaculatory ducts empty into the vagina (Walsh and associates, 1974).

A composite photograph of the external genitalia of subjects with each of four types of androgen resistance is shown in [Figure 4-18](#).

Category 3: Dysgenetic Gonads. This category includes abnormalities of sexual differentiation that have in common several features:

1. Mullerian-inhibiting substance is not produced.
2. Fetal androgen exposure is variable.
3. The karyotype varies among subjects and is commonly abnormal.
4. Neither normal ovaries nor testes are present but rarely, both ovarian and testicular tissues are found.

The uterus, fallopian tubes, and upper vagina are present in all of the subjects in this category.

In the majority, the gonads are dysgenetic. With the most common form of gonadal dysgenesis, *Turner syndrome (46X)*, the phenotype is female, but secondary gender characteristics do not develop at the time of expected puberty, and genital infantilism persists. In some persons with dysgenetic gonads, the genitalia are ambiguous, a finding indicating that an abnormal gonad produced androgen, albeit in small amounts, during embryonic-fetal life. Generally, there is mixed gonadal dysgenesis in these subjects, and an example is a dysgenetic gonad on one side and an abnormal testis or dysontogenetic tumor on the other side.

Category 4: True Hermaphroditism. In most subjects with true hermaphroditism, the guidelines for category 3 are met. In addition, true hermaphrodites have both ovarian and testicular tissues, and in particular, germ cells (ova and sperm) of both sexes are found in the abnormal gonads.

Preliminary Diagnosis of the Cause of Genital Ambiguity. A preliminary diagnosis of the etiology and pathogenesis of genital ambiguity can be made at the time of birth of an affected child. By physical and ultrasonic examination of the newborn, the experienced examiner can ascertain important findings. These include whether gonads are palpable, and if so, where they are; phallus length and diameter; position of the urethral meatus; degree of labioscrotal fold fusion; and whether there is a vagina, vaginal pouch, or urogenital sinus (Speroff and associates, 1994). If the uterus is present, the diagnosis must be female pseudohermaphroditism, testicular or gonadal dysgenesis, or true hermaphroditism. A family history of congenital adrenal hyperplasia is helpful. If the uterus is not present, the diagnosis is male pseudohermaphroditism. Androgen resistance and enzymatic defects in testicular testosterone biosynthesis are often familial.

5. Maternal Physiology

INTRODUCTION

The anatomical, physiological, and biochemical adaptations to pregnancy are profound. Many of these remarkable changes begin soon after fertilization and continue throughout gestation, and most occur in response to physiological stimuli provided by the fetus. Equally astounding is that the woman who was pregnant is returned almost completely to her prepregnancy state after delivery and lactation. The understanding of these adaptations to pregnancy remains a major goal of obstetrics, and without such knowledge, it is almost impossible to understand the disease processes that can threaten women during pregnancy and the puerperium.

Many of these physiological adaptations could be perceived as abnormal in the nonpregnant woman. For example, cardiovascular changes during pregnancy normally include substantive increases in blood volume and cardiac output, which may mimic thyrotoxicosis. On the other hand, these same adaptations may lead to ventricular failure if there is underlying heart disease. Thus, physiological adaptations of normal pregnancy can be misinterpreted as pathological and can also unmask or worsen preexisting disease.

During normal pregnancy, virtually every organ system undergoes anatomical and functional changes that can alter appreciably the criteria for diagnosis and treatment of diseases. The impact of these marked physiological changes on underlying disease, and vice versa, is considered in detail in Section VIII.

REPRODUCTIVE TRACT

UTERUS. In the nonpregnant woman, the uterus is an almost-solid structure weighing about 70 g and with a cavity of 10 mL or less. During pregnancy, the uterus is transformed into a relatively thin-walled muscular organ of sufficient capacity to accommodate the fetus, placenta, and amniotic fluid. The total volume of the contents at term averages about 5 L but may be 20 L or more, so that by the end of pregnancy the uterus has achieved a capacity that is 500 to 1000 times greater than in the nonpregnant state. The corresponding increase in uterine weight is such that, by term, the organ weighs approximately 1100 g.

During pregnancy, uterine enlargement involves stretching and marked hypertrophy of muscle cells, whereas the production of new myocytes is limited. Accompanying the increase in the size of muscle cells is an accumulation of fibrous tissue, particularly in the external muscle layer, together with a considerable increase in elastic tissue. The network that is formed adds materially to the strength of the uterine wall. Although the walls of the corpus become considerably thicker during the first few months of pregnancy, they actually thin gradually as gestation advances, such that by term they are only about 1.5 cm or even less in thickness. In these later months, the uterus is changed into a muscular sac with thin, soft, readily indentable walls, demonstrable by the ease with which the fetus usually can be palpated.

Early in gestation, uterine hypertrophy probably is stimulated chiefly by the action of estrogen and perhaps that of progesterone. It is apparent that hypertrophy of early pregnancy does not occur entirely in response to mechanical distention by the products of conception, because similar uterine changes are observed with ectopic pregnancy (see [Chap. 10](#), p. 258). But after about 12 weeks, the increase in uterine size is related predominantly in some manner to pressure exerted by the expanding products of conception.

Uterine enlargement is most marked in the fundus. In the early months of pregnancy, the fallopian tubes and ovarian and round ligaments attach only slightly below the apex of the fundus, whereas in the later months, they are located slightly above the middle of the uterus (see [Fig. 2-10](#), p. 24). The position of the placenta also influences the extent of uterine hypertrophy, because the portion of the uterus surrounding the placental site enlarges more rapidly than does the rest.

Arrangement of the Muscle Cells. The uterine musculature during pregnancy is arranged in three strata:

1. An outer hoodlike layer, which arches over the fundus and extends into the various ligaments.
2. A middle layer, composed of a dense network of muscle fibers perforated in all directions by blood vessels.
3. An internal layer, consisting of sphincter-like fibers around the orifices of the fallopian tubes and the internal os of the cervix.

The main portion of the uterine wall is formed by the middle layer, which consists of an interlacing network of muscle fibers between which extend the blood vessels. Each cell in this layer has a double curve, so that the interlacing of any two gives approximately the form of a figure eight. As a result of this arrangement, when the cells contract after delivery, they constrict the penetrating blood vessels and thus act as ligatures.

Uterine Size, Shape, and Position. For the first few weeks, the uterus maintains its original pear shape, but as pregnancy advances, the corpus and fundus assume a more globular form, becoming almost spherical by 12 weeks. Subsequently, the organ increases more rapidly in length than in width and assumes an ovoid shape. By the end of 12 weeks, the uterus has become too large to remain totally within the pelvis. As the uterus continues to enlarge, it contacts the anterior abdominal wall, displaces the intestines laterally and superiorly, and continues to rise, ultimately reaching almost to the liver. With ascent of the uterus from the pelvis, it usually undergoes rotation to the right, and this *dextrorotation* likely is caused by the rectosigmoid on the left side of the pelvis. As the uterus rises, tension is exerted on the broad and round ligaments.

With the pregnant woman standing, the longitudinal axis of the uterus corresponds to an extension of the axis of the pelvic inlet. The abdominal wall supports the uterus and, unless it is quite relaxed, maintains this relation between the long axis of the uterus and the axis of the pelvic inlet. When the pregnant woman is supine, the uterus falls back to rest on the vertebral column and the adjacent great vessels, especially the inferior vena cava and aorta.

Contractility. From the first trimester onward, the uterus undergoes irregular contractions that are normally painless. In the second trimester, these contractions may be detected by bimanual examination. Because attention was first called to this phenomenon in 1872 by J. Braxton Hicks, the contractions have been known by his name. Such contractions appear unpredictably and sporadically, are usually nonrhythmic, and their intensity varies between approximately 5 and 25 mm Hg (Alvarez and Caldeyro-Barcia, 1950). Until the last month of gestation, *Braxton Hicks contractions* are infrequent, but they increase during the last week or two. At this time, the contractions may occur as often as every 10 to 20 minutes and also may assume some degree of rhythmicity. Late in pregnancy, these contractions may cause some discomfort and account for so-called *false labor* (see [Chap. 17](#), p. 424).

Uteroplacental Blood Flow. The delivery of most substances essential for growth and metabolism of the fetus and placenta, as well as removal of most metabolic wastes, is dependent on adequate perfusion of the placental intervillous space (see [Chap. 3](#), p. 61). Placental perfusion is dependent on total uterine blood flow, which is principally from the uterine and ovarian arteries. Uteroplacental blood flow increases progressively during pregnancy, ranging from approximately 450 to 650 mL/min near term (Edman and associates, 1981; Kauppila and co-workers, 1980).

The results of studies conducted in rats by Page and co-workers (2002) suggest that the uterine veins also undergo significant adaptations during pregnancy. Specifically, remodeling of the uterine veins by numerous factors that include reduced elastin content and adrenergic nerve density results in increased venous caliber and distensibility. Logically, such changes are necessary to accommodate massively increased uteroplacental blood flow.

Assali and co-workers (1968), using electromagnetic flow probes placed directly on a uterine artery, studied the effects of labor on uteroplacental blood flow in sheep and dogs at term. They found that uterine contractions, either spontaneous or induced, caused a decrease in uterine blood flow that was approximately proportional to the intensity of the contraction. They also showed that a tetanic contraction caused a precipitous fall in uterine blood flow. Harbert and associates (1969) made a similar observation in gravid monkeys. Uterine contractions appear to affect fetal circulation much less, and Brar and colleagues (1988) reported no adverse effects on umbilical artery flow.

CONTROL OF UTEROPLACENTAL BLOOD FLOW. The progressive increase in maternal-placental blood flow during gestation occurs principally by means of vasodilation, whereas fetal-placental blood flow is increased by a continuing growth of placental vessels. Palmer and colleagues (1992) showed that uterine artery diameter doubled by 20 weeks and concomitant mean Doppler velocimetry was increased eightfold. It appears likely that vasodilation at this stage of pregnancy is at least in part the consequence of estrogen stimulation. Naden and Rosenfeld (1985) found that 17β -estradiol administration to nonpregnant sheep induced cardiovascular changes similar to those observed in pregnant animals. Using measurements of the uterine artery resistance index, Jauniaux and associates (1994) found that both estradiol and progesterone contributed to the downstream fall in vascular resistance in women with advancing gestational age (see [Chap. 16](#), p. 403).

Other mediators, in addition to estradiol and progesterone, modify vascular resistance during pregnancy, including within the uteroplacental circulation. For example, significant decreases in placental perfusion have been demonstrated in sheep following *catecholamine* infusions (Rosenfeld and co-workers, 1976; Rosenfeld and West, 1977). This response is likely the consequence of greater sensitivity of the uteroplacental vascular bed to epinephrine and norepinephrine when compared with that of the systemic vasculature. In contrast, normal pregnancy is characterized by vascular refractoriness to the pressor effects of *angiotensin II* (see p. 135). This insensitivity serves to increase uteroplacental blood flow (Gant and co-workers, 1973; Rosenfeld and Gant, 1981). *Nitric oxide*, previously termed *endothelium-derived relaxing factor*, is a potent vasodilator released by endothelial cells. It may also have important implications for modifying vascular resistance and, thus, uteroplacental perfusion during pregnancy (Hull and associates, 1994; Seligman and co-workers, 1994). As discussed in [Chapter 34](#) (see p. 769), abnormal synthesis of nitric oxide has been linked to the development of preeclampsia (Savvidou and co-workers, 2003).

Figure 2-10. Vertical section through the uterine end of the right broad ligament.

CERVIX. As early as 1 month after conception, the cervix begins to undergo pronounced softening and cyanosis. These changes result from increased vascularity and edema of the entire cervix, together with hypertrophy and hyperplasia of the cervical glands. Although the cervix contains a small amount of smooth muscle, its major component is connective tissue. Rearrangement of this collagen-rich connective tissue is necessary to permit functions as diverse as maintenance of a pregnancy to term, dilatation to facilitate delivery, and repair following parturition so that a successful pregnancy can be repeated. The complex dynamic changes that occur in the anatomy and physiology of the cervix as gestation advances were reviewed by Ludmir and Sehdev (2000) and are detailed further in [Chapter 6](#).

As shown in [Figure 5-1](#), the glands of the cervix undergo such marked proliferation that by the end of pregnancy they occupy approximately half of the entire cervical mass, rather than a small fraction as in the nonpregnant state. These normal pregnancy-induced changes represent an extension, or eversion, of the proliferating columnar endocervical glands. This tissue tends to be red and velvety and bleeds even with minor trauma, such as with taking Pap smears.

The endocervical mucosal cells produce copious amounts of a tenacious mucus that obstruct the cervical canal soon after conception. As discussed on page 131, this mucus is rich in immunoglobulins and cytokines (Kutteh and Franklin, 2001). At the onset of labor, if not before, this *mucus plug* is expelled, resulting in a *bloody show*. Moreover, the consistency of the cervical mucus changes during pregnancy. In the great majority of pregnant women, cervical mucus, spread and dried on a glass slide, is characterized by crystallization, or *beading*, as a result of progesterone. In some women, arborization of the crystals, or *ferning*, is observed as a result of amniotic fluid leakage (see [Figs. 8-3 and 8-4](#), p. 205).

During pregnancy, basal cells near the squamocolumnar junction are likely to be prominent in size, shape, and staining qualities. These changes are considered to be estrogen induced. Because of these basal cell changes, the frequency of less-than-optimal Pap smears is increased in the pregnant woman (Kost and associates, 1993).

Figure 8-4. Photomicrograph of dried cervical mucus obtained from the cervical canal of a woman pregnant at 32 to 33 weeks. The beaded pattern is characteristic of progesterone action on the endocervical gland mucus composition. (Courtesy of Dr. J. C. Ullery.)

OVARIES. Ovulation ceases during pregnancy and the maturation of new follicles is suspended. Ordinarily, only a single corpus luteum of pregnancy can be found in the ovaries of pregnant women. This most likely functions maximally during the first 6 to 7 weeks of pregnancy (4 to 5 weeks postovulation), and thereafter contributes relatively little to progesterone production. These observations have been confirmed by surgical removal of the corpus luteum before 7 weeks (5 weeks postovulation), which results in a rapid fall in maternal serum progesterone and then spontaneous abortion (Csapo and co-workers, 1973). After this time, however, corpus luteum removal ordinarily does not cause abortion.

A *decidual reaction* on and beneath the surface of the ovaries, similar to that found in the endometrial stroma, is common in pregnancy and may be observed at cesarean delivery. These elevated patches of tissue bleed easily and may, on first glance, resemble freshly torn adhesions. Similar decidual reactions are seen on the posterior uterine serosa and on or within other pelvic or even extrapelvic abdominal organs. Although the ontogeny of such decidual reactions is incompletely understood, Taussig (1906) and others have deduced that these findings likely represent cellular detritus from the endometrium that has passed through the fallopian tubes.

The enormous caliber of the ovarian veins viewed at cesarean delivery is startling. Hodgkinson (1953) found that the diameter of the ovarian vascular pedicle increased during pregnancy from 0.9 cm to approximately 2.6 cm at term.

Relaxin. This protein hormone has structural features that are similar to insulin and insulin-like growth factors I and II. Its major biological action is remodeling of the connective tissue of the reproductive tract, thus allowing accommodation of pregnancy and successful parturition (Weiss and colleagues, 1993). Relaxin is secreted by the corpus luteum, decidua, and placenta in a pattern similar to that of chorionic gonadotropin (hCG). It is also secreted by the heart, and increased levels have been found in association with heart failure (Fisher and co-workers, 2002).

The role of relaxin during human pregnancy is not completely defined, however, it is known to have effects on the biochemical structure of the cervix (Bell and colleagues, 1993). The hormone also affects myometrial contractility, which may be implicated in preterm birth. Increases in peripheral joint laxity during human pregnancy do not correlate with serum relaxin levels (Marnach and co-workers, 2003; Schauburger and colleagues, 1996).

Pregnancy Luteoma. In 1963, Sternberg described a solid ovarian tumor that developed during pregnancy and was composed of large acidophilic luteinized cells. These represented an exaggerated luteinization reaction of the normal ovary. These so-called *luteomas of pregnancy* are variable in size, ranging from microscopic to over 20 cm in diameter (Fig. 5-2). Typical ultrasonographic characteristics include a solid, complex-appearing unilateral or bilateral mass with cystic features that correspond to areas of hemorrhage. It is usually not possible to differentiate luteomas from other solid ovarian neoplasms, such as luteinized thecoma, granulosa cell tumor, or Leydig cell tumor, based on the ultrasound characteristics alone (Choi and associates, 2000). Although luteomas regress after delivery, they may recur in subsequent pregnancies (Shortle and associates, 1987).

Pregnancy luteomas may result in maternal virilization, but usually the female fetus is not affected. This is presumably because of the protective role of the placenta and its high capacity to convert androgens and androgen-like steroids to estrogens (Edman and co-workers, 1979). Occasionally, however, a female fetus can become virilized (Cohen and associates, 1982).

Theca-Lutein Cysts. These benign ovarian lesions result from exaggerated physiological follicle stimulation, which is termed *hyperreactio luteinalis*. The reaction is associated with markedly elevated serum levels of hCG. Although the cellular pattern of hyperreactio luteinalis is similar to that of a luteoma, these usually bilateral cystic ovaries are moderately to massively enlarged. These are found frequently with gestational trophoblastic disease (see Chap. 11, p. 276). They are more likely in

pregnancies associated with a large placenta, for example, diabetes, D-isoimmunization, and multiple fetuses (Tanaka and colleagues, 2001). Theca-lutein cysts have been reported in chronic renal failure as a result of reduced hCG clearance, and in hyperthyroidism as a result of the structural homology between hCG and thyroid-stimulating hormone (Coccia and colleagues, 2003; Gherman and co-workers, 2003). They also are encountered in women with otherwise normal pregnancies but increased hCG concentrations (Bidus and associates, 2002). Their diagnosis and management is discussed in [Chapter 40](#) (see p. 965).

Although usually asymptomatic, hemorrhage into the cysts may cause abdominal pain. In addition, maternal virilization may be seen in up to 25 percent of women (Fouk and associates, 1997). Changes include temporal balding, hirsutism, and clitoromegaly associated with massively elevated levels of androstenedione and testosterone (Bradshaw and co-workers, 1986). The diagnosis typically is based on ultrasonographic findings of bilateral enlarged ovaries containing multiple cysts in the appropriate clinical settings. The condition is self-limited and eventually undergoes spontaneous resolution after delivery. In some women, increased ovarian responsiveness to gonadotropin can be confirmed by several weeks postpartum (Bradshaw and colleagues, 1986).

Figure 5-2. Large luteoma of pregnancy removed at laparotomy postpartum.

FALLOPIAN TUBES. The musculature of the fallopian tubes undergoes little hypertrophy during pregnancy. The epithelium of the tubal mucosa, however, becomes somewhat flattened. Decidual cells may develop in the stroma of the endosalpinx, but a continuous decidual membrane is not formed.

VAGINA AND PERINEUM. During pregnancy, increased vascularity and hyperemia develop in the skin and muscles of the perineum and vulva, with softening of the underlying abundant connective tissue. Increased vascularity prominently affects the vagina and results in the violet color characteristic of the *Chadwick sign*. The vaginal walls undergo striking changes, presumably in preparation for the distention that occurs during labor. These changes include a considerable increase in the thickness of the mucosa, loosening of the connective tissue, and hypertrophy of smooth muscle cells. The papillae of the vaginal mucosa also undergo considerable hypertrophy, creating a fine, hobnailed appearance.

The considerably increased volume of cervical secretions within the vagina during pregnancy consists of a somewhat thick, white discharge. The pH is acidic, varying from 3.5 to 6, the result of increased production of lactic acid from glycogen in the vaginal epithelium by the action of *Lactobacillus acidophilus*.

Histopathology. Early in pregnancy the vaginal epithelial cells are similar to those found during the luteal phase. As pregnancy advances, two patterns of response may be seen:

1. Small intermediate cells, called *navicular cells* by Papanicolaou, are found in abundance in small, dense clusters. These ovoid cells contain a vesicular, somewhat elongated nucleus.
2. Vesicular nuclei without cytoplasm, or so-called *naked nuclei*, are evident along with an abundance of *Lactobacillus*.

SKIN

ABDOMINAL WALL. In the later months of pregnancy, reddish, slightly depressed streaks commonly develop in the skin of the abdomen and sometimes in the skin over the breasts and thighs. These are called *striae gravidarum* or "stretch marks." In multiparous women, in addition to the reddish striae of the present pregnancy, glistening, silvery lines that represent the cicatrices of previous striae frequently are seen.

Occasionally, the muscles of the abdominal walls do not withstand the tension to which they are subjected, and the rectus muscles separate in the midline, creating a *diastasis recti* of varying extent. If severe, a considerable portion of the anterior uterine wall is covered by only a layer of skin, attenuated fascia, and peritoneum.

PIGMENTATION. In many women, the midline of the abdominal skin — *linea alba* — becomes markedly pigmented, assuming a brownish-black color to form the *linea nigra*. Occasionally, irregular brownish patches of varying size appear on the face and neck, giving rise to *chloasma* or *melasma gravidarum*, which is the so-called mask of pregnancy. Pigmentation of the areolae and genital skin may also be accentuated. These pigmentary changes usually disappear, or at least regress considerably, after delivery (see [Chap. 56](#), p. 1250). Oral contraceptives may cause similar pigmentation. Very little is known of the nature of these pigmentary changes, although melanocyte-stimulating hormone, a polypeptide similar to corticotropin, has been shown to be elevated remarkably from the end of the second month of pregnancy until term. Estrogen and progesterone also are reported to have melanocyte-stimulating effects. These conditions are considered in greater detail in [Chapter 56](#).

VASCULAR CHANGES. Angiomas, called *vascular spiders*, develop in about two thirds of white women and approximately 10 percent of black women. These are minute, red elevations on the skin, particularly common on the face, neck, upper chest, and arms, with radicles branching out from a central lesion. The condition is often designated as nevus, angioma, or telangiectasis. *Palmar erythema* is encountered in pregnancy in about two thirds of white women and one third of black women. The two conditions are of no clinical significance and disappear in most women shortly after pregnancy. They are most likely the consequence of the hyperestrogenemia.

BREASTS

In the early weeks of pregnancy, women often experience breast tenderness and tingling. After the second month, the breasts increase in size, and delicate veins become visible just beneath the skin. The nipples become considerably larger, more deeply pigmented, and more erectile. After the first few months, a thick, yellowish fluid $\text{\textcircled{R}}$ — *colostrum* $\text{\textcircled{R}}$ — can often be expressed from the nipples by gentle massage. During the same months, the areolae become broader and more deeply pigmented. Scattered through the areolae are a number of small elevations, the *glands of Montgomery*, which are hypertrophic sebaceous glands. If the increase in size of the breasts is very extensive, striations similar to those observed in the abdomen may develop. Rarely, breast enlargement may become so pathologically extensive $\text{\textcircled{R}}$ — referred to as *gigantomastia* $\text{\textcircled{R}}$ — that it becomes life threatening and often requires surgical intervention (Vidaeff and associates, 2003). Interestingly, prepregnancy breast size and volume of milk production do not correlate (Hyttén, 1995). Histological and functional changes of the breasts induced by pregnancy and lactation are further discussed in [Chapter 30](#) (see p. 699).

METABOLIC CHANGES

In response to the increased demands of the rapidly growing fetus and placenta, the pregnant woman undergoes metabolic changes that are numerous and intense. Certainly no other physiological event in postnatal life induces such profound metabolic alterations. For example, the additional total pregnancy energy demands have been estimated to be as high as 80,000 kcal or about 300 kcal/day (Hyttén and Chamberlain, 1991).

WEIGHT GAIN. Most of the increase in weight during pregnancy is attributable to the uterus and its contents, the breasts, and increases in blood volume and extravascular extracellular fluid. A smaller fraction of the increased weight is the result of metabolic alterations that result in an increase in cellular water and deposition of new fat and protein, so-called *maternal reserves*. Hyttén (1991) reported that the average weight gain during pregnancy is approximately 12.5 kg or 27.5 lb ([Table 5-1](#)). Maternal aspects of weight gain are considered in greater detail in [Chapter 8](#) (see p. 213).

WATER METABOLISM. Increased water retention is a normal physiological alteration of pregnancy. This retention is mediated, at least in part, by a fall in plasma osmolality of approximately 10 mOsm/kg induced by a resetting of osmotic thresholds for thirst and vasopressin secretion (Heenan and colleagues, 2003; Lindheimer and Davison, 1995). As shown in [Figure 5-3](#), this phenomenon is functioning by early pregnancy.

At term, the water content of the fetus, placenta, and amniotic fluid amounts to about 3.5 L. Another 3.0 L accumulates as a result of increases in the maternal blood volume and in the size of the uterus and the breasts. Thus, the minimum amount of extra water that the average woman accrues during normal pregnancy is about 6.5 L. Clearly demonstrable pitting edema of the ankles and legs is seen in most pregnant women, especially at the end of the day. This accumulation of fluid, which may amount to a liter or so, is caused by an increase in venous pressure below the level of the uterus as a consequence of partial occlusion of the vena cava. A decrease in interstitial colloid osmotic pressure induced by normal pregnancy also favors edema late in pregnancy (Iain and co-workers, 1985).

Longitudinal studies of body composition have shown a progressive increase in total body water and fat mass during pregnancy. It has been known for decades that both initial maternal weight and the weight gained during pregnancy are highly associated with birthweight. It is unclear, however, what role maternal fat or water have in fetal growth. Studies in well-nourished term women suggest that maternal body water, rather than fat, contributes more significantly to infant birthweight (Lederman and co-workers, 1999; Mardones-Santander and associates, 1998).

Figure 5-3. Mean values ($\text{\textcircled{R}} \pm \text{SD}$) for plasma osmolality measured at weekly intervals in nine women from preconception to 16 weeks. (LMP = last menstrual period; MP = menstrual period.) (From Davison and colleagues, 1981, with permission.)

PROTEIN METABOLISM. The products of conception, the uterus, and maternal blood are relatively rich in protein rather than fat or carbohydrate. At term, the fetus and placenta together weigh about 4 kg and contain approximately 500 g of protein, or about half of the total pregnancy increase (Hyttén and Leitch, 1971). The remaining 500 g is added to the uterus as contractile protein, to the breasts primarily in the glands, and to the maternal blood as hemoglobin and plasma proteins.

Mojtahedi and associates (2002) measured nitrogen balance in 12 healthy women before pregnancy and again at 12, 23, and 34 weeks. They found that it increased with gestation, suggesting a more efficient use of dietary protein. In addition, urinary excretion of 3-methylhistidine did not change significantly toward term, indicating that breakdown of maternal muscle is not required to meet the demands of growing maternal and fetal tissues. Supporting the concept that pregnancy is associated with nitrogen conservation, Kalhan and colleagues (2003) found that the turnover rate of the nonessential amino acid serine decreases with advancing gestational age. The daily requirements for dietary protein intake during pregnancy are discussed in [Chapter 8](#) (see p. 215).

CARBOHYDRATE METABOLISM. Normal pregnancy is characterized by mild fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia ([Fig. 5-4](#)). The fasting plasma glucose concentration falls somewhat, possibly as a result of the increased plasma levels of insulin observed in pregnancy. This cannot be explained by a decrease in the metabolism of insulin because its half-life during pregnancy is not changed (Lind and associates, 1977).

The increased basal level of plasma insulin in normal pregnancy is associated with several unique responses to glucose

ingestion. For example, after an oral glucose meal, gravid women demonstrate both prolonged hyperglycemia and hyperinsulinemia, with a greater suppression of glucagon (Phelps and associates, 1981). This response is consistent with a pregnancy-induced state of peripheral resistance to insulin, the purpose of which is likely to ensure a sustained postprandial supply of glucose to the fetus. Indeed, it has been estimated that insulin action in late normal pregnancy is 50 to 70 percent lower than that of healthy, nonpregnant women (Butte, 2000).

The mechanism(s) responsible for insulin resistance is not completely understood. Progesterone and estrogen may act, directly or indirectly, to mediate this resistance. Plasma levels of placental lactogen increase with gestation, and this protein hormone is characterized by growth hormone-like action that may result in increased lipolysis with liberation of free fatty acids (Freinkel, 1980). The increased concentration of circulating free fatty acids also may facilitate increased tissue resistance to insulin.

The pregnant woman changes rapidly from a postprandial state characterized by elevated and sustained glucose levels to a fasting state characterized by decreased plasma glucose and amino acids such as alanine. During fasting, the plasma concentrations of free fatty acids, triglycerides, and cholesterol are higher. Freinkel and colleagues (1985) have referred to this pregnancy-induced switch in fuels from glucose to lipids as *accelerated starvation*. Certainly, when fasting is prolonged in the pregnant woman, these alterations are exaggerated and ketonemia rapidly appears.

Figure 5-4. Diurnal changes in plasma glucose and insulin in normal late pregnancy. (From Phelps and colleagues, 1981, with permission.)

FAT METABOLISM. The concentrations of lipids, lipoproteins, and apolipoproteins in plasma increase appreciably during pregnancy. The storage of fat occurs primarily during midpregnancy (Hyttén and Thomson, 1968; Pipe and co-workers, 1979). This fat is deposited mostly in central rather than peripheral sites. Later in pregnancy, as fetal nutritional demands increase remarkably, maternal fat storage decreases. Hyttén and Thomson (1968) cited some evidence that progesterone may act to reset a lipostat in the hypothalamus, and at the end of pregnancy the lipostat returns to its previous nonpregnant level and the added fat is lost. Such a mechanism for energy storage, theoretically at least, might protect the mother and fetus during time of prolonged starvation or hard physical exertion.

Low-density lipoprotein cholesterol (LDL-C) levels peak at approximately week 36, likely the consequence of the hepatic effects of estradiol and progesterone (Desoye and associates, 1987). High-density lipoprotein cholesterol (HDL-C) peaks at week 25, decreases until week 32, and remains constant for the remainder of pregnancy. The initial increase is believed to be caused by estrogen. Brizzi and colleagues (1999) have suggested that changes in the low-density lipoprotein (LDL) pattern during normal pregnancy might be used to identify those women who later in life may be predisposed to atherogenesis.

During the third trimester, average total serum cholesterol, LDL-C, and HDL-C levels are approximately 245 ± 10 mg/dL, 148 ± 5 mg/dL, and 59 ± 3 mg/dL, respectively (Paradisi and associates, 2002). After delivery, the concentrations of these lipids, as well as lipoproteins and apolipoproteins, decrease at different rates. Lactation speeds the rate of decrease of many of these compounds (Darmady and Postle, 1982).

Leptin. This peptide hormone, primarily secreted by adipose tissue, plays a key role in the regulation of body fat and energy expenditure. During pregnancy, maternal serum leptin levels progressively increase, peaking during the second trimester to plateau at term in concentrations three to four times higher than those in nonpregnant women. This increase is only in part due to the weight gain normally associated with pregnancy, because leptin also is produced by the placenta. Indeed, placental weight is significantly related to leptin levels measured in the umbilical cord blood (Pighetti and co-workers, 2003). Recent investigations have analyzed the relationships between serum leptin levels and preeclampsia as well as fetal growth restriction (Chan, 2003; Lepercq, 2003; Pighetti, 2003; Salomon, 2003, and their many associates). This topic is discussed further in [Chapter 38](#) (see p. 895).

ELECTROLYTE AND MINERAL METABOLISM. During normal pregnancy, nearly 1000 mEq of sodium and 300 mEq of potassium are retained (Lindheimer and colleagues, 1987). Although the glomerular filtration of sodium and potassium is increased, the excretion of these electrolytes is unchanged during pregnancy as a result of enhanced tubular resorption (Brown and colleagues, 1986, 1988). Although pregnancy is associated with increased total accumulations of sodium and potassium, the serum concentrations of these electrolytes are decreased slightly as a result of the expanded plasma volume, however, they remain very near the range of normal for nonpregnant women (Kametas and colleagues, 2003b).

Total serum calcium levels decline during pregnancy, the reduction reflecting lowered plasma albumin concentration and, in turn, the consequent decrease in the amount bound to protein. The levels of serum ionized calcium, however, remain unchanged (Power and associates, 1999). The developing fetus imposes a significant demand on maternal calcium homeostasis. During the third trimester, for example, approximately 200 mg of calcium are deposited in the fetal skeleton per day (Pitkin, 1985). Dietary intake of sufficient calcium (see [Table 8-7](#), p. 215), therefore, is necessary to prevent excess depletion from the mother. This has been reported to be especially important in pregnant adolescents, whose own skeletons are still developing (Repke, 1994).

Serum magnesium levels also decline during pregnancy. Bardicéf and colleagues (1995) concluded that pregnancy is actually a state of extracellular magnesium depletion. Compared with nonpregnant women, they found that both total and ionized magnesium were significantly lower during normal pregnancy. On the other hand, serum phosphate levels are within the nonpregnant range (Kametas and colleagues, 2003b). The renal threshold for inorganic phosphate excretion is elevated in pregnancy due to increased calcitonin (Weiss and colleagues, 1998).

With respect to most other minerals, pregnancy induces little change in their metabolism other than their retention in amounts equivalent to those used for growth of fetal and, to a lesser extent, maternal tissues (see [Chap. 4](#), p. 101, and [Chap. 8](#), p. 216). An important exception, however, is the considerably increased requirement for *iron*, which is discussed later.

HEMATOLOGICAL CHANGES

BLOOD VOLUME. The maternal blood volume increases markedly during pregnancy. In studies of normal women, the blood volumes at or very near term averaged about 40 to 45 percent above their nonpregnant levels (Pritchard, 1965; Whittaker and associates, 1996). The degree of expansion varies considerably. In some women only a modest increase occurs, whereas in others the blood volume nearly doubles. A fetus is not essential for the development of hypervolemia during pregnancy, for increases in blood volume have been demonstrated in some women with hydatidiform mole (Pritchard, 1965).

Pregnancy-induced hypervolemia has several important functions:

1. To meet the demands of the enlarged uterus with its greatly hypertrophied vascular system.
2. To protect the mother, and in turn the fetus, against the deleterious effects of impaired venous return in the supine and erect positions.
3. To safeguard the mother against the adverse effects of blood loss associated with parturition.

Maternal blood volume begins to increase during the first trimester. In fact, by 12 menstrual weeks, the plasma volume expands by approximately 15 percent as compared with that of prepregnancy (Bernstein and co-workers, 2001). As shown in [Figure 5-5](#), maternal blood volume expands most rapidly during the second trimester, and then rises at a much slower rate during the third trimester to plateau during the last several weeks of pregnancy.

Blood volume expansion results from an increase in both plasma and erythrocytes. Although more plasma than erythrocytes is usually added to the maternal circulation, the increase in the volume of erythrocytes is considerable, averaging about 450 mL (Pritchard and Adams, 1960). Moderate erythroid hyperplasia is present in the bone marrow, and the reticulocyte count is elevated slightly during normal pregnancy. As discussed in [Chapter 51](#) (see p. 1144), this change is almost certainly related to the increase in maternal plasma erythropoietin levels, which peak early during the third trimester and correspond to maximal erythrocyte production (Clapp and colleagues, 2003; Harstad and co-workers, 1992).

Hemoglobin Concentration and Hematocrit. In spite of augmented erythropoiesis, hemoglobin concentration and the hematocrit decrease slightly during normal pregnancy. As a result, whole blood viscosity decreases (Huisman and colleagues, 1987). Hemoglobin concentration at term averages 12.5 g/dL and in 6 percent of women it is below 11.0 g/dL (see [Fig. 51-1](#) and [Table 51-1](#)). Thus, in most women, a hemoglobin concentration below 11.0 g/dL, especially late in pregnancy, should be considered abnormal and usually due to iron deficiency rather than to hypervolemia of pregnancy.

Figure 5-5. Changes in total blood volume and its components (plasma and red cell volumes) during pregnancy and postpartum. (From Peck and Arias, 1979, with permission.)

Figure 51-1. Mean hemoglobin concentrations (●—●) and 5th and 95th (○—○) percentiles for healthy pregnant women taking iron supplements. (Data from Centers for Disease Control and Prevention, 1989.)

IRON METABOLISM

Iron Stores. The total iron content of normal adult women ranges from 2.0 to 2.5 g or about half the amount found normally in men. Moreover, the iron stores of normal young women are only about 300 mg (Pritchard and Mason, 1964).

Iron Requirements. The iron requirements of normal pregnancy total approximately 1000 mg. About 300 mg are actively transferred to the fetus and placenta, and about 200 mg are lost through various normal routes of excretion, primarily the gastrointestinal tract. These are obligatory losses and occur even when the mother is iron deficient. The average increase in the total volume of circulating erythrocytes—about 450 mL during pregnancy when iron is available—uses another 500 mg of iron, because 1 mL of normal erythrocytes contains 1.1 mg of iron. Practically all of the iron for these purposes is used during the latter half of pregnancy. Therefore, the iron requirement becomes quite large during the second half of pregnancy, averaging 6 to 7 mg/day (Pritchard and Scott, 1970). Because this amount is not available from body stores in most women, the desired increase in maternal erythrocyte volume and hemoglobin mass will not develop unless exogenous iron is made available in adequate amounts. In the absence of supplemental iron, the hemoglobin concentration and hematocrit fall appreciably as the maternal blood volume increases. Hemoglobin production in the fetus, however, is not impaired, because the placenta obtains iron from the mother even when the mother has severe iron deficiency anemia.

The amount of iron absorbed from diet, together with that mobilized from stores, is usually insufficient to meet the maternal demands imposed by pregnancy. If the nonanemic pregnant woman is not given supplemental iron, serum iron and ferritin concentrations decline during the second half of pregnancy ([Fig. 5-6](#)). The somewhat unexpected early pregnancy increases in serum iron and ferritin (see [Fig. 5-6](#)) are thought to be due to minimal iron demands during the first

trimester as well as to a positive iron balance because of amenorrhoea.

Blood Loss. Generally, not all the iron added to the maternal circulation in the form of hemoglobin is lost from the mother. During normal vaginal delivery and through the next few days, only about half of the erythrocytes added to the maternal circulation are lost from the majority of women. These losses are by way of bleeding from the placental implantation site, the episiotomy or lacerations, and in the lochia. On the average, an amount of maternal erythrocytes corresponding to about 500 to 600 mL of predelivery blood is lost during and after vaginal delivery of a single fetus (Pritchard, 1965; Ueland, 1976). The average blood loss associated with cesarean delivery or with the vaginal delivery of twins is about 1000 mL.

Figure 5-6. Indices of iron turnover during pregnancy in women without overt anemia but who were not given iron supplementation. (From Kaneshige, 1981, with permission.)

IMMUNOLOGICAL AND LEUKOCYTE FUNCTIONS. As discussed in [Chapter 3](#) (see p. 64), pregnancy has been assumed to be associated with suppression of a variety of humoral and cell-mediated immunological functions in order to accommodate the "foreign" semiallogeneic fetal graft (Thellin and Heinen, 2003). One important mechanism appears to involve the suppression of T-helper (Th) 1 and T-cytotoxic (Tc) 1 cells, which decreases secretion of interleukin (IL)-2, interferon- γ , and tumor necrosis factor- β . In addition, interferon- α , which is present in almost all fetal tissues and fluids, is most often absent in normally pregnant women (Chard and co-workers, 1986). Moreover, some polymorphonuclear leukocyte chemotaxis and adherence functions are depressed beginning in the second trimester and continuing throughout pregnancy (Krause and associates, 1987). Although this phenomenon is incompletely understood, it may be related, in part, to the recent finding that relaxin impairs neutrophil activation (Masini and co-workers, 2004). It is possible that these depressed leukocyte functions of pregnant women account in part for the improvement observed in some women with autoimmune diseases and the possibly increased susceptibility to certain infections.

Not all aspects of immunological function, however, are depressed. For example, there is upregulation of Th2 cells to increase secretion of IL-4, IL-6, and IL-13 (Michimata and colleagues, 2003). In cervical mucus, peak levels of immunoglobulins A and G (IgA and IgG) are significantly higher during pregnancy compared with normally menstruating women. Similarly, the amount of interleukin-1 β found in cervical mucus during pregnancy is approximately 10-fold greater than in the nonpregnant state. Because oral contraceptives have been shown to induce similar changes, Kutteh and Franklin (2001) hypothesized that these immunological changes may be a result of increased estrogen and progesterone. Although such enhanced local reproductive tract immunity may be important for protecting the fetus, the actual clinical significance of these observations is as yet unclear.

The leukocyte count varies considerably during normal pregnancy. Usually it ranges from 5000 to 12,000/ μ L. During labor and the early puerperium it may become markedly elevated, attaining levels of 25,000/ μ L or even more, however, it averages 14,000 to 16,000/ μ L (Taylor and co-workers, 1981). The cause for the marked increase is not known, but the same response occurs during and after strenuous exercise. It probably represents the reappearance of leukocytes previously shunted out of the active circulation.

In addition to normal variations in the leukocyte count, the distribution of cell types is altered significantly during pregnancy. Specifically, during the third trimester, the percentages of granulocytes and CD8 T lymphocytes are significantly increased along with a concomitant reduction in the percentages of CD4 T lymphocytes and monocytes. Moreover, circulating leukocytes undergo significant phenotypic changes including, for example, the upregulation of certain adhesion molecules (Luppi and associates, 2002).

Beginning quite early in pregnancy, the activity of *leukocyte alkaline phosphatase* is increased. Such elevated activity is not peculiar to pregnancy but occurs in a wide variety of conditions, including most inflammatory states. The concentration of *C-reactive protein*, an acute-phase serum reactant, rises rapidly to 1000-fold in response to tissue trauma or inflammation. Watts and colleagues (1991) measured C-reactive protein sequentially during 81 normal pregnancies to establish normative values. Median C-reactive protein values during pregnancy were higher than values for nonpregnant women, and these values were elevated further in labor. In women not in labor, 95 percent of values were 1.5 mg/dL or less, and gestational age did not affect serum levels. Another marker of inflammation, the *erythrocyte sedimentation rate (ESR)*, is increased in normal pregnancy because of elevated plasma globulins and fibrinogen (Hytten and Leitch, 1971). Thus, this test cannot be used to reliably diagnose inflammation during pregnancy. *Complement factors C3* and *C4* also are significantly elevated during the second and third trimesters of pregnancy (Gallery and colleagues, 1981).

COAGULATION. In normal pregnancy, the coagulation cascade is in an activated state (Baker and Cunningham, 1999). Evidence of activation includes increased concentrations of all clotting factors, except factors XI and XIII, with increased levels of high-molecular-weight fibrinogen complexes. Considering the substantive physiological increase in plasma volume in normal pregnancy, such increased concentrations represent a markedly augmented production of these procoagulants. For example, plasma fibrinogen (factor I) in normal nonpregnant women averages about 300 mg/dL and ranges from about 200 to 400 mg/dL. During normal pregnancy, fibrinogen concentration increases about 50 percent to average about 450 mg/dL late in pregnancy, with a range from 300 to 600 mg/dL. The percentage of high-molecular-weight fibrinogen is unchanged (Manten and colleagues, 2004). This contributes greatly to the striking increase in the *erythrocyte sedimentation rate*.

High-molecular-weight soluble fibrin-fibrinogen complexes circulate in normal pregnancy, and d-dimer serum concentrations increase with gestational age (Lee and associates, 1996; Nolan and colleagues, 1993). The clotting times of whole blood, however, do not differ significantly in normal pregnant women. Some of the pregnancy-induced changes in the levels of coagulation factors can be duplicated by the administration of estrogen plus progestin contraceptive tablets to nonpregnant women.

Normal pregnancy also involves changes in platelets (Baker and Cunningham, 1999). In a study of almost 7000 healthy

women at term, Boehlen and associates (2000) found that the average platelet count was decreased slightly during pregnancy to 213,000/ μ L compared with 250,000/ μ L in nonpregnant control women. They defined thrombocytopenia as below the 2.5th percentile, which was 116,000/mL. During normal pregnancy, platelet width and volume increase. Decreased platelet concentrations are partially due to the effects of hemodilution, but they also likely represent increased platelet consumption, leading to a greater proportion of younger, and therefore, larger platelets (Tygart and co-workers, 1986). Further supporting this concept, Hayashi and associates (2002) found that, beginning in midpregnancy, production of thromboxane A₂, which induces platelet aggregation, progressively increases.

The end product of the coagulation cascade is fibrin formation, and the main function of the fibrinolytic system is to remove excess fibrin. The inactive precursor plasminogen is activated by plasminogen activators, which are serine proteases that convert plasminogen into plasmin. Their activity is balanced by specific plasma-activator inhibitors present in plasma and platelets. Plasmin activity causes fibrinolysis and produces fibrin degradation products such as d-dimers. Studies of the fibrinolytic system in pregnancy have produced conflicting results, although the majority of evidence suggests that fibrinolytic activity is actually reduced in normal pregnancy, likely related to increased concentrations of plasminogen-activator inhibitors (Baker and Cunningham, 1999; Koh and co-authors, 1993).

Regulatory Proteins. There are a number of natural inhibitors of coagulation, including protein C, protein S, and antithrombin. Inherited or acquired deficiencies of these and other natural regulatory proteins, collectively referred to as thrombophilias, account for more than half of all thromboembolic episodes during pregnancy (Lockwood, 2002). These are discussed in detail in [Chapter 47](#) (see p. 1074).

Activated protein C, along with the co-factors protein S and factor V, functions as an anticoagulant by neutralizing the procoagulants factor Va and factor VIIIa (see [Fig. 47-1](#), p. 1075). As normal pregnancy advances, protein C levels remain unchanged. At the same time, resistance to activated protein C increases progressively and is related to a concomitant decrease in free protein S and increase in factor VIII. Specifically, between the first and third trimesters, the levels of activated protein C decrease from about 2.4 to 1.9 U/mL, and free protein S decreases from 0.4 to 0.16 U/mL (Walker and colleagues, 1997). Oral contraceptives also decrease free protein S levels, leading to speculation that the decrease is hormonally mediated. The discovery that the *factor V Leiden mutation* causes resistance to activated protein C has introduced new variables into thrombophilias. In affected women, measurement of this resistance during pregnancy is difficult and DNA testing is recommended.

Levels of *antithrombin* remain relatively constant throughout gestation and the early puerperium (Delorme and associates, 1992).

Figure 47-1. Overview of the inherited thrombophilias and their effect(s) on the coagulation cascade. (Adapted from Seligsohn and Lubetsky, 2001.)

CARDIOVASCULAR SYSTEM

During pregnancy and the puerperium, the heart and circulation undergo remarkable physiological adaptations. The most important changes in cardiac function occur in the first 8 weeks of pregnancy (McLaughlin and Roberts, 1999). Cardiac output is increased as early as the fifth week of pregnancy, and this initial increase is a function of reduced systemic vascular resistance and an increase in heart rate. Between weeks 10 and 20, notable increases in plasma volume occur such that preload is increased. Ventricular performance during pregnancy is influenced by both the decrease in systemic vascular resistance and changes in pulsatile arterial flow. Vascular capacity increases, in part, because of an increase in vascular compliance. As discussed in the following section, multiple factors contribute to these changes in overall hemodynamic function, allowing the cardiovascular system to adjust to the physiological demands of the fetus while maintaining maternal cardiovascular integrity. These changes during the last half of pregnancy are graphically summarized in [Figure 5-7](#), which also shows the important effects of maternal posture on hemodynamic events during pregnancy.

Figure 5-7. Effect of maternal posture on hemodynamics. PP = postpartum. (From Ueland and Metcalfe, 1975, with permission.)

HEART. The resting pulse rate increases about 10 beats/min during pregnancy (Stein and co-workers, 1999). As the diaphragm becomes progressively elevated, the heart is displaced to the left and upward, while at the same time it is rotated somewhat on its long axis. As a result, the apex of the heart is moved somewhat laterally from its position in the normal nonpregnant state, and an increase in the size of the cardiac silhouette is found in radiographs ([Fig. 5-8](#)). The extent of these changes is influenced by the size and position of the uterus, tone of the abdominal muscles, and configurations of the abdomen and thorax. Furthermore, pregnant women normally have some degree of benign pericardial effusion, which may increase the cardiac silhouette (Enein and colleagues, 1987). Variability of these factors makes it difficult to identify precisely moderate degrees of cardiomegaly by simple radiographic studies. Normal pregnancy induces no characteristic electrocardiographic changes other than slight left-axis deviation as a result of the altered heart position.

Some cardiac sounds may be altered during pregnancy. Cutforth and MacDonald (1966) obtained phonocardiograms at varying

stages of pregnancy in 50 normal women. They documented an exaggerated splitting of the first heart sound with increased loudness of both components; no definite changes in the aortic and pulmonary elements of the second sound; and a loud, easily heard third sound. They heard a systolic murmur in 90 percent of pregnant women that was intensified during inspiration in some or expiration in others, and disappeared very shortly after delivery; a soft diastolic murmur transiently in 20 percent; and continuous murmurs arising from the breast vasculature in 10 percent.

Left ventricular size is increased as a result of eccentric enlargement that increases radius-to-wall thickness, and thus end-diastolic dimension (Dukekot and colleagues, 1993). Markedly attenuated afterload manifested by diminished vascular resistance and mean arterial pressure allows the appreciable increase in cardiac output. Because changes in stroke volume are directly proportional to end-diastolic volume, the implication is that the inotropic state of the myocardium changes little during normal pregnancy (Katz and co-workers, 1978). Moreover, Sadaniantz and associates (1996) reported that these changes are not cumulative with subsequent pregnancies. In multifetal pregnancies, compared with singletons, maternal cardiac output is greater by approximately 20 percent because of a greater stroke volume (15 percent) and heart rate (3.5 percent). In addition, left atrial diameter and left ventricular end-diastolic diameter are greater, reflecting the increase in preload (Kametas and co-authors, 2003a). The increased heart rate and inotropic contractility imply that cardiovascular reserve is reduced.

The sustained cardiac changes during pregnancy are similar to acute changes reported for moderate to strenuous exercise. Veille and colleagues (2001) examined the effects of exercise on a stationary bicycle during pregnancy on left-ventricular diastolic filling. As predicted, exercise-induced tachycardia resulted in decreased ventricular filling time. Interestingly, exercise also was found to be associated with decreased left-ventricular compliance. Although the exact mechanism causing reduced compliance is not known, it may relate to left ventricular wall thickening in response to increased plasma volume.

Cardiac Output. During normal pregnancy, arterial blood pressure and vascular resistance decrease while blood volume, maternal weight, and basal metabolic rate increase. Each of these events would be expected to affect cardiac output. It is now evident that cardiac output *at rest*, when measured in the lateral recumbent position, increases significantly beginning in early pregnancy (Dukekot and colleagues, 1993; Mabie and co-workers, 1994). It continues to increase and remains elevated during the remainder of pregnancy (Fig. 5-9). Typically, cardiac output in late pregnancy is appreciably higher when the woman is in the lateral recumbent position than when she is supine, because in the supine position the large uterus often impedes cardiac venous return. Bamber and Dresner (2003), for example, found cardiac output at term to increase 1200 mL/min—almost 20 percent—when the pregnant woman was moved from her back onto her left side. When she assumes the standing position after sitting, cardiac output falls to the same degree as in the nonpregnant woman (Easterling and associates, 1988).

During the first stage of labor, cardiac output increases moderately, and during the second stage, with vigorous expulsive efforts, it is appreciably greater (see Fig. 5-9). Most of the pregnancy-induced increase is lost very soon after delivery.

Hemodynamic Function in Late Pregnancy. To further elucidate the net changes of normal pregnancy-induced cardiovascular changes, Clark and colleagues (1989) conducted invasive studies to measure hemodynamic function late in pregnancy (Table 5-2). Right heart catheterization was performed in 10 healthy nulliparous women at 35 to 38 weeks, and again at 11 to 13 weeks postpartum. Late pregnancy was associated with the expected increases in heart rate, stroke volume, and cardiac output. Systemic vascular and pulmonary vascular resistance both decreased significantly, as did colloid osmotic pressure. Pulmonary capillary wedge pressure and central venous pressure did not change appreciably between late pregnancy and the puerperium. Thus, as shown in Figure 5-10, although cardiac output is increased, left ventricular function as measured by stroke work index remains similar to the nonpregnant normal range. Put another way, normal pregnancy is not a continuous "high-output" state.

Figure 5-8. Change in cardiac outline that occurs in pregnancy. The colored lines represent the relations between the heart and thorax in the nonpregnant woman, and the black lines represent the conditions existing in pregnancy. These findings are based on radiographic findings in 33 women. (From Klafen and Palugyay, 1927, with permission.)

Figure 5-9. Cardiac output during three stages of gestation, labor, and immediately postpartum compared with values of nonpregnant women. All values were determined with women in the lateral recumbent position. (Adapted from Ueland and Metcalfe, 1975, with permission.)

Figure 5-10. Relationship between left ventricular stroke work index (LVSWI) (cardiac output) and pulmonary capillary wedge pressure (PCWP) in 10 normal pregnant women in the third trimester. (From Hauth and Cunningham, 1999, with permission.)

CIRCULATION AND BLOOD PRESSURE. The posture of the pregnant woman affects arterial blood pressure. Blood pressure in the brachial artery differs when sitting or lying in the lateral recumbent supine position (Bamber and Dresner, 2003). Usually, arterial blood pressure decreases to a nadir at about midpregnancy and rises thereafter. Diastolic pressure decreases more than systolic (Fig. 5-11).

The antecubital *venous pressure* remains unchanged during pregnancy, but in the supine position the femoral venous pressure rises steadily, from 8 cm H₂O early in pregnancy to 24 cm H₂O at term. Employing radiolabeled tracers, Wright and co-workers (1950) demonstrated that blood flow in the legs is retarded during pregnancy except when the lateral recumbent position is assumed. This tendency toward stagnation of blood in the lower extremities during the latter part of pregnancy is attributable to the occlusion of the pelvic veins and inferior vena cava by the enlarged uterus. The elevated venous pressure returns to normal when the pregnant woman lies on her side and immediately after delivery (McLennan, 1943). From a clinical viewpoint, the retarded blood flow and increased lower extremity venous pressure are of great importance. These alterations contribute to the dependent edema frequently experienced by women as they approach term, and to the development of varicose veins in the legs and vulva, as well as hemorrhoids. They also predispose to deep-vein thrombosis, as discussed in [Chapter 47](#) (see p. 1079).

Supine Hypotension. In late pregnancy with the woman in the supine position, the large pregnant uterus rather consistently compresses the venous system that returns blood from the lower half of the body. The results are that cardiac filling may be reduced and cardiac output decreased. In about 10 percent of women, this causes significant arterial hypotension, sometimes referred to as the *supine hypotensive syndrome* (Kinsella and Lohmann, 1994). Moreover, in the supine position, the large pregnant uterus also may compress the aorta sufficiently to lower arterial blood pressure below the level of compression (Bieniarz and associates, 1968). Thus, when the pregnant woman is supine, uterine arterial pressure is significantly lower than that in the brachial artery. In the presence of systemic hypotension, as occurs with spinal analgesia, the decrease in uterine arterial pressure is even more marked than in arteries above the level of aortic compression (see [Chap. 19](#), p. 480).

Renin, Angiotensin II, and Plasma Volume. The renin-angiotensin-aldosterone axis is intimately involved in renal control of blood pressure via salt and water balance. All components of this system are increased in normal pregnancy (Gallery and Lindheimer, 1999). Renin is produced by both the maternal kidney and the uteroplacental unit, and increased renin substrate (angiotensinogen) is produced by both maternal and fetal liver. This increase in angiotensinogen results, in part, from high levels of estrogen production during normal pregnancy. August and colleagues (1995) provided data from first-trimester pregnancies and showed that stimulation of the renin-angiotensin system is important in early blood pressure maintenance.

Gant and associates (1973) conducted a prospective study of vascular reactivity to angiotensin II throughout pregnancy. Normal nulliparas who remained normotensive were refractory to the pressor effects of infused angiotensin II. Conversely, those destined to become hypertensive lost this refractoriness. Later, Gant and co-workers (1974) and Cunningham and associates (1975) found that the increased refractoriness to angiotensin II characteristic of normal pregnancy is likely the consequence of individual vessel refractoriness to angiotensin II. That is, in the woman destined to develop preeclampsia, or in the woman already acutely ill with preeclampsia, the increased sensitivity to angiotensin II is the result of an alteration in vessel wall refractoriness rather than the consequence of changes in blood volume or circulating renin-angiotensin levels.

Cardiac Natriuretic Peptides. These include *atrial natriuretic peptide (ANP)* and *B-type natriuretic peptides (BNP)*, which are produced and secreted by cardiomyocytes. In response to stretch of the atrial wall, these peptides are secreted and regulate blood volume by producing significant natriuresis and diuresis. They also promote vasculature smooth muscle relaxation (Clerico and Emdin, 2004). Recently, BNP has been evaluated as a marker for depressed left ventricular systolic function (Heidenreich and associates, 2004).

When the effects of dietary sodium intake and posture are taken into account, plasma levels of ANP during normal gestation are maintained in the nonpregnant range despite the increased plasma volume (Lowe and co-workers, 1992). This physiological adaptation may be important in allowing the expansion of the extracellular fluid volume and the increase in plasma aldosterone concentrations characteristic of normal pregnancy. Moreover, Thomsen and colleagues (1994) investigated 10 healthy primigravid twin pregnancies and reported that all ANP levels were even lower in twin than in singleton pregnancies. These observations may serve to explain in part the relatively increased plasma volume characteristic of women with twins compared with those with singleton fetuses.

C-type natriuretic peptide (CNP) is predominantly secreted by noncardiac tissues. Walther and Stepan (2004) have provided a detailed review of its role during pregnancy. Among its diverse biological functions, the peptide appears to be a major regulator of bone growth in the fetus.

Prostaglandins. Increased production of prostaglandins in normal pregnancy may well play a central role in control of vascular tone, blood pressure, and sodium balance (Gallery and Lindheimer, 1999). Prostaglandin E₂ synthesis in the renal medulla is increased markedly in late pregnancy and is presumed to be natriuretic. Prostacyclin (PGI₂), the principal prostaglandin of endothelium, also is increased in late pregnancy and functions in regulation of blood pressure as well as coagulation. PGI₂ also has been implicated to be a factor in the angiotensin resistance characteristic of normal pregnancy (Friedman, 1988). The ratio of PGI₂ to thromboxane in maternal urine and blood has been considered an important feature in the pathogenesis of preeclampsia (see [Chap. 34](#), p. 769).

Progesterone. The prostaglandin-mediated vascular responsiveness to angiotensin II may be progesterone related. Normally, pregnant women lose their acquired vascular refractoriness to angiotensin II within 15 to 30 minutes after the placenta is delivered. Interestingly, large amounts of intramuscular progesterone, given during late labor, delay this loss. Conversely, intravenously administered progesterone does not restore angiotensin II refractoriness to women with gestational hypertension, however, the infusion of a major progesterone metabolite $\text{5}\alpha\text{-dihydroprogesterone}$ does.

Endothelin. Endothelin-1 is produced in endothelial cells and vascular smooth muscle and is a potent vasoconstrictor that regulates local vasomotor tone (Levin, 1995). Its production is stimulated by angiotensin II, arginine vasopressin, and thrombin. Endothelins, in turn, stimulate secretion of ANP, aldosterone, and catecholamines. As discussed in [Chapter 6](#) (see p. 175), endothelin receptors are present in pregnant and nonpregnant myometrium, and endothelins also have been identified in the amnion, amniotic fluid, decidua, and placental tissue (Kubota and colleagues, 1992; Sagawa and associates, 1994). They likely play an important role in maintaining vascular tone during pregnancy (Ajne and associates, 2003).

Blood Flow in Skin. Increased cutaneous blood flow in pregnancy serves to dissipate excess heat generated by increased metabolism (see [Chap. 56](#), p. 1250).

Figure 5-11. Sequential changes ($\bar{x} \pm \text{SEM}$) in blood pressure throughout pregnancy in 69 women in supine (*solid line*) and left lateral recumbent (LLR) positions (*dashed line*). (Adapted from Wilson and colleagues, 1980, with permission.)

RESPIRATORY TRACT

The diaphragm rises about 4 cm during pregnancy (see [Fig. 5-8](#)). The subcostal angle widens appreciably as the transverse diameter of the thoracic cage increases about 2 cm. The thoracic circumference increases about 6 cm, but not sufficiently to prevent a reduction in the residual volume of air in the lungs created by the elevated diaphragm. Diaphragmatic excursion is actually greater during pregnancy than when nonpregnant.

PULMONARY FUNCTION. The respiratory rate is little changed during pregnancy, but the *tidal volume*, *minute ventilatory volume*, and *minute oxygen uptake* increase significantly as pregnancy advances. The *maximum breathing capacity* and *forced or timed vital capacity* are not altered appreciably. The *functional residual capacity* and the *residual volume* of air are decreased as a consequence of the elevated diaphragm ([Fig. 5-12](#)). *Lung compliance* is unaffected by pregnancy. *Airway conductance* is increased and *total pulmonary resistance* is reduced, possibly as a result of progesterone action. The *critical closing volume*, or the lung volume at which airways in the dependent parts of the lung begin to close during expiration, has been considered to be higher in pregnancy by some investigators, but not by others (DeSwiet, 1991). The increased oxygen requirements and perhaps the increased critical closing volume imposed by pregnancy tend to make respiratory diseases more serious during gestation (see [Chap. 46](#), p. 1056).

At any stage of normal pregnancy, the amount of oxygen delivered into the lungs by the increase in tidal volume clearly exceeds the oxygen need imposed by pregnancy. Moreover, the amount of hemoglobin in the circulation, and in turn the total oxygen-carrying capacity, increases appreciably during normal pregnancy, as does cardiac output. As a consequence, the *maternal arteriovenous oxygen difference* is decreased.

Hankins and colleagues (1999) used pulmonary and radial artery catheters to measure oxygen transport in 10 normal women between 36 and 38 weeks and again 12 weeks postpartum. The oxygen content of arterial blood was significantly lower in the third trimester than in the postpartum period \bar{x} — 12 versus 16 mL/dL, respectively. Although cardiac output was significantly increased consistent with normal pregnancy, its effects on oxygen delivery were negated by a substantially lower hemoglobin content. Thus, the relative or so-called physiological anemia of pregnancy accounted for the lower arterial oxygen content.

McAuliffe and associates (2002) compared pulmonary function in 140 healthy women with singleton pregnancies, 68 women with twins, and 22 women who were not pregnant. No significant differences in respiratory function were observed between the women with twin versus singleton gestations. Compared with nonpregnant women, however, functional reserve capacity and expiratory reserve volume during the third trimester were lower by about 20 and 30 percent, respectively. Moreover, minute ventilation was increased by approximately 30 percent, and this was demonstrable as early as the first trimester.

Figure 5-12. Respiratory changes during pregnancy. (Reproduced from Bonica, 1967, with permission.)

ACID-BASE EQUILIBRIUM. An increased awareness of a desire to breathe is common even early in pregnancy (Milne and colleagues, 1978). This may be interpreted as dyspnea, which in turn suggests pulmonary or cardiac abnormalities when none exist. The mechanism of physiological dyspnea is thought to be increased tidal volume that lowers the blood Pco_2 slightly, which paradoxically causes dyspnea. The increased respiratory effort, and in turn the reduction in Pco_2 , during pregnancy is most likely induced in large part by progesterone and to a lesser degree by estrogen. The site of progestin action appears to be central through a direct stimulatory effect on the respiratory center.

To compensate for the resulting respiratory alkalosis, plasma bicarbonate levels decrease from 26 to about 22 mmol/L. As a result, blood pH is increased only minimally. This increase shifts the oxygen dissociation curve to the left and increases the affinity of maternal hemoglobin for oxygen \bar{x} — the *Bohr effect* \bar{x} — thereby decreasing the oxygen-releasing capacity of maternal blood. Thus, the hyperventilation that results in a reduced maternal Pco_2 facilitates transport of carbon dioxide from the fetus to the mother but *appears to impair* release of oxygen from maternal blood to the fetus. The increase in blood pH, however, although minimal, stimulates an increase in 2,3-diphosphoglycerate in maternal erythrocytes (Tsai and de Leeuw, 1982). This counteracts the Bohr effect by shifting the oxygen dissociation curve back to the right, facilitating oxygen release to the fetus.

URINARY SYSTEM

KIDNEY. A remarkable number of changes are observed in the urinary system as a result of pregnancy ([Table 5-3](#)). *Kidney size* increases slightly during pregnancy. Bailey and Rolleston (1971), for example, found that the kidney was 1.5 cm

longer during the early puerperium than when measured 6 months later using radiographs. The *glomerular filtration rate* and *renal plasma flow* increase early in pregnancy, the former as much as 50 percent by the beginning of the second trimester, and the latter even greater (Lindheimer and co-workers, 2001). Experiments in animals suggest that both relaxin and neuronal nitric oxide synthase may be important for mediating the increased glomerular filtration and plasma flow during pregnancy (Abram and colleagues, 2001; Novak and associates, 2001). As shown in [Figure 5-13](#), elevated glomerular filtration persists until term, even though renal plasma flow decreases during late pregnancy.

Kallikrein, a tissue protease synthesized in cells of the distal renal tubule, is increased in several conditions associated with increased glomerular perfusion in nonpregnant individuals. Platts and colleagues (2000) studied urinary kallikrein excretion rates during human pregnancy and found increased excretion at 18 and 34 weeks, which returned to nonpregnant levels at term. The significance of these fluctuations remains unknown.

As with blood pressure, maternal posture may have a considerable influence on several aspects of renal function. Late in pregnancy, for instance, urinary flow and sodium excretion average less than half the excretion rate in the supine position compared with that in the lateral recumbent position. The impact of posture on glomerular filtration and renal plasma flow is much more variable.

Loss of Nutrients. One unusual feature of the pregnancy-induced changes in renal excretion is the remarkably increased amounts of various nutrients in the urine. Amino acids and water-soluble vitamins are lost in the urine of pregnant women in much greater amounts than in nonpregnant women (Hyttén, 1973; Powers and associates, 2004).

Tests of Renal Function. The physiological changes in renal hemodynamics induced during normal pregnancy have several implications for the interpretation of tests of renal function. *Serum creatinine* and *urea nitrogen* levels decrease from a mean of 0.7 and 1.2 mg/dL to 0.5 and 0.9 mg/dL, respectively, whereas values of 0.9 and 1.4 mg/dL suggest underlying renal disease and should prompt further evaluation (Lindheimer and associates, 2000). *Creatinine clearance* in pregnancy should be 30 percent higher than the 100 to 115 mL/min normally measured in nonpregnant women (Lindheimer and associates, 2000).

Creatinine clearance is a useful test to estimate renal function in pregnancy provided that complete urine collection is made during an accurately timed period. Incomplete urine concentration tests may give misleading results (Davison and colleagues, 1981). During the day, pregnant women tend to accumulate water in the form of dependent edema, and at night, while recumbent, they mobilize this fluid and excrete it via the kidneys. This reversal of the usual nonpregnant diurnal pattern of urinary flow causes nocturia, and the urine is more dilute than in the nonpregnant state. Failure of a pregnant woman to excrete concentrated urine after withholding fluids for approximately 18 hours does not signify renal damage. In fact, the kidney in these circumstances functions perfectly normally by excreting mobilized extracellular fluid of relatively low osmolality.

Urinalysis. *Glucosuria* during pregnancy is not necessarily abnormal. The appreciable increase in glomerular filtration, together with impaired tubular reabsorptive capacity for filtered glucose, accounts in most cases for glucosuria (Davison and Hyttén, 1974). Chesley (1963) calculated that for these reasons alone, about one sixth of all pregnant women should spill glucose in the urine. Even though glucosuria is common during pregnancy, the possibility of diabetes mellitus should not be ignored when it is identified.

Proteinuria normally is not evident during pregnancy except occasionally in slight amounts during or soon after vigorous labor. Higby and associates (1994) measured protein excretion in 270 normal women throughout pregnancy. Their mean 24-hour excretion was 115 mg, and the upper 95-percent confidence limit was 260 mg/day without significant differences by trimester ([Fig. 5-14](#)). These authors also showed that albumin excretion is minimal and ranges from 5 to 30 mg/day. Nomograms for urinary microalbumin and creatinine ratios during uncomplicated pregnancies have been developed by Waugh and co-workers (2003).

Hematuria, if not the result of contamination during collection, most often suggests a diagnosis of urinary tract disease (see [Chap. 48](#), p. 1093). Difficult labor and delivery, of course, can cause hematuria because of trauma to the lower urinary tract.

Figure 5-14. Scatter plot of all patients showing 24-hour urinary total protein excretion by gestational age. Mean and 95-percent confidence limits are outlined. (From Higby and colleagues, 1994, with permission.)

URETERS. After the uterus rises completely out of the pelvis, it rests upon the ureters, laterally displacing and compressing them at the pelvic brim. Increased intraureteral tonus above this level compared with that of the pelvic portion of the ureter has been identified (Rubi and Sala, 1968). Schulman and Herlinger (1975) found ureteral dilatation to be greater on the right side in 86 percent of pregnant women studied ([Fig. 5-15](#)). The unequal degrees of dilatation may result from a cushioning provided the left ureter by the sigmoid colon and perhaps from greater compression of the right ureter as the consequence of dextrorotation of the uterus. The right ovarian vein complex, which is remarkably dilated during pregnancy, lies obliquely over the right ureter and may contribute significantly to right ureteral dilatation.

Another possible mechanism causing hydronephrosis is from an effect of progesterone. Major support for this

concept was provided by Van Wagenen and Jenkins (1939), who described further ureteral dilatation after removal of the monkey fetus but with the placenta left in situ. The relatively abrupt onset of dilatation in women at midpregnancy, however, is more consistent with ureteral compression from an enlarging uterus rather than a hormonal effect.

Elongation accompanies distention of the ureter, which is frequently thrown into curves of varying size, the smaller of which may be sharply angulated. These so-called kinks are poorly named, because the term connotes obstruction. They are usually single or double curves, which when viewed in the radiograph taken in the same plane as the curve, appear as more or less acute angulations of the ureter (see [Fig. 5-15](#)). Another exposure at right angles nearly always identifies them to be more gentle curves rather than kinks.

Figure 5-15. Normal intravenous pyelogram at 36 weeks. Pregnancy-induced hydronephrosis (*upper arrow*) and hydroureter (*lower arrow*) are more marked on the right. Elongation, dilatation, and peristalsis of the ureter create the appearance of ureteral discontinuity.

BLADDER. There are few significant anatomical changes in the bladder before 12 weeks. From that time onward, however, the increased size of the uterus, together with the hyperemia that affects all pelvic organs, and the hyperplasia of the muscle and connective tissues, elevates the bladder trigone and causes thickening of its posterior, or intraureteric, margin. Continuation of this process to the end of pregnancy produces marked deepening and widening of the trigone. The bladder mucosa undergoes no change other than an increase in the size and tortuosity of its blood vessels.

Using urethrocytometry, Iosif and colleagues (1980) found that bladder pressure in primigravidas increased from 8 cm H₂O early in pregnancy to 20 cm H₂O at term. To compensate for reduced bladder capacity, absolute and functional urethral lengths increased by 6.7 and 4.8 mm, respectively. Finally, to preserve continence, maximal intraurethral pressure increased from 70 to 93 cm H₂O. Still, the majority of women experience urinary incontinence during pregnancy. Indeed, loss of urine is always considered in the differential diagnosis with a question of ruptured membranes.

Nel and co-workers (2001) found that during pregnancy, approximately one fifth of women reported symptoms of stress urinary incontinence for the first time, and Wijma and associates (2001) reported that a similar proportion of nulliparous women actually demonstrate objective evidence of urine leakage. Thorpe and colleagues (1999) found that when pregnant women were asked to compare urinary tract function week by week, they reported a steady deterioration in perceived bladder function.

Toward the end of pregnancy, particularly in nulliparas in whom the presenting part often engages before labor, the entire base of the bladder is pushed forward and upward, converting the normal convex surface into a concavity. As a result, difficulties in diagnostic and therapeutic procedures are greatly increased. In addition, the pressure of the presenting part impairs the drainage of blood and lymph from the base of the bladder, often rendering the area edematous, easily traumatized, and probably more susceptible to infection.

GASTROINTESTINAL TRACT

As pregnancy progresses, the stomach and intestines are displaced by the enlarging uterus. As the result of the positional changes in these viscera, the physical findings in certain diseases are altered. The appendix, for instance, is usually displaced upward and somewhat laterally as the uterus enlarges, and at times it may reach the right flank.

Gastric emptying time, studied using acetaminophen absorption techniques, appears to be unchanged during each trimester and when compared with nonpregnant women (Macfie and colleagues, 1991; Wong and associates, 2002). During labor, however, and especially after administration of analgesic agents, gastric emptying time may be prolonged appreciably. As a result, a major danger of general anesthesia for delivery is regurgitation and aspiration of either food-laden or highly acidic gastric contents (see [Chap. 19](#), p. 490).

Pyrosis (heartburn) is common during pregnancy and is most likely caused by reflux of acidic secretions into the lower esophagus (see [Chap. 49](#), p. 1114). Although the altered position of the stomach probably contributes to its frequent occurrence, lower esophageal sphincter tone also is decreased. In addition, intraesophageal pressures are lower and intragastric pressures higher in pregnant women. At the same time, esophageal peristalsis has lower wave speed and lower amplitude (Ulmsten and Sundstrom, 1978).

The gums may become hyperemic and softened during pregnancy and may bleed when mildly traumatized, as with a toothbrush. A focal, highly vascular swelling of the gums, the so-called *epulis* of pregnancy, develops occasionally but typically regresses spontaneously after delivery. Most evidence indicates that pregnancy does not incite tooth decay.

Hemorrhoids are fairly common during pregnancy. They are caused in large measure by constipation and elevated pressure in veins below the level of the enlarged uterus.

LIVER. Although the liver in some animals increases in size remarkably during pregnancy, there is no increase during human pregnancy (Combes and Adams, 1971). Histological evaluation of liver biopsies, including examination with the electron microscope, has shown no distinct changes in liver morphology in normal pregnant women (Ingerslev and Teilum, 1946). Despite this, the diameter of the portal vein and its blood flow both increase substantively (Clapp and colleagues, 2000).

Some of the laboratory tests used to evaluate hepatic function yield appreciably different results during normal pregnancy.

Moreover, some of the changes are similar to those in nonpregnant patients with liver disease. Total *alkaline phosphatase* activity in serum almost doubles during normal pregnancy, but much of the increase is attributable to heat-stable placental alkaline phosphatase isozymes. Serum aspartate transaminase, alanine transaminase, γ -glutamyl transferase, and bilirubin levels are slightly lower during pregnancy compared with nonpregnant normal values (Girling and colleagues, 1997).

The concentration of serum albumin decreases during pregnancy. Late in pregnancy, for example, albumin concentrations may normally be near 3.0 g/dL compared with approximately 4.3 g/dL in nonpregnant women (Mendenhall, 1970). Total albumin is increased, however, because of a greater volume of distribution. The reduction in albumin concentration, combined with a normal slight increase in serum globulin levels, results in a decrease in the albumin-to-globulin ratio similar to that seen in certain hepatic diseases (see [Chapter 50](#)).

Leucine aminopeptidase activity is markedly elevated in serum from pregnant women. The increase results from the appearance of a pregnancy-specific enzyme(s) with distinct substrate specificities (Song and Kappas, 1968). Pregnancy-induced aminopeptidase has oxytocinase and vasopressinase activity.

GALLBLADDER. During normal pregnancy, the contractility of the gallbladder is reduced, leading to an increased residual volume (Braverman and co-workers, 1980). It has been suggested that progesterone impairs gallbladder contraction by inhibiting cholecystokinin-mediated smooth muscle stimulation, the primary regulator of gallbladder contraction. Impaired gallbladder contraction leads to stasis, and this, associated with the increased cholesterol saturation of pregnancy, at least partially explains the increased prevalence of cholesterol stones in multiparous women.

The effects of pregnancy on maternal bile acid serum concentrations have been incompletely characterized despite the long-acknowledged propensity for pregnancy to cause intrahepatic cholestasis and pruritus gravidarum from retained bile salts. Intrahepatic cholestasis has been linked to high circulating levels of estrogen, which inhibit intraductal transport of bile acids (Simon and colleagues, 1996). In addition, increased progesterone and genetic factors have been implicated in the pathogenesis (Lammert and associates, 2000). Cholestasis of pregnancy is described in greater detail in [Chapter 50](#) (see p. 1126).

ENDOCRINE SYSTEM

Some of the most important endocrine changes of pregnancy are discussed elsewhere, especially in [Chapter 3](#).

PITUITARY GLAND. During normal pregnancy the pituitary gland enlarges by approximately 135 percent (Gonzalez and colleagues, 1988). Although it has been suggested that the increase may be sufficient to compress the optic chiasma and reduce visual fields, changes in vision during normal pregnancy are minimal. Scheithauer and colleagues (1990) have provided evidence that the incidence of pituitary prolactinomas is not increased during pregnancy. When these tumors are large before pregnancy — a macroadenoma is 10 mm or greater — then enlargement during pregnancy is more likely (see [Chap. 53](#), p. 1203).

The maternal pituitary gland is not essential for maintenance of pregnancy. Many women have undergone hypophysectomy, completed pregnancy successfully, and undergone spontaneous labor while receiving glucocorticoids along with thyroid hormone and vasopressin.

Growth Hormone. During the first trimester, growth hormone is secreted predominantly from the maternal pituitary gland, and concentrations in serum and amniotic fluid are within nonpregnant values of 0.5 to 7.5 ng/mL (Kletzky and associates, 1985). As early as 8 weeks, growth hormone secreted from the placenta becomes detectable (Lonberg and co-workers, 2003). By about 17 weeks, the placenta is the principal source of growth hormone secretion (Obuobie and co-workers, 2001). Maternal serum values increase slowly from approximately 3.5 ng/mL at 10 weeks to plateau after 28 weeks at approximately 14 ng/mL. Growth hormone in amniotic fluid peaks at 14 to 15 weeks and slowly declines thereafter to reach baseline values after 36 weeks.

Although growth hormone is abundant in the fetal circulation, at least in the second half of gestation, it has not been considered to be a major hormonal regulator of fetal growth (Lonberg and co-workers, 2003). For example, anencephalic fetuses cannot produce significant amounts of pituitary growth hormone, yet they usually have near normal weight and length (Wollmann, 2000). More recently, however, Chellakooty and co-investigators (2004) were the first to demonstrate that the rate of fetal growth, after adjusting for confounding variables, significantly correlated with the increase in placental growth hormone in the latter half of pregnancy. Interestingly, they also found that the gestational age when peak concentrations of placental growth hormone were reached was associated with the onset of labor. After delivery, growth hormone is elevated for some time but at levels lower than during late pregnancy (Spellacy and Buhi, 1969).

Prolactin. Maternal plasma levels of prolactin increase markedly during the course of normal pregnancy. Serum concentration levels are usually 10-fold greater at term — about 150 ng/mL — compared with normal nonpregnant women. Paradoxically, after delivery, the plasma prolactin concentration decreases even in women who are breast feeding. During early lactation, pulsatile bursts of prolactin secretion occur apparently in response to suckling. The physiological cause of the marked increase in prolactin prior to parturition is not entirely certain. It is known, however, that estrogen stimulation increases the number of anterior pituitary lactotrophs and may stimulate the release of prolactin from these cells (Andersen, 1982). Thyroid-releasing hormone also acts to cause an increased prolactin level in pregnant compared with nonpregnant women, but the response decreases as pregnancy advances (Andersen, 1982; Miyamoto, 1984). Serotonin also is believed to increase prolactin, and prolactin-inhibiting factor (dopamine) inhibits its secretion.

The principal function of maternal serum prolactin is to ensure lactation. Early in pregnancy, prolactin acts to initiate DNA synthesis and mitosis of glandular epithelial cells and the presecretory alveolar cells of the breast. Prolactin also increases the number of estrogen and prolactin receptors in these same cells. Finally, prolactin promotes mammary alveolar cell RNA synthesis, galactopoiesis, and production of casein and lactalbumin, lactose, and lipids (Andersen, 1982). Kauppila and co-workers (1987) found that a woman with an isolated prolactin deficiency failed to lactate after two pregnancies, establishing the absolute necessity of prolactin for lactation but not for successful pregnancy outcome.

Prolactin is present in amniotic fluid in high concentrations. Levels of up to 10,000 ng/mL are found at 20 to 26 weeks, thereafter, levels decrease and reach a nadir after 34 weeks. Several investigators have presented convincing evidence that the uterine decidua is the site of prolactin synthesis in amniotic fluid (see [Chap. 3](#), p. 51). Although the exact function of amniotic fluid prolactin is not known, it has been suggested that amniotic fluid prolactin impairs the transfer of water from the fetus into the maternal compartment, thus preventing fetal dehydration during late pregnancy when amniotic fluid is normally hypotonic.

THYROID GLAND. During pregnancy, important changes in thyroidal economy occur that are due to three modifications in the regulation of thyroid hormones. First, pregnancy induces a marked increase in circulating levels of the major thyroxine transport protein, thyroxine-binding globulin, in response to high estrogen levels. Second, several thyroidal stimulatory factors of placental origin are produced in excess. Third, pregnancy is accompanied by a decreased availability of iodide for the maternal thyroid. This finding occurs because of increased renal clearance and excretion that results in a relative iodine-deficiency state.

Also during pregnancy, the thyroid undergoes moderate enlargement caused by glandular hyperplasia and increased vascularity. Glinoe and colleagues (1990) found that mean thyroid volume increased from 12.1 mL in the first trimester to 15.0 mL at delivery. Moreover, total volume was found to be inversely proportional to serum thyrotropin concentrations. These enlargements are not pathological and normal pregnancy does not typically cause significant thyromegaly, thus, any goiter should be investigated.

Changes in thyroid physiology function during pregnancy are detailed in [Figure 5-16](#). Beginning early in the first trimester, thyroxine-binding globulin increases, reaches its zenith at about 20 weeks, and stabilizes at approximately double baseline values for the remainder of pregnancy. Total serum thyroxine (T_4) increases sharply beginning between 6 and 9 weeks, and reaches a plateau at 18 weeks. Free serum T_4 levels rise slightly and peak along with hCG levels, then they return to normal. The rise in total triiodothyronine (T_3) is more pronounced up to 18 weeks, and thereafter, it plateaus. *Thyroid-releasing hormone (TRH)* levels are not increased during normal pregnancy, but this neurotransmitter does cross the placenta and may stimulate the fetal pituitary to secrete thyrotropin (Thorpe-Beeston and associates, 1991).

Interestingly, the secretion of T_4 and T_3 is not similar for all pregnant women (Glinoe and associates, 1990). Approximately one third of women experience relative hypothyroxinemia, preferential T_3 secretion, and higher, albeit normal, serum thyrotropin levels. Thus, there may be considerable variability in thyroidal adjustments during normal pregnancy.

The modifications in serum thyroid-stimulating hormone and hCG as a function of gestational age also are illustrated in [Figure 5-16](#). As discussed in [Chapter 3](#) (see p. 70), the α -subunits of the two glycoproteins are identical whereas the β -subunits, although similar, differ in their amino acid sequence. As a result of this structural similarity, hCG has intrinsic thyrotropic activity, and thus, high serum levels cause thyroid stimulation. Indeed, thyrotropin levels decrease in more than 80 percent of pregnant women, even though levels are in the normal range for nonpregnant women (see [Fig. 53-1](#), p. 1190).

These many complex alterations in thyroid regulation during pregnancy do not appear to alter maternal thyroid status as measured by metabolic studies. Although basal metabolic rate increases progressively during normal pregnancy by as much as 25 percent, most of this increase in oxygen consumption can be attributed to fetal metabolic activity. If fetal body surface area is considered along with that of the mother, the predicted and observed basal metabolic rates are quite similar to nonpregnant women. Fetal thyroid physiology is discussed in [Chapter 4](#) (see p. 111) and thyroid disorders in [Chapter 53](#) (see p. 1190).

Figure 5-16. Relative changes in maternal thyroid function during pregnancy. Maternal changes include a marked and early increase in hepatic production of thyroxine-binding globulin (TBG) and placental production of chorionic gonadotropin (hCG). Increased thyroxine-binding globulin increases serum thyroxine (T_4) concentrations, and chorionic gonadotropin has thyrotropin-like activity and stimulates maternal T_4 secretion. The transient hCG-induced increase in serum T_4 inhibits maternal secretion of thyrotropin. Except for minimally increased free T_4 levels when hCG peaks, these levels are essentially unchanged. (T_3 = triiodothyronine.) (From Burrow and colleagues, 1994, with permission.)

PARATHYROID GLANDS. The regulation of calcium concentration is closely interrelated to magnesium, phosphate, parathyroid hormone, vitamin D, and calcitonin physiology. Any alteration of one of these factors is likely to change the others. In a longitudinal investigation of 20 women, More and associates (2003) found that all markers of bone turnover increased during normal pregnancy and failed to reach baseline level by 12 months postpartum. They concluded that the calcium needed for fetal growth and lactation may be drawn at least in part from the maternal skeleton.

Parathyroid Hormone and Calcium. Acute or chronic decreases in plasma calcium or acute decreases in magnesium stimulate the release of parathyroid hormone, whereas increases in calcium and magnesium suppress parathyroid hormone levels. The action of this hormone on bone resorption, intestinal absorption, and kidney reabsorption is to increase

extracellular fluid calcium and decrease phosphate.

Parathyroid hormone plasma concentrations decrease during the first trimester and then increase progressively throughout the remainder of pregnancy (Pitkin and associates, 1979). Increased levels likely result from the lower calcium concentration in the pregnant woman. As discussed earlier, this is the result of increased plasma volume, increased glomerular filtration rate, and maternal-fetal transfer of calcium. Ionized calcium is decreased only slightly, and Reitz and co-workers (1977) suggest that during pregnancy a new "set point" is established for ionized calcium and parathyroid hormone. Estrogens also appear to block the action of parathyroid hormone on bone resorption, resulting in another mechanism to increase parathyroid hormone during pregnancy. The net result of these actions is a *physiological hyperparathyroidism* of pregnancy, likely to supply the fetus with adequate calcium.

The potential roles of parathyroid hormone-related peptide production in the fetus, placenta, and maternal tissues are discussed in [Chapter 3](#), p. 74, and [Chapter 6](#), p. 166.

Calcitonin and Calcium. The calcitonin-secreting C cells are derived embryologically from the neural crest and are located predominantly in the perifollicular areas of the thyroid gland. Calcium and magnesium increase the biosynthesis and secretion of calcitonin. Various gastric hormones—gastrin, pentagastrin, glucagon, and pancreaticoimin—and food ingestion also increase calcitonin plasma levels.

The known actions of calcitonin generally are considered to oppose those of parathyroid hormone and vitamin D to protect skeletal calcification during times of calcium stress. Pregnancy and lactation cause profound calcium stress, and during these times, calcitonin levels are appreciably higher than in nonpregnant women (Weiss and co-workers, 1998; Whitehead and associates, 1981).

Vitamin D and Calcium. Vitamin D, a hormone that is synthesized in the skin or ingested, is converted by the liver into 25-hydroxyvitamin D₃. This form then is converted in the kidney, decidua, and placenta to 1,25-dihydroxyvitamin D₃, serum levels of which are increased during normal pregnancy (Weisman and co-workers, 1979; Whitehead and associates, 1981). Most likely this form is the biologically active compound, and it stimulates resorption of calcium from bone and absorption from the intestines. Although its control is unclear, the conversion of 25-hydroxyvitamin D₃ to 1,25-dihydroxyvitamin D₃ is facilitated by parathyroid hormone and by low calcium and phosphate plasma levels and opposed by calcitonin.

ADRENAL GLANDS. In normal pregnancy, the maternal adrenal glands undergo little, if any, morphological change.

Cortisol. The serum concentration of circulating cortisol is increased, but much of it is bound by cortisol-binding globulin, or *transcortin*. The rate of adrenal cortisol secretion is not increased, and probably it is decreased compared with that of the nonpregnant state. The metabolic clearance rate of cortisol, however, is lower during pregnancy because its half-life is nearly doubled over that for nonpregnant women (Migeon and associates, 1957). Administration of estrogen, including most oral contraceptives, causes changes in serum cortisol levels and transcortin similar to those of pregnancy.

In early pregnancy, the levels of circulating corticotropin (ACTH) are reduced strikingly. As pregnancy progresses, the levels of ACTH and free cortisol rise. This apparent paradox is not understood completely. Nolten and Rueckert (1981) have presented evidence that the higher free cortisol levels observed in pregnancy are the result of a "resetting" of the maternal feedback mechanism to higher levels. They further propose that this might result from *tissue refractoriness* to cortisol. Keller-Wood and Wood (2001) later suggested that these may result from an antagonistic action of progesterone on mineralocorticoids. Thus, in response to elevated progesterone levels during pregnancy, an elevated free cortisol is needed to maintain homeostasis. Indeed, experiments in pregnant ewes demonstrate that elevated maternal cortisol and aldosterone secretion are necessary to maintain the normal increase in plasma volume during late pregnancy (Jensen and associates, 2002).

Aldosterone. As early as 15 weeks, the maternal adrenal glands secrete considerably increased amounts of aldosterone. By the third trimester, about 1 mg/day is secreted. If sodium intake is restricted, aldosterone secretion is elevated even further (Watanabe and co-workers, 1963). At the same time, levels of renin and angiotensin II substrate normally are increased, especially during the latter half of pregnancy. This scenario gives rise to increased plasma levels of angiotensin II, which by acting on the zona glomerulosa of the maternal adrenal glands, accounts for the markedly elevated aldosterone secretion. It has been suggested that the increased aldosterone secretion during normal pregnancy affords protection against the natriuretic effect of progesterone and atrial natriuretic peptide discussed earlier.

Deoxycorticosterone. Maternal plasma levels of this potent mineralocorticosteroid progressively increase during pregnancy. Indeed, plasma levels of deoxycorticosterone rise to near 1500 pg/mL by term, a more than 15-fold increase (Parker and associates, 1980). This marked elevation is not derived from adrenal secretion, but instead represents increased kidney production resulting from estrogen stimulation. The levels of deoxycorticosterone and its sulfate in fetal blood are appreciably higher than those in maternal blood, which suggests transfer of fetal deoxycorticosterone into the maternal compartment.

Dehydroepiandrosterone Sulfate. As discussed in [Chapter 3](#) (see p. 78), the levels of *dehydroepiandrosterone sulfate* circulating in maternal blood and excreted in the urine are decreased during normal pregnancy. This finding is a consequence of increased metabolic clearance through extensive 16 α -hydroxylation in the maternal liver and conversion to estrogen by the placenta.

Androstenedione and Testosterone. Maternal plasma levels of these androgens are increased during pregnancy. This finding is not totally explained by alterations in their metabolic clearance. Maternal plasma androstenedione and testosterone are converted to estradiol in the placenta, which increases their clearance rates. Conversely, the increased sex hormone-binding globulin in plasma of pregnant women retards testosterone clearance. Thus, the plasma production rate of maternal testosterone and androstenedione during human pregnancy are increased. The source of this increased C₁₉-steroid production is unknown, but it likely originates in the ovary. Interestingly, little or no testosterone in maternal plasma enters the fetal circulation as testosterone. Even when massive testosterone levels are found in the circulation of pregnant women, as with androgen-secreting tumors, the testosterone levels in umbilical cord venous plasma are likely to be undetectable. This finding

is the result of the near complete conversion of testosterone to 17 β -estradiol by the trophoblast (Edman and associates, 1979).

OTHER SYSTEMS

MUSCULOSKELETAL SYSTEM. Progressive lordosis is a characteristic feature of normal pregnancy. Compensating for the anterior position of the enlarging uterus, the lordosis shifts the center of gravity back over the lower extremities. The sacroiliac, sacrococcygeal, and pubic joints have increased mobility during pregnancy. As discussed on page 124, Marnach and co-workers (2003) found that although joint laxity increased during pregnancy, it did not correlate with maternal estradiol, progesterone, or relaxin levels. Joint mobility may contribute to the alteration of maternal posture, and in turn cause discomfort in the lower back. This is especially bothersome late in pregnancy, during which time aching, numbness, and weakness also occasionally are experienced in the upper extremities. This may occur as a result of the marked lordosis with anterior neck flexion and slumping of the shoulder girdle, which in turn produce traction on the ulnar and median nerves (Crisp and DeFrancesco, 1964).

The bones and ligaments of the pelvis undergo remarkable adaptation during pregnancy. In 1934, Abramson and colleagues described the normal relaxation of the pelvic joints, and particularly the symphysis pubis, that occurs during pregnancy ([Fig. 5-17](#)). They reported that most relaxation takes place in the first half of pregnancy. Retrogression begins immediately following delivery, and it is usually complete within 3 to 5 months.

Figure 5-17. Computed tomography images demonstrating symphyseal diastasis and widening of the left anterior sacroiliac joint. (From Dunbar and Ries, 2002, with permission.)

EYES. Intraocular pressure decreases during pregnancy, attributed in part to increased vitreous outflow (Sunness, 1988). Corneal sensitivity also is decreased, with the greatest changes late in gestation. Most pregnant women demonstrate a measurable but slight increase in corneal thickness that is thought to be due to edema. Consequently, pregnant women may have difficulty with previously comfortable contact lenses. Brownish-red opacities on the posterior surface of the cornea—*Krukenberg spindles*—have also been observed with a higher than expected frequency during pregnancy. Hormonal effects are postulated as the cause of this increased pigmentation. Other than transient loss of accommodation reported with both pregnancy and lactation, visual function is unaffected by pregnancy. These changes, as well as pathological eye aberrations, were reviewed by Dinn and colleagues (2003).

CENTRAL NERVOUS SYSTEM. Women often report problems with attention, concentration, and memory throughout pregnancy and the early postpartum period. Systematic studies of memory in pregnancy, however, are limited and often anecdotal. Keenan and colleagues (1998) longitudinally investigated memory in pregnant women as well as a matched control group. They found pregnancy-related memory decline, which was limited to the third trimester. This decline was not attributable to depression, anxiety, sleep deprivation, or other physical changes associated with pregnancy. It was transient and quickly resolved following delivery.

Zeeman and co-workers (2003) used magnetic resonance imaging to measure cerebral blood flow across pregnancy in 10 healthy women. They found that mean blood flow bilaterally in the middle and posterior cerebral arteries decreased progressively from 147 and 56 mL/min when nonpregnant to 118 and 44 mL/min late in the third trimester, respectively. The mechanism and clinical significance of this decrease, and whether it relates to the diminished memory observed during pregnancy, is unknown.

Beginning as early as about 12 weeks, and extending through the first 2 months postpartum, women have difficulty going to sleep, frequent awakenings, fewer hours of night sleep, and reduced sleep efficiency (Lee and colleagues, 2000; Swain and colleagues, 1997). Trakada and co-workers (2003) found that during normal pregnancy, the frequency and duration of sleep apnea episodes were decreased significantly compared with those postpartum. In the supine position, however, average Pao₂ levels were lower. The greatest disruption of sleep is encountered postpartum and may contribute to *postpartum blues*, or even frank depression (see [Chap. 55](#), p. 1243).

6. Parturition

INTRODUCTION

The last few hours of human pregnancy are characterized by uterine contractions that effect dilatation of the cervix and force the fetus through the birth canal. The myometrial contractions of labor are painful, which is why the term *labor pains* is used to describe this process. Before these forceful, painful contractions begin, however, the uterus must be prepared for labor. During the first 36 to 38 weeks of gestation, the myometrium is unresponsive. After this prolonged period of quiescence, a transitional phase is required during which myometrial unresponsiveness is suspended and the cervix is softened and effaced.

The physiological processes that regulate parturition and the onset of labor continue to be defined. It is clear, however, that the onset of labor represents the culmination of a series of biochemical changes in the uterus that result from endocrine and paracrine signals coming from both the mother and the fetus. The relative role of their contributions varies between species, and it is these differences that complicate the determination of the exact underlying factors regulating human parturition. When parturition is abnormal, the result can be preterm labor, dystocia, or postterm pregnancy. Although dystocia and postterm pregnancy can be treated by cesarean delivery, preterm labor remains the major contributor to neonatal mortality and morbidity in developed countries. What follows is a concise view of the process of parturition and the events that regulate its progression to delivery. Because of the impact of preterm delivery on society, the potential physiological causes of preterm birth also are discussed (see also [Chap. 36](#), p. 859).

PHASES OF PARTURITION

Parturition, the bringing forth of young, encompasses all physiological processes involved in birthing: the prelude to (phase 0), the preparation for (phase 1), the process of (phase 2), and recovery from (phase 3) childbirth. From the disparate nature of these physiological processes, it is evident that multiple transformations in uterine function must be accommodated in a timely manner. As shown in [Figure 6-1](#), parturition can be arbitrarily divided into four uterine phases, which correspond to the major physiological transitions of the myometrium and cervix during pregnancy (Casey and MacDonald, 1993, 1997; Challis and associates, 2000). The *phases of parturition* should not be confused with the clinical stages of labor (first, second, and third stages), which comprise phase 2 of parturition.

Figure 6-1. The phases of parturition and the onset of labor.

PHASE 0 OF PARTURITION: UTERINE QUIESCENCE. Beginning even before implantation, a remarkably effective period of myometrial quiescence is imposed. This phase is characterized by uterine smooth muscle tranquility with maintenance of cervical structural integrity. During this phase, which normally characterizes 95 percent of pregnancy, the inherent propensity of the myometrium to contract is held in abeyance. Thus, the uterine myometrial smooth muscle is rendered unresponsive to natural stimuli, and relative contractile paralysis is imposed against a host of mechanical and chemical challenges that otherwise would promote emptying of the uterine contents. The myometrial unresponsiveness of phase 0 continues until near the end of pregnancy, when the myometrium must be awakened from this prolonged parturitional diapause in preparation for labor.

During phase 0 of parturition, as the myometrium is maintained in a quiescent state, the cervix must remain firm and unyielding. The maintenance of cervical anatomical and structural integrity is essential for successful parturition. Preterm cervical dilatation, structural incompetence, or both, may forecast an unfavorable pregnancy outcome that ends most often in preterm delivery (see [Chap. 36](#), p. 860). Indeed, shortening of the cervix between 24 and 28 weeks was associated with an increased risk of preterm delivery (Iams and colleagues, 1996).

Some myometrial contractions occur during the quiescent phase, but they do not normally cause cervical dilatation. These contractions are characterized by unpredictable occurrence, very low intensity, and brief duration. Any discomfort that they produce usually is confined to the lower abdomen and groin. Near the end of pregnancy, as the uterus undergoes preparation for labor, contractions of this type are more common, especially in multiparous women. They are sometimes referred to as *Braxton-Hicks contractions* or *false labor* (see [Chap. 17](#), p. 424).

PHASE 1 OF PARTURITION: PREPARATION FOR LABOR. To prepare the uterus for labor, the myometrial tranquility of phase 0 of parturition must be suspended through what has been called *uterine awakening* or *activation*. This process is termed *phase 1 of parturition* and represents a progression of changes in the uterus during the last 6 to 8 weeks of pregnancy. It is important to consider that shifting the events associated with phase 1 can cause either preterm or delayed labor. Thus, understanding the modifications in the myometrium and cervix during phase 1 provides a better understanding of events leading to normal labor as well as preterm labor.

Cervical Changes. Although parts of the same organ, the body or fundus of the uterus and the cervix must respond quite differently during pregnancy and parturition. Specifically, it is essential that during most of pregnancy the myometrium be able to stretch but remain quiescent. And, at the same time, the cervix must remain unyielding and reasonably rigid. Then, coincidentally with the initiation of parturition, the cervix must soften, yield, and become more readily dilatable. The fundus must be transformed from the relatively relaxed, unresponsive organ characteristic of most of pregnancy to one that will produce effective contractions that drive the fetus through the yielding (dilatable) cervix and on through the birth canal. Failure of a coordinated interaction between the functions of fundus and cervix is indicative of an unfavorable pregnancy outcome. But despite the apparent reversal of roles between cervix and fundus from before to during labor, it is likely that common agents regulate both.

The cervical modifications during phase 1 of parturition principally involve changes in the connective tissue. These are accompanied by the invasion by inflammatory cells to the extent that the process has been likened to a state of inflammation.

Two complementary changes occur to its connective tissues as the cervix softens. The first change relates to the state of the bundles of collagen fibers that act during most of gestation to provide rigid support. Late in gestation there is an increase in collagen breakdown and a rearrangement of the collagen fiber bundles. This process causes a decrease in the number and size of collagen bundles within the cervix. During this same period, there are changes in the relative amounts of the various glycosaminoglycans, particularly hyaluronic acid, a compound associated with the capacity of the cervix to retain water. The second change relates to the striking increase in the amount of hyaluronic acid in the cervix, with a concomitant increase in water. In addition, there is a decrease in dermatan sulfate, which is needed for collagen fiber cross-linking (Cabrol and associates, 1985). Other cervical changes associated with softening include an increased production of cytokines that causes infiltration of leukocytes, which also degrade collagen. The result of these changes is cervical thinning, softening, and relaxation, which allow the cervix to initiate dilatation.

The exact mechanisms that lead to cervical ripening are still being defined, but several candidates have already been used clinically. Prostaglandins E_2 (PGE_2) and $F_{2\alpha}$ ($PGF_{2\alpha}$) applied directly to the cervix will induce these same maturational softening changes. Specifically, they cause modification of collagen and alterations in the relative concentration of the glycosaminoglycans. This property is useful clinically, and prostaglandin preparations placed intravaginally adjacent to the cervix effect cervical softening or "ripening" to facilitate the induction of labor (see [Chap. 22](#), p. 537). In some species, but not humans, these events are induced by falling levels of progesterone. However, even in humans, progesterone antagonists will cause cervical softening. As discussed later, humans may have developed unique mechanisms to cause a localized decrease in progesterone action in the cervix and myometrium. Despite the enormous importance of cervical softening to the success of parturition, relatively little is known of the precise sequence (or regulation) of the biochemical processes involved.

Myometrial Changes. The uterine smooth muscle must undergo a series of changes during phase 1 to prepare it for labor. Most relate to its state of contractility. These changes are manifest by a transition from a contractile state characterized predominantly by occasional painless contractions to one in which more frequent contractions develop. This shift probably results from alterations in the expression of key proteins that control myometrial contractility. These have been termed the *contraction-associated proteins* (CAPs). During phase 1 there is a striking increase in myometrial oxytocin receptors. There are increased numbers and surface areas of myometrial cell gap junction proteins such as connexin-43. Together these changes result in increased uterine irritability and responsiveness to uterotonins.

Another critical change that occurs in phase 1 is the formation of the lower uterine segment. With the development of a well-formed lower segment, the fetal head oftentimes descends to or even through the pelvic inlet — a distinctive event referred to as *lightening*. The abdomen commonly undergoes a change in shape, an event sometimes described by the mother as "the baby dropped." It is also likely that the myometrium in the lower uterine segment is unique from the adjacent myometrium in the upper uterine segment, resulting in distinct roles for each during labor.

PHASE 2 OF PARTURITION: THE PROCESS OF LABOR. Phase 2 is synonymous with active labor, that is, the uterine contractions that bring about progressive cervical dilatation and delivery. Clinically, phase 2 of parturition is customarily divided into the three stages of labor. These stages compose the labor graph commonly used and shown in [Figure 6-2](#). The clinical stages of labor may be summarized as follows:

1. The first stage of labor begins when widely spaced uterine contractions of sufficient frequency, intensity, and duration are attained to bring about effacement of the cervix. This stage of labor ends when the cervix is fully dilated (about 10 cm) to allow passage of the fetal head. The first stage of labor, therefore, is the stage of cervical effacement and dilatation.
2. The second stage of labor begins when dilatation of the cervix is complete, and ends with delivery of the fetus. Thus, the second stage of labor is the stage of expulsion of the fetus.
3. The third stage of labor begins immediately after delivery of the fetus and ends with the delivery of the placenta and fetal membranes. Thus, the third stage of labor is the stage of separation and expulsion of the placenta.

First Stage of Labor: Clinical Onset of Labor. In some women, the forceful uterine contractions that effect cervical dilatation, fetal descent, and delivery begin suddenly and seemingly without warning. In other women, a rather dependable sign of the initiation of labor is the spontaneous discharge of a small amount of blood-tinged mucus from the vagina. This event represents the extrusion of the mucus plug that had filled the cervical canal during pregnancy, and is referred to as "show" or "bloody show." There is very little blood with the mucus plug, and substantial bleeding is suggestive of an abnormal cause. Passage of the mucus plug indicates that labor is already in progress or likely will ensue during the next several hours to days.

UTERINE CONTRACTIONS CHARACTERISTIC OF LABOR. Unique among physiological muscular contractions, those of uterine smooth muscle during labor are painful. The cause of the pain is not known definitely, but several possibilities have been suggested:

1. Hypoxia of the contracted myometrium (as in angina pectoris).
2. Compression of nerve ganglia in the cervix and lower uterus by the interlocking muscle bundles.
3. Stretching of the cervix during dilatation.
4. Stretching of the peritoneum overlying the fundus.

Compression of nerve ganglia in the cervix and lower uterine segment by the contracting myometrium is an especially attractive hypothesis. Paracervical infiltration with a local anesthetic usually produces appreciable relief of pain during subsequent contractions (see [Chap. 19](#), p. 479). Uterine contractions are involuntary and, for the most part, independent of extrauterine control. Neural blockage from epidural analgesia does not diminish their frequency or intensity. Moreover, the myometrial contractions in paraplegic women are normal, though painless, as in women after bilateral lumbar sympathectomy.

Mechanical stretching of the cervix enhances uterine activity in several species, including humans. This phenomenon has been

referred to as the *Ferguson reflex* (Ferguson, 1941). The exact mechanism by which mechanical dilatation of the cervix causes increased myometrial contractility is not clear. Release of oxytocin was suggested as the cause, but this is not proven. Manipulation of the cervix and "stripping" the fetal membranes is associated with an increase in the levels of prostaglandin $F_{2\alpha}$ metabolite (PGFM) in blood which could also increase contractions.

The interval between contractions diminishes gradually from about 10 minutes at the onset of the first stage of labor to as little as 1 minute or less in the second stage. Periods of relaxation between contractions, however, are essential to the welfare of the fetus. Unremitting contractions compromise uteroplacental blood flow sufficiently to cause fetal hypoxemia. In the active phase of labor, the duration of each contraction ranges from 30 to 90 seconds, averaging about 1 minute. There is appreciable variability in the intensity of contractions during normal labor, as emphasized by Schulman and Romney (1970). They recorded the amniotic fluid pressures generated by contractions during spontaneous labor and found the average to be about 40 mm Hg, with variations from 20 to 60 mm Hg (see [Chap. 18](#), p. 466).

FORMATION OF DISTINCT LOWER AND UPPER UTERINE SEGMENTS. During active labor, the divisions of the uterus that were initiated in phase 1 of parturition become increasingly evident. The actively contracting upper segment becomes thicker as labor advances. The lower or passive segment of the uterus and the cervix are relatively inactive compared with the upper segment. It subsequently develops into a much more thinly walled passage for the fetus. The lower segment is analogous to a greatly expanded and thinned-out isthmus in nonpregnant women and thus is not solely a phenomenon of labor. The lower segment develops gradually as pregnancy progresses and then thins remarkably during labor ([Figs. 6-3](#) and [6-4](#)).

By abdominal palpation, even before rupture of the membranes, the two segments can be differentiated during a contraction. The upper uterine segment is quite firm or hard during contractions. The consistency of the lower uterine segment is much less firm, and it is distended and normally much more passive. If the entire wall of uterine musculature, including the lower uterine segment and cervix, were to contract simultaneously and with equal intensity, the net expulsive force would be decreased markedly. Herein lies the importance of the division of the uterus into an actively contracting upper segment and a more passive lower segment that differ not only anatomically but also physiologically.

The upper segment contracts, retracts, and expels the fetus. In response to the force of these contractions, the softened lower uterine segment and cervix dilate and thereby form a greatly expanded, thinned-out muscular and fibromuscular tube through which the fetus can be extruded. The myometrium of the upper uterine segment does not relax to its original length after contractions. Instead, it becomes relatively fixed at a shorter length.

The upper active segment of the uterus contracts down on its diminishing contents, but myometrial tension remains constant. The net effect is to take up slack, thus maintaining the advantage gained in the expulsion of the fetus, and keeping the uterine musculature in firm contact with the intrauterine contents. As the consequence of retraction, each successive contraction commences where its predecessor left off. Thus, the upper part of the uterine cavity becomes slightly smaller with each successive contraction. Because of the successive shortening of the muscular fibers with contractions, the upper active uterine segment becomes progressively thickened throughout the first and second stages of labor (see [Fig. 6-3](#)). This process continues and results in an upper uterine segment that is tremendously thickened immediately after delivery. The phenomenon of upper segment retraction is contingent upon a decrease in the volume of its contents. For the contents to be diminished, particularly early in labor when the entire uterus is virtually a closed sac with only a minute opening at the cervical os, the musculature of the lower segment must stretch. This permits increasingly more of the uterine contents to occupy the lower segment, and the upper segment retracts only to the extent that the lower segment distends and the cervix dilates.

Relaxation of the lower uterine segment is not complete, but rather the opposite of retraction. The fibers of the lower segment become stretched with each contraction of the upper segment and after which are not returned to the previous length but remain fixed at the longer length. Importantly, the tension remains essentially the same as before. The musculature still manifests tone, still resists stretch, and still contracts somewhat on stimulation. The successive lengthening of the fibers in the lower segment, as labor progresses, is accompanied by thinning, normally to only a few millimeters in the thinnest part. As a result of the lower segment thinning and concomitant upper segment thickening, a boundary between the two is marked by a ridge on the inner uterine surface— the *physiological retraction ring*. When the thinning of the lower uterine segment is extreme, as in obstructed labor, the ring is very prominent, forming a *pathological retraction ring*. This is an abnormal condition, also known as *Bandl ring*, which is illustrated in [Figure 6-3](#) and discussed further in [Chapter 20](#) (see p. 519). The existence of a gradient of diminishing physiological activity from fundus to cervix was established from measurements of differences in behavior of the upper and lower parts of the uterus during normal labor.

CHANGES IN UTERINE SHAPE DURING LABOR. Each contraction produces an elongation of the uterine ovoid with a concomitant decrease in horizontal diameter. By virtue of this change in shape, there are important effects on the process of labor. First, the decrease in horizontal diameter produces a straightening of the fetal vertebral column. This presses the upper pole of the fetus firmly against the fundus, whereas the lower pole is thrust farther downward and into the pelvis. The lengthening of the fetal ovoid thus produced has been estimated as between 5 and 10 cm. The pressure exerted in this fashion is known as the *fetal axis pressure*. Second, with lengthening of the uterus, the longitudinal fibers are drawn taut, and because the lower segment and cervix are the only parts of the uterus that are flexible, these are pulled upward over the lower pole of the fetus. This effect on the musculature of the lower segment and on the cervix is an important factor in cervical dilatation.

ANCILLARY FORCES IN LABOR. After the cervix is dilated fully, the most important force in the expulsion of the fetus is that produced by maternal intra-abdominal pressure. Created by contraction of the abdominal muscles simultaneously with forced respiratory efforts with the glottis closed, this is referred to as "pushing." The nature of the force produced is similar to that involved in defecation, but the intensity usually is much greater. The importance of intra-abdominal pressure in fetal expulsion is most clearly attested to by the labors of women who are paraplegic. Such women suffer no pain, although the uterus may contract vigorously. Cervical dilatation, in large measure the result of uterine contractions acting on a softened cervix, proceeds normally. Expulsion of the infant, however, is accomplished more readily when the woman is instructed to bear down during a uterine contraction.

Although increased intra-abdominal pressure is required for the spontaneous completion of labor, it is futile until the cervix is fully dilated. Specifically, it is a necessary auxiliary to contractions in second-stage labor, but pushing accomplishes little in the first stage.

Cervical Changes Induced During the First Stage of Labor. There are three principal structural components of the cervix: collagen, smooth muscle, and the extracellular matrix. Constituents important in modifications at parturition are those in the extracellular matrix, including the glycosaminoglycans, dermatan sulfate, and hyaluronic acid. The smooth muscle content of the cervix is much less than that of the fundus and varies anatomically from 25 to only 6 percent. Before the onset of labor, during the phase of uterine awakening and preparedness, the cervix is softened, which facilitates dilatation once forceful myometrial contractions of labor begin. The effective force of first-stage labor is the uterine contraction, which in turn exerts hydrostatic pressure through the fetal membranes against the cervix and lower uterine segment. In the absence of intact membranes, the presenting part is forced directly against the cervix and lower uterine segment. As the result of the action of these forces, two fundamental changes—effacement and dilatation—take place in the already softened cervix. For the average-sized fetal head to pass through the cervix, its canal must dilate to a diameter of about 10 cm. At this time, the cervix is said to be completely (or fully) dilated. There may be no fetal descent during cervical effacement, but most commonly the presenting fetal part descends somewhat as the cervix dilates. During second-stage labor, descent of the presenting part typically occurs rather slowly but steadily in nulliparas. In multiparas, however, particularly those of high parity, descent may be rapid.

The "obliteration" or "taking up" of the cervix is the shortening of the cervical canal from a length of about 2 cm to a mere circular orifice with almost paper-thin edges. This process is referred to as *cervical effacement* and takes place from above downward. The muscular fibers at about the level of the internal cervical os are pulled upward, or "taken up," into the lower uterine segment, as the condition of the external os remains temporarily unchanged. As illustrated in [Figures 6-5, 6-6, 6-7 and 6-8](#), the edges of the internal os are drawn upward several centimeters to become a part of the lower uterine segment.

Effacement may be compared with a funneling process in which the whole length of a narrow cylinder is converted into a very obtuse, flaring funnel with a small circular orifice for an outlet. As the result of increased myometrial activity during uterine preparedness for labor, appreciable effacement of the softened cervix sometimes is accomplished before active labor begins. Effacement causes expulsion of the mucus plug as the cervical canal is shortened.

Compared with the body of the uterus, the lower uterine segment and the cervix are regions of lesser resistance. Therefore, during a contraction a centrifugal pull is exerted on the cervix leading to distention, a process referred to as *cervical dilatation* ([Figs. 6-9, 6-10, and 6-11](#)). As the uterine contractions cause pressure on the membranes, the hydrostatic action of the amniotic sac in turn dilates the cervical canal like a wedge. In the absence of intact membranes, the pressure of the presenting part against the cervix and lower uterine segment is similarly effective. Early rupture of the membranes does not retard cervical dilatation so long as the presenting part of the fetus is positioned to exert pressure against the cervix and lower uterine segment. The process of cervical effacement and dilatation causes the formation of the forebag of the amniotic fluid, which is later described in detail.

As depicted in [Figure 6-2](#), two phases of cervical dilatation are the latent phase and the active phase. The active phase has been subdivided further as the acceleration phase, the phase of maximum slope, and the deceleration phase (Friedman, 1978). The duration of the latent phase is more variable and sensitive to changes by extraneous factors, such as sedation, which prolongs the latent phase, and myometrial stimulation, which shortens it. The duration of the latent phase has little bearing on the subsequent course of labor, whereas the characteristics of the accelerated phase are usually predictive of the outcome of a particular labor. The completion of cervical dilatation during the active phase of labor is accomplished by cervical retraction about the presenting part of the fetus. After cervical dilatation, the second stage of labor commences; thereafter, only progressive descent of the presenting fetal part is available to assess the progress of labor.

The Second Stage of Labor: Fetal Descent. In many nulliparas, engagement of the fetal head is accomplished before labor begins, and further descent does not occur until late in labor. In others in whom engagement of the fetal head is initially not so complete, further descent occurs during the first stage of labor. In the descent pattern of normal labor, a typical hyperbolic curve is formed when the station of the fetal head is plotted as a function of the duration of labor. Active descent usually takes place after dilatation has progressed for some time ([Figs. 6-2 and 6-12](#)). In nulliparas, increased rates of descent are observed ordinarily during the phase of maximum slope of cervical dilatation. At this time, the speed of descent increases to a maximum, and this is maintained until the presenting part reaches the perineal floor (Friedman, 1978).

CHANGES IN THE PELVIC FLOOR DURING LABOR. The birth canal is supported and is functionally closed by several layers of tissues that together form the pelvic floor. The most important structures are the levator ani muscle and the fascia covering its upper and lower surfaces, which for practical purposes may be considered as the pelvic floor. This group of muscles closes the lower end of the pelvic cavity as a diaphragm, and thereby a concave upper and a convex lower surface are presented (see [Chapter 2](#), p. 20). The levator ani consists of a pubococcygeus and iliococcygeus portion (Kearney and colleagues, 2004).

The posterior and lateral portions of the pelvic floor, which are not filled out by the levator ani, are occupied bilaterally by the piriformis and coccygeus muscles. The levator ani varies in thickness from 3 to 5 mm, though its margins encircling the rectum and vagina are somewhat thicker. During pregnancy, the levator ani usually undergoes hypertrophy, forming a thick band that extends backward from the pubis and encircles the vagina about 2 cm above the plane of the hymen. On contraction, the levator ani draws both the rectum and the vagina forward and upward in the direction of the symphysis pubis and thereby acts to close the vagina. The more superficial muscles of the perineum are too delicate to serve more than an accessory function.

In the first stage of labor, the membranes, when intact, and the fetal presenting part serve a role in dilating the upper portion of the vagina. The most marked change consists of the stretching of the fibers of the levator ani muscles and the thinning of the central portion of the perineum, which becomes transformed from a wedge-shaped mass of tissue 5 cm in thickness to a thin, almost transparent membranous structure less than 1 cm thick. When the perineum is distended maximally, the anus becomes markedly dilated and presents an opening that varies from 2 to 3 cm in diameter and through which the anterior wall of the rectum bulges. The extraordinary number and size of the blood vessels that supply the vagina and pelvic floor effect a great increase in the amount of blood loss when these tissues are torn.

Third Stage of Labor: Delivery of Placenta and Membranes. The third stage of labor begins immediately after delivery of the fetus and involves the separation and expulsion of the placenta and membranes. As the infant is born, the uterus spontaneously contracts around its diminishing contents. Normally, by the time the infant is completely delivered, the uterine cavity is nearly obliterated and the organ consists of an almost solid mass of muscle, several centimeters thick, above the thinner lower segment. The uterine fundus now lies just below the level of the umbilicus.

This sudden diminution in uterine size is inevitably accompanied by a decrease in the area of the placental implantation site (Fig. 6-13). For the placenta to accommodate itself to this reduced area, it increases in thickness, but because of limited placental elasticity, it is forced to buckle. The resulting tension causes the weakest layer of the decidua—the decidua spongiosa—to give way, and cleavage takes place at that site. Therefore, separation of the placenta results primarily from a disproportion created between the unchanged size of the placenta and the reduced size of the underlying implantation site. During cesarean delivery, this phenomenon may be directly observed when the placenta is implanted posteriorly.

Cleavage of the placenta is facilitated greatly by the nature of the loose structure of the spongy decidua, which may be likened to the row of perforations between postage stamps. As separation proceeds, a hematoma forms between the separating placenta and the remaining decidua. The hematoma is usually the result, rather than the cause, of the separation, because in some cases bleeding is negligible. The hematoma may, however, accelerate the process of cleavage. Because the separation of the placenta is through the spongy layer of the decidua, part of the decidua is cast off with the placenta, whereas the rest remains attached to the myometrium. The amount of decidual tissue retained at the placental site varies.

Placental separation ordinarily occurs within a very few minutes after delivery. Brandt (1933) and others, based on results obtained in combined clinical and radiographic studies, supported the idea that because the periphery of the placenta is probably the most adherent portion, separation usually begins elsewhere. Occasionally some degree of separation begins even before the third stage of labor, probably accounting for certain cases of fetal heart rate decelerations that occur just before expulsion of the infant.

SEPARATION OF AMNIOCHORION. The great decrease in the surface area of the uterine cavity simultaneously causes the fetal membranes (amniochorion) and the parietal decidua to be thrown into innumerable folds that increase the thickness of this layer from less than 1 mm to 3 to 4 mm. The lining of the uterus early in the third stage indicates that much of the parietal layer of decidua parietalis is included between the folds of the festooned amnion and chorion laeve (Fig. 6-14). The membranes usually remain in situ until the separation of the placenta is nearly completed. These are then peeled off the uterine wall, partly by the further contraction of the myometrium and partly by traction that is exerted by the separated placenta, which lies in the thin lower uterine segment or in the upper portion of the vagina. The body of the uterus at that time normally forms an almost solid mass of muscle, the anterior and posterior walls of which, each measuring 4 to 5 cm in thickness, lie in close apposition such that the uterine cavity is almost obliterated.

PLACENTAL EXTRUSION. After the placenta has separated from its implantation site, the pressure exerted upon it by the uterine walls causes it to slide downward into the lower uterine segment or the upper vagina. In some cases the placenta may be expelled by an increase in abdominal pressure, but women in the recumbent position frequently cannot expel the placenta spontaneously. An artificial means of completing the third stage is therefore generally required. The usual method employed is alternately to compress and elevate the fundus, while exerting minimal traction on the umbilical cord.

When the central, or usual, type of placental separation occurs, the retroplacental hematoma is believed to push the placenta toward the uterine cavity, first the central portion and then the rest. The placenta, thus inverted and weighted with the hematoma, then descends. Because the surrounding membranes are still attached to the decidua, the placenta can descend only by dragging the membranes along as they peel off its periphery. Consequently, the sac formed by the membranes is inverted, with the glistening amnion over the placental surface presenting at the vulva. The retroplacental hematoma either follows the placenta or is found within the inverted sac. In this process, known as the *Schultze mechanism* of placental expulsion, blood from the placental site pours into the inverted sac, not escaping externally until after extrusion of the placenta. In the other method of placental extrusion, known as the *Duncan mechanism*, separation of the placenta occurs first at the periphery, with the result that blood collects between the membranes and the uterine wall and escapes from the vagina. In this circumstance, the placenta descends to the vagina sideways, and the maternal surface is the first to appear at the vulva.

Figure 6-2. Composite of the average dilatation curve for nulliparous labor based on analysis of the data derived from the patterns traced from a large, nearly consecutive, series of gravidas. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts: an acceleration phase, a linear phase of maximum slope, and a deceleration phase. (Redrawn from Friedman, 1978.)

Figure 6-3. Sequence of development of the segments and rings in the uterus in pregnant women at term and in labor. Note comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower segment of the uterine body is derived from the isthmus; the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. (Anat. Int. Os = anatomical internal os; E.O. = external os; Hist. Int. Os = histological internal os; Ph.R.R. = physiological retraction ring.)

Figure 6-4. The uterus at the time of vaginal delivery. The active upper segment of the uterus retracts about the fetus as the fetus descends through the birth canal. In the passive lower segment, there is considerably less myometrial tone.

Figure 6-5. Cervix near the end of pregnancy but before labor. Top, primigravida; bottom, multipara. Note that the internal os and external cervical os are more dilated in the multipara.

Figure 6-6. Beginning effacement of the cervix. Note dilatation of the internal os and funnel-shaped cervical canal. Top, primigravida; bottom, multipara.

Figure 6-7. Further effacement of the cervix. Top, primigravida; bottom, multipara.

Figure 6-8. Cervical canal obliterated — that is, the cervix is completely effaced. Top, primigravida; bottom, multipara.

Figure 6-9. Hydrostatic action of membranes in effecting cervical effacement and dilatation. In the absence of intact membranes, the presenting part, applied to the cervix and the forming lower uterine segment, acts similarly. In this and [Figures 6-10](#) and [6-11](#), note changing relations of the external os (E.O.) and internal os (I.O.).

Figure 6-10. Hydrostatic action of membranes at completion of effacement. (E.O. = external os; I.O. = internal os.)

PHASE 3 OF PARTURITION: THE PUERPERIUM. Immediately after delivery, and for about an hour or so thereafter, the myometrium must be held in a state of rigid and persistent contraction and retraction, which effects compression of the large uterine vessels and thrombosis of their lumens. In this coordinated fashion, severe postpartum hemorrhage is prevented. During the early puerperium, a maternal-type behavior pattern develops and maternal-infant bonding begins. The onset of lactogenesis and milk let-down in maternal mammary glands also is, in an evolutionary sense, crucial to the bringing forth of young. Finally, involution of the uterus, which restores this organ to the nonpregnant state, and the reinstatement of ovulation must be accomplished in preparation for the next pregnancy. Four to six weeks usually are required for complete uterine involution; however, this process is dependent on the duration of breast feeding. Infertility usually persists as long as breast feeding is continued because of lactation-induced (prolactin-mediated) anovulation and amenorrhea (see [Chap. 32](#), p. 746).

PHYSIOLOGICAL AND BIOCHEMICAL PROCESSES REGULATING PARTURITION

The physiological processes in human pregnancy that result in the initiation of parturition and the onset of labor remain poorly defined. Presently, there are two general theorems on the mechanisms regulating the initiation of labor. Viewed simplistically, these are the *retreat from pregnancy maintenance* and the *uterotonin induction of parturition* hypotheses. Several combinations of selected tenets of these two postulates are incorporated into the theorems of most investigators.

Some researchers also speculate that the mature human fetus is the source of the initial signal for the commencement of the parturitional process. Other investigators suggest that one or more uterotonins, produced in increased amounts or an elevation in the population of its myometrial receptors, is the proximate cause of the initiation of human parturition. Indeed, an obligatory role for one or more uterotonins is included in most parturition theories, either as a primary or a secondary phenomenon in the final events of childbirth. Both of these suppositions rely on careful regulation of the activity of the myometrial smooth muscle cell contraction. Therefore, a detailed understanding of this critical tissue and its regulation aids in understanding normal and pathological progression of the various phases of parturition.

ANATOMICAL AND PHYSIOLOGICAL CONSIDERATIONS OF THE MYOMETRIUM.

There are unique characteristics of smooth muscle, including myometrium, compared with those of skeletal muscle. Huszar and Walsh (1989) point out that these differences create an advantage for the myometrium in the efficiency of uterine contractions and delivery of the fetus. First, the degree of shortening of smooth muscle cells with contractions may be one order of magnitude greater than that attained in striated muscle cells. Second, forces can be exerted in smooth muscle cells in any direction, whereas the contraction force generated by skeletal muscle is always aligned with the axis of the muscle fibers. Third, smooth muscle is not organized in the same manner as skeletal muscle, viz., in myometrium the thick and thin filaments are found in long, random bundles throughout the cells. This arrangement facilitates greater shortening and force-generating capacity of smooth muscle. Fourth, there is the advantage that multidirectional force generation in the uterus — fundus versus lower uterine segment — permits versatility in expulsive force directionality that can be brought to bear irrespective of the lie or presentation of the fetus.

REGULATION OF MYOMETRIAL CONTRACTION AND RELAXATION.

The control of myometrial contraction is at the heart of understanding both the maintenance of pregnancy and the onset of labor. The regulation of myometrial cell contraction versus relaxation can be divided temporally into acute and chronic mechanisms. Acutely, the interaction of myosin and actin is essential to muscle contraction. Myosin (Mr about 500,000) is comprised of multiple light and heavy chains and is arranged in thick myofilaments. The interaction of myosin and actin, which causes activation of adenosine triphosphatase, adenosine triphosphate hydrolysis, and force generation, is effected by enzymatic phosphorylation of the 20-kd light chain of myosin (Stull and colleagues, 1988, 1998). This phosphorylation reaction is catalyzed by the enzyme *myosin light chain kinase*, which is activated by calcium ([Fig. 6-15](#)). Calcium binds to calmodulin, a calcium-binding regulatory protein, which in turn binds to and activates myosin light chain kinase. In this manner, agents that act on myometrial smooth muscle cells to cause an increase in the intracellular cytosolic concentration of calcium ($[Ca^{2+}]_i$) promote contraction. The increase in $[Ca^{2+}]_i$ is often transient, but contractions can be prolonged through the inhibition of myosin phosphatase activity by Rho kinase, which is activated in a receptor-dependent fashion (Woodcock and associates, 2004). Conditions that cause a decrease in $[Ca^{2+}]_i$ favor relaxation. Ordinarily, agents that cause an increase in the intracellular concentration of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP) promote uterine relaxation. It is believed that cAMP and cGMP act to cause a decrease in $[Ca^{2+}]_i$, although the exact mechanism(s) is not defined.

Myometrial cell contractions also can be greatly influenced by the chronic action of hormones on the contractile status of the cell. This influence can occur through the effects that mediate the transcription of key genes that repress or enhance the contractility of the cell. Considerable data indicate that uterine activity is influenced through the regulation of the so-called *contraction-associated proteins (CAPs)*. These proteins include channels associated with smooth muscle excitation and contraction, gap junction components, and uterotonic stimulatory or inhibitory receptors.

Myometrial Gap Junctions. Like other muscle cells, the cellular signals that control myometrial contraction and relaxation

can be effectively transferred between cells through intercellular junctional channels. Communication is established between myometrial cells by gap junctions that facilitate the passage of electrical or ionic coupling currents as well as metabolite coupling. The transmembrane channels that make up the gap junctions consist of two protein "hemi-channels," termed *connexons*. Each connexon is hexameric assemblage of a type of protein called a connexin. These pairs of connexons establish a conduit for the exchange of small molecules (Mr less than 1000) and ions between cells.

The physiological importance of optimal numbers (area) of functional permeable gap junctions between myometrial cells is believed to be the establishment of electrical synchrony in the myometrium, which effects coordination of contractions and thereby greater force during labor. As discussed below, the regulated expression of gap junction proteins is one way to regulate uterine quiescence.

Cell Surface Receptors As Regulators of Myometrium. Myometrial cells have developed a unique system of regulatory pathways that rely not only on estrogen and progesterone receptors but also on a variety of cell surface receptors that can directly regulate the contractile state of the cell. The three major classes of cell surface receptors are the G-protein-linked, ion channel-linked, and enzyme-linked. Multiple examples of each class of receptors have been identified in human myometrium, and examples of each class appear to be modified during the phases of parturition. Most of these heptahelical receptors are associated with the activation of adenylyl cyclase. Other heptahelical receptors in myometrium, however, are more commonly associated with G-protein-mediated activation of phospholipase C, which will lead to increased $[Ca^{2+}]_i$ and myometrial cell contraction. Many G-protein-coupled receptors that participate in regulation of myometrial activity have been characterized. These were reviewed recently by Lopez (2003).

Ligands for the heptahelical receptors include neuropeptides, hormones, and autacoids. Many of these are available to the myometrium during pregnancy in high concentration by several routes: from maternal blood (endocrine), contiguous tissues or adjacent cells (paracrine), or direct synthesis in the myometrial smooth muscle cells (autocrine) (Fig. 6-16). It is important to note that the myometrial response to a hormone can change during the course of pregnancy. Thus, it is conceivable that hormone action on the myometrium is regulated at several levels, including the expression of the heptahelical receptor, its associated G-proteins, or the effector proteins in the plasma membrane. Specifically, the imposition of quiescence (activation of adenylyl cyclase) or the facilitation of contractions (activation of phospholipase C and increased $[Ca^{2+}]_i$) may in some cases be regulated by the same hormone.

Figure 6-15. Regulation of myometrial smooth muscle cell contraction and relaxation. There are numerous agonists that bind cell surface receptors and activate phospholipase C and its production of inositol 1,4,5-trisphosphate (IP_3). IP_3 will bind receptors on the sarcoplasmic reticulum and cause release of calcium (Ca^{2+}) into the cytoplasm. Ca^{2+} can also be increased through voltage- or receptor-activated channels. Ca^{2+} will activate calmodulin, leading to increased activity of myosin light chain kinase (MLC kinase) and phosphorylation of myosin light chain (MLC). Phosphorylated MLC interacts with actin, activating adenosine triphosphatase and, through the hydrolysis of adenosine triphosphate (ATP), generates the force needed for contraction. Contraction can be sustained by activation of the guanosine triphosphate (GTP)-binding protein, RhoA, and Rho kinase, which will phosphorylate and inhibit myosin phosphatase. Relaxation results from reversal by removal of the ligand from its receptor. Relaxation also can occur through the activity of hormones that inactivate MLC kinase, as has been seen for agents that activate the cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate signaling pathway. (PAF = platelet-activating factor.) (Based on Webb, 2003.)

Figure 6-16. Theoretical fail-safe system involving endocrine, paracrine, and autocrine mechanisms for the maintenance of phase 0 of parturition, uterine quiescence. (CRH = corticotropin-releasing hormone; hCG = human chorionic gonadotropin; PGE_2 = prostaglandin E_2 ; PGI_2 = prostaglandin I_2 ; PTH-rP = parathyroid hormone-related peptide.)

A FAIL-SAFE SYSTEM THAT MAINTAINS UTERINE QUIESCENCE. The myometrial smooth muscle is, inherently, a contractile tissue. Isolated strips of myometrium from uteri of nonpregnant women placed in an isotonic water bath contract in a rhythmical fashion without added stimuli, even in the presence of prostaglandin synthase inhibitors (Crankshaw and Dyal, 1994). Therefore, it is difficult to comprehend how the uterus can be expanded to accommodate a 3500-g fetus, 1 liter of amniotic fluid, and 800 g of placenta and membranes without erupting into powerful contractions. The myometrial quiescence of phase 0 of parturition is so remarkable and successful that it probably is induced by multiple independent and cooperative biomolecular processes. Individually, some of these processes may be redundant; that is, pregnancy may continue in the absence of one or more processes that normally contribute to the fail-safe system of pregnancy maintenance.

The physiological investments that must be made to sustain the uterine quiescence of phase 0 are enormous. It is likely that all manner of biomolecular systems—neural, endocrine, paracrine, and autocrine—are called on to implement and coordinate a state of relative uterine unresponsiveness. Moreover, a complementary fail-safe system that protects the uterus against agents that could perturb the tranquil state of phase 0 also must be in place.

Phase 0 of human parturition and its quiescent state are likely the result of many factors, including:

1. Actions of estrogen and progesterone via intracellular receptors.
2. Myometrial cell plasma membrane receptor-mediated increases in cAMP.
3. The generation of cGMP.
4. Other systems, including modifications in myometrial cell ion channels.

Because phase 0 is the result of several independent pathways, it is likely that defects—either naturally occurring or pharmacologically induced—in one component of this system might not necessarily preclude the successful maintenance of pregnancy to term (Fig. 6-17).

Progesterone and Estrogen Contributions to Phase 0 of Parturition. In many species the role of the sex steroids is clear—progesterone inhibits and estrogen promotes the events leading to parturition. In humans, however, it seems most likely that both estrogen and progesterone are components of a broader-based fail-safe biomolecular system that implements and maintains phase 0 of human parturition and thus the maintenance of pregnancy. In many species the removal of progesterone, or *progesterone withdrawal*, directly precedes the progression of phase 0 into phase 1 of parturition. In addition, providing progesterone to some species will delay parturition and decrease myometrial activity (Challis and Lye, 1994). In these species the progestational effects of progesterone have been well studied, leading to a better understanding of why the myometrium of phase 0 is relatively noncontractile.

The plasma levels of estrogen and progesterone in normal human pregnancy are enormous. Both are in great excess of the affinity constants for estrogen and progesterone receptors. For this reason, it is difficult to comprehend how relatively subtle changes in the ratio of the concentrations of these two steroids could modulate physiological processes during human pregnancy. The teleological evidence, however, for a role of the progesterone-to-estrogen ratio in the maintenance of pregnancy and parturition is overwhelming. The rationale for the supraphysiological concentrations of both estrogens and progesterone in human pregnancy is still poorly defined.

It has been presumed for decades that progesterone action is essential for the successful maintenance of pregnancy. Regrettably, however, neither the biomolecular evidence for this nor the role of other agents in promoting uterine quiescence is clearly defined. Because of its action in other mammalian species, however, it is presumed that progesterone acts to establish and maintain the uterine phase 0 of parturition.

The exact role of estrogen in regulating the human uterine contractile state has always proven difficult to elucidate. Defining estrogen action is complicated by the presence of cell surface and nuclear receptors that can respond to estrogen. It would appear, however, that estrogen can act to promote progesterone responsiveness and in doing so promote uterine quiescence. In many responsive tissues, the estrogen receptor, acting via the estrogen response element of the progesterone receptor gene, induces progesterone receptors synthesis.

Steroid Hormone Regulation of Myometrial Cell-to-Cell Communication. Considerable data indicate that progesterone increases uterine quiescence by direct or indirect effects that cause decreased expression of the contraction-associated proteins. Key proteins in the CAP grouping would include channels associated with smooth muscle excitation-contraction, gap junction components, and uterotonic stimulatory receptors. Progesterone has been shown to inhibit expression of the gap junctional protein connexin 43 in several rodent models of labor. Administration of progesterone prevents or delays labor and prevents the normal induction of connexin 43 expression seen at term during uterine activation prior to labor. Inhibition of progesterone activity at midgestation using the progesterone receptor antagonist RU 486 leads to a premature induction of connexin 43 protein production in the uterus and thus stimulates labor.

Estrogen treatment promotes myometrial gap junction formation in some animals by increasing connexin 43 synthesis. The simultaneous administration of anti-estrogens prevents this (Burghardt and colleagues, 1984). Progesterone treatment also negates the stimulatory effect of estrogen on the development of gap junctions in some animals. Conversely, progesterone antagonists lead to the premature development of gap junctions and preterm labor and delivery (Chwalisz and colleagues, 1991). In myometrial tissue obtained from pregnant women before labor, when the number of gap junctions is small, a spontaneous increase in the number of gap junctions occurs when the tissue is placed in vitro (Hayashi and collaborators, 1985). This suggests that the excised tissue is relieved from a pregnancy endocrine milieu that prevented gap junction development in vivo. The mechanisms leading to increased gap junctions at the time of labor, however, are still unclear. Chow and Lye (1994) found that the level of connexin 43 mRNA in human myometrial tissues increased before labor, between 37 and 40 weeks, and increased further after labor began. Gap junctions also increased in myometrium from laboring women. Interestingly the expression of connexin 43 protein did not increase during gestation or at labor, leaving in question the intracellular regulator of actual gap junction assembly at the time of labor. These processes appear to be regulated in part by estrogen and progesterone.

Heptahelical Receptors That Promote Myometrial Relaxation. The possibility also must be considered that the contractile unresponsiveness imposed on the uterus during most of human pregnancy is ensured by multiple processes that act independently and cooperatively to establish uterine quiescence. A number of heptahelical receptors that nominally are associated with G_{os} -mediated activation of adenylyl cyclase and increased levels of cAMP are present in myometrium. These receptors together with appropriate ligands may act (in concert with sex steroid hormones) as part of a fail-safe system to maintain uterine quiescence, phase 0 of parturition (Price and associates, 2000; Sanborn and colleagues, 1998).

BETA-ADRENORECEPTORS. In studies of the role of cAMP signaling in causing myometrium relaxation, the β -adrenergic receptors have served as prototypes. Most commonly, the β -adrenergic receptors mediate G_{os} -stimulated increases in adenylyl cyclase, increased levels of cAMP, and myometrial cell relaxation. The rate-limiting factor in the β -receptor system is likely the number of β -receptors expressed and the level of adenylyl cyclase expression. The number of G-proteins in most systems far exceeds the number of receptors and effector molecules. The exact role of catecholamines in maintaining uterine quiescence in vivo remains ill defined.

LUTEINIZING HORMONE (LH) AND CHORIONIC GONADOTROPIN (Hcg). The heptahelical receptor for LH-hCG has been demonstrated in a number of extragonadal tissues, including myometrial smooth muscle and blood vessels (Lei and co-workers, 1992; Ziecik and colleagues, 1992). Initially, their identification seemed quite aberrant considering the more commonly recognized tissue localization in the ovary and testis. The levels of the LH-hCG receptor in myometrium during pregnancy are greater before than during labor (Zuo and colleagues, 1994). Chorionic gonadotropin acts to activate adenylyl cyclase by way of a plasma membrane receptor- $G_{\alpha s}$ -linked system. This causes a decrease in contraction frequency and force and a decrease in tissue-specific myometrial cell gap junctions (Ambrus and Rao, 1994; Eta and co-workers, 1994). Thus, the high circulating levels of hCG during pregnancy may be one mechanism causing uterine quiescence.

RELAXIN. This peptide hormone is a member of the insulin-like growth factor family of proteins, consisting of an A and B chain (Bogic and associates, 1995; Weiss, 1995). There are two separate human relaxin genes, designated H1 and H2. Relaxin in plasma of pregnant women is believed to originate exclusively by secretion from the corpus luteum. Plasma levels of relaxin are greatest and peak at about 1 ng/mL between 8 and 12 weeks, and thereafter decline to lower levels that persist until term. The plasma membrane receptor for relaxin mediates the activation of adenylyl cyclase and promotes myometrial relaxation, but also effects cervical softening. Consequently, it has not been possible to envision a clear-cut role for this hormone in human parturition.

CORTICOTROPIN-RELEASING HORMONE (CRH). This heptahelical receptor is present in myometrium during pregnancy. There are multiple isoforms of the receptor in myometrium, and their affinity and coupling are modified late in pregnancy (Grammatopoulos and associates, 1994, 1995; Hillhouse and colleagues, 1993). CRH is synthesized in the placenta, amnion, decidua, and myometrium. As discussed below, plasma levels of CRH increase during the final 6 to 8 weeks of normal pregnancy in dramatic fashion. Because of this, several investigators have suggested that CRH is involved in the initiation of human parturition (Wadhwa and colleagues, 1998). CRH receptors can signal through either cAMP or calcium, thus CRH may cause relaxation or contraction of myometrial cells depending on the receptor isoform present. It is for that reason that CRH could potentially play the role of a uterorelaxant during phase 0 and a uterotonic in phases 1 and 2 of parturition.

PARATHYROID HORMONE-RELATED PROTEIN (PTH-rP). The receptor for PTH-rP is a plasma membrane heptahelical receptor. Most often this receptor initiates $G_{\alpha s}$ -mediated activation of adenylyl cyclase. PTH-rP is expressed in myometrium, decidua, amnion, and trophoblast. Treatment of human myometrial cells with estrogen and transforming growth factor- β causes an increase in the levels of PTH-rP mRNA (Casey and associates, 1992; Paspaliaris and associates, 1995). PTH-rP expression in smooth muscle, including myometrium, is increased by muscle stretch (Daifotis and associates, 1992; Yamamoto and colleagues, 1992). Whereas the function of PTH-rP in uterine physiology is not established, it may serve to maximize uterine blood flow during myometrial contractions by its vasorelaxant action (Thiede and colleagues, 1991a, 1991b). PTH-rP also may act on myometrial smooth muscle to facilitate the maintenance of uterine tranquility.

PROSTAGLANDINS. The prostanoids interact with a family of eight different heptahelical receptors, several of which are expressed in the myometrium (Myatt and Lye, 2004). Although prostaglandins most commonly have been considered as uterotonins (see p. 173), prostanoids can sometimes act as smooth muscle relaxants. Because the individual prostanoid can have such diverse effects, it is important to review the major synthetic pathways involved in prostaglandin biosynthesis (Fig. 6-18). Prostaglandins are produced using plasma membrane-derived arachidonic acid, which usually is released by the action of the phospholipases A_2 or C on membrane phospholipids. Arachidonic acid can then act as substrate for both type 1 and type 2 prostaglandin H synthase (PGHS-1 and -2), also called cyclooxygenase-1 and -2. In general PGHS-1 is constitutively expressed, whereas PGHS-2 expression is highly regulated. These two isoforms share 65-percent sequence similarity, and both will convert arachidonic acid to the unstable endoperoxide prostaglandin G_2 and then to prostaglandin H_2 . These enzymes are the target of many nonsteroidal anti-inflammatory drugs (NSAIDs), and the ability of these or new specific NSAIDs to act as tocolytics to safely prevent preterm labor is an active area of research (Loudon and co-workers, 2003; Olson, 2003). As substrate for several prostaglandin isomerases, prostaglandin H_2 is converted to active prostaglandins, including PGE_2 , $PGF_{2\alpha}$ and PGI_2 . The expression of the prostaglandin isomerases is tissue-specific, thus controlling the relative production of the various prostaglandins. However, within a tissue the activity of these enzymes does not appear to be rate limiting. Another important control point for prostaglandin activity is metabolism, which most often occurs through the action of 15-hydroxyprostaglandin dehydrogenase (PGDH). The expression of this enzyme can be regulated in the uterus, which is important because of its ability to rapidly inactivate prostaglandins to their respective 15-keto metabolites.

The effect of prostaglandins on tissue targets is complicated by the fact that there are a number of G-protein-coupled prostaglandin receptors (Coleman and associates, 1994). The prostaglandin family of receptors is classified according to the specificity of binding of a given receptor to a particular prostaglandin. The receptors (and their naturally occurring, preferred ligands) are TP (thromboxane A_2), DP (PGD_2), IP (prostacyclin or PGI_2), FP ($PGF_{2\alpha}$), and EP₁ to EP₄ (PGE_2). The signaling pathways activated by these receptors differ in that DP and IP receptors increase intracellular cAMP, whereas FP receptors increase intracellular calcium. In addition, the EP receptor family has several isoforms, including EP₂ and EP₄, which activate cAMP production, and EP₁ and EP₃, which increase intracellular calcium levels. With this in mind, both PGE_2 and PGI_2 could act to maintain uterine quiescence by increasing cAMP signaling.

Indeed, PGE_2 , PGD_2 , and PGI_2 have been shown to cause relaxation of vascular smooth muscle and vasodilatation in many circumstances. Thus, either the generation of specific prostaglandins or the relative expression of the various prostaglandin receptors may determine the responses of human myometrium to prostaglandins. For example, Breuiller and co-workers (1991) found that prostanoids stimulate adenylyl cyclase activity in myometrium obtained at 32 to 35 weeks, but not in tissue obtained at 39 to 40 weeks. More recent studies have shown alterations in the expression of the EP receptor isoforms in myometrium in laboring women and baboons (Lyll and associates, 2002; Smith and colleagues, 1998, 2001). In addition to changes with gestation, several studies show that there may be regional changes in the upper and lower uterine segments. Thus, it is entirely possible that prostanoids contribute to myometrial relaxation at one stage of pregnancy and to regional myometrial contractions in the fundus after the initiation of parturition (Myatt and Lye, 2004).

ATRIAL AND BRAIN NATRIURETIC PEPTIDES AND CYCLIC GUANOSINE MONOPHOSPHATE (cGmp). The activation of guanylyl cyclase gives rise to increased intracellular levels of cGMP, which also promotes smooth muscle relaxation (Word and

colleagues, 1993). The intracellular levels of cGMP can be stimulated by either of the two forms of atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) receptors that are both present in the myometrium during human pregnancy (Itoh and co-workers, 1994). These receptors structurally include the enzymatic activity of guanylyl cyclase and mediate an increase in the cellular levels of cGMP. Specifically, the ANP-BNP receptor molecule is a guanylyl cyclase. BNP is secreted by amnion in large amounts, and ANP is expressed in placenta (Itoh and associates, 1993; Lim and Gude, 1995).

The soluble form of guanylyl cyclase is activated by nitric oxide, which, because of its very hydrophobic nature, readily penetrates the plasma membrane to enter cells. Nitric oxide reacts with iron in the active site of the soluble guanylyl cyclase enzyme, stimulating it to produce cGMP, and acts to cause myometrial relaxation (Izumi and colleagues, 1993). Nitric oxide is synthesized in decidua, myometrial blood vessels, and nerves (Yallampalli and colleagues, 1994a, 1994b). Whether nitric oxide gains access to the myometrium and how the synthesis and action of nitric oxide is regulated as it pertains to a potential contribution to uterine quiescence is not understood.

Accelerated Uterotonin Degradation and Phase 0 of Parturition. In addition to pregnancy-induced compounds that stimulate myometrial cell refractoriness, there are striking increases in the activities of enzymes that degrade or inactivate endogenously produced uterotonins. Some of these uterotonins (and their degradative enzymes) include prostaglandins (e.g., PGDH), endothelins (e.g., enkephalinase), oxytocin (e.g., oxytocinase), histamine (e.g., diamine oxidase), catecholamines (e.g., catechol O-methyltransferase), angiotensin-II (e.g., angiotensinases), and platelet-activating factor (PAF) (e.g., PAF-acetylhydrolase). The activities of several of these enzymes are increased by progesterone action and many decrease late in gestation (Bates and co-workers, 1979; Casey and associates, 1980, Germain and colleagues, 1994; Yasuda and Johnston, 1992).

Figure 6-17. The key factors thought to regulate the phases of parturition. (CRH = corticotropin-releasing hormone; hCG = human chorionic gonadotrophin; PTH-rP = parathyroid hormone-related peptide.) (Based on Challis and co-workers, 2002.)

FAIL-SAFE SYSTEMS FOR UTERINE ACTIVATION. The morphological and functional changes in the myometrium and cervix that prepare the uterus for labor are considered phase 1 of parturition. This process is characterized by the development of uterotonin sensitivity, improved intercellular communicability via gap junctions, and alterations in the capacity of myometrial cells to regulate the concentration of cytoplasmic Ca²⁺. The processes leading to enhanced uterine responsiveness also have been termed *activation* by Challis and associates (2000). There are likely multiple systems responsible for the uterine activation seen during phase 1 (see Fig. 6-17). As the functional contractile capacity of the myometrium is realized and the cervix is ripened, phase 1 merges into phase 2, active labor. Alterations in the timing of these processes are likely to cause preterm and delayed labor, making an understanding of these prelabor events key.

Classical Progesterone Withdrawal Does Not Cause Human Parturition. In many species the drop in maternal plasma progesterone levels, *progesterone withdrawal*, allows activation of the uterus in preparation for labor. This decrease in progesterone levels is associated with an increase in estrogen levels in several species, and this shift in the steroid milieu is thought to have dramatic effects on both the cervix and the myometrium. In primates, however, plasma progesterone levels do not decrease before labor (Challis and Lye, 1994). Plasma levels decline only after delivery of the placenta. Nonetheless, the morphological and functional modifications that prepare the uterus for labor occur in a timely manner in human pregnancy just as in those species in which progesterone withdrawal is a clearly demonstrable endocrine antecedent of parturition.

In species that exhibit progesterone withdrawal, progression of parturition to labor can be blocked by administering progesterone to the mother. In pregnant women, however, there are conflicting reports as to whether or not progesterone administration can delay the timely onset of parturition or prevent preterm labor. The majority of studies suggest that progesterone cannot prevent preterm labor and does not appear to extend labor in the control group (Goldstein and associates, 1989). In contrast, there have been some optimistic reports on the ability of the progesterone metabolite, 17-hydroxyprogesterone, to minimally decrease the incidence of preterm labor in high-risk populations (Johnson and associates, 1979; Keirse, 1990; Meis and co-workers, 2003; Yemini and colleagues, 1985). The fact that 17-hydroxyprogesterone is much less potent than progesterone at binding and activating the progesterone receptor suggests that additional research needs to be done to explain the action of this steroid and how it could prevent the onset of preterm labor.

Progesterone Receptor Antagonists and Human Parturition. When the steroidal antiprogesterin RU 486, or mifepristone, is administered to women during the latter phase of the ovarian cycle, it induces menstruation prematurely. It is also quite effective in the induction of abortion during early stages of pregnancy (Avrech and co-workers, 1991). This compound is a classical steroid antagonist, acting at the level of the progesterone receptor. Although less effective in inducing abortion or labor in women later in pregnancy, RU 486 remains effective in ripening the cervix and increasing myometrium sensitivity to uterotonins (Chwalisz and Garfield, 1994; Chwalisz, 1994). Further support for the ability of progesterone withdrawal to effect labor in primates can be found in studies that decreased circulating progesterone by inhibiting the enzyme 3 β -hydroxysteroid dehydrogenase, which induced labor (Haluska and associates, 1997; Selinger and co-workers, 1987). One interpretation for these data is that in humans the inhibition of progesterone action is important for activation phase of parturition, but there is a "hidden" or unique form of functional progesterone withdrawal that ends uterine quiescence.

Functional Progesterone Withdrawal in Human Parturition. As an alternative to classical progesterone withdrawal, many researchers have focused on determining if humans have evolved unique mechanisms to inhibit progesterone action. This theory of functional progesterone withdrawal or progesterone antagonism could be mediated in the uterus through several mechanisms, including:

1. Changes in the relative expression of the progesterone receptor or of its two isoforms (PR-A and PR-B).
2. Posttranslational modifications of the progesterone receptor causing decreased activity.
3. Alterations in progesterone receptor activity through changes in the expression of co-activators or co-repressors that directly influence receptor function.
4. Local inactivation of progesterone by steroid-metabolizing enzymes or the synthesis of a natural antagonist.

Indeed, there is experimental evidence that lends support to each of these possible explanations for a functional progesterone withdrawal that could occur in the presence of high circulating progesterone levels. The most obvious possibility would be a late gestational decrease in activity of the progesterone receptor expression that would cause a functional withdrawal. There are now several lines of evidence that suggest that the activity of the progesterone receptor is decreased late in gestation. As was discussed in [Chapter 3](#), there are two isoforms of the progesterone receptor (PR-A and PR-B). The PR-B isoform is more transcriptionally active than the PR-A isoform, which has actually been shown to inhibit PR-B activity. In a series of studies, it has been shown that there is a shift in relative ratio of PR-A to PR-B within the myometrium late in gestation that may be the cause of a functional progesterone withdrawal (Haluska, 2002; Madsen, 2004; Mesiano, 2002; Pieber, 2001, and all of their colleagues). Analysis of the placental membranes for PR-A and PR-B suggests that the ratio is similarly modified in decidua and chorion, but that there is a drop in overall progesterone receptor expression in the amnion (Haluska and co-workers, 2002). The activity of progesterone receptors for gene transcription also is impacted through the levels of several co-activators and co-repressors. It would appear that there is a decrease in co-activators and an increase in co-repressors for the progesterone receptor in late gestation, which would further enhance a functional withdrawal (Allport and co-workers, 2001; Condon and colleagues, 2003).

There is also evidence using rodent models that functional progesterone withdrawal within the cervix results from local inactivation of progesterone. Indeed, if mice are produced without the expression of 5α -reductase, the cervix does not ripen and parturition does not occur (Mahendroo and colleagues, 1999). Finally, there is also some support for antiprogestin-like activities of glucocorticoids on progesterone receptor activity (Karalis and co-workers, 1996). Because glucocorticoids play an important role in the initiation of parturition in several species, examining their potential role as an antiprogestin in humans warrants further study. Taken together, these observations support the concept that humans do undergo a progesterone withdrawal, which results from a decrease in receptor activity.

Oxytocin Receptors. There is still controversy as to whether oxytocin plays a role in the early phases of uterine activation or solely in the expulsive phase of labor. Most studies to evaluate the regulation of myometrial oxytocin receptor synthesis have been performed in the rat and mouse. Disruption of the oxytocin gene in the mouse does not affect parturition, suggesting that at least in this species multiple systems are in place to ensure that parturition occurs. There is little doubt, however, that there is an increase in oxytocin receptors in the myometrium during phase 1 of parturition.

Progesterone and estradiol appear to be the primary regulators of oxytocin receptor expression. Estradiol treatment either in vivo or in myometrial explants causes an increase in myometrial oxytocin receptors. This action is prevented by simultaneous treatment with progesterone (Fuchs and colleagues, 1983). Progesterone also may act within the myometrial cell to increase oxytocin receptor degradation and at the cell surface to inhibit oxytocin activation of its receptor (Bogacki and associates, 2002; Soloff and colleagues, 1983). These data indicate that one of the mechanisms whereby progesterone maintains uterine quiescence is through the inhibition of myometrial oxytocin response.

The increase in oxytocin receptors appears to be mainly regulated either directly or indirectly by estradiol. Estradiol treatment of several species leads to an increase in uterine oxytocin receptors (Blanks and co-workers, 2003; Challis and Lye, 1994). In vitro studies using myometrial cells have shown that estradiol can increase the expression of oxytocin receptors (Adachi and Oku, 1995). The level of oxytocin receptor mRNA in myometrium obtained at caesarean delivery at term is greater than that found in preterm myometrium (Wathes and co-workers, 1999). Thus, the increase in oxytocin receptor number in myometrium at term may be attributable to increased oxytocin gene transcription. An estrogen response element, however, is not present in the oxytocin receptor gene, suggesting that the stimulatory effects of estrogen may occur indirectly. Oxytocin receptors also are present in human endometrium and in decidua at term, and these stimulate prostaglandin production (Fuchs and associates, 1981). Oxytocin receptors also are present, albeit at lower levels, in amnion and chorion-decidual tissues (Benedetto and associates, 1990; Wathes and co-workers, 1999).

FETAL CONTRIBUTIONS TO INITIATION OF PARTURITION. It is intellectually intriguing to envision that the fetus, after appropriate growth and maturation of vital organs, provides the initial signal that sets the parturitional process in motion. Teleologically, this seems to be the most logical manner by which parturition could begin in a timely fashion. A signal from the human fetus could be transmitted in one of several ways, but however accomplished, the end result must include the suspension of uterine quiescence. This system of fetal signals has been most studied in fetal sheep, where the parturitional process is believed to proceed via the fetal brain, pituitary gland, adrenal glands, and fetal blood to the placenta. The human fetus also may provide a signal through a blood-borne agent that acts on the placenta. It is unlikely, however, that the initial signal for phase 1 of parturition is a uterotonic such as oxytocin, prostaglandins, or endothelin-1. Rather, it is more likely that the uterus first must be prepared for labor before a uterotonic can be optimally effective (Casey and MacDonald, 1994).

Role of Uterine Stretch in Parturition. There is now considerable evidence that fetal growth is an important component in the activation of the uterus seen in phase 1 of parturition. During the course of gestation, and in association with fetal growth, there is a significant increase in myometrial tensile stress and amniotic fluid pressure (Fisk and co-workers, 1992). Much of the work demonstrating a role for stretch in the activation of the uterus prior to labor comes from studies in rat models of parturition. In this model, stretch was required for the normal induction of specific contraction-associated proteins (CAPs).

Stretch also increased expression of the gap junction protein, connexin 43, as well as oxytocin receptors. Other studies have led to the hypothesis that stretch plays an integrated role with fetal-maternal endocrine cascades in uterine activation prior to labor (Lyll and co-workers, 2002; Ou and colleagues, 1997, 1998).

Support for a role of stretch in human parturition comes from the observation that twin pregnancies are at a much greater risk of preterm labor than singletons (Gardner and co-workers, 1995). In addition, preterm labor is also significantly more common in pregnancies complicated by hydramnios, where uterine stretch would occur (Many and colleagues, 1996). Although the mechanisms causing preterm birth in twin pregnancies and in hydramnios are still debated, a role for uterine stretch must be considered.

The cell signaling systems used by stretch to regulate the myometrial cell continue to be defined. This process, termed *mechanotransduction*, may include activation of cell surface receptors or ion channels, signaling through extracellular matrix, or through the release of autocrine molecules that act directly on the myometrial cells. It appears likely that the elevated expression of CAP genes allows the myometrium to be more responsive to the uterotonins that appear late in gestation at the time of labor.

Fetal Endocrine Cascades Leading to Parturition. The ability of the fetus to provide endocrine signals that set into motion the parturitional process has been demonstrated in several species. More than 30 years ago, Liggins and associates (1967, 1973) demonstrated that the fetus provides the signal for the timely onset of parturition in sheep, and this signal was shown to come from the fetal hypothalamic-pituitary-adrenal axis. It is now well established that parturition in the sheep results from the initiation of an endocrine cascade involving a hypothalamic-pituitary-adrenal-placental axis (Whittle and co-workers, 2001).

Defining the exact mechanisms regulating human parturition has proven more difficult, and all evidence suggests that it is not regulated in the exact manner seen in the sheep. There is considerable evidence, however, that there is a placental-pituitary-adrenal axis that may play a key, albeit different, role in the timing of human parturition. Indeed, activation of the human fetal hypothalamic-pituitary-adrenal axis is considered a critical component of normal parturition. Moreover, premature activation of this axis is considered a cause of many cases of preterm labor (Challis and co-workers, 2000, 2001). As in the sheep, the steroid products of the human fetal adrenal gland are believed to have effects on the placenta and membranes that eventually promote the myometrium to transform from a quiescent to contractile state. If true, then this cascade is an important component of the activation phase of parturition. Current evidence suggests that human parturition is regulated in part through an endocrine cascade that includes the hypothalamic-pituitary-adrenal-placental axis that is quite unique from that seen in the sheep model. A key component in the human may be the unique ability of the placenta to produce large amounts of corticotropin-releasing hormone (CRH).

Actions of CRH on the Fetal Adrenal Gland. As discussed in [Chapter 3](#) (see p. 78), the human fetal adrenal glands are morphologically, functionally, and physiologically remarkable organs. At term, the fetal adrenal glands weigh the same as those in the adult and are similar in size to the adjacent fetal kidney. The daily production of steroids by the fetal adrenal glands near term is estimated to be 100 to 200 mg/day, which is higher than the 30 to 40 mg/day seen in adult adrenals at rest. Within the fetal adrenal gland, steroidogenic function and zonation are different from the adult. For example, significant amounts of cortisol are not produced in the fetal adrenal gland until the last trimester. As a result, fetal cortisol levels increase during the last weeks of gestation (Murphy, 1982). During this same period, levels of dehydroepiandrosterone sulfate (DHEA-S) production also are increasing significantly, leading to increases in maternal estrogens, particularly estriol. The increase in adrenal activity occurs in contrast to fetal adrenocorticotrophic hormone (ACTH) levels which do not increase until the stress of actual labor.

This substantial growth and increased steroid synthesis during latter gestation is at a time when fetal plasma ACTH levels appear to decline (Winters and co-workers, 1974). Thus, many investigators have surmised that there must be growth and steroidogenesis stimuli for these glands in addition to ACTH. Two observations have made it extremely likely that factors secreted by the placenta play a key role in the regulation of steroidogenesis during late gestation. First, the fact that ACTH levels do not increase significantly during the last part of gestation makes it likely that growth and differentiation of the fetal adrenal glands are influenced by factors secreted by the placenta. Second, the fetal zone of the adrenal gland undergoes rapid involution immediately after birth when placenta-derived factors are no longer available. Many believe that CRH of placental origin is one of the critical components that facilitates fetal adrenal hypertrophy and increased steroidogenesis late in gestation. Indeed, *in vitro* studies have shown that CRH is able to stimulate fetal adrenal DHEA-S and cortisol biosynthesis (Parker and associates, 1999; Smith and co-workers, 1998). The ability of CRH to regulate the adrenal glands and of the adrenals to regulate placental production of CRH has led to the idea of a feed-forward endocrine cascade that occurs late in gestation ([Fig. 6-19](#)).

Placental CRH Production. In addition to maternal and fetal hypothalamic CRH, an identical CRH hormone is synthesized by the placenta in relatively large amounts (Grino and associates, 1987; Saijonmaa and colleagues, 1988). Unlike hypothalamic CRH, which is under glucocorticoid negative feedback, cortisol has been shown to stimulate placental CRH production both *in vitro* and *in vivo*, in humans and other primates (Jones and associates, 1989; Karalis and Majzoub, 1995; Marinoni and associates, 1998). The ability of cortisol to stimulate placental CRH makes it possible to create a feed-forward endocrine cascade that does not end until separation of the fetus from the placenta at delivery. It is this cascade that has been proposed to drive the rise in CRH as well as fetal adrenal steroidogenesis in late gestation.

Maternal plasma CRH levels are low in the first trimester, rising from midgestation to term. In the last 12 weeks of gestation, CRH plasma levels rise exponentially, peaking during labor and then falling precipitously after delivery (Frim and associates, 1988; Goland and co-workers, 1986; Sasaki and colleagues, 1987). Amniotic fluid levels of CRH similarly increase in late gestation. Umbilical cord blood levels of CRH are lower than those in maternal circulation but are still quite substantial and well within the range of concentrations that we and others have found (see below) to stimulate fetal adrenal steroidogenesis (Goland and co-workers, 1986, 1993; Perkins and associates, 1995).

CRH is the only trophic hormone-releasing factor to have a specific serum binding protein. During most of pregnancy, it appears that CRH-binding protein (CRH-BP) binds the majority of circulating CRH in the maternal compartment. Binding likely serves to inactivate the ACTH-stimulating activity of placental CRH (Lowry, 1993). During later pregnancy, however, CRH-BP levels in both maternal plasma and amniotic fluid decline when CRH levels are increasing strikingly, giving rise to markedly

increased levels of bioavailable CRH (Perkins and co-workers, 1995; Petraglia and associates, 1997).

In pregnancies in which the fetus can be considered to be stressed as a result of various complications, the concentrations of CRH in fetal plasma, amniotic fluid, and maternal plasma are increased over those seen in normal gestation (Berkowitz, 1996; Goland, 1993; McGrath, 2002; Perkins, 1995, and all of their co-workers). The placenta is likely the source for stress-associated increases in CRH because the placental content of CRH has been found to be fourfold higher in placentas from women with preeclampsia than in those from normal pregnancies (Perkins and co-workers, 1995). Moreover, the biological impact of increased CRH levels is likely to be amplified in such instances as a result of subnormal levels of CRH-BP (Petraglia and co-workers, 1996). Such increases in placental CRH production during normal gestation and the excessive secretion of placental CRH in complicated pregnancies may play a role in the normal gestational increases in fetal adrenal cortisol synthesis (Murphy, 1982). It also may result in the supranormal levels of umbilical cord blood cortisol noted to occur in stressed neonates (Falkenberg and colleagues, 1999; Goland and co-workers, 1994).

Potential Roles of CRH in Timing of Parturition. Placental CRH has been proposed to play several roles in the regulation of parturition. First, placental CRH may enhance fetal cortisol production, which would provide positive feedback on the placenta to produce more CRH. The resulting high level of CRH may modulate myometrial contractility. Second, cortisol has been proposed to affect the myometrium indirectly by stimulating the membranes to increase prostaglandin synthesis. Third, CRH has been shown to stimulate fetal adrenal C₁₉-steroid synthesis, leading to increased substrate for placental aromatization. The resulting elevation in estrogens would shift the estrogen-to-progesterone ratio and promote the expression of a series of contractile proteins in the myometrium, leading to a loss of myometrial quiescence.

Some investigators have proposed that the rising level of CRH at the end of gestation reflects a *fetal-placental clock* (McLean and colleagues, 1995). In this regard, the human placenta and fetus, through endocrine events, influence the timing of parturition at the end of normal gestation. The origin for the signals to initiate the onset of parturition in humans remains controversial, in contrast to animal models such as the sheep. The role of cortisol and the feed-forward cascade of placental CRH, however, is an intriguing explanation for the timing of human parturition.

Fetal Anomalies and Delayed Parturition. There is fragmentary evidence that pregnancies with hypoestrogenism are sometimes associated with prolonged gestation. Examples of this include fetal anencephaly, adrenal hypoplasia, and placental sulfatase deficiency. However, the broad range of gestational length in these disorders has left in question the exact role of estrogen in the initiation of human parturition.

Other fetal abnormalities that prevent or severely reduce the entry of fetal urine into amniotic fluid (renal agenesis) or lung secretions (pulmonary hypoplasia) do not prolong human pregnancy. Thus, a fetal signal through the paracrine arm of the fetal-maternal communication system does not appear to be mandated for initiation of parturition.

Anomalies of the brain of the fetal calf, fetal lamb, and sometimes the human fetus delay the normal timing of parturition. With congenital absence of the pituitary gland in the bovine fetus, gestation is prolonged by several weeks. Adrenal hypoplasia in the bovine fetus also is associated with delayed parturition. Rea (1898) observed an association between fetal anencephaly and prolonged human gestation. Malpas (1933) extended these observations and described a human pregnancy with an anencephalic fetus that went to 374 days (53 weeks). He concluded that the association between fetal anencephaly and prolonged human gestation was attributable to anomalous brain-pituitary-adrenal function in the anencephalic fetus. The adrenal glands of the anencephalic fetus are very small, and at term may be only 5 to 10 percent as large as those of a normal fetus. This decrease in size is caused by failure of development of the fetal zone that normally accounts for most of fetal adrenal mass and C₁₉-steroid biosynthesis (see [Chap. 3](#), p. 78). Also, in pregnancies in which the fetal adrenal glands are hypoplastic, the onset of labor may be delayed (Anderson and Turnbull, 1973). These findings were suggestive that in humans, as in sheep, the fetal adrenal glands are important for the timely onset of parturition.

Figure 6-19. The placental-fetal adrenal endocrine cascade. In late gestation, placental corticotropin-releasing hormone (CRH) stimulates fetal adrenal production of dehydroepiandrosterone sulfate (DHEA-S) and cortisol. The cortisol stimulates the production of placental CRH, which leads to a feed-forward cascade that enhances adrenal steroid hormone production. (ACTH = adrenocorticotropin hormone.)

FAIL-SAFE SYSTEMS TO ENSURE SUCCESS OF PHASE 2 OF PARTURITION.

Phase 2 of parturition is synonymous with the uterine contractions that bring about progressive cervical dilatation and delivery. Several researchers have investigated the possibility that an increase in the formation of uterotonins is the most likely cause of the initiation of labor. This widely accepted concept represents the *uterotonins theory of the initiation of labor*. Once phase 0 is suspended and uterine phase 1 processes are implemented, a number of uterotonins may be important to the success of phase 2, viz., active labor (see [Fig. 6-17](#)). Just as multiple processes likely contribute to the maintenance of the myometrial unresponsiveness of phase 0 of parturition, other processes may contribute jointly to a system to ensure the success of labor. There are many candidate uterotonins for the induction of labor that include oxytocin, prostaglandins, serotonin, histamine, PAF, angiotensin II, and many others. As opposed to the receptor-mediated G_{αs}-adenylyl cyclase-linked systems of myometrium that may promote cAMP accumulation, other heptahelical receptors have been identified in myometrium that more commonly activate G_{αi}- or G_{αq}-mediated processes that eventuate in increased myometrial cell [Ca²⁺]_i. The preceding factors all have been shown to stimulate smooth muscle contraction through such G-protein coupling.

Oxytocin and Phase 2 of Parturition. Late in pregnancy, during phase 1 of parturition, there is a 50-fold or more increase in the number of myometrial oxytocin receptors (Fuchs and associates, 1982; Kimura and co-workers, 1996). This increase coincides with the increase in uterine contractile responsiveness to oxytocin (Soloff and co-workers, 1979). Also, prolonged gestation is associated with a delay in this increase in these receptors (Fuchs and collaborators, 1984).

Oxytocin, which means *quick birth*, was the first uterotonic to be implicated in the initiation of parturition. In 1906, Sir Henry Dale discovered uterotonic bioactivity in extracts of the posterior pituitary gland. By 1909, the uterotonic property of these extracts was confirmed, and by 1911, they were in use in clinical obstetrics. In 1950, Pierce and du Vigneaud determined the structure of oxytocin, the uterotonic agent of the posterior pituitary. Oxytocin is a nanopeptide synthesized in the magnocellular neurons of the supraoptic and paraventricular neurons. The oxytocin prohormone is transported, with the carrier protein *neurophysin*, along the axons to the neural lobe of the posterior pituitary gland in membrane-bound vesicles for storage and later release. Oxytocin prohormone is converted enzymatically to oxytocin during transport (Gainer and colleagues, 1988; Leake, 1990). Oxytocin does not appear to cause the initiation of parturition, but it may be one of several participants in ensuring the effectiveness of active labor. Oxytocin acts by way of a heptahelical receptor, which likely activates phospholipase (Ku and colleagues, 1995). Oxytocin also is a very important hormone of phase 3 of parturition.

ROLE OF OXYTOCIN IN PHASES 2 AND 3 OF PARTURITION. There is a long history of safe and successful labor induction by oxytocin administration to near-term pregnant women. It was straightforward, therefore, to hypothesize that oxytocin was involved physiologically in the initiation of parturition. Several lines of evidence provided sufficient reasons for suspecting that oxytocin might be involved in the initiation of parturition: the effectiveness of oxytocin in inducing labor at term, the great potency of this uterotonic, and its natural occurrence in humans. More recent discoveries provide additional support for this theory:

1. There is a striking increase in the number of oxytocin receptors in myometrial and decidual tissues near the end of gestation.
2. Oxytocin acts on decidual tissue to promote prostaglandin release.
3. Oxytocin is synthesized directly in decidual and extraembryonic fetal tissues and in the placenta (Chibbar and associates, 1993; Zingg and colleagues, 1995).

Although there is little evidence in favor of a role for oxytocin in phase 1 of parturition, there is a large body of evidence in support of an important role for oxytocin during second-stage labor and the puerperium (phase 3 of parturition). There are increased maternal oxytocin levels (1) during second-stage labor (the end of phase 2 of parturition), (2) in the early postpartum period, and (3) during breast feeding (phase 3 of parturition) (Nissen and co-workers, 1995). This timing of increased oxytocin release is indicative of a role for oxytocin at the end of labor and during the puerperium. Immediately after delivery of the fetus, placenta, and membranes (completion of uterine phase 2), firm and persistent contraction and retraction of the uterus are essential to prevent postpartum hemorrhage. Oxytocin likely causes persistent contractions. Certainly, maternal plasma oxytocin levels are increased at this time, and the increase in myometrial oxytocin receptors before the onset of labor favors this process.

Oxytocin infusion in women promotes increased levels of mRNAs in myometrium of genes that encode proteins essential for uterine involution. These include interstitial collagenase, monocyte chemoattractant protein-1, interleukin-8 (IL-8), and urokinase plasminogen activator receptor. Therefore, oxytocin action at the end of labor and during phase 3 of parturition may be involved in uterine involution.

Prostaglandins and Phase 2 of Parturition. Many investigators have accepted and fostered the view that prostaglandins, particularly $\text{PGF}_{2\alpha}$ and PGE_2 , are involved in phase 2 of parturition, the process of labor. Many lines of evidence are supportive of this theory, including:

1. The levels of prostaglandins (or their metabolites) in amniotic fluid, maternal plasma, and maternal urine are increased during labor (Keirse, 1979).
2. The treatment of pregnant women with prostaglandins, by any of several routes of administration, causes abortion or labor at all stages of gestation (Novy and Liggins, 1980).
3. Administration of prostaglandin H synthase type 2 (PGHS-2) inhibitors to pregnant women will delay the time of onset of spontaneous labor and sometimes arrest preterm labor (Loudon and co-workers, 2003).
4. Prostaglandin treatment of myometrial smooth muscle tissues in vitro sometimes causes contraction, dependent on the prostanoid tested and the physiological status of the tissue treated.

Although a critical role for prostaglandins in phase 2 of parturition is clear, their role in phase 1 (activation phase) of noncomplicated pregnancies is less well defined (MacDonald and Casey, 1993). However, like oxytocin, prostaglandins produced directly in or adjacent to myometrial tissue are likely to play a major role in the effectiveness of myometrial contractions of active labor once labor is initiated.

UTERINE EVENTS REGULATING PROSTAGLANDIN PRODUCTION. The production of prostaglandins at the time of labor within the myometrium could be seen as a most efficient mechanism of activating contractions. However, the fetal membranes and placenta also are able to produce prostaglandins. Indeed, prostaglandins, primarily PGE_2 (but also $\text{PGF}_{2\alpha}$), are detected in amniotic fluid at all stages of gestation. As the fetus grows, the levels of prostaglandins in amniotic fluid increase gradually. The major increases in amniotic fluid, however, occur after labor begins (MacDonald and Casey, 1993) and are now believed to be the result of an inflammatory response that signals the events leading to active labor.

To understand the source of prostaglandins in amniotic fluid at parturition, the anatomical changes involving the fetal membranes during cervical dilatation must be envisioned. The lowermost pole of the fetal membranes is structurally modified in the formation of the forebag of the amniotic sac. Before labor, the fetal membranes are contiguous with and attached to the uterine decidua vera, which in the lower uterine segment of the uterus is thin and poorly developed. As the lower pole of the amniotic sac is pulled away from the wall of the uterus, fragments of decidua parietalis are torn away but remain attached rather firmly to the outer surface of the chorion laeve ([Fig. 6-20](#)).

This normal phenomenon of early labor is complementary to successful cervical dilatation. Membranes that slide readily over the lower uterine segment and partly through the cervix are much more efficacious dilators. As the cervix is opened, the forebag presents through the cervix in the upper vagina, like the tip of a fluid-filled balloon under pressure being pushed through the enlarging diameter of a hollow cylinder. The surface area of the exposed forebag increases as cervical dilatation progresses during phase 2 of parturition. The innermost tissue of the forebag is the avascular amnion, which is bathed by the amniotic fluid on its epithelial surface. The outer surface of the amnion is adherent to the avascular chorion laeve. The traumatized, devascularized decidual tissue fragments that are torn away from the uterus form an irregular lining on the outer surface of the forebag, which presents in the vagina (see [Fig. 6-20](#)). Thereafter, the forebag tissues are bathed continuously by the vaginal fluid, which in all women (pregnant and nonpregnant) contains a large number and variety of microorganisms, bacterial toxins in large amounts, and prostaglandins and cytokines (Cox and associates, 1993b).

Because of (1) trauma to decidual tissues in the formation of the forebag, (2) devascularization of the decidual fragments that are pulled away from the uterus, and (3) the action of the constituents of the vaginal fluids on these tissues, an inflammatory response in the decidual fragments of the forebag develops and is readily demonstrable. During labor, the levels of cytokines in the forebag are much greater than those found in the upper compartment of the amniotic sac (MacDonald and associates, 1991). The cytokines produced in the forebag are thought to greatly enhance the levels of prostaglandins produced by the amnion. This scenario leads to substantially higher levels of prostaglandins in the forebag compartment ([Fig. 6-21](#)). The prostaglandins synthesized in forebag tissues also are released into the vagina ([Fig. 6-22](#)).

Recent findings of Kemp and co-workers (2002) and Kelly (2002) support the possibility that inflammatory mediators facilitate cervical dilatation and alterations to the lower uterine segment. These cytokines and chemokines lead to further extracellular matrix degradation, increase levels of hyaluronic acid, and cause an influx of leukocytes into the area. Together the increases in cytokines and prostaglandins cause further degradation of the extracellular matrix, thus weakening the fetal membranes. It can be envisioned that they also add to the relatively rapid changes in the cervix that are characteristic of the parturitional process.

Platelet-Activating Factor (PAF). The PAF receptor also is a member of the heptahelical family of transmembrane receptors and acts to increase myometrial cell calcium and promote uterine contractions. The levels of PAF in amniotic fluid are increased during labor, and PAF treatment of myometrial tissue promotes contraction (Billah and Johnston, 1983; Nishihara and associates, 1984; Zhu and colleagues, 1992). It is likely that PAF, like prostaglandins, cytokines, and endothelin-1, is produced in leukocytes as a result of the inflammatory process that develops when cervical dilatation brings about exposure of the traumatized forebag tissues to the vaginal fluids.

The transport of PAF from amniotic fluid to myometrium is uncertain but unlikely. PAF is inactivated enzymatically by PAF-acetylhydrolase. This enzyme is present and possesses high specific activity in macrophages which are present in large numbers in decidua (Prescott and associates, 1990). Thus, the myometrium may be protected from PAF action by PAF-acetylhydrolase in a manner similar to that for uterotonins: oxytocin by oxytocinase, endothelin-1 by enkephalinase, and prostaglandins by prostaglandin dehydrogenase.

Endothelin-1. The endothelins are very powerful inducers of myometrial smooth muscle contraction, and endothelin receptors are demonstrable in myometrial tissue (Word and colleagues, 1990). The endothelin A receptor, preferentially expressed in smooth muscle cells, including the myometrium, acts to effect an increase in intracellular calcium, apparently by linkage to both $G_{\alpha q}$ - and $G_{\alpha i}$ -subunits of the G-proteins. Endothelin-1 is produced in myometrium, but the exact cellular site of synthesis is not clearly established, and the potential contribution of myometrial endothelin-1 to phase 2 of parturition is not defined.

Endothelin-1 also is synthesized in amnion. Like other uterotonins synthesized in amnion, it is unlikely that endothelin-1 can be transported from reflected amnion (or amniotic fluid), to the myometrium without degradation (Eis and colleagues, 1992). One obstacle to endothelin-1 transport across the fetal membranes is the enzyme enkephalinase (membrane metalloendopeptidase), which is present in chorion laeve and highly active (Germain and associates, 1994). Enkephalinase catalyzes the degradation of endothelin-1 as well as several other small, bioactive peptides— for example, the enkephalins, substance P, and atrial and brain natriuretic peptides. However, in situations such as premature rupture of the fetal membranes, endothelin-1 could then play a role in uterine contraction.

Angiotensin II. There are two heptahelical G-protein-linked angiotensin II receptors (AT1 and AT2) expressed in the uterus. In nonpregnant women, the AT2 receptor is predominant, but in myometrium of pregnant women, it is the AT1 receptor that is preferentially expressed (Cox and associates, 1993a). This fact likely explains why nonpregnant myometrial tissue does not contract in response to angiotensin II treatment (Cox and co-workers, 1996). Most commonly, angiotensin II binding to the plasma membrane receptor on smooth muscle cells evokes contraction. During pregnancy, vascular smooth muscle, which expresses the AT2 receptor, is refractory to the pressor effects of angiotensin II (see [Chap. 5](#), p. 135). In myometrium near term, however, angiotensin II may be another component of the uterotonin system of phase 2 of parturition, acting to promote increased myometrial cell calcium.

CRH, hCG, and PTH-rP. There may be a late pregnancy modification in the receptor for CRH, hCG, or PTH-rP or in their G-protein coupling in myometrium that favors a switch from cAMP formation to increased myometrial cell calcium. Oxytocin acts to attenuate CRH-stimulated accumulation of cAMP in myometrial tissue, and CRH augments the contraction-inducing potency of a given dose of oxytocin in human myometrial strips (Quarero and colleagues, 1991, 1992). CRH also acts to increase myometrial contractile force in response to $PGF_{2\alpha}$ (Benedetto and associates, 1994).

Contribution of Intrauterine Tissues to Parturition. The potential role of amnion, chorion laeve, and decidua vera has been studied to define their participation in promoting initiation of parturition. In uncomplicated pregnancy, an alternative role for these tissues appears to be more likely. The membranes and decidua comprise an important tissue shell around the fetus that serves as a physical, immunological, and metabolic shield that protects against the untimely initiation of parturition. However, late in gestation the fetal membranes have been reported to change and may indeed act to prepare for labor.

AMNION. The amnion provides virtually all of the tensile strength of the membranes, that is, resistance to tearing and rupture (see [Chap. 3](#), p. 66). The avascular amnion is highly resistant to penetration by leukocytes, microorganisms, and neoplastic cells from the maternal compartment. It also constitutes a selective filter to prevent fetal particulate-bound lung and skin

secretions from reaching the maternal compartment. In this manner, maternal tissues are protected from constituents in the amniotic fluid that could adversely affect decidual or myometrial function or even maternal well-being, such as seen in amniotic fluid embolism (see [Chap. 35](#), p. 845).

Several bioactive peptides and prostaglandins, which could cause myometrial relaxation or contraction, are synthesized in amnion. It is the late gestation production of prostaglandins that has been most studied. There appears to be an overall increase in amnion prostaglandin biosynthetic capability late in gestation. Amnion does increase its activity for phospholipase A₂ and PGHS-2 late in gestation (Johnson and colleagues, 2002; Smieja and co-workers, 1993). This increase in ability to produce prostaglandins has made it the topic of many hypotheses as a regulator of the events leading to parturition. It is likely that the major source for prostaglandins in the amniotic fluid is the amnion, and a role for amnion-derived factors in uterine quiescence and activation has been proposed. However, it is the transport of prostaglandins and active peptides from amnion through the chorion to access maternal tissues that has been at issue.

CHORION LAEVE. The chorion is similar to the amnion in that it serves primarily as a protective tissue, in this case providing immunological acceptance. In addition, the chorion laeve is enriched with enzymes that inactivate uterotonins such as prostaglandin dehydrogenase (PGDH), oxytocinase, and enkephalinase (Cheung and co-workers, 1990; Germain and associates, 1994). As seen in [Figure 6-18](#), PGDH through its metabolism of active prostaglandins will prevent passage of amnion-derived prostaglandins across the fetal membranes. Thus, during most of gestation the prostaglandins produced by the amnion could be released into the amniotic fluid or metabolized by the adjacent chorion. In cases with rupture of the fetal membranes, this barrier would be lost and prostaglandins could readily have an impact on the adjacent decidua and myometrium. Recent evidence suggests that the level of PGDH found in chorion can be regulated. It is through PGDH regulation that prostaglandins produced in the amnion may play a regulatory role in maternal tissues of uncomplicated pregnancies (Patel and colleagues, 1999; Van Meir and associates, 1996; Wu and co-workers, 2000). It is currently believed that progesterone maintains chorion PGDH expression, whereas cortisol decreases its expression. With this in mind, PGDH would decrease late in gestation as fetal cortisol production increases and as part of progesterone withdrawal. The exact role of fetal membrane-derived peptides or prostaglandins in the initiation of parturition (phase 1) is still under debate; however, these compounds are likely to be important for the process of labor itself (phase 2) and could continue to play a role in involution (phase 3).

DECIDUA PARIETALIS. A metabolic contribution of decidua parietalis to the initiation of parturition has been an appealing possibility for a number of reasons, both anatomical and functional. The generation of uterotonins in decidua that act in a paracrine manner on contiguous myometrium is an interesting option. There are also several lines of evidence that decidual activation is an accompaniment of human parturition (Casey and MacDonald, 1988a, 1988b, 1990; MacDonald and colleagues, 1991). The central question, however, is whether decidual activation precedes or follows the onset of labor. The process of decidual activation appears to be localized to the exposed decidual fragments lining the forebag. Trauma, hypoxia, and exposure of forebag decidua to endotoxin lipopolysaccharide, microorganisms, and interleukin-1 β (IL-1 β) in the vaginal fluids provoke an inflammatory reaction, which is an inevitable and consistent sequela of labor.

During this inflammatory reaction, a whole series of cytokines is produced that can either increase the production of uterotonins (principally prostaglandins) or act directly on myometrium to cause contraction. These include tumor necrosis factor- α (TNF- α) and interleukins 1, 6, 8, and 12. In addition, these molecules can act as chemokines that recruit neutrophils and eosinophils to the uterus and further increase uterine activity and labor (Keelan and co-workers, 2003).

Regulation of Phase 2 of Parturition: Summary. It is likely that multiple (possibly redundant) processes contribute to the success of phase 2 (active labor) once phase 0 is suspended and phase 1 of parturition is implemented. A variety of myometrial heptahelical receptors may promote uterine quiescence, but there is another group that should inhibit cAMP formation or activate phospholipase C or A₂, or both. The source of regulatory ligands for these receptors varies from endocrine hormones such as oxytocin to locally produced prostaglandins. It is likely that functional progesterone withdrawal modifies the myometrium, perhaps in a regional manner—fundus versus lower uterine segment—such that the heptahelical receptor-G-protein-effector phenotype can contribute to a regional relaxation or contraction in a manner that effectively promotes delivery.

Figure 6-20. Sagittal view of the exposed forebag and attached decidual fragments after cervical dilatation during labor. (From MacDonald and Casey, 1996. Illustration by Michael Reingold.)

Figure 6-21. Mean values of prostaglandin F_{2 α} (PGF_{2 α} ; panel A), prostaglandin FM (PGFM; panel B), PGF_{2 α} + PGFM (panel C), and prostaglandin E₂ (PGE₂; panel D) in amniotic fluid at term before labor and in the upper and forebag compartments during labor. Values are in labor at all stages of cervical dilatation. (From MacDonald and Casey, 1993, with permission.)

Figure 6-22. Prostaglandins recovered from vaginal fluid (by lavage) before and during labor. Prostaglandin E₂ (open bar); prostaglandin F_{2 α} (solid bar); prostaglandin FM (hatched bar). (From Cox and associates, 1993b, with permission.)

PHYSIOLOGY AND BIOCHEMISTRY OF PRETERM LABOR

As discussed in [Chapter 36](#), preterm birth is one of the major health hazards of humans, being the greatest cause—after congenital anomalies—of neonatal morbidity and mortality. Although there are many conditions that lead to preterm delivery, one can place most of the causes into three major categories:

1. Complications of pregnancy that severely jeopardize fetal and sometimes maternal health often mandate preterm delivery. These medically indicated or iatrogenic causes represent about 25 percent of preterm births.
2. Preterm premature rupture of the fetal membranes (PPROM), which is followed by preterm delivery, causes approximately 25 percent of preterm births.
3. Spontaneous preterm labor in pregnancies with intact fetal membranes represents the largest cause of preterm delivery, accounting for about half of preterm births.

MANDATED PRETERM DELIVERY. All too often, pregnancy complications require a clinical decision to effect preterm delivery rather than continue pregnancy in a deteriorating intrauterine environment. A host of pregnancy disorders may mandate such a choice (Iams, 2003). Most commonly, these complications of pregnancy threaten fetal health so that a continued intrauterine existence will likely result in fetal death. Many examples may be cited, but the most common are maternal hypertension, severe diabetes mellitus, failure of fetal growth, multiple pregnancies, and abruptio placenta. The causes of iatrogenic preterm delivery are further discussed in [Chapter 36](#).

PRETERM PREMATURE RUPTURE OF THE MEMBRANES (PPROM). This nomenclature is used to denote spontaneous rupture of the fetal membranes that occurs before 37 completed weeks and *before the onset of labor*. It is likely that PPRM has a variety of causes, but many believe intrauterine infection to be one of the major predisposing events (Gomez and colleagues, 1997; Mercer, 2003).

Recent studies suggest that the pathogenesis of PPRM relates to increased apoptosis of the cellular components of the fetal membranes as well as an elevation in specific proteases in the membranes and amniotic fluid. Much of the tensile strength of the fetal membranes is provided by the extracellular matrix within the amnion. Interstitial amniotic collagens, primarily types I and III, are produced in mesenchymal cells and are the structural component most important for its strength (Casey and MacDonald, 1996). For that reason, the degradation of collagens has been a focus of research.

The matrix metalloproteinase (MMP) family of proteinases is involved with normal tissue remodeling and particularly the degradation of collagens. The MMP-2, MMP-3, and MMP-9 members of this family are found in higher concentrations in amniotic fluid from pregnancies with PPRM (Fortunato and co-workers, 1999a, 2001; Park and colleagues, 2003; Romero and associates, 2002). The activity of the MMPs is in part regulated by tissue inhibitors of matrix metalloproteinases (TIMPs). Interestingly, several of the TIMP family members are found in lower concentrations in amniotic fluid from women with PPRM. The elevation of these proteases at a time when protease inhibitor expression drops further supports the idea that their expression alters the tensile strength of the amnion and increases the incidence of PPRM. Studies using isolated amniochorion explants have demonstrated that the expression of MMPs can be increased by treatment with IL-1, TNF- α , and IL-6 (Fortunato and colleagues, 1999a, 1999b, 2002). Thus, MMP induction may be part of an inflammatory process.

In addition to an increase in collagen breakdown, the amnion from PPRM exhibits a higher degree of cell death than is seen in the term amnion (Arechavaleta-Velasco and colleagues, 2002; Fortunato and Menon, 2003; Fortunato and co-workers, 2001). Markers of apoptosis (programmed cell death) are increased in membranes with PPRM compared with those in normal term membranes. In vitro studies have shown that apoptosis is likely regulated by bacterial endotoxin, IL-1 β , and TNF- α . Taken together, these observations suggest that many cases of PPRM result from an activation of collagen breakdown and cell death leading to a weakening of the amnion.

Studies have been undertaken to ascertain the incidence of infection-induced PPRM. The number of positive cultures of amniotic fluid in PPRM supports a role for infection in a significant proportion of cases. A survey of 18 independent studies between 1979 and 2000 that consisted of 1462 women with PPRM indicates that a third had bacteria isolated from amniotic fluid (Goncalves and co-workers, 2002). Because of this, studies have been performed to address prophylactic antimicrobial treatment to prevent PPRM. As discussed in [Chapter 36](#) (see p. 862), although the results of these studies are conflicting, there is evidence that early treatment of some asymptomatic lower genital tract infections, as well as active periodontal inflammation, will reduce the incidence of PPRM and preterm birth. Thus, the evidence is compelling that infection causes a significant proportion of cases of PPRM. The inflammatory response that leads to the weakening of the fetal membranes is now being defined in detail. Current research is being focused on certain mediators of this process that accumulate in amniotic fluid and may provide early markers for women at risk for PPRM.

SPONTANEOUS PRETERM LABOR. Pregnancies with intact fetal membranes and spontaneous preterm labor— for clinical as well as research purposes— must be distinguished from those in which there has been preterm premature membrane rupture. Even so, pregnancies complicated by spontaneous preterm labor do not constitute a homogeneous group characterized singularly by the early initiation of parturition. Among the more common associated findings are multifetal pregnancy, intrauterine infection, bleeding, placental infarction, premature cervical dilatation, cervical incompetence, uterine fundal abnormalities, and fetal anomalies. Severe maternal illness as a result of nonobstetrical infections, autoimmune diseases, and gestational hypertension increase the incidence of preterm labor. These disorders cause about half of spontaneous preterm deliveries, and their relative contribution varies between populations.

Although there are unique aspects to each of the causes of preterm labor, recent studies have suggested that they share certain common denominators. Thus, the fetal or maternal conditions provide important clues to the cause of the premature onset of parturition. It seems important to reemphasize that the actual process of preterm labor should be considered a final step—one that results from premature uterine activation that was initiated weeks before the onset of labor. Indeed, many

of the forms of spontaneous preterm labor that result from premature initiation of phase 1 of parturition may be viewed in this light (see [Fig. 6-17](#)). Specifically, many of the alterations discussed earlier with regard to normal parturition also occur with preterm labor, including cervical ripening and myometrial activation. Identification of common factors has begun to explain the physiological processes of human parturition at term and preterm. Three major causes of spontaneous preterm labor include uterine distention, maternal-fetal stress, and infection.

Uterine Distention. There is no doubt that multifetal pregnancy as well as hydramnios lead to an increased risk of preterm birth (see [Chap. 39](#), p. 924). As discussed on page 169, uterine stretch can play an important role in the normal process of myometrial activation in preparation for labor. In multifetal gestation or hydramnios, it is likely that early uterine distention acts to initiate expression of contraction-associated proteins (CAPs) in the myometrium. The CAP genes influenced by stretch include those coding for gap junction proteins, such as connexin 43, for oxytocin receptors, and for prostaglandin synthase (Korita and colleagues, 2002; Lyall and co-workers, 2002; Sooranna and associates, 2004). The result of excessive uterine stretch is the premature loss of myometrial quiescence.

In addition to direct action of uterine stretch on the myometrium, these pregnancies also exhibit an early activation of the placental-fetal endocrine cascade shown in [Figure 6-19](#). This cascade results in an early rise in maternal CRH and estrogen levels, which can further enhance the expression of myometrial CAP genes (Warren and co-workers, 1990; Wolfe and colleagues, 1988).

Finally, the influence of uterine stretch also should be considered with regard to the cervix. Cervical length is an important risk factor in multifetal pregnancies (Goldenberg and co-workers, 1996). The premature increase in stretch and endocrine activity that is seen in multifetal gestations may initiate the sequence of events causing a shift in the timing of uterine activation seen in [Figure 6-17](#), including premature cervical ripening.

Maternal-Fetal Stress. The complexities of measuring stress and other moderating psychosocial factors that lead to stress contribute to the difficulty of defining its exact role in preterm birth (Lobel, 1994). There is, however, a large body of evidence that shows a correlation between maternal stress and preterm birth (Hobel and Culhane, 2003; Ruiz and colleagues, 2003). Prospective studies involving women of different ethnicity, socioeconomic, and behavioral risk factors have shown a correlation between stress, low birthweight, and preterm birth (Hedegaard and associates, 1993; Wadhwa and co-workers, 1993, 2001; Zambrana and colleagues, 1999). During recent years, studies showing a correlation between maternal psychological stress and the placental-adrenal endocrine axis have provided a potential mechanism for stress-induced preterm birth (Lockwood, 1999; Wadhwa and associates, 2001).

As discussed earlier, the last trimester is marked by rising maternal serum levels of placental-derived CRH. This hormone works with ACTH to increase adult and fetal adrenal steroid hormone production, including the initiation of fetal cortisol biosynthesis. Rising levels of maternal and fetal cortisol further increase placental CRH secretion, which develops a feed-forward endocrine cascade that does not end until delivery (see [Fig. 6-19](#)). In addition, the rising levels of CRH further stimulate fetal adrenal DHEA-S biosynthesis, which acts as substrate to increase maternal circulating estrogens, particularly estriol. It has been hypothesized that a premature rise in cortisol and estrogens causes an early loss of uterine quiescence.

Supporting this hypothesis are numerous studies indicating that spontaneous preterm labor is associated with an early rise in maternal circulating CRH (Holzman, 2001; McGrath, 2002; Moawad, 2002, and all their co-workers). It appears that levels of CRH in term and preterm women are similar; *however*, women destined for preterm labor exhibit a rise in CRH that occurs 2 to 6 weeks earlier (McLean and co-workers, 1995). The rise in CRH has been noted as early as 18 weeks' gestation, leading some to suggest that this assay might provide a useful marker for preterm delivery.

As discussed in [Chapter 3](#) (see p. 75), placental CRH also enters the fetal circulation, albeit at lower levels than those seen in the maternal circulation. In vitro studies have shown that CRH can directly stimulate fetal adrenal production of DHEA-S and cortisol (Parker and colleagues, 1999; Smith and co-workers, 1998). If preterm delivery is associated with premature activation of the fetal adrenal-placental endocrine cascade, it would be hypothesized that maternal estrogen levels would be prematurely elevated. And this is seen for CRH. Moreover, several studies have shown an early rise of serum estriol concentrations in women with subsequent preterm labor (Heine and co-workers, 2000; McGregor and co-workers, 1995). Physiologically, this premature rise in estrogens may alter myometrial quiescence. Taken together, these observations suggest that preterm birth is associated, in many cases, with a maternal-fetal biological stress response. The nature and variety of the stressors that activate this cascade likely are broad. For example, several studies have noted that CRH or estriol levels are prematurely activated in preterm birth due to infection and multifetal pregnancies (Gravett and colleagues, 2000; Warren and co-workers, 1990). Thus, activation of this axis may be considered a common feature for the activation of phase I of parturition. Further study will be needed to define the exact biochemical role of CRH, estrogens, and cortisol in preterm birth, as well as the exact nature of the stressors that lead to the activation of this endocrine cascade.

Infection and Preterm Labor. It has been known for more than 50 years that the administration to animals of bacteria or bacterial endotoxin (e.g., lipopolysaccharide) causes abortion or preterm delivery, which is accompanied by decidual hemorrhage and necrosis (Zahl and Bjerknes, 1943). It was not until many years later, however, that the biomolecular particulars of the inflammatory response were defined in detail (Dudley, 1997; Goldenberg and colleagues, 2000; Romero and co-workers, 2003). Determining the details associated with intrauterine infection during pregnancy has helped provide an attractive explanation as to how infection might cause preterm labor.

There is great interest in the role of infection as a primary cause of preterm labor in pregnancies with intact membranes. It has been estimated that as much as 40 percent of preterm labor may be caused by intrauterine infection. This concept has been promoted because of widespread suspicion that subclinical infection is a common accompaniment and cause of preterm labor. The term *subclinical* has been used to describe the condition in which intrauterine infection is accompanied by little or no clinical evidence of infection, and at times, microorganisms cannot be recovered from the amniotic fluid (Goncalves and co-workers, 2002; Iams and colleagues, 1987).

The incidence of positive cultures of amniotic fluid during preterm labor varies from 10 to 40 percent, the average being about 13 percent (Goncalves and co-workers, 2002). Importantly, these women were more likely to develop chorioamnionitis and PPRM than women with negative cultures. They are also more likely to have neonates with complications (Hitti and co-workers, 2001). The earlier the onset of preterm labor, the greater is the likelihood of documented amniotic fluid infection

(Goldenberg and associates, 2000; Watts and colleagues, 1992). At the same time, however, the incidence of culture-positive amniotic fluids collected by amniocentesis during spontaneous term labor is similar or even greater than it is during preterm labor (Gomez and colleagues, 1994; Romero and co-workers, 1993). It has been suggested that at term, amniotic fluid is infiltrated by bacteria as a consequence of the processes of labor, whereas in preterm pregnancies bacteria represent an important cause of labor. Although plausible, this explanation questions the contribution of fetal infection as a major contributor to preterm birth.

Certainly, there are considerable data to associate chorioamnionitis with preterm labor (Chellam and Rushton, 1985; Goldenberg and associates, 2002; Mueller-Heubach and colleagues, 1990; Ustun and colleagues, 2001). In such infections, the microbes may invade maternal tissue only, and not amniotic fluid. Despite this, endotoxins can stimulate amniotic cells to secrete cytokines that enter amniotic fluid. This scenario may serve to explain the apparently contradictory observations concerning an association between amniotic fluid cytokines and preterm labor, in which microbes were not detectable in the amniotic fluid.

It seems logical that infection-mediated preterm deliveries should be preventable by antimicrobial treatment. However, there continues to be debate on the effectiveness of antimicrobial prophylaxis to prevent spontaneous preterm birth, and as discussed in [Chapter 36](#) (see p. 862), it is recommended in only a few situations to prevent spontaneous preterm delivery (Andrews and associates, 2003; Kenyon and co-workers, 2001, 2003; King and Flenady, 2002).

SOURCES FOR INTRAUTERINE INFECTION. The patency of the female reproductive tract, although essential for achievement of pregnancy and delivery, is theoretically problematic during phase 0 of parturition. It has been suggested that bacteria can gain access to the intrauterine tissues through (1) transplacental transfer of maternal systemic infection, (2) retrograde flow of infection from the peritoneal cavity via the fallopian tubes, or (3) ascending infection with bacteria from the vagina and cervix. The lower pole of the fetal membrane-decidual junction embraces the orifice of the cervical canal, which anatomically is patent to the vagina. This anatomical arrangement provides a passageway for microorganisms to enter intrauterine tissues. For this reason, the ascending route of infection is considered the most common. A thoughtful description of the potential degrees of intrauterine infection has been provided by Goncalves and co-workers (2002). They categorize intrauterine infection into four stages of microbial invasion that include bacterial vaginosis (stage I), decidual infection (stage II), amniotic infection (stage III), and finally fetal systemic infection (stage IV). As expected, progression of these stages is thought to increase the effects on preterm birth as well as neonatal morbidity.

Based on these insights into the process of infection, it is straightforward to construct a theory for the pathogenesis of infection-induced preterm labor ([Fig. 6-23](#)). Microorganisms originating in the vagina or cervix, after ascending, colonize the decidua and possibly the fetal membranes, where they then may enter the amniotic sac. Lipopolysaccharide or other toxins elaborated by these bacteria induce cytokine production in cells within the decidua, membranes, or fetus itself. Both lipopolysaccharide and a variety of cytokines that increase due to its presence provoke prostaglandin release from fetal membranes, the decidua, or both. The rise in cytokines and prostaglandins will then influence both cervical ripening and loss of myometrial quiescence with resultant myometrial stimulation (Challis, 2002; Keelan, 2003; Loudon, 2003; Olson, 2003; and all their associates).

MICROBES ASSOCIATED WITH PRETERM BIRTH. Some microorganisms, for example, *Gardnerella vaginalis*, *Fusobacterium*, *Mycoplasma hominis*, and *Ureaplasma urealyticum*, are detected more commonly than others in amniotic fluid of women with preterm labor (Gerber, 2003; Hillier, 1988; Romero, 1989; Yoon, 1998, and all their co-workers). This finding was interpreted by some as presumptive evidence that specific microorganisms are more commonly involved as pathogens in the induction of preterm labor. Another interpretation, however, is that given direct access to the membranes after cervical dilatation, selected microorganisms, such as fusobacteria that are more capable of burrowing through these exposed tissues, will do so. Fusobacteria are found in the vaginal fluid of only 9 percent of women but in 28 percent of positive amniotic fluid cultures from preterm labor pregnancies with intact membranes (Chaim and Mazor, 1992). Further studies are needed to better define the intrauterine site of infection that most influences the timing of delivery as well as why some pregnant women appear more susceptible to microbes associated with bacterial vaginosis.

INTRAUTERINE INFLAMMATORY RESPONSE TO INFECTION. The initial inflammatory response elicited by bacterial toxins is mediated, in large measure, by specific receptors on mononuclear phagocytes, decidual cells, and trophoblasts. These *toll-like receptors* represent a family of receptors that has evolved to recognize pathogen-associated molecules (Janssens and Beyaert, 2003). Toll-like receptors are present in the placenta on trophoblast cells as well as fixed and invading leukocytes (Chuang and Ulevitch, 2000; Holmlund and co-workers, 2002). Under the influence of ligands such as bacterial lipopolysaccharide, these receptors increase the local release of chemokines, cytokines, and prostaglandins as part of an inflammatory response. For example, IL-1 β is produced rapidly after lipopolysaccharide stimulation (Dinarello, 2002). IL-1 in turn acts to promote a series of responses that include increased synthesis of other cytokines, viz., TNF- α , IL-6, and IL-8; the proliferation, activation, and migration of leukocytes; modifications in extracellular matrix proteins; and mitogenic and cytotoxic effects, including fever and the acute phase response (El-Bastawissi and colleagues, 2000). IL-1 also acts to promote prostaglandin formation in many tissues, including myometrium, decidua, and amnion (Casey and co-workers, 1990). Thus, there appears to be a cascade of events once an inflammatory response is initiated that can result in preterm labor.

ORIGIN OF CYTOKINES IN INTRAUTERINE INFECTION. Cytokines within the normal term uterus are likely important for normal and preterm labor. The transfer of cytokines such as IL-1 from decidua across the membranes into amniotic fluid appears to be severely limited. Thus, it is likely that cytokines produced in maternal decidua and myometrium will have effects on that side, whereas cytokines produced in the membranes or in cells within the amniotic fluid will not be transferred to the maternal tissues. In most cases of inflammation resulting from infection, resident and invading leukocytes produce the bulk of cytokines. Indeed, leukocytes—mainly neutrophils, macrophages, and T lymphocytes— infiltrate the cervix, lower uterine segment, and fundus at the time of labor. Other studies have shown that leukocytes invade membranes and cervix with preterm labor. Thus, invading leukocytes may be the major source of cytokines at the time of labor.

Immunohistochemistry studies of cytokine expression have shown that, in the term laboring uterus, both invading leukocytes and certain parenchymal cells produce cytokines. These leukocytes appear to be the primary source of myometrial cytokines, including IL-1, IL-6, IL-8, and TNF- α (Young and co-workers, 2002), although in the decidua both stromal cells and invading leukocytes are likely to contribute because they have been shown to produce IL-1, IL-6, TNF- α , and IL-8. In the cervix, glandular and surface epithelial cells appear to produce IL-6, IL-8, and TNF- α . In fact, IL-8 is considered a critical cytokine in

cervical ripening, and it is produced in both epithelial and stromal cells of the cervix.

The presence of cytokines in amniotic fluid and their association with preterm labor has been well documented; however, their exact cellular origin—with or without culturable microorganisms—has not been well defined. Although the rate of IL-1 secretion from forebag decidual tissue is great, Kent and colleagues (1994) found that there is negligible *in vivo* transfer of radiolabeled IL-1 across the membranes. Amniotic fluid IL-1 probably does not arise from amnion tissue, fetal urine, or fetal lung secretions, but most likely is secreted by mononuclear phagocytes or neutrophils activated and recruited into the amniotic fluid. Therefore, IL-1 in amniotic fluid likely is generated *in situ* from newly recruited cells. This scenario is supported by immunohistochemical studies that show invading leukocytes are the primary cells expressing IL-1, IL-8, TNF- α , and IL-6 in membranes at the time of labor (Young and co-workers, 2002). Thus, the amount of amniotic fluid IL-1 would be determined by the number of leukocytes recruited, their activation status, or the effect of amniotic fluid constituents on their rate of IL-1 secretion.

Leukocyte infiltration may be regulated by fetal membrane synthesis of specific chemokines. In term labor, there are increased amniotic fluid concentrations of the potent chemoattractant and monocyte-macrophage activator, *monocyte chemoattractant protein-1 (MCP-1)*. As is true for prostaglandins and other cytokines, the levels of MCP-1 are much higher in the forebag compared with the upper compartment (Esplin and co-workers, 2003). Levels in preterm labor were significantly higher than those found in normal term amniotic fluid (Jacobsson and colleagues, 2003). It has been proposed that MCP-1 may be the factor that initiates fetal leukocyte infiltration of the placenta and membranes. In addition, the production of MCP-1 may act as a marker for intra-amniotic infection and inflammation.

SUMMARY OF INFECTION AND PRETERM LABOR. It is likely that intrauterine infection causes a significant number of cases currently categorized as idiopathic spontaneous preterm labor. The variety of sites for intrauterine infection—maternal, fetal, or both—and the similarities between the inflammatory responses of preterm and term labor make it difficult to determine the proportion of pregnancies that end prematurely due to infection.

Mechanistically, infection-induced preterm labor should be discussed as a process causing the early initiation of phase 1 of parturition (see [Figs. 6-1](#) and [6-17](#)). This process, illustrated in [Figure 6-23](#), involves the initial exposure to bacterial endotoxins leading to production of cytokines. In the cervix, these cytokines are the cause of infiltration of leukocytes and ripening. Activation of proteases in the cervix promotes cervical dilatation and can, in some cases, weaken the fetal membranes and cause PPROM. Transfer of bacteria or cytokines into the fetal circulation is likely to cause premature activation of CRH and the placental-adrenal endocrine cascade, causing a loss of myometrial quiescence. With continued leukocyte infiltration, proinflammatory cytokines further increase prostaglandins within maternal decidua and myometrium, which then act as uterotonins to cause preterm labor.

Figure 6-23. Potential pathways for infection-induced preterm birth. Exposure to bacterial endotoxins causes an early initiation of the normal processes associated with parturition, including cervical ripening, loss of uterine quiescence, and increased production of uterotonins. (CRH = corticotropin-releasing hormone; DHEA-S = dehydroepiandrosterone sulfate; HPA = hypothalamic-pituitary-adrenal; PPROM = preterm premature rupture of membranes.)

SECTION III - ANTEPARTUM

7. Preconceptional Counseling

INTRODUCTION

In the early part of the 20th century, women with medical problems were often unable to conceive or were advised not to. Discoveries such as insulin and the development of effective antihypertensive medications subsequently made it possible for many of these women to contemplate pregnancy. Obstetrical care of women with medical problems during this time dealt almost exclusively with protecting maternal health, as little was known about pathological influences on fetal development. In the 1960s, research began to focus on the pathophysiology of pregnancy and perinatal outcome. As a result, prenatal care was gradually extended to include fetal concerns, and interest in perinatal research increased dramatically. The etiologies of many maternal and fetal conditions were determined, and research also clarified the genetic origins of many diseases. At the same time, effective contraception was developed, allowing women to postpone pregnancy and limit family size while striving to optimize perinatal outcome. The focus of obstetrical care thus changed once again, from treating maternal and fetal diseases to predicting and preventing them.

In 2000, the Public Health Service released *Healthy People 2010*, a guide for the second nationwide preventive medicine program. The major goals are to increase the quality and years of healthy life and to eliminate health disparities between individuals. More specifically, it strives to improve the health and well-being of women, infants, children, and families.

Preconceptional counseling can play a major role in achieving these goals. As stated in the Department of Health and Human Services report on the program: "Preconceptional screening and counseling offer an opportunity to identify and mitigate maternal risk factors before pregnancy begins." For example, the two leading causes of death in the first year of life—birth defects and disorders caused by preterm birth—can both be significantly reduced or eliminated by the preconceptional initiation of specific preventive strategies. Morbidity caused by a variety of factors, including uncontrolled maternal disease, environmental exposures, and nutritional deficiencies, also can be prevented by preconceptional care. Furthermore, as discussed in [Chapter 38](#) (see p. 904), the intrauterine fetal environment has a tremendous impact on the health and well-being of the adult that fetus will become—the *Barker hypothesis* (Barker, 1994). Thus, optimizing pregnancy conditions and outcomes has long-term health impacts that are only beginning to be apparent. The 1989 Public Health Service Expert Panel on the Content of Prenatal Care rightfully concluded: "The preconceptional visit may be the single most important health care visit when viewed in the context of its effect on pregnancy."

DEFINITION

Preconceptional counseling is preventive medicine for obstetrics. Factors that could potentially affect perinatal outcome are identified, and the woman is advised of her risks. Whenever possible, a strategy is provided to reduce or eliminate the pathological influences revealed by her family, medical, or obstetrical history, or by specific testing. This chapter reviews data confirming that preconceptional counseling has a measurable positive impact on pregnancy outcome. It also provides a description of the components of a thorough preconceptional assessment. In most cases, specific guidelines for the preconceptional management of a variety of medical, obstetrical, and genetic disorders are provided in chapters pertaining to each topic.

BENEFITS OF PRECONCEPTIONAL COUNSELING

Randomized trials of the efficacy of preconceptional counseling are scarce, partly because withholding such counseling for research purposes would in many cases be considered unethical. In addition, because maternal and perinatal outcomes are dependent on the interaction of a variety of maternal, fetal, and environmental factors, it is often difficult to ascribe pregnancy outcome to a specific intervention (Moos, 2004). Nevertheless, what follows are several prospective and case-control trials that clearly demonstrate that preconceptional counseling improves pregnancy outcome.

UNPLANNED PREGNANCY. To be effective, counseling about potential pregnancy risks and strategies to prevent them must be provided before conception. By the time most women realize they are pregnant—1 to 2 weeks after the first missed period—the fetal spinal cord has already formed and the heart is beating (Moore, 1983). Many prevention strategies, for example, folic acid to prevent neural-tube defects, are ineffective if initiated at this time. The Centers for Disease Control and Prevention (1999) estimate that up to half of all pregnancies are unplanned, and there is evidence that these may be at greatest risk.

Adams and colleagues (1993) conducted a population-based survey of almost 12,500 women in four states and found that women with unintended pregnancies were more likely than those with planned pregnancies to have an indication for preconceptional counseling. Hellerstedt and co-workers (1998) surveyed nearly 7200 pregnant women and found that women with unintended pregnancies were more likely to have high-risk behaviors. Jack and associates (1995) administered a comprehensive risk survey to 136 women at the time of a negative pregnancy test. They found that (1) the majority did not want to be pregnant, (2) half reported a medical or reproductive risk that could adversely affect pregnancy, (3) half reported a genetic risk, and (4) one fourth reported risks for human immunodeficiency virus (HIV) and hepatitis B infection or alcohol or recreational drug use. Unwanted pregnancies are particularly common in the unmarried urban poor (Besculides and Laraque, 2004).

An important measure of the effectiveness of preconceptional counseling is, therefore, its influence in reducing the number of unintended pregnancies. Moos and colleagues (1996) instituted a preconceptional care program for reproductive-aged women who visited a health department clinic and then also studied 1378 women who sought prenatal care. They reported that the 456 women who had preconceptional counseling had a 50-percent greater likelihood of describing their pregnancies as intended compared with that of 309 women with health care but no counseling, and a 65-percent greater likelihood compared

with that of women with no health care prior to pregnancy.

CHRONIC MEDICAL DISORDERS

Diabetes Mellitus. Because maternal and fetal pathology associated with hyperglycemia is well known, diabetes is the prototype of a condition for which preconceptional counseling is beneficial. Diabetes-associated risks to both mother and fetus are discussed in detail in [Chapter 52](#) (see p. 1176). Many of these complications can be avoided if conception occurs when glucose control is optimal (Jovanovic and colleagues, 1981). Such control requires either that glucose levels be chronically well regulated — always a goal, but difficult to achieve — or that the woman make necessary changes before attempting conception. Preconceptional counseling can educate her about risks and provide a program designed to reduce them (Bernasko, 2004).

The utility of preconceptional counseling in preventing diabetes-related complications at all stages of pregnancy has been confirmed. Shown in [Figure 7-1](#) are summaries of major studies in which the incidence of anomalies in infants born to diabetic women who received preconceptional counseling was compared with that of women without such counseling. Importantly, all studies showed that counseling is associated with significantly fewer malformations.

Dunne and co-workers (1999) reviewed the impact of preconceptional counseling on other diabetes-related neonatal morbidity. Women who received counseling sought prenatal care earlier, had lower hemoglobin A_{1c} levels, and were less likely to smoke during pregnancy. Their outcomes were compared with those of a cohort of women who did not receive such counseling. Of the women who received counseling, none were delivered before 30 weeks compared with 17 percent in the uncounseled group. In addition, the counseled women had fewer macrosomic infants — 25 versus 40 percent; they had no growth-restricted infants compared with 8.5 percent; they had no neonatal deaths compared with 6 percent; and their infants had 50 percent fewer admissions to the intensive care nursery — 17 versus 34 percent.

Preconceptional counseling also reduces obstetrical complications and health care costs in diabetic women. In a prospective multicenter observational trial from five Michigan centers, Herman and colleagues (1999) confirmed these benefits. They reported that diabetic women who received preconceptional counseling reported for prenatal care 3 weeks earlier than uncounseled women; they had lower hemoglobin A_{1c} levels; they were significantly less likely to require antepartum hospitalization for diabetes control — 8 versus 68 percent; and they had significantly fewer hospitalization days — 4.5 versus 15.7. Counseled women also had fewer episodes of hypoglycemia and diabetic ketoacidosis; they had no hypertensive complications; and their postpartum stay was 2 days shorter than that of uncounseled women. These improved outcomes were associated with savings of \$34,000 in direct medical costs per patient who received counseling.

Epilepsy. Women with epilepsy are two to three times more likely to have infants with structural anomalies than unaffected women (Chang and McAuley, 1998; Wide and associates, 2004). Some reports indicate that epilepsy itself increases the incidence of congenital anomalies, independent of the effects of antiseizure medication. In a recent study, however, Holmes and colleagues (2001) compared 509 epileptic women who took antiseizure medication during pregnancy to 606 who did not. They found that only infants exposed to anticonvulsant medications had an increased incidence of structural anomalies. Fetuses exposed to one drug had significantly fewer malformations than those exposed to two or more drugs — 21 versus 28 percent. By contrast, the incidence of defects in fetuses of epileptic mothers who did not take medication was only 8.5 percent — the same as in fetuses of women without seizure disorders. Preconceptional counseling usually includes recommendations to switch to monotherapy with the least teratogenic medication (Adab and colleagues, 2004; American Academy of Neurology, 1998). The risks of antiseizure medication are described in detail in [Chapter 14](#) (see p. 347).

Epileptic women also are advised to take supplemental folic acid. Biale and Lewenthal (1984) performed a retrospective case-control study to evaluate effects of periconceptional folate supplementation in women taking anticonvulsants. Although 10 of 66 (15 percent) unsupplemented pregnancies resulted in offspring with congenital malformations, none of 33 neonates of supplemented women had anomalies. Depending on the history, a trial period without anticonvulsants also may be recommended.

Other Chronic Diseases. Cox and co-workers (1992) reviewed pregnancy outcomes of 1075 high-risk women who received preconceptional counseling. If they received counseling, 240 women with hypertension, renal disease, thyroid disease, asthma, and heart disease had significantly better outcomes than previous pregnancies. Indeed, 80 percent of those counseled gave birth to a normal infant compared with only 40 percent in the previous uncounseled gestation.

Figure 7-1. Major congenital anomalies in diabetic women according to whether they had preconceptional counseling. (Data from Gregory and Tattersall, 1992.)

GENETIC DISEASES. Birth defects are currently the leading cause of infant mortality and account for 20 percent of all infant deaths. These defects can be avoided with three types of prevention strategies. The preferred strategy is *primary prevention* — avoidance of causal factors — which is becoming possible for more congenital diseases as their etiologies are discovered. *Secondary prevention* — identifying and terminating affected pregnancies — is an alternative strategy for single-gene disorders and other defects that cannot be prevented. Surgical correction of structural defects is one type of *tertiary prevention*, but it is not possible for most genetic disorders. The benefits of preconceptional counseling usually are measured by comparing the incidence of new cases before and after the initiation of a counseling program. Some examples of congenital conditions that clearly benefit from counseling include neural-tube defects, phenylketonuria, Tay-Sachs disease, and the thalassemias.

Neural-Tube Defects (NTDs). The incidence of these defects is 1 to 2 per 1000 live births, and they are second only to cardiac anomalies as the most frequent structural fetal malformation (see [Chap. 12](#), p. 302). Some NTDs are associated with a specific mutation in the methylene tetrahydrofolate reductase gene (677C → T), the adverse effects of which appear to be

largely overcome by periconceptional folic acid supplementation (Ou and associates, 1996; van der Put and colleagues, 1995). The Medical Research Council on Vitamin Study Research Group (1991) conducted a randomized double-blind study of preconceptional folic acid therapy at 33 centers in seven European countries. Women with a previous affected child who took supplemental folic acid before conception and throughout the first trimester reduced their NTD recurrence risk by 72 percent. Perhaps more importantly, because 90 to 95 percent of NTDs occur in families with no prior history, Czeizel and Dudas (1992) subsequently showed that supplementation reduced the a priori risk of a *first* NTD occurrence.

Phenylketonuria (PKU). This disorder is an inborn error of phenylalanine metabolism. It is an example of a disease in which the fetus is not at risk to inherit the disease but may be damaged by the effects of maternal genetic disease. For such conditions, preconceptional counseling regarding strategies to improve the intrauterine environment constitutes primary prevention and may significantly reduce fetal morbidity. Individuals with PKU who eat an unrestricted diet have abnormally high blood phenylalanine levels. This amino acid readily crosses the placenta and can damage developing fetal organs, especially neural and cardiac tissues (see [Chap. 12](#), p. 297). With preconceptional counseling and adherence to a phenylalanine-restricted diet before pregnancy, the incidence of fetal malformations is dramatically reduced (Guttler and colleagues, 1990; Koch and associates, 1990).

The Maternal Phenylketonuria Collaborative Study evaluated the effectiveness of preconceptional care in preventing PKU-related fetal defects (Rouse and co-workers, 1997). Almost 300 women with PKU began a low-phenylalanine diet before pregnancy. Compared with infants whose mothers had poor dietary control, infants of women achieving good control had a lower incidence of microcephaly (6 versus 15 percent), neurological abnormalities (4 versus 14 percent), and cardiac defects (none versus 16 percent). The proportion of women treated preconceptionally increased from 7 to 51 percent from 1984 to 1994 (Platt and colleagues, 2000).

Tay-Sachs Disease. This disease is a severe, autosomal-recessive neurodegenerative disorder that leads to death in childhood. The effectiveness of preconceptional counseling in reducing genetic disease has been most clearly demonstrated in Tay-Sachs disease. In the early 1970s, there were approximately 60 new cases in the United States each year, primarily in individuals of Jewish heritage. An intensive worldwide campaign was initiated to counsel Jewish men and women of reproductive age, to identify carriers through genetic testing, to provide prenatal testing — secondary prevention — for high-risk couples, and even to help heterozygote carriers choose unaffected mates — primary prevention! The outcome of this initiative has been monitored by the National Tay-Sachs Disease and Allied Disorders Association (Kaback and colleagues, 1993). Within 8 years of its inception, nearly 1 million young adults around the world had been tested and counseled, and the incidence of new Tay-Sachs cases has plummeted to only about five new cases per year. Currently, most new cases are in the non-Jewish population.

Thalassemias. These disorders of globin-chain synthesis are the most common single-gene disorders worldwide. Approximately 200 million people carry a gene for one of these hemoglobinopathies (Benz, 2001). Hundreds of mutations have been identified that cause several important thalassemia syndromes, discussed in [Chapter 51](#) (see p. 1154). Some of these could be avoided by both primary and secondary prevention (Fucharoen and associates, 1991; Wong, 1985). In endemic areas such as Mediterranean countries, counseling and other prevention strategies have reduced the incidence of new cases by at least 80 percent (Angastiniotis and Modell, 1998). Experiences with a long-standing counseling program aimed at Montreal high school students at risk were summarized by Mitchell and colleagues (1996). Over a 20-year period, 25,274 students of Mediterranean origin were counseled and tested for β -thalassemia. Within a few years of initiating the preconceptional program, all high-risk couples who requested prenatal diagnosis had already been counseled, and no affected children have been born since that time.

PRECONCEPTIONAL COUNSELORS

Practitioners providing routine health maintenance for reproductive-aged women have the best opportunity to provide preventive counseling. Gynecologists, internists, family practitioners, and pediatricians can do so at the annual examination. The occasion of a negative pregnancy test is a good time for counseling. Jack and associates (1995) administered a comprehensive preconceptional risk survey to 136 women who had a negative pregnancy test in an ambulatory general practice clinic. Almost 95 percent of these women reported at least one problem that could affect a future pregnancy. These included medical or reproductive problems (52 percent), a family history of genetic diseases (50 percent), increased risk of contracting HIV (30 percent), increased risk of contracting hepatitis B and use of illegal substances (25 percent), alcohol use (17 percent), and nutritional risk (54 percent).

Basic preconceptional advice regarding diet, alcohol use, smoking, illicit drug use, vitamin intake, exercise, and other behaviors can be provided by the primary care provider, including the obstetrician-gynecologist. Medical records should be obtained and reviewed. Counselors should be knowledgeable about relevant medical diseases, prior surgery, reproductive disorders, or genetic conditions, and must be able to interpret data and recommendations provided by other specialists. The practitioner who is uncomfortable providing counseling should refer the woman or couple to a counselor with special expertise.

PRECONCEPTIONAL COUNSELING VISIT

PERSONAL AND FAMILY HISTORY. Counseling begins with a thorough review of the medical, obstetrical, social, and family histories. Useful information is more likely to be obtained by asking specific questions about each aspect of the history and about each member of the family than by asking general, open-ended questions. The interview may take 30 minutes to an hour. Some important information can be obtained by questionnaire, ideally at a routine prepregnancy visit. Commercially prepared questionnaires are available that address medical and surgical history; reproductive history, including outcomes of each prior pregnancy; medication use and drug allergies; family history of medical or genetic diseases and reproductive abnormalities; racial or ethnic origin; social risk factors such as alcohol, illicit drugs, smoking, high-risk sexual behavior, and spousal abuse; environmental risk factors such as exposure to pesticides or other chemicals; and home environment and stress inducers. Answers should be reviewed with the patient to ensure appropriate follow-up, including obtaining relevant medical records or consultant notes.

MEDICAL HISTORY. Preconceptional counseling should address all risk factors pertinent to both mother and fetus. General questions to be answered include how pregnancy will affect maternal health, and how a high-risk condition will affect the fetus. Almost any medical, obstetrical, or genetic condition warrants some consideration prior to pregnancy. These conditions should be discussed in terms of general maternal and fetal risks, and suggestions for prepregnancy evaluation should be offered. Finally, advice for improving outcome is provided. More detailed information on specific diseases such as diabetes, hypertension, collagen vascular disorders, and others are found in the relevant chapters.

Genetic Diseases. Women whose ethnic background, race, or personal or family history places them at increased risk to have a fetus with a genetic disease should receive appropriate counseling. This includes the possibility of prenatal diagnosis as discussed in [Chapter 13](#). Women who have a genetic disease usually require additional counseling about their own risks by someone knowledgeable about genetics. This is because genetic conditions are often associated with unique medical problems that may be adversely affected by pregnancy or that can adversely affect pregnancy outcome. They also may benefit from consultation with other specialists, for example, anesthesiologists, cardiologists, or surgeons. A variety of genetic resources can be accessed for detailed information about many inherited disorders.

Reproductive History. This component includes questions regarding infertility; abnormal pregnancy outcomes, including miscarriage, ectopic pregnancy, recurrent pregnancy loss, and preterm delivery; and complications such as preeclampsia or placental abruption. The reproductive history of first-degree relatives also may be helpful. For example, if a patient with recurrent pregnancy loss has other family members with the same history, her risk of carrying a familial translocation or another chromosomal rearrangement is increased. A history suggesting an incompetent cervix or a uterine anomaly should prompt an appropriate evaluation. The need for assisted reproductive technologies should be noted and associated risks discussed (Jackson and associates, 2004). The latter include a significantly increased risk of multiple gestation (see [Chap. 39](#)). Counseling regarding intracytoplasmic sperm injection and cryopreservation of embryos also should be provided (Bowen and colleagues, 1998; Hansen and co-workers, 2002). Risk factors for recurrent preterm delivery, preeclampsia, placental abruption, and repeat cesarean delivery are summarized in discussions of these disorders later in this text.

SOCIAL HISTORY

Maternal Age. The mother's age can have an impact on pregnancy at both ends of the reproductive spectrum.

TEENAGE PREGNANCY. According to the American College of Obstetricians and Gynecologists (2003), the pregnancies of women between the ages of 15 and 19 years accounted for about 11 percent of all births in 2001. Teenagers are more likely to be anemic, and they are at increased risk to have growth-restricted infants, preterm labor, and higher infant mortality (Fraser and associates, 1995). The incidence of sexually transmitted diseases—common in adolescents—is even higher during pregnancy (Nicolai and colleagues, 2003). Because most teenage pregnancies are unplanned, teens rarely seek preconceptional counseling.

Teenagers usually are still growing and developing, and thus have greater caloric requirements than older women. The normal or underweight teenager should be advised to increase caloric intake by 400 kcal/day. Alternatively, as discussed in [Chapter 43](#), the obese teenager may not need additional calories. Nonjudgmental questioning may elicit a history of substance abuse. Instructions regarding the identification or prevention of common pregnancy complications should be given.

PREGNANCY AFTER AGE 35. Currently, about 10 percent of pregnancies occur in women in this age group. The older woman is more likely to request preconceptional counseling, either because she has postponed pregnancy and now wishes to optimize her outcome, or because she plans to undergo infertility treatment. In the past, the indelicate term *elderly gravida* was used to arbitrarily define women over 35. Although the term is now passe, certain age-related adverse pregnancy outcomes do begin to increase at this age.

Some studies indicate that after age 35, women are at increased risk for obstetrical complications as well as perinatal morbidity and mortality. There is no doubt that the older woman who has a chronic illness or who is in poor physical condition has increased risks. For the physically fit woman without medical problems, however, the risks are much lower than previously reported.

The influence of socioeconomic and health status on pregnancy outcome in the older woman is illustrated by two studies involving different populations of women. Berkowitz and co-workers (1990) described outcomes of almost 800 privately insured nulliparas, age 35 and older, who were cared for at Mount Sinai Hospital in New York City. These authors reported only slightly increased risks of gestational diabetes, pregnancy-induced hypertension, placenta previa or abruption, and cesarean delivery. The women did not have an increased incidence of preterm delivery, growth-restricted infants, or perinatal death. In contrast, a study from Parkland Hospital, which included nearly 900 socioeconomically disadvantaged women older than 35 years of age, identified a significantly increased incidence of hypertension, diabetes, placenta previa and abruption, preterm delivery, and perinatal mortality ([Fig. 7-2](#)). The disparate outcomes in these two groups of women are likely attributable to socioeconomic status, which influences lifestyle and access to health care and thus health status.

Maternal mortality is higher in women age 35 and older, but improved medical care may ameliorate this risk. Buehler and colleagues (1986) reviewed maternal deaths in the United States from 1974 through 1982. From 1974 through 1978, older women had a fivefold increased relative risk of maternal death compared with that of younger women. By 1982, however, the mortality rates for older women had decreased by 50 percent. They concluded that this was probably due to improvements in health care.

Maternal age-related fetal risks primarily stem from (1) iatrogenic preterm delivery required for maternal complications such as hypertension and diabetes, (2) spontaneous preterm delivery, (3) fetal growth disorders related to chronic maternal disease or multiple gestation, (4) fetal aneuploidy, and (5) pregnancies resulting from use of assisted reproductive technology.

Most researchers have found that fetal aneuploidy is the only congenital abnormality related to maternal age. A study of 577,000 births in British Columbia by Baird and co-workers (1991) and another of 574,000 live births in Sweden by Pradat (1992) found no association between nonaneuploid structural defects and maternal age. An exception was the study by Hollier and colleagues (2000) of nearly 103,000 pregnancies that included 3885 infants with congenital malformations delivered at

Parkland Hospital. They reported that the incidence of nonaneuploid structural abnormalities increased significantly with maternal age. Some contend, however, that ascertainment bias was likely because older mothers commonly underwent targeted ultrasound examination but not amniocentesis, and the study population was enriched with regional referrals for women with malformed fetuses.

Older paternal age is associated with an increased incidence of genetic diseases caused by new autosomal-dominant mutations, but the incidence is still low (see [Chap. 12](#), p. 289). Accordingly, whether targeted ultrasound examinations should be performed solely for advanced maternal or paternal age is controversial.

Although the incidence of dizygotic twinning increases with maternal age, the most important cause of multifetal gestations in older women currently is conception with the use of *assisted reproductive technology* and *ovulation induction*. According to the Centers for Disease Control and Prevention (2002), 0.7 percent of all 3.9 million births in the United States in 1998 were the result of these techniques. More than half of this percentage were multiple infant births, which account for much of the morbidity from preterm delivery and neurological sequelae (Adashi and collaborators, 2003, 2004; Schieve and colleagues, 2002; Stromberg and associates, 2002). Finally, Hansen and co-workers (2002) reported that 8.6 percent of 301 infants conceived using intracytoplasmic sperm injection and 9 percent of 837 infants conceived by in vitro fertilization had major birth defects — compared with 4.2 percent in 4000 control women.

Recreational Drugs and Smoking. Fetal risks associated with alcohol, marijuana, cocaine, amphetamines, and heroin are discussed in [Chapter 14](#) (see p. 363). Alcohol-related mental retardation is currently the only mental retardation syndrome amenable to primary prevention. The first step in preventing this and other types of drug-related fetal damage is the woman's honest assessment of her usage. Questions regarding usage should be asked in a nonjudgmental manner. The alcoholic patient can be identified by asking the well-studied TACE questions, which correlate with DSM-IV criteria for lifetime alcoholism diagnoses (Chang and associates, 1998). TACE is a series of four questions concerning *tolerance* to alcohol, being *annoyed* by comments about their drinking, attempts to *cut down*, and a history of drinking early in the morning — the *eye opener*.

According to the Centers for Disease Control and Prevention (2003), almost one fourth of women who are between the ages of 18 and 44 years smoke cigarettes. Smoking affects fetal growth in a dose-dependent manner. It increases the risk of preterm labor, fetal growth restriction, and low birthweight. It has also been associated with an increased incidence of attention-deficit/hyperactivity disorder and behavioral and learning problems typically identified by school age (American College of Obstetricians and Gynecologists, 1999). Smoking also increases the risk of pregnancy complications related to vascular damage, such as uteroplacental insufficiency and placental abruption (see [Chap. 35](#), p. 811). After counseling, the woman should be provided with a pre-pregnancy program to reduce or eliminate smoking.

Environmental Exposures. Everyone is exposed to environmental substances, but fortunately only a few agents have an impact on pregnancy outcome. Exposures to infectious organisms and chemicals impart the greatest risk. Examples of high-risk exposures include pregnant nurses exposed to cytomegalovirus or respiratory syncytial virus; day-care workers exposed to parvovirus and rubella; industrial workers exposed to chemicals such as heavy metals or organic solvents; and women living in rural areas exposed to potentially harmful chemicals through pesticide use or contaminated well water.

Methyl mercury is a recently recognized environmental contaminant that is especially important because all pregnant women are potentially at risk. It is now well established that certain kinds of large fish are contaminated (see [Chap. 14](#), p. 355). Mercury is a neurotoxin that readily crosses the placenta and has adverse effects on fetal neurological development. Accordingly, the US Food and Drug Administration (2004) has recommended that pregnant women not eat shark, swordfish, king mackerel, or tilefish and that they consume no more than 12 ounces of other kinds of shellfish or other fish per week. Albacore or "white" tuna has more mercury than other canned tuna. Oken and colleagues (2003) have provided data that since the original FDA advisory, there has been a decline of ingestion by pregnant women of suspect fish species.

Figure 7-2. Incidence of some pregnancy complications in 20,525 women delivered at Parkland Hospital, 1987-1988. (Data from Cunningham and Leveno, 1995.)

LIFESTYLE AND WORK HABITS. A number of personal and work habits as well as lifestyle issues may have an impact on pregnancy outcome.

Diet. Pica for ice, laundry starch, clay, dirt, or other nonfood items should be discouraged (see [Chap. 8](#), p. 255). In some cases, it may represent an unusual physiological response to iron deficiency (Federman and colleagues, 1997). Many vegetarian diets are protein deficient but can be corrected by increasing egg and cheese consumption. As discussed in [Chapter 43](#), obesity is associated with a number of maternal complications such as hypertension, preeclampsia, gestational diabetes, labor abnormalities, postterm pregnancy, cesarean delivery, and operative complications (Wolfe, 1998). It is also associated with adverse fetal outcomes, including spina bifida and ventral wall defects, late fetal death, and preterm delivery (Cnattingius and co-workers, 1998).

In addition to nutritional deficiencies, anorexia and bulimia increase the risk of associated maternal problems such as electrolyte disturbances, cardiac arrhythmias, and gastrointestinal pathology (Becker and associates, 1999). In a study of 23 pregnancies in 15 women previously treated for anorexia nervosa or bulimia, Stewart and colleagues (1987) reported that those whose anorexia was not in remission at the time of conception had increased symptoms during pregnancy. They also gained less weight and had smaller infants.

Exercise. There are no data to suggest that exercise is deleterious during pregnancy; thus, conditioned pregnant women usually can continue to exercise throughout gestation (American College of Obstetricians and Gynecologists, 2002). As pregnancy progresses, balance problems and joint relaxation may predispose to orthopedic injury. The woman should be advised to not exercise to exhaustion, avoid supine positions, avoid activities requiring good balance, augment heat dissipation and fluid replacement, and avoid extreme weather conditions.

Domestic Abuse. Pregnancy can exacerbate interpersonal problems and is a time of increased risk from an abusive partner. As discussed in [Chapter 42](#) (see p. 997), one in six women is abused during pregnancy (Eisenstat and Bancroft, 1999). The interviewer should inquire about risk factors for domestic violence, and should offer intervention as appropriate. Abuse is more likely in women whose partners abuse alcohol or drugs, are recently unemployed, have a poor education or low income, or have a history of arrest (Grisso and colleagues, 1999; Kyriacou and associates, 1999).

FAMILY HISTORY. The most thorough method for obtaining a family history is to construct a pedigree using the symbols shown in [Figure 7-3](#). The health and reproductive status of each "blood relative" should be individually reviewed for medical illnesses, mental retardation, birth defects, infertility, and pregnancy loss. Certain racial, ethnic, or religious backgrounds may indicate increased risk for specific recessive disorders. Although most women can provide some information regarding their history, their understanding may be limited. For example, several studies have shown that pregnant women often fail to report a birth defect in the family or report it incorrectly. Romitti and associates (1997) interviewed 345 women who had a relative with a birth defect and 380 women without such a history. They verified their responses about family history by contacting relatives. Only 30 percent of these 725 women correctly reported familial birth defects. Rasmussen and colleagues (1990) used the Atlanta Birth Defects Registry to identify 4929 women whose child had a verified birth defect. When contacted, only 60 percent accurately reported the defect. It is thus important to verify the type of reported defect or genetic disease by reviewing pertinent medical records or by contacting affected relatives for additional information.

Figure 7-3. Symbols used for pedigree construction. (From Thompson and colleagues, 1991, with permission.)

IMMUNIZATIONS. Preconceptional counseling includes assessment of immunity to rubella and hepatitis B. Depending on health status, travel plans, and time of year, other immunizations may be in order (see [Table 8-9](#), p. 222). Vaccines consist of either toxoids (e.g., tetanus); killed bacteria or viruses (e.g., influenza, pneumococcus, hepatitis B, meningococcus, and rabies); or attenuated live viruses (e.g., varicella-zoster, measles, mumps, polio, rubella, chickenpox, yellow fever). Immunization during pregnancy with toxoids or killed bacteria or viruses has not been associated with adverse fetal outcomes (Chutivongse and colleagues, 1995; Czeizel and Rockenbauer, 1999). Alternatively, live-virus vaccines are not recommended during pregnancy and ideally should be given at least 1 month before attempts to conceive. Women inadvertently given measles, mumps, rubella, or varicella vaccines during pregnancy, however, are not necessarily advised to seek pregnancy termination. Most reports indicate that immunization to any of these agents poses only a theoretical risk to the fetus. Lastly, immunization to smallpox, anthrax, and other bioterrorist diseases should be discussed (see [Chap. 8](#), p. 221).

SCREENING TESTS

Certain laboratory tests may be helpful in assessing the risk of complications during pregnancy. These include basic tests that are usually performed during prenatal care. For example, rubella, varicella, and hepatitis B immune status should be determined so that vaccination can be carried out as part of preconceptional care. A complete blood count with mean red blood cell volume will exclude most serious inherited anemias. Hemoglobin electrophoresis is performed in individuals at increased risk, such as African-Americans for sickle syndromes and women of Mediterranean or Asian origin for thalassemias. Women with Jewish ancestry are candidates for carrier testing for Tay-Sachs and Canavan disease, whereas Caucasians of northern European descent may elect screening for cystic fibrosis. Specific counseling issues pertaining to these genetic diseases are discussed throughout [Chapter 12](#). Partners of women discovered to be carriers of autosomal-recessive diseases should be tested to determine the risk to future offspring. Couples discovered to be at significant increased risk of having an affected child can then contemplate their reproductive options before undertaking a pregnancy.

More specific tests may assist the evaluation of women with certain chronic medical diseases. Examples of some, but certainly not all, chronic diseases that may be assessed by prenatal testing include kidney disease, cardiovascular diseases, and diabetes. In the first example, the outcome of pregnancies complicated by chronic renal disease can be predicted to some extent by the serum creatinine level ([Table 7-1](#)). In the second example, the likelihood that a woman with cyanotic heart disease will have a successful pregnancy outcome can be predicted by a number of factors shown in [Table 7-2](#). The third example is the use of hemoglobin A_{1c} measurement to assess diabetic control during the preceding 6 weeks. This in turn can be used to compute risks for major anomalies ([Table 7-3](#)). These figures may be useful in gauging patient compliance and motivation. Although these data are from women with severe diabetes, the incidence of fetal anomalies in women who have gestational diabetes associated with fasting hyperglycemia is increased fourfold compared with nondiabetic control women (Sheffield and associates, 2002). Other specific tests used for the assessment of these and other diseases are discussed more fully in later chapters.

Electromagnetic Energy. There is no evidence in humans or animals that exposure to various electromagnetic fields such as high-voltage power lines, electric blankets, microwave ovens, and cellular phones causes adverse fetal effects (O'Connor, 1999; Robert, 1999). Electrical shock is discussed further in [Chapter 41](#) (see p. 1001).

8. Prenatal Care

INTRODUCTION

Organized prenatal care in the United States was introduced largely by social reformers and nurses (Merkatz and colleagues, 1990). In 1901, Mrs. William Lowell Putnam of the Boston Infant Social Service Department began a program of nurse visits to women enrolled in the home delivery service of the Boston Lying-in Hospital. This work was so successful that an outpatient prenatal clinic was established in 1911. Former authors of *Williams Obstetrics* were early supporters of prenatal care. In 1915, J. Whitridge Williams reviewed 10,000 consecutive deliveries at Johns Hopkins Hospital and concluded that 40 percent of 705 perinatal deaths could have been prevented by prenatal care. In 1954, Nicholas J. Eastman credited organized prenatal care with having "done more to save mothers' lives in our time than any other single factor" (Speert, 1980). In the 1960s, Jack Pritchard established a network of neighborhood prenatal clinics located in the most underserved communities in Dallas County. In large part because of increased accessibility, approximately 95 percent of medically indigent women now delivering at Parkland Hospital receive prenatal care. Importantly and related, the perinatal mortality rate of women in this system is less than that of the United States overall.

OVERVIEW OF PRENATAL CARE

Almost a century since its introduction, prenatal care has become one of the most frequently used health services in the United States. In 2001, there were approximately 50 million prenatal visits—the median was 12.3 visits per pregnancy—and, as shown in [Figure 8-1](#), many women had 17 or more visits (Martin and associates, 2002b). More than 83 percent of women began prenatal care during the first trimester, and all but 1.1 percent received some prenatal care. Over the past decade, the largest gains in timely prenatal care have been among minority groups ([Fig. 8-2](#)), but disparity continues. Significant obstetrical and medical risk factors or complications identifiable during prenatal care are summarized in [Table 8-1](#). Importantly, many of these complications are *treatable*.

Figure 8-1. Frequency distribution of the number of prenatal visits for the United States in 2001. (Adapted from Martin and associates, 2002b.)

Figure 8-2. Percent of women in the United States with prenatal care beginning in the first trimester by ethnicity, 1989 compared with 2001. (Adapted from Martin and associates, 2002b.)

INADEQUATE PRENATAL CARE. A commonly employed system for measuring the adequacy of prenatal care is the Kessner Index (Kessner and colleagues, 1973). As shown in [Table 8-2](#), this index incorporates information from three items recorded on the birth certificate: length of gestation, timing of the first prenatal care visit, and number of visits. Although the index measures the quantity of care better than either the number or timing of prenatal visits alone, it does not measure the quality of care. Similarly, the index does not consider the relative risk of the mother. Despite these limitations, the index remains a useful measure of prenatal care adequacy. Using the Kessner Index, the National Center for Health Statistics concluded that 12 percent of American women delivering in 2000 received inadequate prenatal care (Martin and associates, 2002a).

The Centers for Disease Control and Prevention (2000) analyzed birth certificate data for the years 1989 to 1997 and concluded that half of women with delayed or no prenatal care wanted to begin care earlier. Reasons for inadequate prenatal care varied by social and ethnic group, age, and method of payment. The most common reason cited was that the woman did not know she was pregnant. The second most commonly cited barrier was lack of money or insurance for such care. The third was inability to obtain an appointment.

EFFECTIVENESS OF PRENATAL CARE. Over the past several decades, some have concluded that prenatal care offers no benefits, and indeed may be disadvantageous. In an extensive review, Fiscella (1995) found no conclusive evidence that prenatal care improved birth outcomes. Other authors raised concern about the effectiveness of prenatal care because in the 1980s and 1990s, when use of prenatal care increased substantively, the rates of low-birthweight and preterm birth increased in the United States (Kogan and colleagues, 1998).

Conversely, Herbst and associates (2003) found that failure to obtain prenatal care was associated with more than a twofold increased risk of preterm birth. Schramm (1992) compared the costs and benefits of prenatal care in over 12,000 Medicaid patients in Missouri in 1988. He found that for each \$1 spent for prenatal care, there were estimated savings of \$1.49 in newborn and postpartum costs. Vintzileos and colleagues (2002b) analyzed data for the years 1995 to 1997 from the National Center for Health Statistics to measure the relationship between prenatal care and the risk of fetal death. They found that prenatal care was associated with an overall fetal death rate of 2.7 per 1000 compared with 14.1 per 1000 for women without prenatal care. Stated differently, failure to receive prenatal care increased the adjusted relative risk of stillbirth 3.3-fold. Vintzileos and colleagues (2002a) later reported that prenatal care significantly lowered the rate of neonatal death associated

with several high-risk conditions, including placenta previa, fetal growth restriction, and postterm pregnancy. They also found that prenatal care was associated with fewer preterm births (Vintzileos and colleagues, 2003).

It must also be remembered that prenatal care designed during the early 1900s was focused on lowering the extremely high incidence of maternal death. Prenatal care undoubtedly contributed to the dramatic decline in maternal mortality from 690 per 100,000 births in 1920 to 50 per 100,000 by 1955 (Loudon, 1992). As discussed in [Chapter 1](#) (see p. 7), the current maternal mortality rate of about 8 per 100,000 is likely associated with the high utilization of prenatal care. Indeed, in a population-based study from North Carolina, Harper and co-workers (2003) found that the risk of pregnancy-related maternal death was decreased fivefold among recipients of prenatal care.

Logically, the effectiveness of prenatal care cannot be gauged in isolation from other innovations. In the seventh edition of *Williams Obstetrics* (1929), prenatal care was specifically designated as one part of an organized program for pregnant women. Thus, in this context, prenatal care is not an end in itself but an initial step for coordinated intrapartum and postpartum care that often extends even beyond into a woman's later life.

ORGANIZATION OF PRENATAL CARE

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have defined prenatal care as: "A comprehensive antepartum care program that involves a coordinated approach to medical care and psychosocial support that optimally begins before conception and extends throughout the antepartum period." The content of such a comprehensive program includes (1) preconceptional care, (2) prompt diagnosis of pregnancy, (3) initial presentation for pregnancy care, and (4) follow-up prenatal visits.

PRECONCEPTIONAL CARE. Because health during pregnancy depends on health before pregnancy, preconceptional care should logically be an integral part of prenatal care. As discussed in detail in [Chapter 7](#), a comprehensive preconceptional care program has the potential to assist women by reducing risks, promoting healthy lifestyles, and improving readiness for pregnancy.

DIAGNOSIS OF PREGNANCY. The diagnosis of pregnancy usually begins when a woman presents with symptoms, and possibly a positive home urine pregnancy test. Typically, such women receive confirmatory testing for human chorionic gonadotropin (hCG) in urine or blood. There may be presumptive or diagnostic findings of pregnancy on examination. Ultrasound is often used, particularly in those cases in which there is question about pregnancy viability or location.

Signs and Symptoms. A number of clinical findings and symptoms may indicate an early pregnancy.

CESSATION OF MENSES. The abrupt cessation of menstruation in a healthy reproductive-aged woman who previously has experienced spontaneous, cyclical, predictable menses is highly suggestive of pregnancy. There is appreciable variation in the length of the ovarian and thus menstrual cycle among women, and even in the same woman. Thus, the absence of menses is not a reliable indication of pregnancy until 10 days or more after the time of expected onset of the menstrual period. When a second menstrual period is missed, the probability of pregnancy is much greater.

Uterine bleeding somewhat suggestive of menstruation occurs occasionally after conception. One or two episodes of bloody discharge, somewhat reminiscent of and sometimes mistaken for menstruation, are not uncommon during the first half of pregnancy. Such episodes are interpreted to be physiological, and likely the consequence of blastocyst implantation.

CHANGES IN CERVICAL MUCUS. If cervical mucus is aspirated, spread on a glass slide, allowed to dry for a few minutes, and examined microscopically, characteristic patterns can be discerned that are dependent on the stage of the ovarian cycle and the presence or absence of pregnancy. From about the 7th to the 18th day of the menstrual cycle, a fernlike pattern of dried cervical mucus is seen ([Fig. 8-3](#)). After approximately the 21st day, a different pattern forms that gives a beaded or cellular appearance ([Fig. 8-4](#)). This beaded pattern also is usually encountered during pregnancy.

The crystallization of the mucus, which is necessary for the production of the fern pattern, is dependent on an increased concentration of sodium chloride. This concentration, and in turn the presence or absence of the fern pattern, is determined by cervical glandular response to hormonal action. Specifically, cervical mucus is relatively rich in sodium chloride when estrogen, but not progesterone, is being produced. Progesterone secretion—even without a reduction in estrogen secretion—acts promptly to lower sodium chloride concentration to levels at which ferning will not occur. During pregnancy, progesterone usually exerts a similar effect, even though the amount of estrogen produced is enormous. Thus, if copious thin mucus is present and if a fern pattern develops on drying, early pregnancy is unlikely.

CHANGES IN THE BREASTS. Generally, the anatomical changes in the breasts that accompany pregnancy are quite characteristic during the first pregnancy (see [Chap. 5](#), p. 126). These are less obvious in multiparas, whose breasts may contain a small amount of milky material or colostrum for months or even years after the birth of their last child, especially if breast feeding was chosen.

DISCOLORATION OF THE VAGINAL MUCOSA. During pregnancy, the vaginal mucosa usually appears dark bluish or purplish-red and congested—the so-called *Chadwick sign* (Chadwick, 1886). This appearance is presumptive evidence of pregnancy, but it is not conclusive.

SKIN CHANGES. Increased pigmentation and changes in appearance of abdominal striae are common to, but not diagnostic of, pregnancy. They may be absent during pregnancy, and they may be seen in women taking estrogen-progestin contraceptives (see [Chap. 5](#), p. 126, and [Chap. 56](#), p. 1250).

CHANGES IN THE UTERUS. During the first few weeks of pregnancy, the increase in uterine size is limited principally to the anteroposterior diameter. By 12 weeks, the body of the uterus is almost globular, and an average uterine diameter of 8 cm is attained. On bimanual examination, the uterus during pregnancy feels doughy or elastic and sometimes becomes exceedingly soft. At about 6 to 8 weeks' menstrual age, on bimanual examination a firm cervix is felt which contrasts the now softer body

of the uterus and compressible interposed softened isthmus. This contrast is the *Hegar sign*. The softening at the isthmus may be so marked that the cervix and the body of the uterus seem to be separate organs. In fact, the inexperienced examiner may mistakenly conclude that the cervix is a small uterus, and that the softened body of the fundus is an adnexal mass.

CHANGES IN THE CERVIX. The cervix undergoes increased softening as pregnancy advances. In primigravidas, the consistency of the cervical tissue that surrounds the external os is more similar to that of the lips of the mouth than to that of nasal cartilage characteristic of the nonpregnant cervix. Other conditions, such as estrogen-progestin contraceptives, may cause cervical softening. As pregnancy progresses, the cervical canal may become sufficiently patulous to admit the fingertip.

FETAL HEART ACTION. The fetal heartbeat can be detected by auscultation with a standard nonamplified stethoscope by a mean of 17 weeks, and by 19 weeks in nearly all pregnancies in non-obese women (Jimenez and co-workers, 1979). The fetal heart rate now ranges from 110 to 160 beats/min and is heard as a double sound resembling the tick of a watch under a pillow. Because the fetus moves freely in amniotic fluid, the site on the maternal abdomen where fetal heart sounds can be heard best will vary.

Instruments incorporating Doppler ultrasound are often used to easily detect fetal heart action (see [Chap. 18](#), p. 445). Fetal cardiac action can be detected almost always by 10 weeks with Doppler equipment. Using real-time sonography with a vaginal probe, fetal heart action can be seen following as little as 5 weeks of amenorrhea.

In the later months of pregnancy, the examiner may often hear other sounds, the most common of which are:

1. The funic (umbilical cord) "souffle."
2. The uterine "souffle."
3. Sounds resulting from fetal movement.
4. Maternal pulse.
5. Sounds from maternal intestinal peristalsis.

The *funic souffle* is caused by the rush of blood through the umbilical arteries. It is a sharp, whistling sound that is synchronous with the fetal pulse. It is not heard consistently, even in the same pregnancy. The *uterine souffle* is a soft, blowing sound that is synchronous with the maternal pulse. It is usually heard most distinctly near the lower portion of the uterus. This sound is produced by the passage of blood through the dilated uterine vessels. It also may be heard with any condition in which uterine blood flow is greatly increased, for example, with large uterine myomas or ovarian tumors.

Frequently, the maternal pulse can be heard distinctly by auscultation of the abdomen, and in some women, the pulsation of the aorta is unusually loud. Occasionally the pulse of the mother may become so rapid as to simulate fetal heart sounds.

PERCEPTION OF FETAL MOVEMENTS. At or about 20 weeks, the examiner can begin to detect fetal movements.

Chorionic Gonadotropin. Detection of hCG in maternal blood and urine provides the basis for endocrine tests of pregnancy. This hormone is a glycoprotein with a high carbohydrate content. The molecule is a heterodimer composed of two dissimilar subunits, designated α and β , which are noncovalently linked (see [Chap. 3](#), p. 70). The α -subunit is similar to those of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). HCG prevents involution of the corpus luteum, the principal site of progesterone formation during the first 6 weeks.

Trophoblast cells produce hCG in amounts that increase exponentially following implantation. With a sensitive test, the hormone can be detected in maternal plasma or urine by 8 to 9 days after ovulation. The doubling time of plasma hCG concentration is 1.4 to 2.0 days. Levels increase from the day of implantation and reach peak levels at about 60 to 70 days. Thereafter, the concentration declines slowly until a nadir is reached at about 14 to 16 weeks ([Fig. 8-5](#)).

MEASUREMENT OF hCG.

With the recognition that LH and hCG were both composed of an α - and a β -subunit, but that the β -subunits of each were structurally distinct, antibodies were developed with high specificity for the β -subunit of hCG. This specificity is the basis for detection of hCG in urine or blood. Numerous commercial immunoassays are available for measuring serum and urine levels of hCG, each employing a slightly different combination of antibodies. Although each detects a slightly different mixture of hormone, its free subunits, or its metabolites, all of these immunoassays are appropriate for normal pregnancy testing (Cole, 1998).

One commonly employed technique for detection and quantification of hCG is the *sandwich-type immunoassay*. This test uses a monoclonal antibody against the β -subunit, which is bound to a solid-phase support. The bound antibody is then exposed to hCG in the serum or urine specimen. A second antibody is then added to "sandwich" the bound hCG. In some assays, the second antibody is linked to an enzyme, such as alkaline phosphatase. When substrate for the enzyme is added, a color develops, the intensity of which is proportional to the amount of enzyme and thus to the amount of the second antibody bound. This, in turn, is a function of the amount of hCG in the test sample. The sensitivity for the laboratory detection of hCG in serum is as low as 1.0 mIU/mL using this technique. With extremely sensitive immunoradiometric assays, the detection limit is even lower (Wilcox and associates, 2001).

False-positive hCG test results are rare (Braunstein, 2002). However, some women have circulating factors in their serum that may interact with the hCG antibody. The most common are heterophilic antibodies, which are human antibodies directed against animal-derived antigens used in immunoassays. Women who have worked closely with animals are more likely to develop such heterophilic antibodies. The American College of Obstetricians and Gynecologists (2002a) has suggested alternative laboratory techniques if heterophilic antibodies are suspected.

HOME PREGNANCY TESTS. In 1999, approximately 19 million over-the-counter pregnancy test kits were sold in the United

States, with sales of about \$230 million (Wilcox and associates, 2001). Bastian and colleagues (1998) evaluated published results of 16 home pregnancy test kits, of which only five met their inclusion criteria. If testing was done by volunteers, a mean 91-percent sensitivity was obtained. Importantly, however, actual patients obtained only 75-percent sensitivity.

Cole and colleagues (2004) also questioned the utility of home testing. They found that a detection limit of 12.5 mIU/mL would be required to diagnose 95 percent of pregnancies at the time of missed menses. In their study of the accuracy of 18 different home pregnancy tests, they also found that only one brand had this degree of sensitivity. Two other brands gave false-positive or invalid results. In fact, clearly positive results were given by only 44 percent of the brands at an hCG concentration of 100 mIU/mL. A test capable of detecting this level would be expected to identify only about 15 percent of pregnancies at the time of the missed menses.

Ultrasonic Recognition of Pregnancy. The use of transvaginal sonography has revolutionized imaging of early pregnancy and its growth and development. A gestational sac may be demonstrated by abdominal sonography after only 4 to 5 weeks' menstrual age (Fig. 8-6). By 35 days, all normal sacs should be visible, and after 6 weeks, a heartbeat should be detectable. Up to 12 weeks, the crown-rump length is predictive of gestational age within 4 days. These measurements are discussed in detail in Chapter 16 (see p. 392).

Figure 8-3. Scanning electron microscopy of cervical mucus obtained on day 11 of the menstrual cycle. (From Zaneveld and associates, 1975, with permission.)

Figure 8-4. Photomicrograph of dried cervical mucus obtained from the cervical canal of a woman pregnant at 32 to 33 weeks. The beaded pattern is characteristic of progesterone action on the endocervical gland mucus composition. (Courtesy of Dr. J. C. Ullery.)

Figure 8-5. Mean concentration of chorionic gonadotropin (hCG) in serum of women throughout normal pregnancy. The free β -subunit of hCG is in low concentration throughout pregnancy. (Data from Ashitaka and colleagues, 1980; Selenkow and co-workers, 1971.)

INITIAL PRENATAL EVALUATION. Prenatal care should be initiated as soon as there is a reasonable likelihood of pregnancy. The major goals are:

1. To define the health status of the mother and fetus.
2. To estimate the gestational age of the fetus.
3. To initiate a plan for continuing obstetrical care.

Typical components of the initial visit are summarized in Table 8-3. The initial plan for subsequent care may range from relatively infrequent routine visits to prompt hospitalization because of serious maternal or fetal disease.

Prenatal Record. Use of a standardized record within a perinatal health care system greatly facilitates antepartum and intrapartum management. A prototype is provided by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002).

DEFINITIONS. There are several definitions pertinent to establishment of an accurate prenatal record:

• **Nulligravida:** a woman who is not now and never has been pregnant.

• **Gravida:** a woman who is or has been pregnant, irrespective of the pregnancy outcome. With the establishment of the first pregnancy, she becomes a primigravida, and with successive pregnancies, a multigravida.

• **Nullipara:** a woman who has never completed a pregnancy beyond 20 weeks' gestation. She may or may not have been

pregnant or may have had a spontaneous or elective abortion(s).

¶ • **Primipara:** a woman who has been delivered only once of a fetus or fetuses born alive or dead with an estimated length of gestation of 20 or more weeks. In the past, a 500-g birthweight threshold was used to define parity. This threshold is no longer as pertinent because of the survival of infants with birthweights less than 500 g.

¶ • **Multipara:** a woman who has completed two or more pregnancies to 20 weeks or more. Parity is determined by the number of pregnancies reaching 20 weeks and not by the number of fetuses delivered. That is, parity is not greater if a single fetus, twins, or quintuplets were delivered, nor lower if the fetus or fetuses were stillborn.

In some locales, the obstetrical history is summarized by a series of digits connected by dashes. These usually refer to the number of term infants, preterm infants, abortions, and children currently alive. For example, a woman who is para 6-1-2-6 has had six term deliveries, one preterm delivery, and two abortions, and has six children living. Such shorthand is often confusing because no one system is widely adopted.

Normal Pregnancy Duration. The mean duration of pregnancy calculated from the first day of the last normal menstrual period is very close to 280 days, or 40 weeks. In a study of 427,581 singleton pregnancies abstracted in the Swedish Birth Registry, Bergsjö and colleagues (1990) found that the mean duration of pregnancy was 281 days with a standard deviation of 13 days.

It is customary to estimate the expected date of delivery by adding 7 days to the date of the first day of the last normal menstrual period and counting back 3 months (Naegele rule). For example, if the last menstrual period began on September 10, the expected date of delivery would be June 17. It is apparent that pregnancy is erroneously considered to have begun about 2 weeks before ovulation if the duration is so calculated. Nonetheless, clinicians conventionally calculate *gestational age* or *menstrual age* from the first day of the last menstrual period to identify temporal events in pregnancy. Embryologists and other reproductive biologists more often employ *ovulatory age* or *fertilization age*, both of which are typically 2 weeks shorter. Bracken and Belanger (1989) tested the accuracy of various "pregnancy wheels" provided by three pharmaceutical companies and found that such devices were remarkably prone to error. Specifically, incorrect delivery dates were predicted in 40 to 60 percent of estimates, with a 5-day error being typical.

It has become customary to divide pregnancy into three equal *trimesters* of approximately 3 calendar months. Historically, the *first trimester* extended through the completion of 14 weeks, the *second trimester* through 28 weeks, and the third trimester included the 29th through 42nd weeks of pregnancy. Put another way, trimesters can be obtained by division of 42 into three periods of 14 weeks each. There are certain major obstetrical problems that cluster in each of these time periods. For example, the majority of spontaneous abortions take place during the first trimester, whereas most women with hypertensive disorders due to pregnancy are diagnosed during the third trimester.

The clinical use of trimesters to describe the duration of a specific pregnancy is too imprecise. For example, it is inappropriate in cases of uterine hemorrhage to categorize the problem temporally as "third-trimester bleeding." Appropriate management for the mother and her fetus will vary remarkably, depending on whether the bleeding is encountered early or late in the third trimester (see [Chap. 35](#), p. 810). **Precise knowledge of the age of the fetus is imperative for ideal obstetrical management!** Therefore, expert attention must be given to this important measurement. The clinically appropriate unit of measure is *weeks of gestation completed*. Increasingly, clinicians designate gestational age using completed weeks and days, for example, 33 3/7 weeks for 33 completed weeks and 3 days.

History. For the most part, the same essentials go into appropriate history-taking from the pregnant woman as elsewhere in medicine. **Detailed information concerning past obstetrical history is crucial because many prior pregnancy complications tend to recur in subsequent pregnancies.**

The *menstrual history* is extremely important. The woman who spontaneously menstruates regularly every 28 days or so is most likely to ovulate at midcycle. Thus, the gestational age (menstrual age) becomes simply the number of weeks since the onset of the last menstrual period. If her menstrual cycles were significantly longer than 28 to 30 days, ovulation more likely occurred well beyond 14 days. Similarly, if the intervals were much longer and irregular, chronic anovulation is likely to have preceded some of the episodes of vaginal bleeding identified as menses. **Without a history of regular, predictable, cyclic, spontaneous menses that suggest ovulatory cycles, accurate dating of pregnancy by history and physical examination is difficult.**

It is important to ascertain whether or not *steroidal contraceptives* were used before the pregnancy. Because ovulation may not have resumed 2 weeks after the onset of the last withdrawal bleeding, and instead, may have occurred at an appreciably later and highly variable date, using the time of ovulation for predicting the time of conception in this circumstance may be erroneous. Use of ultrasonography in early pregnancy can clarify gestational age in these situations.

Psychosocial Screening. The American College of Obstetricians and Gynecologists (1999b) has concluded that addressing psychosocial issues is an essential step toward improving women's health and birth outcomes. Shown in [Table 8-4](#) is a psychosocial screening tool, recommended for this purpose, that was developed by the Healthy Start Program of the Florida Department of Health.

CIGARETTE SMOKING. Since 1984, the Surgeon General has required four specific, rotating health warnings on all cigarette packages, including: "Smoking by pregnant women may result in fetal injury, premature birth, and low birthweight" (United States Department of Health and Human Services, 2000). Information on maternal smoking during pregnancy has been included on the birth certificate since 1989. According to this information, reported smoking during pregnancy has progressively declined from 20 percent in 1989 to 12 percent in 2001 (Martin and colleagues, 2002b). In 2001, as in previous years, the smoking rate of 19 percent was highest for older teenagers ¶— those aged 18 to 19 years.

Various adverse outcomes have been linked to smoking during pregnancy. Included are spontaneous abortion, low birthweight due to either preterm delivery or fetal growth restriction, infant and fetal deaths, and placental abruption (Ananth, 1996; Centers for Disease Control and Prevention, 2002d; Lin and Santolaya-Forgas, 1998; Martin, 2002b; Ness, 1999, and all their associates). Suggested pathophysiological mechanisms for these adverse pregnancy effects include increased fetal

carboxyhemoglobin, reduced uteroplacental blood flow, and fetal hypoxia (Jazayeri and colleagues, 1998; Monheit and co-workers, 1983). To put the smoking problem into a national perspective, in 2001 the incidence of low birthweight among infants born to American women who reported smoking during pregnancy was two-thirds higher than that for nonsmokers—11.9 compared with 7.3 percent. Even among births to women who smoked only 1 to 5 cigarettes daily, 11.3 percent were low birthweight, and this rate was more than 50-percent higher than for nonsmokers (Martin and co-workers, 2002b). Jacqz-Aigrain and associates (2002) found that maternal cigarette consumption correlated directly with levels of cotinine measured in neonatal hair samples.

The most successful efforts for smoking cessation during pregnancy involve interventions that emphasize how to stop smoking. The Food and Drug Administration (FDA) classifies nicotine gum as category C (risk cannot be excluded), and transdermal systems are rated category D (positive evidence of risk). The American College of Obstetricians and Gynecologists (2000) has concluded, however, that it is reasonable to use these nicotine medications during pregnancy if prior nonpharmacological attempts have failed. Optimally, smokers should be treated before conception. Wisborg and co-workers (2000) randomly assigned 250 women who smoked at least 10 cigarettes per day after the first trimester to receive nicotine or placebo patches. Overall, 26 percent stopped smoking, however, no significant differences in smoking cessation, birthweight, or preterm delivery were detected between the nicotine and placebo groups. Of note, no serious adverse effects from the patches were reported, but compliance with the assigned treatments was low.

ALCOHOL AND ILLICIT DRUGS DURING PREGNANCY. Ethanol is a potent teratogen and causes the fetal alcohol syndrome, which is characterized by growth restriction, facial abnormalities, and central nervous system dysfunction (see [Chap. 14](#), p. 346). The Surgeon General recommends that women who are pregnant or considering pregnancy abstain from using any alcoholic beverages.

Alcohol use is substantively underreported on the birth certificate—less than 1 percent of women reported any alcohol use during pregnancy in 2001 (Martin and colleagues, 2002b). According to the Centers for Disease Control and Prevention (2002a), about 13 percent of pregnant women used alcohol in 1999, down from 16 percent in 1995. Unfortunately, rates of binge and frequent drinking during pregnancy have not declined.

Chronic use of large quantities of illicit drugs, including opium derivatives, barbiturates, and amphetamines, is harmful to the fetus. Fetal distress, low birthweight, and drug withdrawal soon after birth are well documented. Often the mother who uses such drugs does not seek prenatal care, and even if she does, she may not admit to the use of such substances. El-Mohandes and associates (2003) have found that when women who use illicit drugs receive prenatal care, the risks for preterm birth and low birthweight are reduced.

The effects of several illicit drugs are considered in detail in [Chapter 14](#) (see p. 363). The American College of Obstetricians and Gynecologists (1999b) has reviewed methods for screening women during pregnancy for use of illicit drugs and for alcohol abuse.

DOMESTIC VIOLENCE SCREENING. The term *domestic violence* usually refers to violence against adolescent and adult females within the context of family or intimate relationships. Such violence has been increasingly recognized as a major public health problem (see also [Chap. 42](#), p. 997). Unfortunately, the majority of abused women continue to be victimized during pregnancy. With the possible exception of preeclampsia, domestic violence is more prevalent than any major medical condition detectable through routine prenatal screening (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002). In their survey of 4750 women, Janssen and colleagues (2003) found that 1.2 percent were exposed to physical violence by an intimate partner during pregnancy. This finding was associated with an approximate threefold increased risk of antepartum hemorrhage and fetal growth restriction and an eightfold increased risk of perinatal death.

The American College of Obstetricians and Gynecologists (1999a) has provided methods for screening for domestic violence and recommends their use at the first prenatal visit, then again at least once per trimester, and again at the postpartum follow-up. Webster and Holt (2004) found that a simple, six-question self-report survey is an effective alternative to direct questioning for identifying pregnant women who are experiencing partner violence. Physicians should be familiar with state laws that may require reporting of domestic violence (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002).

Physical Examination. A thorough, general physical examination should be completed at the initial prenatal encounter. Expected changes in physical examination findings resulting from normal pregnancy are addressed in [Chapters 2](#) and [5](#).

PELVIC EXAMINATION. The cervix is visualized employing a speculum lubricated with warm water. Bluish-red passive hyperemia of the cervix is characteristic, but not of itself diagnostic, of pregnancy (see p. 205). Dilated, occluded cervical glands bulging beneath the exocervical mucosa, so-called *nabothian cysts*, may be prominent. The cervix is not normally dilated above the level of the internal os. Next, to identify cytological abnormalities, a Pap smear is obtained and specimens for identification of *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are obtained if screening is indicated.

Digital pelvic examination is completed by palpation, with special attention given to the consistency, length, and dilatation of the cervix; to the fetal presentation later in pregnancy; to the bony architecture of the pelvis; and to any anomalies of the vagina and perineum, including cystocele, rectocele, and relaxed or torn perineum. The vulva and contiguous structures are carefully inspected. All cervical, vaginal, and vulvar lesions are evaluated further by appropriate use of colposcopy, biopsy, culture, or dark-field examination. The perianal region should be visualized and digital rectal examination performed.

Laboratory Tests. Recommended routine laboratory tests at the first prenatal encounter are listed in [Table 8-3](#). The Institute of Medicine recommended that a national policy of universal screening be developed for human immunodeficiency virus (HIV) testing, with patient notification, as a routine part of prenatal testing. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) support this recommendation. If a woman declines testing, this should be noted in the prenatal record. All pregnant women should also be screened for hepatitis B virus infection. Based on their prospective investigation of 1000 women, Murray and co-workers (2002) concluded that in the absence of hypertension, routine urinalyses beyond the initial prenatal visit were not necessary.

High-Risk Pregnancies. There are many risk factors that can be identified and given appropriate consideration in pregnancy

management, and these are shown in [Table 8-5](#). Some conditions may require the involvement of a maternal-fetal medicine subspecialist, geneticist, pediatrician, anesthesiologist, or other medical specialist in the evaluation, counseling, and care of the patient (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002).

SUBSEQUENT PRENATAL VISITS. Traditionally, the timing of subsequent prenatal visits has been scheduled at intervals of 4 weeks until 28 weeks, and then every 2 weeks until 36 weeks, and weekly thereafter. Women with complicated pregnancies often require return visits at 1- to 2-week intervals. For example, Luke and co-workers (2003) found that a specialized prenatal care program that emphasized nutrition and education and required return visits every 2 weeks resulted in improved outcomes in twin pregnancies. In 1986, the Department of Health and Human Services convened an expert panel to review the content of prenatal care (Rosen and associates, 1991). The panel recommended that the number of prenatal visits be reduced in women at no apparent risk. They suggested that such women would best be served by return visits targeted at specific times; an example is alpha-fetoprotein screening at 16 weeks. Parous women with normal obstetrical histories are seen even less frequently.

The World Health Organization conducted a multicenter randomized trial with almost 25,000 women comparing routine prenatal care with an experimental model designed to minimize visits (Villar and associates, 2001). In the new model, women were seen once in the first trimester and screened for certain risk factors. Those without any anticipated complications were seen again at 26, 32, and 38 weeks. Compared with routine prenatal care, which required a median of eight visits, the new model required a median of only five visits. No disadvantages were found in women with fewer visits. These results are consistent with other randomized trials (Clement and co-workers, 1999; McDuffie and colleagues, 1996).

Prenatal Surveillance. At each return visit, steps are taken to determine the well-being of mother and fetus (see [Table 8-3](#)). Certain information—for example, assessment of gestational age and accurate measurement of blood pressure (Jones and associates, 2003)—is especially important.

• Fetal

• Heart rate(s)

• Size—current and rate of change

• Amount of amniotic fluid

• Presenting part and station (late in pregnancy)

• Activity

• Maternal

• Blood pressure—current and extent of change

• Weight—current and amount of change

• Symptoms—including headache, altered vision, abdominal pain, nausea and vomiting, bleeding, vaginal fluid leakage, and dysuria

• Height in centimeters of uterine fundus from symphysis

• Vaginal examination late in pregnancy often provides valuable information:

• Confirmation of the presenting part.

• Station of the presenting part (see [Chap. 17](#), p. 426).

• Clinical estimation of pelvic capacity and its general configuration (see [Chap. 2](#), p. 36).

• Consistency, effacement, and dilatation of the cervix.

Assessment of Gestational Age. One of the most important determinations at prenatal examinations is assessment of fetal age. Precise knowledge of gestational age is important because a number of pregnancy complications may develop for which optimal treatment will depend on fetal age. Fortunately, it is possible to identify this with considerable precision through an appropriately timed, carefully performed clinical examination, coupled with knowledge of the time of onset of the last menstrual period.

FUNDAL HEIGHT. Between 20 and 31 weeks, the height of the uterine fundus, measured in centimeters, correlates closely with gestational age in weeks (Jimenez and co-workers, 1983). Quaranta and associates (1981) and Calvert and colleagues (1982) reported essentially identical observations up to 34 weeks. Obesity, however, may distort this relationship. The fundal height should be measured as the distance over the abdominal wall from the top of the symphysis pubis to the top of the fundus. *The bladder must be emptied before making the measurement.* Worthen and Bustillo (1980), for example, demonstrated that at 17 to 20 weeks, fundal height was 3 cm higher with a full bladder.

FETAL HEART SOUNDS. The fetal heart can first be heard in most women between 16 and 19 weeks when carefully auscultated with a DeLee fetal stethoscope. The ability to hear unamplified fetal heart sounds will depend on factors such as patient size and the examiner's hearing acuity. Herbert and co-workers (1987) reported that the fetal heart was audible by 20 weeks in 80 percent of women. By 21 weeks audible fetal heart sounds were present in 95 percent, and by 22 weeks in all.

ULTRASOUND. When gestational age cannot be clearly identified, sonography is of considerable value. Compared with the last menstrual period, Taipale and Hiilesmaa (2001) found that ultrasonography performed between 8 and 16 weeks was slightly more accurate, by approximately 2 days, for predicting the actual date of delivery. Although controversial, as discussed in [Chapter 13](#) (see p. 326), routine ultrasound is not currently recommended in low-risk pregnancies by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002).

Subsequent Laboratory Tests. If the initial results were normal, most tests need not be repeated (see [Table 8-3](#)). Maternal serum screening at 16 to 18 weeks (15 to 20 weeks is acceptable) is recommended for detecting open neural-tube defects and some chromosomal anomalies (see [Chap. 13](#), p. 319). Hematocrit (or hemoglobin) determination, along with syphilis serology if it is prevalent in the population, should be repeated at about 28 to 32 weeks (Hollier and co-workers, 2003; Kiss and colleagues, 2004).

Cystic fibrosis carrier screening should be offered to couples with a family history of cystic fibrosis and to Caucasian couples of European or Ashkenazi Jewish descent planning a pregnancy or seeking prenatal care. Ideally, screening is performed before conception or during the first or early second trimester. Information about cystic fibrosis screening also should be provided to patients in other racial and ethnic groups who are at lower risk (see [Chap. 13](#), p. 325).

ANCILLARY PRENATAL TESTS

Gestational Diabetes. All pregnant women should be screened for gestational diabetes mellitus, whether by history, clinical risk factors, or routine laboratory testing. Although laboratory testing between 24 and 28 weeks is the most sensitive approach, there may be pregnant women at low risk who are less likely to benefit from testing (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002). Gestational diabetes is discussed in [Chapter 52](#) (see p. 1172).

Chlamydial Infection. Women at high risk for *C trachomatis* infection should be screened during the first prenatal visit (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002). Risk factors include unmarried status, recent change in sexual partner or multiple concurrent partners, age under 25 years, inner-city residence, history or presence of other sexually transmitted diseases, and little or no prenatal care. The United States Preventive Services Task Force (2001) concluded that evidence that screening and treatment of women at risk for chlamydia improves pregnancy outcome is "fair." They concluded that benefits of screening outweigh potential harms. A negative prenatal chlamydia or gonorrhea test should not preclude postpartum screening (Mahon and associates, 2002).

Gonococcal Infection. Risk factors for gonorrhea are similar for those for chlamydia. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) recommend that pregnant women with risk factors or symptoms be cultured for *N gonorrhoeae* at an early prenatal visit and again in the third trimester. Treatment is given for gonorrhea as well as possible coexisting chlamydial infection, as outlined in [Chapter 59](#) (see p. 1305).

Fetal Fibronectin. Detection of this protein in vaginal fluid has been used to forecast preterm delivery in women with contractions (see [Chap. 36](#), p. 862). The American College of Obstetricians and Gynecologists (2001b) does not recommend routine screening.

Group B Streptococcal (GBS) Infection. Universal prenatal screening for GBS carriage has been controversial. Based largely on a retrospective study comparing risk-based and culture-based approaches (Schrage and co-workers, 2002), the American College of Obstetricians and Gynecologists (2002c) and the Centers for Disease Control and Prevention (2002c) now recommend that vaginal and rectal GBS cultures be obtained in all women between 35 and 37 weeks. Intrapartum antimicrobial prophylaxis is given for those whose cultures are positive. Women with GBS bacteriuria or a previous infant with invasive disease are given empirical intrapartum prophylaxis. These infections are discussed in detail in [Chapter 58](#) (see p. 1284).

Special Screening for Genetic Diseases. Selected screening can be offered based on maternal age, family history, or the ethnic or racial background of the couple (American College of Obstetricians and Gynecologists, 1995). Examples include testing for Tay-Sachs disease for people of Eastern European Jewish or French Canadian ancestry; β -thalassemia for those of Mediterranean, Southeast Asian, Indian, Pakistani, or African ancestry; α -thalassemia for people of Southeast Asian or African ancestry; and sickle-cell anemia for people of African, Mediterranean, Middle Eastern, Caribbean, Latin American, or Indian descent (see [Chap. 7](#), p. 192).

NUTRITION

Meaningful studies of nutrition in human pregnancy are exceedingly difficult to design. For ethical reasons, experimental dietary deficiency must not be produced deliberately. In those instances in which severe nutritional deficiencies have been induced as a consequence of social, economic, or political disaster, coincidental events often have created many variables, the effects of which are not amenable to quantification. Some past experiences suggest, however, that in otherwise healthy women a state of near starvation is required to establish clear differences in pregnancy outcome.

During the severe European winter of 1944-1945, nutritional deprivation of known intensity prevailed in a well-circumscribed area of the Netherlands occupied by the German military (Stein and associates, 1972). At the lowest point during the *Hunger Winter*, rations reached 450 kcal/day, with generalized rather than selective malnutrition. Smith (1947) analyzed the outcomes of pregnancies that were in progress during this 6-month famine. Median infant birthweights decreased about 250 g and rose again after food became available. This indicated that birthweight can be influenced significantly by starvation during later pregnancy. The perinatal mortality rate, however, was not altered, nor was the incidence of malformations significantly increased. Interestingly, the frequency of pregnancy "toxemia" was found to decline.

Evidence of impaired brain development has been obtained in some animal fetuses whose mothers had been subjected to intense dietary deprivation. Subsequent intellectual development was studied by Stein and associates (1972) in young Dutch adults whose mothers had been starved during pregnancy. The comprehensive study was made possible because all males at age 19 underwent compulsory examination for military service. It was concluded that severe dietary deprivation during

pregnancy caused no detectable effects on subsequent mental performance.

Conversely, there is evidence that maternal weight gain during pregnancy influences birthweight. This was studied by Martin and colleagues (2002b) who used birth certificate data for 2001. As shown in [Figure 8-7](#), nearly two thirds of pregnant women gained 26 lb or more. The median weight gain was 30.5 lb. Maternal weight gain had a positive correlation with birthweight, and women with the greatest risk— 14 percent— for delivering an infant weighing less than 2500 g were those with weight gains less than 16 lb. This incidence was 20 percent in African-American women who gained 15 lb or less. Cohen and associates (2001) studied more than 4000 pregnant women and concluded that ethnic differences in pregnancy outcomes were not explained by nutritional variations.

Figure 8-7. Maternal weight gain in the United States reported on the birth certificate in 2001. (From Martin and colleagues, 2002b.)

RECOMMENDATIONS FOR WEIGHT GAIN. For the first half of the 20th century, it was recommended that weight gain during pregnancy be limited to less than 20 lb (9.1 kg). It was believed that such restriction would prevent pregnancy hypertensive disorders and fetal macrosomia resulting in operative deliveries. By the 1970s, however, women were encouraged to gain at least 25 lb (11.4 kg) to prevent preterm birth and fetal growth restriction, a recommendation that subsequent research continues to support (Ehrenberg and associates, 2003). In 1990, the Institute of Medicine recommended a weight gain of 25 to 35 lb (11.5 to 16 kg) for women with a normal prepregnancy body mass index (BMI). This index is easily calculated using the chart shown in [Figure 43-1](#) (see p. 1008). Weight gains recommended by the Institute of Medicine (1990) according to prepregnant BMI categories are shown in [Table 8-6](#). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have endorsed these guidelines. Of note, in 2001, almost 1 in 3 women had weight gains outside the Institute of Medicine guidelines (Martin and colleagues, 2002b).

Feig and Naylor (1998) from Canada have challenged recommendations for liberal weight gain in industrial nations. They concluded that these recommendations encourage women to overeat during pregnancy without addressing other causes of low-birthweight infants such as adolescent pregnancy, drug abuse, and heavy smoking. They endorsed the recommendation by the Committee on Medical Aspects of Food Policy (1991) in the United Kingdom that a pregnant woman with a normal BMI should gain 15 to 25 lb during pregnancy.

Disadvantages of excessive maternal weight gain and fetal macrosomia must be considered. Thorsdottir and associates (2002) analyzed pregnancy outcome in relation to weight gain in 615 healthy women with a normal BMI before pregnancy. The frequency of antepartum and intrapartum complications, including fetal macrosomia, was highest among women who gained more than 44 lb (20 kg) during pregnancy. Conversely, these complications were lowest among those whose weight gain was within the range recommended by the Institute of Medicine. Similarly, Rhodes and co-workers (2003) found in their analysis of 1999-2000 United States birth certificate data that excessive weight gain— defined as more than 40 lb— correlated closely with fetal macrosomia.

Weight Retention After Pregnancy. Not all the weight put on during pregnancy is lost during and immediately after parturition (Hyttén, 1991). The average-sized normal woman who gains 28 lb (12.5 kg) in pregnancy is about 9 lb (4.4 kg) above her prepregnant weight when discharged postpartum. Schauburger and co-workers (1992) studied prenatal and postpartum weights in 795 women delivered in Wisconsin. Their average weight gain was 28.6 lb ± 10.6 lb (13.0 kg ± 4.8 kg). As shown in [Figure 8-8](#), the majority of maternal weight loss was at delivery— about 12 lb (5.5 kg)— and in the ensuing 2 weeks thereafter— about 9 lb (4 kg). An additional 5.5 lb (2.5 kg) was lost between 2 weeks and 6 months postpartum. The average total weight loss resulted in an average retained weight of 3 lb ± 10.5 lb (1.4 kg ± 4.8 kg) due to pregnancy. Overall, the more weight gained during pregnancy, the more that was lost postpartum. Parous women retained more of their pregnancy weight, and this is linked to long-term obesity (see [Chap. 43](#), p. 1012). The effect of breast feeding on maternal weight loss was negligible.

Summary of Weight Gain. Perhaps the most remarkable finding about weight gain in pregnancy is that a wide range is compatible with good clinical outcomes. Moreover, departures from "normal" are nonspecific for any outcome in a given individual.

Figure 8-8. Cumulative weight loss from last antepartum visit to 6 months postpartum. *Statistically different from 2-week weight loss, **Statistically different from 6-week weight loss. (From Schauburger and co-workers, 1992, with permission.)

Figure 43-1. Chart for estimating body mass index (BMI). To find the BMI category (e.g., obese) for a particular subject, locate the point at which the height and

weight intersect. The BMI is the bold number on the dashed line closest to this point. The "High" category is now termed "Overweight."

RECOMMENDED DIETARY ALLOWANCES. Periodically, the Food and Nutrition Board of the Institute of Medicine recommends dietary allowances for women, including those who are pregnant or lactating. Its latest recommendations (2004) are summarized in [Table 8-7](#). Certain prenatal vitamin-mineral supplements may lead to intakes well in excess of the recommended allowances. Moreover, the use of excessive supplements— for example, 10 times the recommended daily allowances— which often are self-prescribed, has led to concern about nutrient toxicities during pregnancy. Nutrients that can potentially exert toxic effects include iron, zinc, selenium, and vitamins A, B₆, C, and D. Vitamin and mineral intake more than twice the recommended daily dietary allowance shown in [Table 8-7](#) should be avoided during pregnancy (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002).

Calories. As shown in [Figure 8-9](#), pregnancy requires an additional 80,000 kcal, which are accumulated primarily in the last 20 weeks. To meet this demand, a caloric increase of 100 to 300 kcal per day is recommended during pregnancy (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002). Calories are necessary for energy, and whenever caloric intake is inadequate, protein is metabolized rather than being spared for its vital role in fetal growth and development. Total physiological requirements during pregnancy are not necessarily the sum of ordinary nonpregnant requirements plus those specific to pregnancy. For example, the additional energy required during pregnancy may be compensated in whole or in part by reduced physical activity (Hyttén, 1991).

Protein. To the basic protein needs of the nonpregnant woman are added the demands for growth and repair of the fetus, placenta, uterus, and breasts, and increased maternal blood volume (see [Chap. 5](#), p. 127). During the second half of pregnancy, about 1000 g of protein are deposited, amounting to 5 to 6 g/day (Hyttén and Leitch, 1971). The concentrations of most amino acids in maternal plasma fall markedly, including ornithine, glycine, taurine, and proline (Hyttén, 1991). Exceptions during pregnancy are glutamic acid and alanine, which rise in concentration.

Preferably, most protein should be supplied from animal sources, such as meat, milk, eggs, cheese, poultry, and fish, because they furnish amino acids in optimal combinations. Milk and dairy products have long been considered nearly ideal sources of nutrients, especially protein and calcium, for pregnant or lactating women.

Minerals. The intakes recommended by the Food and Nutrition Board of the Institute of Medicine (2004) for a variety of minerals are presented in [Table 8-7](#). With the exception of iron, practically all diets that supply sufficient calories for appropriate weight gain will contain enough minerals to prevent deficiency if iodized food is used.

IRON. The reasons for increased iron requirements during pregnancy are discussed in [Chapter 5](#) (see p. 130). Of the approximately 300 mg of iron transferred to the fetus and placenta and the 500 mg incorporated, if available, into the expanding maternal hemoglobin mass, nearly all is used after midpregnancy. During that time, iron requirements imposed by pregnancy and maternal excretion total about 7 mg per day (Pritchard and Scott, 1970). Very few women have sufficient iron stores to supply this amount, and the diet seldom contains enough iron to meet this demand. For these reasons, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) endorse the recommendation by the National Academy of Sciences that at least 27 mg of ferrous iron supplement be given daily to pregnant women. This amount is contained in most prenatal vitamins.

Scott and co-workers (1970) established that as little as 30 mg of elemental iron, supplied as ferrous gluconate, sulfate, or fumarate and taken daily throughout the latter half of pregnancy, provided sufficient iron to meet the requirements of pregnancy and to protect any preexisting iron stores. This amount will also provide for iron requirements for lactation. The pregnant woman may benefit from 60 to 100 mg of iron per day if she is large, has twin fetuses, begins supplementation late in pregnancy, takes iron irregularly, or has a somewhat depressed hemoglobin level. The woman who is overtly anemic from iron deficiency responds well to oral supplementation with iron salts (see [Chap. 51](#), p. 1145).

Because iron requirements are slight during the first 4 months of pregnancy, it is *not necessary* to provide supplemental iron during this time. Withholding iron supplementation during the first trimester of pregnancy avoids the risk of aggravating nausea and vomiting. Ingestion of iron at bedtime or on an empty stomach facilitates absorption and appears to minimize the possibility of an adverse gastrointestinal reaction.

Since 1997, the FDA has required that iron preparations containing 30 mg or more of elemental iron per tablet be packaged as individual doses, such as in blister packages. This regulation is targeted at preventing accidental iron poisoning in children.

CALCIUM. As discussed in [Chapter 5](#) (see p. 129), the pregnant woman retains about 30 g of calcium, most of which is deposited in the fetus late in pregnancy (Pitkin, 1985). This amount of calcium represents only about 2.5 percent of total maternal calcium, most of which is in bone, and which can readily be mobilized for fetal growth. Moreover, Heaney and Skillman (1971) demonstrated increased calcium absorption by the intestine and progressive retention throughout pregnancy. Efforts to prevent preeclampsia using calcium supplementation have not proven efficacious, and it is not recommended for routine use during pregnancy (see [Chap. 34](#), p. 780).

PHOSPHORUS. The ubiquitous distribution of phosphorus ensures an adequate intake during pregnancy. Plasma levels of inorganic phosphorus do not differ appreciably from nonpregnant levels.

ZINC. Severe zinc deficiency may lead to poor appetite, suboptimal growth, and impaired wound healing. Profound zinc deficiency may cause dwarfism and hypogonadism. It may also lead to a specific skin disorder, *acrodermatitis enteropathica*, as the result of a rare, severe congenital zinc deficiency. Although the level of zinc supplementation that is safe for pregnant women has not been clearly established, recommended daily intake during pregnancy is about 12 mg (see [Table 8-7](#)).

Goldenberg and colleagues (1995) randomly assigned 580 indigent women to zinc supplementation (25 mg) or placebo beginning at a mean gestational age of 19 weeks. Plasma zinc levels were significantly higher in women who received

supplements. Infants born to zinc-supplemented women were slightly larger (mean 125 g) and had a slightly larger head circumference (mean 4 mm). Later, Osendarp and colleagues (2001) randomly assigned 420 women in Bangladesh to receive either zinc supplementation (30 mg daily) or placebo from 12 to 16 weeks' gestation until delivery. Although supplementation did not improve birthweight, low-birthweight infants of mothers who received zinc had reduced risks of acute diarrhea, dysentery, and impetigo. In a follow-up study of these infants at 13 months, zinc supplementation was not found to confer any benefits on developmental outcome (Hamadani and co-workers, 2002).

IODINE. The use of iodized salt and bread products is recommended during pregnancy to offset the increased fetal requirements and maternal renal losses. Despite this, iodine intake has declined substantially in the past 15 years, and it is probably inadequate for some populations (see [Chap. 53](#), p. 1196). Interest in increasing dietary iodine was heightened by reports linking subclinical maternal hypothyroidism to adverse pregnancy outcomes and possible neurodevelopmental defects in children studied at age 7 years (Casey and associates, 2004; Haddow and colleagues, 1999). Severe maternal iodine deficiency predisposes offspring to endemic cretinism, characterized by multiple severe neurological defects (see [Chap. 53](#), p. 1196). In parts of China and Africa where this condition is endemic, iodide supplementation very early in pregnancy prevents cretinism (Cao and colleagues, 1994).

MAGNESIUM. Deficiency of magnesium as the consequence of pregnancy has not been recognized. Undoubtedly, during prolonged illness with no magnesium intake, the plasma level might become critically low, as it would in the absence of pregnancy. We have observed magnesium deficiency during pregnancy complicated by the consequences of previous intestinal bypass surgery. Sibai and co-workers (1989) randomly assigned 400 normotensive primigravid women to 365 mg elemental magnesium supplementation or placebo tablets from 13 to 24 weeks. Supplementation did not improve any measures of pregnancy outcome.

COPPER. Enzymes that contain copper, such as cytochrome oxidase, play key roles in many oxidative processes and hence in the production of most of the energy required for metabolism. Pregnancy has a major effect on maternal copper metabolism, with marked increases in serum ceruloplasmin and plasma copper (Reyes and associates, 2000). Copper deficiency has not been documented in humans during pregnancy. No studies of copper supplementation of pregnant women have been reported, although several prenatal supplements currently marketed provide 2 mg of copper per tablet.

SELENIUM. This mineral is an essential component of the enzyme glutathione peroxidase, which catalyzes the conversion of hydrogen peroxide to water. Selenium is an important defensive component against free radical damage. A severe geochemical deficiency has been identified in a large area of China. Deficiency is manifested by a frequently fatal cardiomyopathy in young children and women of childbearing age. Conversely, selenium toxicity resulting from oversupplementation also has been observed. There is no reported need to supplement selenium in American women.

CHROMIUM. Trace amounts of chromium are believed to serve as a co-factor for insulin by facilitating attachment to peripheral receptors. The extent to which chromium is important in human nutrition remains uncertain, and there are no data suggesting that supplementation is advisable during pregnancy.

MANGANESE. This mineral serves as a co-factor for enzymes such as the glycosyltransferases, which are necessary for the synthesis of polysaccharides and glycoproteins. Manganese deficiency has not been observed in human adults, and supplements are not indicated during pregnancy.

POTASSIUM. The concentration of potassium in maternal plasma decreases by about 0.5 mEq/L by midpregnancy (Brown and colleagues, 1986). Potassium deficiency develops in the same circumstances as when the woman is not pregnant. Prolonged nausea and vomiting may lead to hypokalemia and metabolic alkalosis.

SODIUM. Deficiency during pregnancy is unusual unless diuretics are prescribed or dietary sodium intake is reduced drastically. A normal diet provides an abundance of sodium. Although pregnancy is associated with increased total accumulation of sodium, the serum concentration decreases slightly due to the expanded plasma volume. Sodium excretion remains unchanged, and averages 100 to 110 mEq/day (Brown and colleagues, 1986).

FLUORIDE. The value of supplemental fluoride during pregnancy has been questioned. Maheshwari and co-workers (1983) found that fluoride metabolism is not altered appreciably during the course of pregnancy. Horowitz and Heifetz (1967) investigated the prevalence of caries in temporary and permanent teeth of children with the same postnatal exposure to optimally fluoridated water but different patterns of prenatal exposure. They concluded that there were no additional benefits from maternal ingestion of fluoridated water if the offspring ingested such water from birth.

Fluoride supplementation during pregnancy has not been endorsed by the American Dental Association (Institute of Medicine, 1990). Supplemental fluoride ingested by the lactating woman does not increase the fluoride concentration in her milk (Ekstrand and colleagues, 1981).

Vitamins. The increased requirements for vitamins during pregnancy shown in [Table 8-7](#) usually are supplied by any general diet that provides adequate calories and protein. The exception is folic acid during times of unusual requirements, such as pregnancy complicated by protracted vomiting, hemolytic anemia, or multiple fetuses.

FOLIC ACID. In the United States, approximately 4000 pregnancies are affected by neural-tube defects each year; more than half of these defects could be prevented with daily intake of 400 μg of folic acid throughout the periconceptional period (Centers for Disease Control and Prevention, 1999). Since 1992, the Public Health Service has recommended that all women capable of becoming pregnant consume 400 μg of folic acid daily throughout their childbearing years. The FDA (1996) later established standards fortifying grain products such as cereal, bread, rice, and pasta with folic acid. By putting 140 μg of folic acid into each 100 g of grain products, it was estimated that the folic acid intake of the average American woman of childbearing age would increase 100 μg per day. Because nutritional sources alone are insufficient, however, folic acid supplementation is still recommended (American College of Obstetrician and Gynecologists, 2003b).

Honein and co-workers (2001) compared birth certificate reports of neural-tube defects before and after mandatory fortification. Although other factors may have contributed, they found that the prevalence of neural-tube defects declined almost 20 percent following grain fortification. Ray and associates (2002) reported that the prevalence of neural-tube defects

in Ontario, Canada, declined from 1.13 to 0.58 per 1000 births following grain fortification.

There is also evidence that grain fortification is contributing to a rise in the serum folate levels of American women. The Centers for Disease Control and Prevention (2002b) compared serum and red blood cell folate concentrations in childbearing-aged women who participated in National Health and Nutrition Examination Surveys between 1988 and 1994 versus 1999 to 2000. Among the women in the latter group, the median serum folate concentration was increased approximately threefold, and the median red blood cell folate concentration increased approximately twofold. The findings also indicated that a national health objective for 2010 — to increase the median red blood cell folate level among women of childbearing age to 220 ng/mL — has been met for many ethnic groups, but not for African-Americans.

A woman with a prior pregnancy complicated by a neural-tube defect can reduce the 3-percent recurrence risk by more than 70 percent if she supplements her daily diet with 4 mg of folic acid for the month before conception and for the first trimester of pregnancy. As emphasized by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002), this dose should be consumed as a separate supplement, not as multiple multivitamin tablets, to avoid excessive intake of fat-soluble vitamins. Unfortunately, surveys continue to suggest that many women, especially among minorities, remain unaware of the recommendations regarding folic acid supplementation (Perlow, 2001; Rinsky-Eng and Miller, 2002).

The relationship of folic acid deficiency and neural-tube defects as well as other congenital malformations are discussed in detail in [Chapters 7](#) (see p. 192), [12](#) (see p. 302), and [14](#) (see p. 345).

VITAMIN A. Dietary intake of vitamin A in the United States appears to be adequate, and routine supplementation during pregnancy is not recommended (American College of Obstetricians and Gynecologists, 1998b). A small number of case reports suggest an association of birth defects with very high doses during pregnancy — 10,000 to 50,000 IU daily. These malformations are similar to those produced by the vitamin A derivative isotretinoin (Accutane), which is a potent teratogen in humans (see [Chap. 14](#), p. 350). Beta-carotene, the precursor of vitamin A found in fruits and vegetables, has not been shown to produce vitamin A toxicity.

Radhika and colleagues (2002) examined the effects of vitamin A deficiency in 736 Indian women during the third trimester. Overt deficiency, manifested as night blindness, was observed in approximately 3 percent of the women. Subclinical vitamin A deficiency, defined as a serum retinol concentration below 20 µg/dL without clinical signs, was present in 27 percent. Vitamin A deficiency, whether overt or subclinical, was associated with a significantly increased risk of both maternal anemia and spontaneous preterm birth. The former likely reflected the need for vitamin A to facilitate iron absorption, and the latter possibly reflected increased susceptibility to infection associated with vitamin A deficiency.

VITAMIN B₁₂. The level of vitamin B₁₂ in maternal plasma decreases variably in otherwise normal pregnancies (see [Chap. 51](#), p. 1147). This decrease is mostly from a reduction in plasma transcobalamins and is thus prevented only in part by supplementation. Vitamin B₁₂ occurs naturally only in foods of animal origin. It is now established that strict vegetarians may give birth to infants whose vitamin B₁₂ stores are low. Likewise, because breast milk of a vegetarian mother contains little vitamin B₁₂, the deficiency may become profound in the breast-fed infant (Higginbottom and associates, 1978). Excessive ingestion of vitamin C also can lead to a functional deficiency of vitamin B₁₂.

VITAMIN B₆. Most clinical trials in pregnant women have failed to demonstrate any benefits of vitamin B₆ supplements (Institute of Medicine, 1990). For women at high risk for inadequate nutrition (e.g., substance abuse, adolescents, and those with multifetal gestations), a daily supplement containing 2 mg is recommended.

VITAMIN C. The recommended dietary allowance for vitamin C during pregnancy is 80 to 85 mg/day, or about 20 percent more than when nonpregnant (see [Table 8-7](#)). A reasonable diet should readily provide this amount. The maternal plasma level declines during pregnancy, whereas the cord level is higher, a phenomenon observed with most water-soluble vitamins.

Figure 8-9. Cumulative kilocalories of energy required for pregnancy. (From Hytten and Chamberlain, 1991, with permission.)

PRAGMATIC NUTRITIONAL SURVEILLANCE. Although the science of nutrition continues in its perpetual struggle to identify the ideal amounts of protein, calories, vitamins, and minerals for the pregnant woman and her fetus, those directly responsible for their care may best discharge their duties as follows:

1. In general, advise the pregnant woman to eat what she wants in amounts she desires and salted to taste.
2. Make sure that there is ample food to eat in the case of socioeconomically deprived women.
3. Monitor weight gain, with a goal of about 25 to 35 pounds in women with a normal BMI.
4. Periodically explore food intake by dietary recall to discover the occasional nutritionally absurd diet.
5. Give tablets of simple iron salts that provide at least 27 mg of iron daily. Give folate supplementation before and in the early weeks of pregnancy.
6. Recheck the hematocrit or hemoglobin concentration at 28 to 32 weeks to detect any significant decrease.

COMMON CONCERNS

EXERCISE. In general, it is not necessary for the pregnant woman to limit exercise, provided she does not become excessively fatigued or risk injury. Clapp (1989) reported that 18 conditioned pregnant women actually improved their metabolic efficiency during exercise. Specifically, the amount of oxygen required to complete a treadmill exercise actually decreased during pregnancy. Pivarnik and co-workers (1990) used invasive hemodynamic monitoring and compared cardiovascular responses of seven healthy women to aerobic exercise (cycle or treadmill) during late pregnancy and again 3 months postpartum. Oxygen consumption, heart rate, stroke volume, and cardiac output all increased appropriately in response to exercise. Pivarnik and associates (1994) later showed that pregnant women who exercised regularly had significantly larger blood volumes.

Clapp and associates (2000) randomly assigned 46 women who did not exercise regularly to either no exercise or to weight-bearing exercise beginning at 8 weeks. Exercise consisted of treadmill running, step aerobics, or stair stepper use for 20 minutes three to five times each week. They did this throughout pregnancy at an intensity between 55 and 60 percent of the preconceptional maximum aerobic capacity. Both placental size and birthweight were significantly greater in the exercise group. In contrast, Magann and colleagues (2002) prospectively collected information on exercise behavior in 750 healthy women during their pregnancy. Among working women, exercise was associated with smaller infants, more dysfunctional labors, and more frequent upper respiratory infections.

The American College of Obstetricians and Gynecologists (2002b) advises a thorough clinical evaluation be conducted before recommending an exercise program. In the absence of contraindications ([Table 8-8](#)), pregnant women should be encouraged to engage in regular, moderate-intensity physical activity 30 minutes or more a day. Each activity should be reviewed individually for its potential risk. Activities with a high risk of falling or abdominal trauma should be avoided. Similarly, scuba diving should be avoided because the fetus is at an increased risk for decompression sickness.

With some pregnancy complications, the mother and her fetus may benefit from a sedentary existence. For example, some women with hypertensive disorders caused by pregnancy may benefit from being sedentary (see [Chap. 34](#), p. 781), as may some women pregnant with two or more fetuses (see [Chap. 39](#), p. 936), those suspected of having a growth-restricted fetus (see [Chap. 38](#), p. 903), or those with severe heart disease (see [Chap. 44](#), p. 1021).

EMPLOYMENT. The legal and social movements in the United States to provide equality of opportunity in the workplace have reached women who are or might become pregnant. Annas (1991) reviewed the legal issues involved with employment during pregnancy. Importantly, the United States Supreme Court buttressed the Pregnancy Discrimination Act of 1978 by ruling in 1991 that federal law prohibits employers from excluding women from job categories on the basis that they are or might become pregnant. More than 120 nations around the world currently provide paid maternity leave and health benefits by law, including most industrialized nations except the United States, Australia, and New Zealand (Luke and co-authors, 1999).

The Family and Medical Leave Act (FMLA) was passed in 1993, however, a subsequent report to Congress found that because this leave is without pay, eligible women did not take it for financial reasons. It is estimated that nearly half of childbearing-aged women in the United States are in the labor force. For many, an additional financial strain stems from being pressured to stop working during pregnancy. For example, Frazier and colleagues (2001) found that more than 27 percent of 1635 women were advised to stop working. The most frequent reasons included hypertension, vaginal bleeding, and labor. More than half of the women were instructed to stop working before the seventh month of gestation.

Teitelman and co-workers (1990) evaluated maternal work activity and pregnancy outcome in 4186 women delivered at Yale-New Haven Hospital. Women were classified according to the type of jobs they held. *Standing* jobs, such as those of a cashier, bank teller, or dentist, required standing in the same position for more than 3 hours per day. *Active* jobs, such as physicians, waitresses, and real estate agents, involved continuous or intermittent walking. *Sedentary* jobs, such as librarians, bookkeepers, or bus drivers, required less than 1 hour of standing per day. These authors found that pregnant women who work at jobs that require prolonged standing are at greater risk for preterm delivery, but it did not have any effect on fetal growth.

Mozurkewich and colleagues (2000) reviewed 29 studies with over 160,000 pregnancies. They confirmed a 20- to 60-percent increase in preterm birth, fetal growth restriction, or hypertension associated with physically demanding work. In a prospective study of more than 900 healthy primigravidas, Higgins and associates (2002) found that women who worked were about fivefold more likely to develop preeclampsia. Newman and colleagues (2001) reported the relationship between occupational fatigue and preterm birth in 2929 women with singleton pregnancies studied by the Maternal-Fetal Medicine Units Network. They found that occupational fatigue—estimated by the number of hours standing, intensity of physical and mental demands, and environmental stressors—was associated with an increased risk of preterm membrane rupture. For those women reporting the highest degrees of fatigue, the risk was 7.4 percent.

Common sense dictates that any occupation that subjects the pregnant woman to severe physical strain should be avoided. Ideally, no work or play should be continued to the extent that undue fatigue develops. Adequate periods of rest should be provided during the work period. Women with previous pregnancy complications that are likely to be repetitive, such as low-birthweight infants, probably should minimize physical work. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have concluded that women with uncomplicated pregnancies usually can continue to work until the onset of labor. Furthermore, although a period of 4 to 6 weeks generally is required for return of the physiological condition to normal, they advise that individual circumstances should be considered when recommending resumption of full activity.

TRAVEL. In general, travel by the healthy woman has no harmful effect on pregnancy (Aerospace Medical Association, 2003). Travel in properly pressurized aircraft offers no unusual risk, and in the absence of obstetrical or medical complications, the American College of Obstetricians and Gynecologists (2001a, 2004) has concluded that pregnant women can safely fly up to 36 weeks. It is recommended that pregnant women observe the same precautions for air travel as the general population,

including periodic movement of the lower extremities, ambulation at least hourly, and use of seatbelts while seated. Perhaps the greatest risks with travel, especially international travel, are acquiring an infectious disease or developing a complication remote from facilities adequate to manage the complication (Ryan and associates, 2002).

The American College of Obstetricians and Gynecologists (1998a) has formulated guidelines for use of automobile passenger restraints during pregnancy. There is no evidence that safety restraints increase the chance of fetal injury. Indeed, the leading cause of fetal death in a motor accident is the death of the mother (see [Chap. 42](#), p. 997). Therefore, pregnant women should be encouraged to wear properly positioned three-point restraints throughout pregnancy while riding in automobiles. The lap belt portion of the restraining belt should be placed under the woman's abdomen and across her upper thighs. The belt should be as snug as comfortably possible. The shoulder belt also should be snugly applied and positioned between the breasts. Based on limited existing information, the American College of Obstetricians and Gynecologists (1998a) has concluded that it does not appear reasonable to recommend disabling airbags during pregnancy.

BATHING. There are no contraindications to bathing during pregnancy or the puerperium. One caveat is that early pregnancy exposure to a hot tub or Jacuzzi at 100^oF or higher has been associated with an increased risk of miscarriage (Li and co-workers, 2003). It also has been linked to neural-tube defects (see [Chap. 13](#), p. 317). During late pregnancy, the heavy uterus usually upsets the balance of the pregnant woman and increases the likelihood of her slipping and falling in the bathtub. For that reason, showers at the end of pregnancy may be preferable.

CLOTHING. It generally has been recommended that the clothing worn during pregnancy be comfortable and nonconstricting. According to fashion experts, however, pregnancy apparel has changed considerably in recent years (Morgan, 2000). One clothing designer stated: "It used to be about covering it up, and now it's about showing it off. Today's maternity chic is body-hugging not body hiding."

The increasing mass of the breasts may make them pendulous and painful, and a well-fitting supporting brassiere may be indicated for comfort. Constricting leg wear should be avoided.

BOWEL HABITS. Constipation is common, presumably because of prolonged transit time and compression of the lower bowel by the uterus or by the presenting part (see [Chap. 49](#), p. 1115). In addition to discomfort caused by passage of hard fecal material, bleeding and painful fissures may develop in the edematous and hyperemic rectal mucosa. There is also greater frequency of *hemorrhoids* and, much less commonly, prolapse of the rectal mucosa.

Women whose bowel habits are normal before pregnancy may prevent constipation during pregnancy. This is done by ingesting sufficient quantities of fluid along with reasonable amounts of daily exercise. This regimen may be supplemented when necessary by a mild laxative, such as prune juice, milk of magnesia, bulk-producing substances, or stool-softening agents.

COITUS. Whenever abortion or preterm labor threatens, coitus should be avoided. Otherwise it has been generally accepted that in healthy pregnant women, sexual intercourse usually is not harmful. Nearly 10,000 women enrolled in a prospective investigation by the Vaginal Infection and Prematurity Study Group were interviewed regarding sexual activity during pregnancy. There was a significantly decreased frequency of sexual intercourse reported with advancing gestation (Read and Klebanoff, 1993). By 36 weeks, 72 percent of these women reported intercourse less than once weekly. Bartellas and colleagues (2000) reported that the decrease was attributed to decreased desire (58 percent) and fear of harm to the pregnancy (48 percent).

Risks from intercourse late in pregnancy have not been clearly delineated. Grudzinskas and co-workers (1979) found no association between gestational age at delivery and the frequency of coitus during the last 4 weeks of pregnancy. Similarly, Sayle and colleagues (2001) found no increased—and actually a decreased—risk of delivery within 2 weeks of intercourse.

On occasion, sexual drive in the face of admonishment against intercourse late in pregnancy has led to sexual practices with disastrous consequences. Aronson and Nelson (1967) described a fatal case of air embolism late in pregnancy as a result of air blown into the vagina during cunnilingus. Other near-fatal cases have been described (Bernhardt and associates, 1988).

DENTITION. Examination of the teeth should be included in the prenatal examination, and good dental hygiene is encouraged. Dental caries are not aggravated by pregnancy. Likewise, pregnancy is not a contraindication to dental treatment.

IMMUNIZATION. Current recommendations for immunizations during pregnancy are summarized in [Table 8-9](#). The American College of Obstetricians and Gynecologists (2003a) stresses that current information on the safety of vaccines given during pregnancy is subject to change and can be verified from the Centers for Disease Control and Prevention website at www.cdc.gov/nip.

Women who are susceptible to rubella during pregnancy should receive MMR (measles-mumps-rubella) vaccination postpartum. There is no contraindication to this vaccination while breast feeding (American College of Obstetricians and Gynecologists, 2002d).

Biological Warfare and Vaccines. The tragic events of September 11, 2001, and the ongoing threat of bioterrorism require familiarity with smallpox and anthrax vaccines during pregnancy. The smallpox vaccine is actually a live attenuated vaccinia virus that is related both to smallpox and to cowpox viruses. Fetal infection from this vaccine, termed *vaccinia*, is a rare complication, but it may result in abortion, stillbirth, or neonatal death. Therefore, in nonemergency circumstances, smallpox vaccination is contraindicated both during pregnancy and in women who desire to become pregnant within 28 days of vaccination (Centers for Disease Control and Prevention, 2003b). If, however, vaccination is inadvertently performed in early pregnancy, this is not grounds for termination (Suarez and Hankins, 2002). If the pregnant woman is at risk because of exposure to smallpox—either as a direct victim of a bioterrorist attack or as a close contact of an individual case—the

risks from clinical smallpox substantially outweigh any potential risk from vaccination (Suarez and Hankins, 2002).

Anthrax vaccination has been limited principally to individuals who are occupationally exposed, such as special veterinarians, laboratory workers, and members of the armed forces. The vaccine contains no live virus and thus would not be expected to pose significant risk to the fetus. Wiesen and Littell (2002) studied the reproductive outcomes of 385 women in the United States Army who became pregnant after receiving the anthrax vaccine. They found no adverse effects on fertility or pregnancy outcome.

Smallpox, anthrax, and other infections related to bioterrorism are discussed in [Chapter 58](#) (see p. 1293).

CAFFEINE. In 1980, the FDA advised pregnant women to limit caffeine intake. The Fourth International Caffeine Workshop concluded shortly thereafter that there was no evidence that caffeine caused increased teratogenic or reproductive risks (Dews and colleagues, 1984). In small laboratory animals, caffeine is not a teratogen, but if given in massive doses it potentiates mutagenic effects of radiation and some chemicals. When infused intravenously into sheep, caffeine decreases uterine blood flow by 5 to 10 percent (Conover and colleagues, 1983).

The risk of spontaneous abortion related to caffeine consumption is controversial. Klebanoff and co-workers (1999) measured paraxanthine as a biological serum marker of caffeine consumption. They estimated caffeine doses in 487 women with spontaneous abortions and in 2087 controls. Only extremely high serum paraxanthine concentrations were associated with abortion. Such high levels were equivalent to drinking more than 5 cups of coffee per day. Clausson and associates (2002) found no association of moderate caffeine consumption of less than 500 mg daily with low birthweight, fetal growth restriction, or preterm delivery. The American Dietetic Association (2002) recommends that caffeine intake during pregnancy be limited to less than 300 mg daily, or about three, 5-oz cups of percolated coffee.

MEDICATIONS. A number of drugs commonly ingested during pregnancy, and their possible adverse fetal effects, are considered in detail in [Chapter 14](#). Based on interviews with 578 women, Glover and co-workers (2003) found that during pregnancy more than 95 percent took prescription medications and 92 percent self-medicated with over-the-counter preparations. **With rare exceptions, any drug that exerts a systemic effect in the mother will cross the placenta to reach the embryo and fetus.** All physicians should develop the habit of ascertaining the likelihood of pregnancy before prescribing drugs for any woman, because a number of medications in common use are potentially injurious to the embryo and the fetus. Package inserts provided by pharmaceutical companies and approved by the FDA should be consulted before drugs are prescribed for pregnant women.

NAUSEA AND VOMITING. These are common complaints during the first half of pregnancy. Erroneously called *morning sickness*, symptoms usually commence between the first and second missed menstrual period and continue until about 14 to 16 weeks. Although nausea and vomiting tend to be worse in the morning, they may continue throughout the day. Lacroix and co-workers (2000) found that nausea and vomiting were reported by three fourths of pregnant women and lasted an average of 35 days. Half had relief by 14 weeks, and 90 percent by 22 weeks. In 80 percent of the women, nausea lasted all day. It was frequently described to have a character and intensity similar to that experienced by patients undergoing cancer chemotherapy.

The genesis of pregnancy-induced nausea and vomiting is not clear, and it is discussed further in [Chapter 49](#) (see p. 1113). Although high levels of serum hCG have been implicated as causing nausea, this placental hormone is likely a surrogate for increasing estrogen levels which are known to cause such symptoms. Huxley (2000) speculates that nausea and emesis in early gestation have a functional role in promoting and maintaining early placental growth. Specifically, the reduced caloric intake lowers maternal insulin and insulin growth factor-1 levels and suppresses maternal anabolic synthesis, ensuring that nutrient partitioning favors placental growth.

Seldom is the treatment of nausea and vomiting of pregnancy so successful that the affected expectant mother is afforded complete relief. Fortunately, the unpleasantness and discomfort usually can be minimized. Eating small feedings at more frequent intervals but stopping short of satiation is of value. The smell of certain foods often precipitates or aggravates the symptoms and should be avoided. In some women, vomiting may be so severe that dehydration, electrolyte and acid-base disturbances, and starvation ketosis become serious problems. This condition is termed *hyperemesis gravidarum*, and its management is described in [Chapter 49](#) (see p. 1113).

BACKACHE. Low back pain to some extent is reported in nearly 70 percent of pregnant women (Wang and colleagues, 2004). Minor degrees follow excessive strain or fatigue and excessive bending, lifting, or walking. Orvieto and associates (1994) studied 449 women and reported that back pain increased with duration of gestation. Prior low back pain and obesity were risk factors.

Back pain can be reduced by having women squat rather than bend over when reaching down, providing back support with a pillow when sitting down, and avoiding high-heeled shoes. Severe back pain should not be attributed simply to pregnancy until a thorough orthopedic examination has been conducted. Muscular spasm and tenderness, which often are classified clinically as acute strain or fibrositis, respond well to analgesics, heat, and rest. As discussed in [Chapter 53](#) (see p. 1199), some women with severe back and hip pain may have *pregnancy-associated osteoporosis* (Dunne and colleagues, 1993). Severe pain also has other uncommon causes, such as disc disease, vertebral osteoarthritis, or septic arthritis.

Noren and co-workers (2002) studied the long-term outcomes of 231 women who had some type of back pain during pregnancy. Residual pain 3 years after delivery was reported by approximately 20 percent. Women with combined lumbar back and posterior pelvic pain were at greatest risk for disability, which was attributed to impaired back extensor and hip abductor muscle functions.

VARICOSITIES. These enlarged veins generally result from congenital predisposition and are exaggerated by prolonged standing, pregnancy, and advancing age. Usually varicosities become more prominent as pregnancy advances, as weight increases, and as the length of time spent upright is prolonged. As discussed in [Chapter 5](#) (see p. 134), femoral venous

pressure increases appreciably as pregnancy advances. The symptoms produced by varicosities vary from cosmetic blemishes on the lower extremities and mild discomfort at the end of the day to severe discomfort that requires prolonged rest with the feet elevated.

The treatment of varicosities of the lower extremities is generally limited to periodic rest with elevation of the legs, elastic stockings, or both. Surgical correction of the condition during pregnancy generally is not advised, although occasionally the symptoms may be so severe that injection, ligation, or even stripping of the veins is necessary. Vulvar varicosities may be aided by application of a foam rubber pad suspended across the vulva by a belt of the type used with a perineal pad. Rarely, large varicosities may rupture, resulting in profuse hemorrhage.

HEMORRHOIDS. Varicosities of the rectal veins may first appear during pregnancy. More often, pregnancy causes an exacerbation or recurrence of previous hemorrhoids. Their development or aggravation during pregnancy undoubtedly is related to increased pressure in the rectal veins. This is caused by obstruction of venous return by the large uterus as well as by constipation during pregnancy. Pain and swelling usually are relieved by topically applied anesthetics, warm soaks, and stool-softening agents. Thrombosis of a rectal vein can cause considerable pain, but the clot usually can be evacuated by incising the vein wall under topical anesthesia.

HEARTBURN. This symptom is one of the most common complaints of pregnant women and is caused by reflux of gastric contents into the lower esophagus. The increased frequency of regurgitation during pregnancy most likely results from the upward displacement and compression of the stomach by the uterus, combined with relaxation of the lower esophageal sphincter. In most pregnant women, symptoms are mild and are relieved by a regimen of more frequent but smaller meals and avoidance of bending over or lying flat. Antacid preparations may provide considerable relief. Aluminum hydroxide, magnesium trisilicate, or magnesium hydroxide alone or in combination are given. Management for symptoms that do not respond to these simple measures is discussed in [Chapter 49](#) (see p. 1114).

PICA. There has been considerable historical interest in the cravings (pica) of pregnant women for strange foods and, at times, nonfoods such as ice (pagophagia), starch (amylphagia), or clay (geophagia). This desire has been considered by some to be triggered by severe iron deficiency. Although some women crave these items, and although the craving usually is ameliorated after correction of iron deficiency, not all pregnant women with pica are necessarily iron deficient. Indeed, if strange "foods" dominate the diet, iron deficiency will be aggravated or will develop eventually, blurring the distinction between cause and effect.

Patel and colleagues (2004) from the University of Alabama at Birmingham prospectively completed a dietary inventory on more than 3000 women during the second trimester. The prevalence of pica was 4 percent. The most common nonfood items ingested were starch (64 percent), dirt (14 percent), sourdough (9 percent), and ice (5 percent). The prevalence of anemia was 15 percent in women with pica compared with 6 percent in those without it. Interestingly, the rate of spontaneous preterm birth at less than 35 weeks was twice as high in women with pica.

PTYALISM. Women during pregnancy are occasionally distressed by profuse salivation. The cause of this ptyalism sometimes appears to be stimulation of the salivary glands by the ingestion of starch. This cause should be looked for and eradicated if found. Most cases are unexplained.

FATIGUE. Early in pregnancy, most women complain of fatigue and desire for excessive sleep. The condition usually remits spontaneously by the fourth month of pregnancy and has no special significance. It may be due to the soporific effect of progesterone(s).

HEADACHE. This complaint is common early in pregnancy. A few cases may result from sinusitis or ocular strain caused by refractive errors. In the vast majority, however, no cause can be demonstrated. Treatment is largely symptomatic. By midpregnancy, most headaches decrease in severity or disappear. The clinical and pathological significance of headaches as the consequence of hypertensive disorders later in pregnancy is considered in [Chapter 34](#) (see p. 776). Persistent or severe headaches of other origins, for example, migraine, are discussed in [Chapter 55](#) (see p. 1230).

LEUKORRHEA. Pregnant women commonly develop increased vaginal discharge, which in many instances is not pathological. Increased mucus secretion by cervical glands in response to hyperestrogenemia is undoubtedly a contributing factor. Occasionally, troublesome leukorrhea is the result of an infection caused by trichomonal or yeast vulvovaginal infections.

BACTERIAL VAGINOSIS. Not an infection in the ordinary sense, bacterial vaginosis is a maldistribution of normal vaginal flora. Numbers of lactobacilli are decreased, and overrepresented species tend to be anaerobic bacteria, including *Gardnerella vaginalis*, *Mobiluncus*, and some *Bacteroides* species. The prevalence of vaginosis during pregnancy varies from 10 to 30 percent, and it is associated with preterm birth. Treatment is reserved for symptomatic women who usually complain of a fishy-smelling discharge. Metronidazole, 500 mg twice daily orally for 7 days, will achieve cure in about 90 percent of cases. Unfortunately, treatment does not reduce preterm birth, and routine screening is not recommended (American College of Obstetricians and Gynecologists, 2001b). These relationships are discussed further in [Chapters 36](#) (see p. 862) and [59](#) (see p. 1319).

TRICHOMONIASIS. In as many as 20 percent of women, *Trichomonas vaginalis* can be identified during prenatal examination. Symptomatic infection is much less prevalent, and vaginitis is characterized by foamy leukorrhea with pruritus and irritation. Trichomonads are demonstrated readily in fresh vaginal secretions as flagellated, pear-shaped, motile organisms that are somewhat larger than leukocytes.

Metronidazole has proved effective in eradicating *T vaginalis*. The drug may be administered orally or vaginally, and it crosses

the placenta and enters the fetal circulation. The possibility of teratogenicity from first-trimester exposure was raised previously. Rosa and colleagues (1987), however, found no increased frequency of birth defects in over 1000 women given metronidazole during early pregnancy (see [Chap. 14](#), p. 360). Even so, many recommend against its use in early pregnancy. Some studies have linked trichomonal infection with preterm birth, however, treatment has not proven to decrease the risk (see [Chap. 36](#), p. 863). Thus, screening and treatment of asymptomatic women is not recommended during pregnancy.

CANDIDIASIS. *Candidia albicans* can be cultured from the vagina in about 25 percent of women approaching term. Asymptomatic colonization requires no treatment, but the organism may sometimes cause an extremely profuse, irritating discharge associated with a pruritic, painfully tender, and edematous vulva. Miconazole, clotrimazole, and nystatin are effective for the treatment of candidiasis during pregnancy (see [Chap. 14](#), p. 359). In some women, infection is likely to recur, thereby requiring repeated treatment during pregnancy. In these cases, symptomatic infection usually subsides after pregnancy.

9. Abortion

INTRODUCTION

Abortion is the termination of pregnancy, either spontaneously or intentionally, before the fetus develops sufficiently to survive. By convention, abortion is usually defined as pregnancy termination prior to 20 weeks' gestation or less than 500-g birthweight. Definitions vary, however, according to state laws for reporting abortions, fetal deaths, and neonatal deaths.

SPONTANEOUS ABORTION

Abortion occurring without medical or mechanical means to empty the uterus is referred to as *spontaneous*. Another widely used term is *miscarriage*.

PATHOLOGY. Hemorrhage into the decidua basalis, followed by necrosis of tissues adjacent to the bleeding, usually accompanies abortion. If early, the ovum detaches, stimulating uterine contractions that result in its expulsion. When a gestational sac is opened, fluid is commonly found surrounding a small macerated fetus, or alternatively no fetus is visible—the so-called *blighted ovum*.

In later abortions, several outcomes are possible. The retained fetus may undergo *maceration*, in which the skull bones collapse, the abdomen distends with blood-stained fluid, and the internal organs degenerate. The skin softens and peels off in utero or at the slightest touch. Alternatively, when amniotic fluid is absorbed, the fetus may become compressed and desiccated, forming a *fetus compressus*. Occasionally, the fetus may become so dry and compressed that it resembles parchment—a *fetus papyraceus*.

ETIOLOGY. More than 80 percent of abortions occur in the first 12 weeks of pregnancy, and at least half result from chromosomal anomalies. After the first trimester, both the abortion rate and the incidence of chromosomal anomalies decrease (Fig. 9-1).

The risk of spontaneous abortion increases with parity as well as with maternal and paternal age (Warburton and Fraser, 1964; Wilson and associates, 1986). The frequency of clinically recognized abortion increases from 12 percent in women younger than 20 years to 26 percent in those older than 40 years (Fig. 9-2). For the same paternal ages, the frequency increases from 12 to 20 percent. Finally, the incidence of abortion increases if a woman conceives within 3 months following a term birth (Harlap and Shiono, 1980).

The exact mechanisms responsible for abortion are not always apparent, but in the first 3 months of pregnancy, death of the embryo or fetus nearly always precedes spontaneous expulsion of the ovum. For this reason, finding the cause of early abortion involves ascertaining the cause of fetal death. In subsequent months, the fetus frequently does not die before expulsion; therefore, other explanations for its expulsion should be sought.

Figure 9-1. Frequency of chromosomal anomalies in abortuses and stillbirths for each trimester compared with the frequency of chromosomal anomalies in liveborn infants. The percentage for each group is shown in parentheses. (Data adapted from Fantel, 1980; Warburton, 1980, and their associates.)

Figure 9-2. First- and second-trimester spontaneous abortions by maternal age. (From Harlap and colleagues, 1980, with permission.)

FETAL FACTORS

Abnormal Zygotic Development. Early spontaneous abortions commonly display a developmental abnormality of the zygote, embryo, early fetus, or at times the placenta. Of 1000 spontaneous abortions analyzed by Hertig and Sheldon (1943), half demonstrated degenerated or absent embryos, that is, blighted ova (Fig. 9-3). Poland and co-workers (1981) identified morphological disorganization of growth in 40 percent of abortuses that were expelled spontaneously before 20 weeks.

Aneuploid Abortion. Approximately 50 to 60 percent of embryos and early fetuses that are spontaneously aborted contain chromosomal abnormalities, accounting for most of early pregnancy wastage (Table 9-1). Jacobs and Hassold (1980) reported that approximately 95 percent of chromosomal abnormalities were due to maternal gametogenesis errors and 5 percent to paternal errors.

Autosomal trisomy is the most frequently identified chromosomal anomaly associated with first-trimester abortions (see Table 9-1). Although most trisomies result from *isolated nondisjunction*, balanced structural chromosomal rearrangements are present in one partner in 2 to 4 percent of couples with a history of recurrent abortions (American College of Obstetricians and Gynecologists, 2001a). Trisomies for all autosomes except chromosome number 1 have been identified in abortuses, but autosomes 13, 16, 18, 21, and 22 have been found most commonly.

Monosomy X (45,X), the second most frequent chromosomal abnormality, usually results in abortion and much less frequently in liveborn female infants (Turner syndrome). Conversely, autosomal monosomy is rare and incompatible with life.

Triploidy is often associated with hydropic placental (molar) degeneration. Incomplete (partial) hydatidiform moles may contain triploidy or trisomy for only chromosome 16. Although these fetuses frequently abort early, the few carried longer are all grossly malformed. Advanced maternal and paternal age does not increase the incidence of triploidy.

Tetraploid abortuses rarely are liveborn and most often are aborted early in gestation.

Chromosomal structural abnormalities, identified only since the development of banding techniques, infrequently cause abortion. Some of these infants who are liveborn with balanced translocations may appear normal.

Euploid Abortion. Euploid fetuses tend to abort later in gestation than aneuploid ones. Kajii and co-workers (1980) reported that although three fourths of aneuploid abortions occurred before 8 weeks, euploid abortions peaked at about 13 weeks. Stein and associates (1980) presented evidence that the incidence of euploid abortions increased dramatically after maternal age exceeded 35 years.

Figure 9-3. Abnormal ovum. A cross-section of a defective ovum showing an empty chorionic sac embedded within a polypoid mass of endometrium. (From Hertig and Rock, 1944.)

MATERNAL FACTORS. The causes of euploid abortions are poorly understood, although a variety of medical disorders, environmental conditions, and developmental abnormalities have been implicated.

Infections. Various infections are uncommon causes of abortion in humans (American College of Obstetricians and Gynecologists, 2001a). Although *Brucella abortus* and *Campylobacter fetus* cause chronic abortion in cattle, they are not significant in humans (Sauerwein and associates, 1993). Researchers also found no evidence that either *Listeria monocytogenes* or *Chlamydia trachomatis* produced abortions in humans (Feist and associates, 1999; Osler and Persson, 1996; Paukku and associates, 1999). In the only prospective study of serological conversion, the herpes simplex virus did not increase the incidence of abortion following infection in early pregnancy (Brown and colleagues, 1997).

Serological evidence supporting a role for *Mycoplasma hominis* and *Ureaplasma urealyticum* in abortion was provided by Quinn and co-workers (1983). Conversely, Temmerman and associates (1992) found no link between genital mycoplasma and spontaneous abortion. They did, however, report that spontaneous abortion was independently associated with maternal serological evidence of syphilis and human immunodeficiency virus-1 (HIV-1), and with vaginal colonization with group B streptococci. More recently, van Benthem and associates (2000) reported that women with HIV infection showed no greater risk of spontaneous abortion after being diagnosed with HIV than before. Evidence that *Toxoplasma gondii* causes abortion in humans remains inconclusive. In 2002, Oakeshott and associates reported an association between second- but not first-trimester spontaneous abortion and bacterial vaginosis.

Chronic Debilitating Diseases. In early pregnancy, fetuses seldom abort secondary to chronic wasting diseases such as tuberculosis or carcinomatosis. Celiac sprue, however, has been reported to cause both male and female infertility and recurrent abortions (Sher and colleagues, 1994).

Endocrine Abnormalities

HYPOTHYROIDISM. Iodine deficiency may be associated with excessive miscarriages (Castaneda and co-workers, 2002). The effects of clinical hypothyroidism on early pregnancy wastage have not been adequately studied (see [Chap. 53](#), p. 1194). Thyroid autoantibodies, however, were associated with an increased incidence of abortion despite the lack of overt hypothyroidism (Dayan and Daniels, 1996; Stagnaro-Green and associates, 1990). Conversely, others have found that women with recurrent abortions have no greater incidence of antithyroid antibodies than normal controls (Esplin and colleagues, 1998; Pratt and associates, 1994). Moreover, Rushworth and colleagues (2000) studied a group of 870 women with recurrent abortion and found that untreated women with antithyroid antibodies were as likely to achieve a live birth as women without antibodies.

DIABETES MELLITUS. The rates of spontaneous abortion and major congenital malformations are both increased in women with insulin-dependent diabetes (Greene, 1999). The risk appears related to the degree of metabolic control in the first trimester. In a prospective study, Mills and associates (1988) reported that excellent glucose control within 21 days of conception resulted in a spontaneous abortion rate similar to that in nondiabetic controls. Poor glucose control, however, resulted in a marked increase in the abortion rate. Craig and co-workers (2002) have reported a higher incidence of insulin resistance in women with recurrent pregnancy loss.

PROGESTERONE DEFICIENCY. Termed *luteal phase defect*, insufficient progesterone secretion by the corpus luteum or placenta has been suggested as a cause of abortion. Deficient progesterone production, however, may be the consequence rather than the cause of early pregnancy failure (Salem and co-workers, 1984). Currently, the diagnostic criteria and efficacy of therapy for this supposed disorder require validation (American College of Obstetricians and Gynecologists, 2001a). If the corpus luteum is removed surgically, such as for an ovarian tumor, progesterone replacement is indicated in pregnancies less than 8 to 10 weeks (see [Chap. 40](#), p. 966).

Nutrition. Dietary deficiency of any one nutrient or moderate deficiency of all nutrients do not appear important causes of abortion. Similarly, the nausea and vomiting that develop commonly during early pregnancy and any subsequent weight loss

are rarely followed by spontaneous abortion.

Drug Use and Environmental Factors. A variety of different agents has been reported to be associated with an increased incidence of abortion.

TOBACCO. Smoking has been linked with an increased risk for euploid abortion (Harlap and Shiono, 1980). For women who smoked more than 14 cigarettes a day, the risk was approximately twofold greater than the risk for controls (Kline and associates, 1980). Armstrong and associates (1992) calculated that the abortion risk increased in a linear fashion by a factor of 1.2 for each 10 cigarettes smoked per day, consistent with the factor of 1.4 calculated by Chatenoud and colleagues (1998). Two more recent studies, however, have failed to support this association (Rasch, 2003; Wisborg and colleagues, 2003).

ALCOHOL. Both spontaneous abortion and fetal anomalies may result from frequent alcohol use during the first 8 weeks of pregnancy (Floyd and associates, 1999). Spontaneous abortion rates increased even when alcohol was consumed "in moderation." Kline and co-workers (1980) reported that the abortion rate doubled in women who drank twice a week and tripled in women who consumed alcohol daily compared with the rate for nondrinkers.

Armstrong and colleagues (1992) computed that abortion risk increased by an average of 1.3 for each drink per day. In contrast, Cavallo and associates (1995) and Kesmodel and co-workers (2002) found that a low level of alcohol consumption during pregnancy was not associated with a significant risk for abortion.

CAFFEINE. Armstrong and associates (1992) reported that women who consumed at least 5 cups of coffee per day exhibited a slightly increased risk of abortion, and for those who drank above this daily 5-cup threshold, the risk correlated with the number of cups consumed per day. Similarly, Cnattingius and colleagues (2000) observed a significantly increased abortion risk only in women who consumed at least 500 mg of caffeine a day, or roughly equivalent to 5 cups of coffee. Klebanoff and associates (1999) noted that pregnant women in whom paraxanthine (a caffeine metabolite) levels were extremely elevated experience an almost twofold risk for spontaneous abortion. In their review of 15 studies, Signorello and McLaughlin (2004) deemed the evidence for a causal link between spontaneous abortion and caffeine inconclusive.

RADIATION. In sufficient doses, radiation is a recognized abortifacient. As discussed in [Chapter 41](#) (see p. 977), the human dose to effect abortion is not precisely known.

CONTRACEPTIVES. Oral contraceptives or spermicidal agents used in contraceptive creams and jellies are not associated with an increased incidence of abortion. When intrauterine devices fail to prevent pregnancy, however, the risk of abortion, and specifically septic abortion, increases substantively (see [Chap. 32](#), p. 739).

ENVIRONMENTAL TOXINS. Accurately assessing the relationship between environmental exposures and spontaneous abortion poses challenges. Investigators may encounter difficulties in measuring the intensity and duration of exposure and in establishing when and whether abortion actually occurred. Thus, in most instances, research provides little information to conclusively indict (or absolve) any specific environmental agent. Although this is generally true, work by Barlow and Sullivan (1982) implicated arsenic, lead, formaldehyde, benzene, and ethylene oxide as possible abortifacients. Video display terminals and exposure to the accompanying electromagnetic fields do not adversely affect abortion rates (Schnorr and co-workers, 1991). Similarly, no effects were found with occupational exposure to ultrasound (Taskinen and colleagues, 1990). Rowland and associates (1995) reported an increased risk of spontaneous abortion among dental assistants exposed to 3 or more hours of nitrous oxide per day in offices without gas-scavenging equipment, but not in offices using such equipment. In a meta-analysis of data from the prescavenging era, Boivin (1997) concluded that women occupationally exposed to anesthetic gases exhibited an increased risk of spontaneous abortion.

Immunological Factors. Much attention has focused on the immune system as important in recurrent pregnancy loss. In analyzing compiled studies, Kutteh and Pasqualette (1995) determined that 15 percent of more than 1000 women with recurrent pregnancy loss had recognized autoimmune factors. Two primary pathophysiological models are the *autoimmune theory* (immunity against self) and the *alloimmune theory* (immunity against another person).

AUTOIMMUNE FACTORS. Antiphospholipid antibodies are a family of autoantibodies that bind to negatively charged phospholipids, phospholipid-binding proteins, or a combination of the two (Branch and Khamashta, 2003). They are discussed in more detail in [Chapter 54](#) (see p. 1215). Two of these, lupus anticoagulant and anticardiolipin antibody, have been implicated in spontaneous abortion. Criteria for the diagnosis of the *antiphospholipid syndrome* have been specified by Levine and associates (2002) and are discussed in [Chapter 54](#) (see p. 1217). Recurrent abortion before 12 weeks along with laboratory criteria for anticardiolipin antibodies or lupus anticoagulant satisfy the diagnosis.

Antiphospholipid antibodies can be an immunoglobulin G (IgG), IgA, or IgM isotype. The mechanism of pregnancy loss in women with these antibodies involves placental thrombosis and infarction. In one postulated mechanism, antibodies may inhibit the release of prostacyclin, a potent vasodilator and inhibitor of platelet aggregation. In contrast, platelets produce thromboxane A₂, a vasoconstrictor and platelet aggregator. They have also been shown to inhibit protein C activation, resulting in coagulation and fibrin formation.

Women with both a history of early fetal loss and high levels of these antibodies may suffer a 70-percent abortion recurrence (Dudley and Branch, 1991). In a prospective study of 860 women screened for anticardiolipin antibody in the first trimester, Yasuda and colleagues (1995) reported that only 7 percent tested positive for antibodies. Spontaneous abortion occurred in 25 percent of the antibody-positive group compared with only 10 percent of the negative group. In another study, however, Simpson and associates (1998) found no association between early pregnancy loss and the presence of either anticardiolipin antibody or lupus anticoagulant.

Despite these controversies with early abortion, researchers agree regarding increased second-trimester pregnancy losses and the antiphospholipid syndrome. As further discussed in [Chapter 54](#), p. 1217, this autoimmune condition is characterized by moderate to high levels of antiphospholipid IgG antibodies with variable incidence of thrombosis, thrombocytopenia, and fetal loss (American College of Obstetricians and Gynecologists, 1998; Blumenfeld and Brenner, 1999; Cowchock, 1997; Simpson and associates, 1998).

There are therapies for antiphospholipid syndrome that can increase live birth rates. Two randomized trials support the premise that, compared with treatment with low-dose aspirin alone, treatment with a combination of heparin and low-dose aspirin can improve the chance of live birth in a subsequent pregnancy in women with the syndrome. Kutteh (1996) randomized 50 such women to receive either low-dose aspirin alone or low-dose aspirin with heparin. Women who received both aspirin and heparin had significantly more viable infants ¶— 80 versus 44 percent. Rai and colleagues (1997) reported a 77-percent live birth rate with low-dose aspirin and low-dose heparin therapy (5000 units twice a day) versus one of 42 percent with low-dose aspirin alone. In contrast, Farquharson and associates (2002) observed a 72-percent live birth rate using low-dose aspirin alone versus one of 78 percent using low-dose aspirin plus low-dose, low-molecular-weight heparin.

As emphasized by Branch and Khamashta (2003), the discrepant reports are confusing and therapeutic guidelines are blurred. Because of this, we individualize therapy for women who meet the criteria for antiphospholipid syndrome and involve them in the decision-making process. We recommend low-dose aspirin, 81 mg per day, given along with unfractionated heparin, 5000 units subcutaneously twice daily. This therapy, begun when pregnancy is diagnosed, is continued until labor or delivery. Therapies are discussed further in [Chapter 54](#) (see p. 1218).

ALLOIMMUNE FACTORS. Various alloimmune disorders have been posited to cause recurrent abortion, and a variety of therapies to correct these disorders have been put forth. None, however, has withstood rigorous scrutiny, including use of paternal cell immunization, third-party donor leukocytes, trophoblast membranes, and intravenous immunoglobulin (Scott, 2000). Accordingly, we do not endorse the use of immunotherapy for recurrent abortion outside the context of properly conceived, designed, and executed randomized clinical trials.

Inherited Thrombophilia. Several genetic disorders of blood coagulation may increase the risk of thrombosis. Research with the growing number of recognized inherited thrombophilias, such as factor V Leiden mutation, continues to evolve. Many studies of aggregated thrombophilias ¶— including antiphospholipid antibodies ¶— cite excessive recurrent abortions (see [Chap. 47](#), p. 1078). Reports by Carp and associates (2002) and the review by Adelberg and Kuller (2002) cast doubt on the importance of mutant-gene inherited thrombophilias in early spontaneous abortion. Even if these disorders do play an etiological role in abortion, proper treatment trials have not been conducted to determine whether abortion might be prevented.

Conversely, *late abortions*, viz., midpregnancy losses before 20 weeks, are linked to some of these thrombophilias. Although controversial, treatment is thought by many to improve outcomes, as discussed in [Chapter 47](#) (see p. 1074).

Laparotomy. Uncomplicated abdominal or pelvic surgery performed during early pregnancy does not appear to increase the risk of abortion. Certain complications, for example peritonitis, may be the indication for, or the consequence of surgery (see [Chap. 41](#), p. 974). Ovarian tumors generally are removed without interfering with pregnancy. An important exception involves early removal of the corpus luteum cyst or the ovary in which the corpus luteum resides. If performed prior to 10 weeks' gestation, supplemental progesterone is indicated ([Chap. 40](#), p. 966).

Physical Trauma. Clearly, major abdominal trauma can precipitate abortion. Determining the effect of minor trauma on abortion rates, however, poses problems. Minor trauma that fails to interrupt a pregnancy is often forgotten, whereas minor trauma temporally associated with abortion is more likely recalled. In general, trauma contributes minimally to the incidence of abortion.

Uterine Defects

ACQUIRED UTERINE DEFECTS. Even large and multiple uterine leiomyomas usually do not cause abortion. When associated with abortion, their location is more important than their size (see [Chap. 40](#), p. 962). *Asherman syndrome*, characterized by uterine synechiae, usually results from destruction of large areas of endometrium by curettage. If pregnancy follows, the amount of remaining endometrium may be insufficient to support the pregnancy, and abortion may ensue. A hysterosalpingogram that shows characteristic multiple filling defects may indicate Asherman syndrome, but hysteroscopy most accurately and directly identifies this condition (Raziel and colleagues, 1994).

Recommended treatment consists of lysis of the adhesions via hysteroscopy and placement of an intrauterine contraceptive device to prevent recurrence. Some practitioners also recommend continuous high-dose estrogen therapy for 60 to 90 days following adhesiolysis. March and Israel (1981) reported that abortions decreased from 80 to 15 percent with this therapy.

DEVELOPMENTAL UTERINE DEFECTS. Abnormal mullerian duct formation or fusion defects may develop spontaneously or may follow in utero exposure to diethylstilbestrol (see [Chap. 40](#), p. 953). Controversy surrounds the question of whether uterine defects cause abortion, and therefore, whether their correction prevents it (American College of Obstetricians and Gynecologists, 2001a). Thus, corrective procedures of the uterus for the prevention of abortion, if done at all, should be performed as a last resort, with a full understanding that they may lack efficacy.

Incompetent Cervix. Traditionally, the term *incompetent cervix* describes a discrete obstetrical entity. Classically, it is characterized by painless cervical dilatation in the second trimester, with prolapse and ballooning of membranes into the vagina, followed by expulsion of an immature fetus. Unless effectively treated, this sequence may repeat in future pregnancies.

Unfortunately, women with pregnancies that abort in the second trimester often have histories and clinical findings that make it difficult to distinguish true cervical incompetence from other causes of midtrimester pregnancy loss. Almost 1300 women with nonclassical histories of cervical incompetence were studied in a randomized trial that had as its primary outcome delivery before 33 weeks. Cerclage was found to be beneficial, albeit marginally, in that 13 percent of women in the cerclage group delivered prior to 33 weeks versus 17 percent in the noncerclage group (MacNaughton and colleagues, 1993). Thus, for every 25 cerclage procedures, one birth prior to 33 weeks was prevented.

Currently, interest is focused on the use of transvaginal ultrasound to aid in diagnosing cervical incompetence. Multiple studies have demonstrated that certain features of the cervix, primarily cervical length, when measured in the mid-second trimester, may predict preterm delivery. Another feature termed *funneling* ¶— ballooning of the membranes into a dilated internal os, but with a closed external os ¶— also has been assessed (Owen and associates, 2003).

The clinical relevance of these cervical features, however, is uncertain. Three randomized cerclage trials that included women found by transvaginal ultrasound to have either cervical shortening or funneling reported conflicting results. Rust and colleagues (2001) randomized 113 women with a cervical length of less than 25 mm, or with substantial funneling, to undergo either cerclage or expectant management. The incidence of preterm birth was 35 percent in the cerclage group and 36 percent in the control group. Similarly, To and colleagues (2004) reported that following their randomized trial involving cerclage placement in 253 women, the risk of early preterm birth was not significantly reduced. The results of a smaller randomized European trial of 35 women suggested that cerclage might be beneficial (Althuisius and colleagues, 2001).

Unless ongoing studies demonstrate compellingly that cerclage performed for ultrasonographically diagnosed cervical abnormalities prevents preterm delivery, the use of ultrasound to diagnose cervical incompetence is not recommended.

ETIOLOGY. Although the cause of cervical incompetence is obscure, previous trauma to the cervix—especially in the course of dilatation and curettage, conization, cauterization, or amputation—appears to be a factor in some cases. In other instances, abnormal cervical development, including that following exposure to diethylstilbestrol in utero, may play a role (see [Chap. 40](#), p. 957).

TREATMENT. The treatment of classical cervical incompetence is cerclage. The operation is performed to surgically reinforce the weak cervix by some type of purse-string suturing. Bleeding, uterine contractions, or ruptured membranes are usually contraindications to cerclage.

Preoperative Evaluation. Sonography to confirm a living fetus and to exclude major fetal anomalies should precede cerclage. Preoperatively, cervical specimens are tested for gonorrhea and chlamydia. If positive, or if there are other obvious cervical infections, treatment is given. For at least a week before and after surgery, sexual intercourse should be restricted.

Cerclage may be performed prophylactically before cervical dilatation, or emergently after the cervix has dilated. Although prophylactic surgery generally is performed between 12 and 16 weeks, experts disagree as to how late emergency cerclage should be performed. The more advanced the pregnancy, the more likely the risk that surgical intervention will stimulate preterm labor or membrane rupture. We usually do not perform cerclage after about 23 weeks, although others have done so (Caruso and associates, 2000; Terkildsen and colleagues, 2003).

In a 10-year review of 75 emergency cerclage procedures, Chasen and Silverman (1998) reported that 65 percent of infants were delivered at 28 weeks or later, and half delivered after 36 weeks. Only 44 percent of cases with bulging membranes at the time of cerclage reached 28 weeks. Caruso and associates (2000) reported their experience with emergency cerclage from 17 to 27 weeks in 23 women, all with a dilated cervix and protruding membranes. Because only 11 liveborn infants resulted, they concluded that success was unpredictable. Based on their 20-year experience with 116 women undergoing emergency cerclage, Terkildsen and colleagues (2003) reported that nulliparous women and those with bulging membranes were significantly more likely to be delivered before 28 weeks. Paradoxically, cerclage after 22 weeks was associated with a better chance of delivery beyond 28 weeks.

If the clinical indication for cerclage is questionable, these women may be advised to decrease physical activity and abstain from intercourse. Cervical examinations are performed each week or every 2 weeks to assess cervical effacement and dilatation. Unfortunately, rapid effacement and dilatation can develop despite such precautions (Witter, 1984).

Cerclage Procedures. Two types of vaginal operations commonly are used during pregnancy. One is the simple procedure, developed by McDonald (1963) and shown in [Figure 9-4](#). The second, a more complicated operation shown in [Figure 9-5](#), is a modification of the original procedure described by Shirodkar (1955). Compared with historical controls, women with classical histories of cervical incompetence have success rates approaching 85 to 90 percent when either technique is performed prophylactically (Caspi and associates, 1990; Kuhn and Pepperell, 1977). For these reasons, most practitioners reserve the modified Shirodkar procedure for women with a previous failure of the McDonald cerclage or those with structural cervical abnormalities.

During emergency cerclage, moving the prolapsed amniotic sac back into the uterus may facilitate suture placement (Locatelli and associates, 1999). In some cases, filling the bladder with 600 mL of sterile saline through an indwelling Foley catheter will reduce prolapsing membranes. Unfortunately, this maneuver also can carry the cervix cephalad, away from the operating field. Alternatively, placing a Foley catheter with a 30-mL balloon through the cervix and inflating the balloon will deflect the amniotic sac cephalad. The balloon is then deflated gradually as the cerclage stitch is cinched tight.

Transabdominal cerclage with the suture placed at the uterine isthmus is used in some cases of severe anatomical defects of the cervix or cases of prior transvaginal cerclage failure (Cammarano and colleagues, 1995; Gibb and Salaria, 1995). In a review of 14 retrospective reports, Zaveri and associates (2002) concluded that when a prior transvaginal cerclage failed to prevent preterm delivery, the risk of perinatal death or delivery prior to 24 weeks following transabdominal cerclage (6 percent) was only slightly lower than the risk following repeat transvaginal cerclage (13 percent). Importantly, 3 percent of women who underwent transabdominal cerclage had serious operative complications, whereas there were none in women in the transvaginal group. Although transabdominal cerclage has been performed through the laparoscope, it generally requires laparotomy for initial suture placement and subsequent laparotomy for removal of the suture, for delivery of the fetus, or both.

COMPLICATIONS. Charles and Edward (1981) identified complications, especially infection, to be less frequent when cerclage was performed by 18 weeks. In the large trial of MacNaughton and colleagues (1993), membrane rupture complicated only 1 of over 600 procedures. Cerclage was associated with higher rates of subsequent hospitalization and tocolysis, as well as a doubling of the incidence of puerperal fever—6 percent versus 3 percent. Thomason and co-workers (1982) found that prophylactic antimicrobials failed to prevent most infection and tocolytics failed to halt most labor. With clinical infection, the suture should be cut, and labor induced or augmented if necessary. Similarly, if signs of imminent abortion or delivery develop, the suture should be released at once. Failure to do so may enable vigorous uterine contractions to tear the uterus or cervix.

Membrane rupture during suture placement or within the first 48 hours following surgery is considered by some practitioners to be an indication to remove the cerclage. Kuhn and Pepperell (1977) reported that membrane rupture in the absence of labor increased the likelihood of serious fetal or maternal infection if the suture was left in situ and delivery delayed. Still, the range of management options spans from observation, to removal of the cerclage and observation, to removal of the cerclage and

labor induction (Barth, 1995). Insufficient data limit firm recommendations, and the optimal management of such patients remains controversial (O'Connor and associates, 1999).

Following the modified Shirodkar operation, the suture may be left in place, and delivery affected by cesarean. Conversely, it may be removed, and vaginal delivery permitted.

Figure 9-4. McDonald cerclage procedure for incompetent cervix. **A.** Start of the cerclage procedure with a suture of number 2 monofilament being placed in the body of the cervix very near the level of the internal os. **B.** Continuation of suture placement in the body of the cervix so as to encircle the os. **C.** Completion of encirclement. **D.** The suture is tightened around the cervical canal sufficiently to reduce the diameter of the canal to 5 to 10 mm, and then the suture is tied. The effect of the suture placement on the cervical canal is apparent. Placement somewhat higher may be of value, especially if the first is not in close proximity to the internal os.

Figure 9-5. Modified Shirodkar cerclage for incompetent cervix. **A.** A transverse incision is made in the mucosa overlying the anterior cervix, and the bladder is pushed cephalad. **B.** A 5-mm Mersilene tape on a Mayo needle is passed anteriorly to posteriorly. **C.** The tape is then directed posteriorly to anteriorly on the other side of the cervix. Allis clamps placed so as to bunch the cervical tissue to diminish the distance the needle must travel submucosally facilitate placement of the tape. **D.** The tape is snugly tied anteriorly, after ensuring that all slack has been taken up. The cervical mucosa is then closed with a continuous chromic suture to bury the anterior Mersilene knot.

PATERNAL FACTORS. Little is known about paternal factors in the genesis of spontaneous abortion. Certainly, chromosomal abnormalities in sperm have been associated with abortion (Carrell and colleagues, 2003).

CATEGORIES OF SPONTANEOUS ABORTION. The clinical aspects of spontaneous abortion separate into five subgroups: threatened, inevitable, complete or incomplete, missed, and recurrent abortion.

Threatened Abortion. The clinical diagnosis of threatened abortion is presumed when a bloody vaginal discharge or bleeding appears through a closed cervical os during the first half of pregnancy. Occurring commonly, vaginal spotting or heavier bleeding during early gestation may persist for days or weeks and may affect one out of four or five pregnant women. Overall, approximately half of these pregnancies will abort, although the risk is substantially lower if fetal cardiac activity can be documented (Tongsong and colleagues, 1995). Even without abortion, these fetuses are at increased risk for preterm delivery, low birthweight, and perinatal death (Batzofin, 1984; Funderburk, 1980; Weiss, 2004, and their colleagues). Importantly, the risk of a malformed infant does not appear to be increased.

Some bleeding near the time of expected menses may be physiological. Cervical lesions commonly bleed in early pregnancy, especially after intercourse. Polyps presenting at the external cervical os and decidual reaction in the cervix also tend to bleed in early gestation. Lower abdominal pain and persistent low backache do not accompany bleeding from these benign causes.

Bleeding usually begins first, and cramping abdominal pain follows a few hours to several days later. The pain of abortion may manifest as anterior and clearly rhythmic cramps; as a persistent low backache, associated with a feeling of pelvic pressure; or as a dull, midline, suprapubic discomfort. Whichever form the pain takes, the combination of bleeding and pain predicts a poor prognosis for pregnancy continuation.

Because ectopic pregnancy, ovarian torsion, and the other types of abortion may mimic threatened abortion, the threshold to examine women with vaginal bleeding and pain should be low. If the bleeding is persistent or heavy, a hematocrit should be obtained. If blood loss is sufficient to cause significant anemia or hypovolemia, uterine evacuation is done.

There are no effective therapies for threatened abortion. Bed rest, although often prescribed, does not alter the course of threatened abortion. Acetaminophen-based analgesia may be given to help relieve the pain. As discussed in [Chapter 10](#) (see p. 259), vaginal sonography, serial serum quantitative human chorionic gonadotropin (hCG) levels, and serum progesterone values, used alone or in various combinations, can help ascertain if the fetus is alive and its location. None of these tests, however, especially early in gestation, is 100 percent accurate to confirm fetal death; thus, repeat evaluations over 1 or 2 weeks may be necessary. **Ectopic pregnancy should always be considered in the differential diagnosis of threatened abortion.**

ANTI-D IMMUNOGLOBULIN. We as well as others recommend treatment of D-negative women with anti-D immunoglobulin after abortion because up to 5 percent of D-negative women will become isoimmunized without it (see [Chap. 29](#), p. 663). In D-negative women with threatened abortion, this practice is controversial, because it lacks evidence-based support (American College of Obstetricians and Gynecologists, 1999; Weissman and associates, 2002).

Inevitable Abortion. Gross rupture of the membranes, evidenced by leaking amniotic fluid, in the presence of cervical dilatation signals almost certain abortion. Commonly, either uterine contractions begin promptly, resulting in abortion, or infection develops. Rarely, a gush of fluid from the uterus during the first half of pregnancy is without serious consequence. The fluid may have collected previously between the amnion and chorion. Thus, if a sudden discharge of fluid in early

pregnancy occurs before any pain, fever, or bleeding, the woman may be put to bed and observed. If after 48 hours no additional amniotic fluid has escaped, and there is no bleeding, pain, or fever, she may resume her usual activities except for any form of vaginal penetration. If, however, the gush of fluid is accompanied or followed by bleeding, pain, or fever, abortion should be considered inevitable and the uterus emptied.

Complete and Incomplete Abortion. When the placenta, in whole or in part, detaches from the uterus, bleeding ensues. Following complete detachment and expulsion of the conceptus, termed complete abortion, the internal cervical os closes. During incomplete abortion, however, the internal cervical os remains open and allows passage of blood. The fetus and placenta may remain entirely in utero or may partially extrude through the dilated os. Incomplete abortion may or may not require additional cervical dilatation before curettage. In many cases, retained placental tissue simply lies loosely in the cervical canal, allowing easy extraction from an exposed external os with ring forceps. Suction curettage, as described later, effectively evacuates the uterus. In clinically stable women, expectant management also can be a reasonable option (Blohm and colleagues, 2003).

Hemorrhage from the incomplete abortion of a more advanced pregnancy, though rarely fatal, is occasionally severe. Therefore, in women with more advanced pregnancies or with heavy bleeding, evacuation should proceed promptly. Fever should not prohibit curettage once appropriate antimicrobials have been administered (see p. 247).

Missed Abortion. In this case, the uterus retains dead products of conception behind a closed cervical os for days or even weeks. In the typical instance, early pregnancy appears to be normal, with amenorrhea, nausea and vomiting, breast changes, and growth of the uterus. After fetal death, there may or may not be vaginal bleeding or other symptoms of threatened abortion. For days or weeks, the uterus remains stationary in size, but then gradually becomes smaller. Mammary changes usually regress, and women often lose a few pounds. Many women have no symptoms during this period except persistent amenorrhea. If the missed abortion terminates spontaneously, and most do, the process of expulsion is the same as in any abortion.

After death of the conceptus, management can be individualized, depending on individual circumstances. Expectant, medical, and surgical approaches can all be reasonable options, each with its own merits and disadvantages. Surgery is generally definitive and predictable but is invasive and is not necessary for all women. Expectant and medical management spare some women from curettage, but are associated with unpredictable bleeding and, in some women, the need for unscheduled surgery. These approaches may require more follow-up, may cause significant pain, and may carry time delays, all or one of which some women may not accept.

Nielsen and Hahlin (1995) performed a randomized study comparing expectant management with curettage for missed abortions earlier than 13 weeks. Spontaneous resolution occurred within 3 days in 80 percent of women treated conservatively, although vaginal bleeding averaged 1 day longer. Complications were similar between the groups. Luise and colleagues (2002), in an observational study of almost 1100 women with suspected first-trimester abortion, reported spontaneous resolution in 81 percent. In this study, compared with the report by Nielsen and Hahlin (1995), however, pregnancies were aborted later, and only half of those with a fetal pole or gestational sac aborted within 2 weeks of diagnosis.

Muffley and colleagues (2002) randomized 50 women with pregnancy failure prior to 12 weeks either to dilatation and curettage, or to 800 µg of misoprostol placed in the posterior vaginal fornix and repeated in 24 hours if necessary. Failure of medical therapy, defined as retained gestational sac at 48 hours, occurred in 60 percent of those treated medically. There were no differences between groups in hematocrit level changes or in the time to disappearance of serum hCG levels. One woman in the misoprostol group returned 6 hours after initial dosing with profuse vaginal bleeding.

In another randomized trial, Chung and colleagues (1999) reported that approximately 50 percent of the group given medical treatment subsequently required surgical evacuation. Following abortion completion with medical therapy, vaginal or abdominal ultrasound can be used to document an empty uterine cavity. If significant amounts of material remain within the uterine cavity, curettage should follow.

In some cases after prolonged retention of a dead fetus, serious coagulation defects develop and are more likely if there is fetal death after midpregnancy. Coagulopathies may cause troublesome maternal bleeding from the nose, gums, and sites of slight trauma. The pathogenesis and treatment of these defects are considered in [Chapter 35](#) (see p. 843).

Recurrent Abortion. Defined by various criteria of number and sequence, recurrent abortion in its generally accepted definition refers to three or more consecutive spontaneous abortions. In the majority of cases, repeated spontaneous abortions are likely to be chance phenomena. Accepting an independent risk of spontaneous abortion occurrence to be 15 percent, a second loss could be calculated to occur at a rate of 2.3 percent and a third loss at a rate of 0.34 percent. Confirming this, a study of women physicians reported the occurrences of one, two, and three miscarriages to be 10.4, 2.3, and 0.34 percent, respectively (Alberman, 1988).

The American College of Obstetricians and Gynecologists (2001a) recognizes only two types of tests as having clear value in the investigation of recurrent miscarriage: (1) parental cytogenetic analysis, and (2) lupus anticoagulant and anticardiolipin antibodies assays (see p. 235). Cytogenetics, in addition to providing a potential explanation for the abortions, may identify couples at risk of giving birth to an infant with a deleterious unbalanced chromosomal translocation. Thrombophilia antibody assays rarely identify a treatable condition (see p. 236).

PROGNOSIS. The majority of women who attempt pregnancy after being diagnosed with recurrent abortion will have successful outcomes, with or without treatment. Warburton and Fraser (1964) reported that the likelihood of recurrent abortion was 25 to 30 percent regardless of the number of previous abortions. Poland and associates (1977) noted that if a woman with this diagnosis had previously delivered a liveborn infant, the risk for subsequent recurrent abortion was approximately 30 percent. If, however, a woman had no liveborn infants, and had at least one spontaneous fetal loss, the risk of abortion was 46 percent.

INDUCED ABORTION

Induced abortion is *the medical or surgical termination of pregnancy before the time of fetal viability*. In 2000, a total of 857,475 legal abortions were reported to the Centers for Disease Control and Prevention (2003). These numbers are underestimated because clinics inconsistently report medically induced abortions. Of those reported, about 20 percent involved women aged 19 years or younger, and the majority were younger than 25 years, white, and unmarried. Almost 60 percent of induced abortions were performed during the first 8 weeks, and 88 percent during the first 12 weeks of pregnancy.

HISTORY OF ABORTION. Until the United States Supreme Court decision of 1973, only therapeutic abortions could be performed legally in most states. The most common legal definition of therapeutic abortion until then was termination of pregnancy before the period of fetal viability for the purpose of saving the life of the mother. A few states extended their laws to read "to prevent serious or permanent bodily injury to the mother" or "to preserve the life or health of the woman." Some states allowed abortion if a pregnancy was likely to result in the birth of an infant with grave malformations.

The stringent abortion laws in effect prior to 1973 were of fairly recent origin. Abortion before quickening — the first definite perception of fetal movement, which most often occurs between 16 and 20 weeks' gestation — was either lawful or widely tolerated in both the United States and Great Britain until 1803. In that year, as part of a general restructuring of British criminal law, a statute was enacted that made all induced abortions regardless of gestational age illegal. The Roman Catholic Church's traditional prohibition of abortion did not receive the ultimate sanction of universal law (excommunication) until 1869 (Pilpel and Norwich, 1969).

In this country, it was not until 1821 that Connecticut enacted the first abortion law. Subsequently, abortion became illegal throughout the United States except to save the life of the mother. Because therapeutic abortion to save the life of the woman is rarely necessary or definable, it follows that the great majority of such operations previously performed in this country went beyond legal boundaries. Borgmann and Jones (2000) have extensively reviewed these legal issues.

INDICATIONS. Some indications for therapeutic abortion are discussed with the diseases that commonly lead to the operation. Well-documented indications include persistent heart disease after cardiac decompensation, advanced hypertensive vascular disease, and invasive carcinoma of the cervix. In addition to medical and surgical disorders that may be an indication for termination of pregnancy, there are others. Certainly, in cases of rape or incest, most authorities consider termination to be indicated. Another commonly cited indication is to prevent a viable birth of a fetus with a significant anatomical or mental deformity. The seriousness of fetal deformities is wide ranging and frequently defies social or legal classification.

ELECTIVE (VOLUNTARY) ABORTION. Elective or voluntary abortion is the interruption of pregnancy before viability at the request of the woman but not for reasons of impaired maternal health or fetal disease. Most abortions performed today fall into this category. Approximately one pregnancy is electively aborted for every four live births delivered in the United States (Ventura and colleagues, 2003). The Executive Board of the American College of Obstetricians and Gynecologists (2000) supports the right of women to choose abortion and considers this a medical matter between the woman and her physician.

In 1973, the United States Supreme Court legalized abortion. Several Supreme Court decisions in the history of abortion merit explanation.

Roe v Wade. The legality of elective abortion was established by the Supreme Court in its 1973 decision in *Roe v Wade*. It defined the extent to which states might regulate abortion:

1. For the stage prior to approximately the end of the first trimester, the abortion decision and its effectuation must be left to the medical judgment of the attending physician.
2. For the stage subsequent to approximately the end of the first trimester, the State, in promoting its interest in the health of the mother, may, if it chooses, regulate the abortion procedures in ways that are reasonably related to maternal health.
3. For the stage subsequent to viability, the State, in promoting its interest in the potential of human life, may, if it chooses, regulate, and even proscribe, abortion, except where necessary, in appropriate medical judgment, for the preservation of the life or health of the mother.

Webster v Reproductive Health Services. Since the *Roe v Wade* decision, many different pieces of legislation have been introduced at both the state and national level, and some enacted, to regulate or even dismantle its three provisions. All such attempts were unsuccessful until the United States Supreme Court ruled in the 1989 case *Webster v Reproductive Health Services* that states could place restrictions interfering with the provision of abortion services on such items as waiting periods, specific informed consent requirements, parental or spousal notification, and hospital requirements. Based on this decision, numerous restrictions now limit choice and access to abortion services. A more recent choice-limiting decision is the federal law banning the poorly defined "partial birth abortion" (see p. 243). At least two federal courts — June 2004 in San Francisco and August 2004 in New York — have ruled the law unconstitutional.

In its statement on abortion policy, the American College of Obstetricians and Gynecologists (2000) affirmed: *The intervention of legislative bodies into medical decision making is inappropriate, ill advised, and dangerous.*

Counseling Before Elective Abortion. Three choices available to a woman considering an abortion include continued pregnancy with its risks and parental responsibilities; continued pregnancy with its risks and its responsibilities of arranged adoption; or the choice of abortion with its risks. Knowledgeable and compassionate counselors should objectively describe and provide information about these choices.

Abortion can be performed either medically or surgically ([Table 9-2](#)), and each has distinctive clinical features ([Table 9-3](#)). Stubblefield and colleagues (2004) summarized in detail many abortion techniques.

Surgical Techniques for Abortion. A pregnancy may be removed surgically through an appropriately dilated cervix or transabdominally by either hysterotomy or hysterectomy.

DILATATION AND CURETTAGE. Transcervical approaches to surgical abortion require first dilating the cervix and then evacuating the pregnancy by mechanically scraping out the contents (sharp curettage), by suctioning out the contents (suction curettage), or both. Vacuum aspiration, the most common form of suction curettage, requires a rigid cannula attached to an electric-powered vacuum source. Alternatively, manual vacuum aspiration uses a similar cannula that attaches to a handheld syringe for its vacuum source (Goldberg and associates, 2004). The likelihood of complications increases after the first trimester. These include uterine perforation, cervical laceration, hemorrhage, incomplete removal of the fetus and placenta, and infections. Accordingly, sharp or suction curettage should be performed before 14 to 15 weeks.

Beginning at 16 weeks, fetal size and structure dictate use of the *dilatation and evacuation (D & E)* technique. Wide mechanical cervical dilatation, achieved with metal or hygroscopic dilators, precedes mechanical destruction and evacuation of fetal parts. With complete removal of the fetus, a large-bore vacuum curette is used to remove the placenta and remaining tissue.

A *dilatation and extraction (D & X)* is similar to a dilatation and evacuation except that suction evacuation of the intracranial contents after delivery of the fetal body through the dilated cervix facilitates extraction and minimizes uterine or cervical injury from instruments or fetal bones. In political parlance, this procedure has been termed *partial birth abortion*.

Antimicrobial prophylaxis should be provided to all women undergoing a transcervical surgical abortion. Based on their review of 11 randomized trials, Sawaya and associates (1996) concluded that antimicrobials decreased the risk of infection by approximately 40 percent. No one regimen appears superior. One convenient, inexpensive, and effective regimen is doxycycline, 100 mg orally before the procedure and 200 mg orally after.

In the absence of maternal systemic disease, abortion procedures do not require hospitalization. When abortion is performed outside a hospital setting, capabilities for cardiopulmonary resuscitation and for immediate transfer to a hospital must be available.

Hygroscopic Dilators. Trauma from mechanical dilatation can be minimized by using devices that slowly dilate the cervix. These devices, called *hygroscopic dilators*, draw water from cervical tissues and expand, gradually dilating the cervix. One type of hygroscopic dilator originates from the stems of *Laminaria digitata* or *Laminaria japonica*, a brown seaweed (Fig. 9-6). The stems are cut, peeled, shaped, dried, sterilized, and packaged according to size—small, 3 to 5 mm in diameter; medium, 6 to 8 mm; and large, 8 to 10 mm. The strongly hygroscopic laminaria presumably act by drawing water from proteoglycan complexes, causing the complexes to dissociate, and thereby allowing the cervix to soften and dilate.

Synthetic hygroscopic dilators, such as Lamicel, a polyvinyl alcohol polymer sponge impregnated with anhydrous magnesium sulfate, also effectively dilate the cervix (Nicolaidis and co-workers, 1983).

An interesting dilemma is presented by the woman who has a hygroscopic dilator placed overnight preparatory to elective abortion, but who then changes her mind. Schneider and associates (1991) described this in 7 first-trimester and 14 second-trimester pregnancies. Four patients returned to their original decision and aborted their pregnancies. Of the remaining 17, there were 14 term deliveries, 2 preterm deliveries, and 1 spontaneous abortion 2 weeks later. None of the patients suffered infectious morbidity, including three untreated women with cervical cultures positive for chlamydia. In spite of this generally reassuring report, an attitude of irrevocability with regard to dilator placement and abortion seems prudent.

Technique for Insertion. The cervix is cleansed with povidone-iodine solution and is grasped anteriorly with a tenaculum. A laminaria of the appropriate size is then inserted using a uterine packing forceps so that the tip rests at the level of the internal os (see Fig. 9-6). After 4 to 6 hours, the laminaria will have swollen and will have dilated the cervix sufficiently to allow easier mechanical dilatation and curettage. Cramping frequently accompanies expansion of the laminaria.

Prostaglandins. As an alternative to hygroscopic dilators, various prostaglandin preparations may be placed into the posterior vaginal fornix to facilitate subsequent dilatation. MacIsaac and colleagues (1999) randomized women to 400 µg of misoprostol placed vaginally 4 hours before first-trimester abortion versus laminaria placement. Misoprostol effected equal or greater dilatation, caused less pain on insertion, and produced similar side effects. It is important to emphasize that this 400-µg dose is far in excess of oral or vaginal dosing for labor induction (see Chap. 22, p. 538).

Technique for Dilatation and Curettage. A bimanual examination is performed to determine the size and orientation of the uterus. After speculum insertion, the cervix is swabbed with povidone-iodine or equivalent solution and the anterior cervical lip is grasped with a toothed tenaculum. A local anesthetic, such as 5 mL of 1 or 2 percent lidocaine, is injected bilaterally into the cervix. Alternatively, a paracervical block may be used with dilute vasopressin added to the local anesthetic to decrease blood loss (Keder, 2003).

If required, the cervix is further dilated with Hegar or Pratt dilators until a suction cannula of the appropriate diameter can be inserted. Choosing the most appropriately sized cannula balances competing factors: small cannulas carry the risk of retained intrauterine tissue postoperatively, whereas large cannulas risk cervical injury and more discomfort. The fourth and fifth fingers of the hand introducing the dilator should rest on the perineum and buttocks as the dilator is pushed through the internal os (Fig. 9-7). This technique minimizes forceful dilatation and provides a safeguard against uterine perforation. Uterine sounding measures the depth and inclination of the uterine cavity prior to cannula insertion. The suction cannula is moved toward the fundus, then back toward the os and is turned circumferentially to cover the entire surface of the uterine cavity. When no more tissue is aspirated, a gentle sharp curettage should follow to remove any remaining placental or fetal fragments.

Because uterine perforations rarely occur on the downstroke of instrumentation, and characteristically occur on the insertion of any instrument into the uterus, manipulations should be carried out with the thumb and forefinger only (Fig. 9-8). If beyond 16 weeks' gestation, the fetus is extracted, usually in parts, using Sopher forceps and other destructive instruments. Risks include uterine perforation, cervical laceration, and uterine bleeding due to the larger fetus and placenta and to the thinner uterine walls. Morbidity can be minimized if (1) the cervix is adequately dilated before attempting to remove the products of conception, (2) instruments are introduced into the uterus and manipulated without force, and (3) all tissue is removed.

Complications. The incidence of uterine perforation associated with elective abortion varies. Two important determinants are the skill of the physician and the position of the uterus, with a much greater likelihood of perforation if the uterus is retroverted. Accidental uterine perforation usually is recognized easily when the instrument passes without resistance deep into the pelvis. Observation may be sufficient if the uterine perforation is small, as when produced by a uterine sound or narrow dilator.

Considerable intra-abdominal damage can be caused by instruments, especially suction and sharp curettes, passed through a uterine defect into the peritoneal cavity (Keegan and Forkowitz, 1982). In this circumstance, laparotomy to examine the abdominal contents is often the safest course of action. Depending on the circumstances, laparoscopy may be substituted. Unrecognized bowel injury can cause severe peritonitis and sepsis (Kambiss and associates, 2000).

Some women may develop cervical incompetence or uterine synechiae following dilatation and curettage. Rarely, abortion performed by curettage on more advanced pregnancies may induce sudden, severe consumptive coagulopathy, which can prove fatal. Those contemplating abortion should understand the potential for these rare but serious complications.

MENSTRUAL ASPIRATION. Aspiration of the endometrial cavity using a flexible 5- or 6-mm Karman cannula and attached syringe within 1 to 3 weeks after a missed menstrual period has been referred to as *menstrual extraction*, *menstrual induction*, *instant period*, *traumatic abortion*, and *mini-abortion*. At this early stage of gestation, pregnancy can be misdiagnosed, an implanted zygote can be missed by the curette, ectopic pregnancy can be unrecognized, or infrequently, a uterus can be perforated. Even so, Paul and associates (2002) reported a 98-percent success rate in more than 1000 women who underwent this procedure. A positive pregnancy test will eliminate a needless procedure on a nonpregnant woman whose period has been delayed for other reasons.

To identify placenta in the aspirate, MacIsaac and Darney (2000) recommend that the syringe contents be rinsed in a strainer to remove blood, then placed in a clear plastic container with saline and examined with back lighting. Placental tissue macroscopically appears soft, fluffy, and feathery. A magnifying lens, colposcope, or microscope also can improve visualization.

LAPAROTOMY. In a few circumstances, abdominal hysterotomy or hysterectomy for abortion is preferable to either curettage or medical induction. If significant uterine disease is present, hysterectomy may provide ideal treatment. Either hysterotomy with tubal ligation or, on occasion, hysterectomy may be indicated for women who desire pregnancy termination and sterilization. At times, a failed medical induction during the second trimester may necessitate hysterotomy or hysterectomy.

Medical Induction of Abortion. Throughout history, many naturally occurring substances have been tried as abortifacients. Most often, serious systemic illness or even death has resulted rather than abortion. Even today, only a few effective, safe abortifacient drugs are used.

EARLY ABORTION. According to the American College of Obstetricians and Gynecologists (2001b), outpatient medical abortion is an acceptable alternative to surgical abortion in appropriately selected women with pregnancies of less than 49 days' gestation. Beyond this point, the available data, though less robust, support surgical abortion as a preferable method of early abortion. Three medications for early medical abortion have been widely studied and used: the antiprogesterin *mifepristone*, the antimetabolite *methotrexate*, and the prostaglandin *misoprostol*. These agents cause abortion by increasing uterine contractility, either by reversing the progesterone-induced inhibition of contractions (*mifepristone* and *methotrexate*), or by stimulating the myometrium directly (*misoprostol*).

Various dosing schemes have proven effective (Table 9-4). *Mifepristone* or *methotrexate* is administered initially, and followed after some time interval by *misoprostol*. *Methotrexate* and *misoprostol* are teratogens. Their use thus requires a commitment on the part of both patient and caregiver to complete the abortion, even if surgical evacuation becomes necessary.

Contraindications to medical abortion have evolved from the exclusion criteria of various medical abortion trials. In addition to specific allergies to the medicines, they have included an in situ intrauterine device, severe anemia, coagulopathy or anticoagulant use, and significant medical conditions, such as active liver disease, cardiovascular disease, and uncontrolled seizure disorders. Additionally, because *misoprostol* can lower glucocorticoid activity, women with adrenal disease or with disorders requiring glucocorticoid therapy should be excluded (American College of Obstetricians and Gynecologists, 2001b). Women contemplating medical abortion should receive thorough counseling regarding the risks, benefits, and requirements of both medical and surgical approaches.

With the *mifepristone* regimen, according to the Food and Drug Administration package labeling, the *misoprostol* is to be provider-administered. Afterward, the woman typically remains in the office for 4 hours, although her activity is not restricted. If the products of conception appear to have been expelled, she is examined to confirm expulsion. If during observation the conceptus does not appear to have been expelled, a pelvic examination is performed before discharge and the woman is rescheduled for an appointment in 1 to 2 weeks. At this later appointment, if both history and physical examination or ultrasound fail to confirm completed abortion, a suction procedure usually is performed.

In regimens employing *methotrexate*, women typically are seen at least 24 hours after *misoprostol* administration, and approximately 7 days after *methotrexate* administration, at which time an ultrasound examination is performed. If the pregnancy persists, another dose of *misoprostol* is given, and the woman is seen again in 1 week if fetal cardiac activity is present, or in 4 weeks if there is no fetal cardiac activity. If, by the second visit, abortion has not occurred, it usually is completed by suction curettage (American College of Obstetricians and Gynecologists, 2001b).

Bleeding and cramping with medical termination can be significantly worse than symptoms experienced with menses. Adequate pain medication, usually including a narcotic, should be provided. According to the American College of Obstetricians and Gynecologists (2001b), soaking two pads or more per hour for at least 2 hours is a threshold at which the woman should be instructed to contact her provider to determine whether she needs to be seen.

Early medical abortion is highly effective—90 to 98 percent of women will not require surgical intervention (Kahn and associates, 2000). According to Hausknecht (2003), when *mifepristone* was given with *misoprostol* to 80,000 women for medical abortion, only 139 complications were reported to the manufacturer. Unnecessary surgical intervention in women

undergoing medical abortion can be avoided if ultrasound results are interpreted appropriately. Specifically, if no gestational sac is present, in the absence of heavy bleeding, intervention in most women is unnecessary. This is true even when, as is common, the uterus contains ultrasonographically evident debris (Cowett and associates, 2004).

SECOND-TRIMESTER ABORTION. Invasive means of second-trimester medical abortion have long been available (see [Table 9-2](#)). In the past decade, however, the ability to safely and effectively accomplish noninvasive second-trimester abortion has evolved considerably. Principal among these noninvasive methods are high-dose intravenous oxytocin and vaginal prostaglandin administration, including prostaglandin E₂ suppositories and prostaglandin E₁ (misoprostol) pills. Regardless of method, laminaria placement as shown in [Figure 9-6](#) will shorten the duration (Stubblefield and colleagues, 1975).

Oxytocin. Given as a single agent in high doses, oxytocin will effect second-trimester abortion in 80 to 90 percent of cases. For more than 15 years, the regimen shown in [Table 9-5](#) has been used with a high degree of safety and effectiveness at the University of Alabama. By always mixing the oxytocin in an isotonic solution such as normal saline, and avoiding excessive administration of dilute intravenous solutions, we have not observed hyponatremia or water intoxication.

Prostaglandin E₂. Suppositories of 20-mg prostaglandin E₂ placed in the posterior vaginal fornix are a simple and effective means of effecting second-trimester abortion. This method is not more effective than high-dose oxytocin, and it causes more frequent side effects such as nausea, vomiting, fever, and diarrhea (Owen and associates, 1992). If prostaglandin E₂ is used, an antiemetic such as metoclopramide, an antipyretic such as acetaminophen, and an antidiarrheal such as diphenoxylate/atropine are given either to prevent or to treat symptoms.

Prostaglandin E₁. Misoprostol can be used easily and inexpensively as a single agent for second-trimester pregnancy termination. In their randomized trial, Ramsey and co-workers (2004) administered misoprostol, 600 µg vaginally followed by 400 µg every 4 hours, and reported that this effected abortion significantly faster than concentrated oxytocin given in combination with prostaglandin E₂-median time to abortion 12 versus 17 hours, respectively. Misoprostol achieved abortion within 24 hours in 95 percent of women compared with 85 percent in the other group. Importantly, only 2 percent of women in the misoprostol group required curettage for retained placenta compared with 15 percent in the oxytocin/prostaglandin E₂ group.

The safety of medically induced second-trimester abortion after a previous cesarean delivery was reported by Boulot and associates (1993). At a mean gestational age of almost 24 weeks, 20 of 23 fetuses aborted. At hysterotomy in the three treatment failures, there was one uterine rupture that was successfully repaired. Chapman and colleagues (1996) reported a uterine rupture rate of 3.8 percent in 79 women with a prior cesarean delivery undergoing medical termination at a mean gestational age of 21 weeks.

Figure 9-6. Insertion of laminaria prior to dilatation and curettage. **A.** Laminaria immediately after being appropriately placed with its upper end just through the internal os. **B.** Several hours later the laminaria is now swollen, and the cervix is dilated and softened. **C.** Laminaria inserted too far through the internal os; the laminaria may rupture the membranes. **D.** Laminaria not inserted far enough to dilate the internal os.

Figure 9-7. Dilatation of cervix with a Hegar dilator. Note that the fourth and fifth fingers rest against the perineum and buttocks, lateral to the vagina. This maneuver is a most important safety measure because if the cervix relaxes abruptly, these fingers prevent a sudden and uncontrolled thrust of the dilator, a common cause of uterine perforation.

Figure 9-8. Introduction of a sharp curet. Note that the instrument is held with the thumb and forefinger; in the upward movement of the curet, only the strength of these two fingers should be used.

CONSEQUENCES OF ELECTIVE ABORTION

Maternal Mortality. Legally induced abortion, performed by trained gynecologists, especially when performed during the first 2 months of pregnancy, has a mortality rate of only 0.7 per 100,000 procedures (Bartlett and co-workers, 2004; Gissler and associates, 2004; Grimes, 1994). The relative risk of dying as the consequence of abortion approximately doubles for each 2 weeks after 8 weeks' gestation.

Impact on Future Pregnancies. In a scholarly review of the impact of elective abortion on subsequent pregnancy outcome, Hogue (1986) summarized data from more than 200 publications. Data relating abortion to subsequent pregnancy outcome are observational, and therefore subject to bias and uncontrolled confounding factors. All studies on this topic must be interpreted with these limitations in mind.

Fertility does not appear to be diminished by an elective abortion, except infrequently as a consequence of infection. Vacuum aspiration does not increase the subsequent incidence of second-trimester spontaneous abortion or preterm delivery. Similarly, subsequent ectopic pregnancies are not increased, except possibly in women with preexisting chlamydial infection or in those who develop postabortion infections. Multiple sharp curettage abortion procedures may increase the subsequent risk of placenta previa, whereas vacuum aspiration procedures likely do not (Johnson and co-workers, 2003).

Septic Abortion. Although serious complications of abortion most often occur with criminal abortion, even spontaneous abortion and legal elective abortion continue to be associated with severe and even fatal infections (Barrett and colleagues, 2002). Severe hemorrhage, sepsis, bacterial shock, and acute renal failure have all developed in association with abortion but at a much lower frequency. Uterine infection is the usual outcome, but parametritis, peritonitis, endocarditis, and septicemia may all occur (Vartian and Septimus, 1991).

Among 300 women with septic abortions at Parkland Hospital, one fourth had a positive blood culture result. The organisms were predominantly anaerobic bacteria and coliforms, but others, including *Haemophilus influenzae*, *Campylobacter jejuni*, and group A streptococcus, also were noted (Denton and Clarke, 1992; Dotters and Katz, 1991; Pinhas-Hamiel and associates, 1991). Treatment of infection includes prompt intravenous administration of broad-spectrum antimicrobials followed by evacuation of the products of conception. If sepsis and shock supervene, then supportive care is essential, as discussed in [Chapter 42](#) (see p. 993). Septic abortion also may lead to disseminated intravascular coagulopathy (see [Chap. 35](#), p. 843).

RESUMPTION OF OVULATION AFTER ABORTION

Ovulation may resume as early as 2 weeks after an abortion. Lahteenma ki and Luukkainen (1978) detected surges of luteinizing hormone (LH) 16 to 22 days in 15 of 18 women studied. Moreover, plasma progesterone levels, which had plummeted after the abortion, increased soon after the LH surges. These hormonal events agree with histological changes observed in endometrial biopsies (Boyd and Holmstrom, 1972). **Therefore, if pregnancy is to be prevented, effective contraception should be initiated soon after abortion.** If contraception is not desired, Grossman and colleagues (2004) concluded that a visit to assess for complications is not necessary for procedures done before 50 days' gestation.

10. Ectopic Pregnancy

INTRODUCTION

The blastocyst normally implants in the endometrial lining of the uterine cavity. Implantation anywhere else is an ectopic pregnancy. Almost 2 in 100 pregnancies in the United States are ectopic, and over 95 percent of these involve the oviduct. The risk of death from an extrauterine pregnancy is greater than that for pregnancy that either results in a live birth or is intentionally terminated. Moreover, the chance for a subsequent successful pregnancy is reduced after an ectopic pregnancy. With earlier diagnosis, however, both maternal survival and conservation of reproductive capacity are enhanced.

GENERAL CONSIDERATIONS

RISK FACTORS. There are a number of risk factors for tubal damage and dysfunction (Table 10-1). Prior tubal surgery, either to restore patency or to perform sterilization, confers the highest risk of obstruction (Ankum and colleagues, 1996). After one previous ectopic pregnancy, the chance of another is 7 to 15 percent (Ankum and colleagues, 1996; Coste and associates, 1991). Prior salpingitis — pelvic inflammatory disease — is a common risk factor. Peritubal adhesions subsequent to postabortal or puerperal infection, appendicitis, or endometriosis may cause tubal kinking and narrowing of the lumen and thereby increase the risk of tubal pregnancy (Coste and associates, 1991). Previous cesarean delivery has been linked to a small increase in ectopic pregnancy risk (Hemminki and Merilainen, 1996).

Hormonal perturbations have been implicated in tubal dysfunction. An increased relative incidence of ectopic pregnancy has been reported with use of progestin-only oral contraceptives, postovulatory high-dose estrogens to prevent pregnancy (the "morning after pill"), and following ovulation induction (Morris and Van Wagenen, 1973; Ory, 1981; Sivin, 1991).

Assisted Reproduction. Rates of tubal pregnancy are increased following gamete intrafallopian transfer (GIFT) and in vitro fertilization (IVF) to as high as 3 percent (Coste and associates, 1991; Guirgis and Craft, 1991). Moreover, "atypical" implantations — cornual, abdominal, cervical, ovarian, and heterotypic (concomitant uterine and extrauterine pregnancy) — are more common following assisted reproductive procedures.

Failed Contraception. With any form of contraceptive, the absolute number of ectopic pregnancies is decreased because pregnancy occurs less often. In some contraceptive failures, however, the relative number of ectopic pregnancies is increased. Examples include some forms of tubal sterilization, intrauterine devices, and progestin-only minipills (Sivin, 1991).

EPIDEMIOLOGY. The rate of ectopic pregnancies per 1000 reported pregnancies increased fourfold in the United States from 1970 to 1992. This increase was greater for nonwhite than for white women, and for both, the incidence increased with age. In 1992, there were 108,800 ectopic pregnancies in the United States — almost 2 percent of all pregnancies. Importantly, ectopic pregnancy accounted for 10 percent of all pregnancy-related deaths (Koonin and colleagues, 1997).

The incidence of ectopic pregnancy for nonwhite women is higher in every age category compared with that for whites, and this disparity increases with age (Fig. 10-1). Overall, in 1989 a nonwhite woman had a 1.4 times increased risk for ectopic pregnancy compared with a white woman. Because of the increasing use of in-office medical therapy for ectopic pregnancy, reliable data on the actual number of ectopic pregnancies in the United States are not available after 1990.

Increasing Ectopic Pregnancy Rates. The reasons for the increased number and rate of ectopic pregnancies in the United States are not entirely clear. Similar increases for the 1970s and 1980s were reported from Eastern Europe, Scandinavia, and Great Britain. Some likely causes include an increase in the following factors:

1. Prevalence of sexually transmitted tubal infection and damage (Brunham and associates, 1992; Maccato and colleagues, 1992).
2. Ascertainment through earlier diagnosis of some ectopic pregnancies otherwise destined to resorb spontaneously (Ong and Wingfield, 1999).
3. Popularity of contraception that predisposes failures to be ectopic.
4. Use of tubal sterilization techniques that increase the likelihood of ectopic pregnancy.
5. Use of assisted reproductive techniques.
6. Use of tubal surgery, including salpingotomy for tubal pregnancy and tuboplasty for infertility.

Figure 10-1. Ectopic pregnancy rates for white and black women — United States, 1970 through 1990. (Data from Goldner and colleagues, 1993.)

MORTALITY. Deaths from ectopic pregnancy in the United States decreased from a total of 63 in 1970, to 46 in 1980, and to 30 in 1987. The proportion of all maternal deaths attributed to ectopic pregnancy, however, increased from 8 percent in 1970 to 11 percent in the 3-year period ending 1990 (Koonin and associates, 1997). As shown in Figure 10-2, the death rate from ectopic pregnancy declined markedly from 1970 to 1986 and then plateaued for both white and black women.

Over the same time period, the case-fatality rate decreased 10-fold, from 35 per 10,000 ectopic pregnancies in 1970 to 3.8 per 10,000 in 1989. This decrease is likely due to improved diagnosis and management. Anderson and colleagues (2004) report that about one maternal death per year due to ectopic pregnancy occurred in Michigan from 1985 to 1999. Concurrently, black women in the state had an ectopic pregnancy-related mortality ratio 18 times higher than white women. In the United States, ectopic pregnancy is the most common cause of maternal mortality in the first trimester (Centers for Disease Control and Prevention, 1995).

Figure 10-2. Death rate from ectopic pregnancy for white and black women in the United States, 1970 through 1989. (From Goldner and co-workers, 1993.)

PATHOGENESIS OF ECTOPIC PREGNANCIES

TUBAL PREGNANCY. The fertilized ovum may lodge in any portion of the oviduct, giving rise to ampullary, isthmic, and interstitial tubal pregnancies (see [Fig. 2-13](#), p. 27). In rare instances, the fertilized ovum may implant in the fimbriated extremity. The ampulla is the most frequent site, followed by the isthmus. Interstitial pregnancy accounts for only about 3 percent of all tubal gestations. From these primary types, secondary forms of tubo-abdominal, tubo-ovarian, and broad-ligament pregnancies occasionally develop.

Because the tube lacks a submucosal layer, the fertilized ovum promptly burrows through the epithelium, and the zygote comes to lie within the muscular wall. At the periphery of the zygote is a capsule of rapidly proliferating trophoblast that invades and erodes the subjacent muscularis. At the same time, maternal blood vessels are opened, and blood pours into the spaces lying within the trophoblast or between it and the adjacent tissue. The tubal wall in contact with the zygote offers only slight resistance to invasion by the trophoblast, which soon burrows through it ([Fig. 10-3](#)). The embryo or fetus in an ectopic pregnancy is often absent or stunted.

Figure 2-13. The oviduct of an adult woman with cross-sectioned illustrations of the gross structure of the epithelium in several portions: **(A)** isthmus, **(B)** ampulla, and **(C)** infundibulum.

Figure 10-3. Early tubal pregnancy. Amniotic sac (*arrow*) is surrounded by chorionic villi, which in turn are encased in blood clot. (Courtesy of Dr. Richard Voet.)

TUBAL ABORTION. The frequency of tubal abortion depends in part on the implantation site. Abortion is common in ampullary tubal pregnancy, whereas rupture is the usual outcome with isthmic pregnancy. The immediate consequence of hemorrhage is further disruption of the connection between the placenta and membranes and the tubal wall. If placental separation is complete, all of the products of conception may be extruded through the fimbriated end into the peritoneal cavity. At this point, hemorrhage may cease and symptoms eventually disappear. Some bleeding usually persists as long as products remain in the oviduct. Blood slowly trickles from the tubal fimbria into the peritoneal cavity and typically pools in the rectouterine cul-de-sac. If the fimbriated extremity is occluded, the fallopian tube may gradually become distended by blood, forming a hematosalpinx.

TUBAL RUPTURE. The invading, expanding products of conception may rupture the oviduct at any of several sites. Before sophisticated methods to measure chorionic gonadotropin were available, many cases of tubal pregnancy ended in rupture during the first trimester. As a rule, whenever there is tubal rupture in the first few weeks, the pregnancy is situated in the isthmic portion of the tube. When the fertilized ovum is implanted well within the interstitial portion, rupture usually occurs later. Rupture is usually spontaneous, but it may be caused by trauma associated with coitus or bimanual examination.

With intraperitoneal rupture, the entire conceptus may be extruded from the tube, or if the rent is small, profuse hemorrhage may occur without extrusion. In either event, the woman commonly shows signs of hypovolemia. If an early conceptus is expelled essentially undamaged into the peritoneal cavity, it may reimplant almost anywhere, establish adequate circulation, survive, and grow. This, however, occurs rarely. Most small conceptuses are resorbed. Occasionally, if larger, they may remain in the cul-de-sac for years as an encapsulated mass, or even become calcified to form a *lithopedion* ([Fig. 10-4](#)).

Abdominal Pregnancy. If only the fetus is extruded at the time of rupture, the effect on the pregnancy will vary, depending on the extent of injury sustained by the placenta. The fetus dies if the placenta is damaged appreciably, but if the greater portion of the placenta retains its tubal attachment, further development is possible. The fetus may then survive for some time, giving rise to an abdominal pregnancy. Typically in such cases, a portion of the placenta remains attached to the tubal wall and the periphery grows beyond the tube and implants on surrounding structures.

Broad-Ligament Pregnancy. When original zygote implantation is toward the mesosalpinx, rupture may occur at the portion of the tube not immediately covered by peritoneum. The gestational contents may be extruded into a space formed between the folds of the broad ligament and then become an intraligamentous or broad-ligament pregnancy.

Interstitial Pregnancy. Implantation within the tubal segment that penetrates the uterine wall results in an interstitial or cornual pregnancy (Fig. 10-5). These account for about 3 percent of all tubal gestations. Although rupture may not occur until up to 16 weeks, all 32 cases reported to the Society of Reproductive Surgeons were diagnosed before 12 weeks (Tulandi and A1-Jaroudi, 2004). Because the implantation site is located between the ovarian and uterine arteries, there is severe hemorrhage. Many fatal ectopic pregnancies are interstitial implantations (Dorfman and associates, 1984). Moon and colleagues (2000) and Tulandi and A1-Jaroudi (2004) described a total of 56 women with an interstitial pregnancy treated with uterus-sparing laparoscopic surgery or methotrexate. Katz and colleagues (2003) used a combined hysteroscopic and laparoscopic approach to successfully treat two such cases.

Figure 10-4. Abdominal radiograph of a 78-year-old woman demonstrating a lithopedion. (From Berman and Katsiyannis, 2001, with permission.)

Figure 10-5. Right interstitial tubal pregnancy. Fetus weighed 55 g and measured 90 mm crown to rump (14 to 15 weeks' gestational age). Note abundant decidua (arrow) filling the uterine cavity. The patient sought medical help because of sudden severe abdominal pain with syncope following intercourse. Hysterectomy and 2000 mL blood transfusion were necessary.

MULTIFETAL ECTOPIC PREGNANCY

Heterotypic Ectopic Pregnancy. Tubal pregnancy may be accompanied by a coexisting uterine gestation. Until recently, such heterotypic pregnancies were rare, with an incidence of 1 per 30,000 pregnancies. Currently, because of assisted reproduction, the incidence is likely 1 in 7000 overall, and following ovulation induction it may be as high as 1 in 900 (Glassner and associates, 1990). In vitro fertilization and embryo transfer also increase its incidence (Dimitry and colleagues, 1990; Marcus and associates, 1995).

A heterotypic pregnancy is more likely, and should be considered:

1. After assisted reproductive techniques.
2. With persistent or rising chorionic gonadotropin levels after dilatation and curettage for an induced or spontaneous abortion.
3. When the uterine fundus is larger than menstrual dates.
4. With more than one corpus luteum.
5. With absence of vaginal bleeding in the presence of signs and symptoms of an ectopic pregnancy.
6. When there is ultrasonographic evidence of uterine and extrauterine pregnancy (Kouyoumdjian and Kirkpatrick, 1990; Nugent, 1992).

Multifetal Tubal Pregnancy. Twin tubal pregnancy has been reported with both embryos in the same tube, as well as with one in each tube (Rolle and colleagues, 2004).

TUBO-UTERINE, TUBO-ABDOMINAL, AND TUBO-OVARIAN PREGNANCIES.

These various forms of ectopic pregnancy are very uncommon. A tubo-uterine pregnancy results from the gradual extension into the uterine cavity of products of conception that originally implanted in the interstitial portion of the tube. Tubo-abdominal pregnancy is derived from a tubal pregnancy in which the zygote, originally implanted near the fimbriated end of the tube, gradually extends into the peritoneal cavity. A tubo-ovarian pregnancy occurs when the fetal sac is adherent partly to tubal and partly to ovarian tissue. Such cases arise from zygote development in a tubo-ovarian cyst or in a tube, the fimbriated extremity of which was adherent to the ovary during or soon after fertilization.

CLINICAL FEATURES OF ECTOPIC PREGNANCY

Clinical manifestations of a tubal pregnancy are diverse and depend on whether rupture has occurred. Earlier presentation and more precise diagnostic technology have enabled identification before rupture in most cases. Usually, the woman does not suspect pregnancy, or thinks that she has a normal pregnancy, or that she is having a miscarriage. **In contemporary practice, symptoms and signs of ectopic pregnancy are often subtle or even absent.**

In what used to be considered "classical" cases, normal menstruation is replaced by variably delayed slight vaginal bleeding, or "spotting." With rupture, the woman suddenly is stricken with severe lower abdominal pain, frequently described as sharp, stabbing, or tearing in character. Vasomotor disturbances develop, ranging from vertigo to syncope. There is tenderness on abdominal palpation, and bimanual pelvic examination, especially cervical motion, causes exquisite pain. The posterior vaginal fornix may bulge because of blood in the cul-de-sac, or a tender, boggy mass may be felt to one side of the uterus. Symptoms of diaphragmatic irritation, characterized by pain in the neck or shoulder, especially on inspiration, develop in perhaps 50

percent of women with sizable intraperitoneal hemorrhage.

SYMPTOMS AND SIGNS. Because of earlier diagnosis, the presenting symptoms and physical findings in the woman with an ectopic pregnancy have changed markedly over the past two decades.

Pain. The most frequently experienced symptoms of ectopic pregnancy are pelvic and abdominal pain (95 percent) and amenorrhea with some degree of vaginal spotting or bleeding (60 to 80 percent). With more advanced gestation, Dorfman and associates (1984) reported that gastrointestinal symptoms (80 percent) and dizziness or light-headedness (58 percent) were common. With rupture, pain may be anywhere in the abdomen.

Abnormal Menstruation. Most women experience amenorrhea, however one fourth do not— they mistake the uterine bleeding that frequently occurs with tubal pregnancy for true menstruation. Although profuse vaginal bleeding is suggestive of an incomplete abortion rather than an ectopic gestation, such bleeding occasionally is seen with tubal gestations.

Abdominal and Pelvic Tenderness. Exquisite tenderness on abdominal and vaginal examination, especially on motion of the cervix, is demonstrable in over three fourths of women with ruptured or rupturing tubal pregnancies. Such tenderness, however, may be absent prior to rupture.

Uterine Changes. The uterus may be pushed to one side by an ectopic mass, or if the broad ligament is filled with blood, the uterus may be greatly displaced. In 25 percent of women, the uterus enlarges due to hormonal stimulation of pregnancy (Stabile and Grudzinskas, 1990). The degree to which the endometrium is converted to decidua in the presence of ectopic pregnancy is variable. The finding of uterine decidua without trophoblast suggests ectopic pregnancy but not absolutely, and absence of decidual tissue does not exclude it. Uterine decidual casts are passed by only 5 to 10 percent of women. Their passage may be accompanied by cramps similar to those occurring with a spontaneous abortion.

Blood Pressure and Pulse. Before rupture, vital signs generally are normal. Early responses to moderate hemorrhage range from no change in vital signs to a slight rise in blood pressure, or a vasovagal response with bradycardia and hypotension. Birkhahn and colleagues (2003) noted that in 25 women with ruptured ectopic pregnancy, the majority on presentation had a heart rate of less than 100 beats per minute and a systolic blood pressure greater than 100 mm Hg. Blood pressure will fall and pulse will rise only if bleeding continues and hypovolemia becomes significant. Stabile and Grudzinskas (1990) reviewed several reports totaling almost 2400 women with surgically confirmed ectopic pregnancy. Almost one fourth presented in shock, with a range of from 1 to 50 percent in various series.

Pelvic Mass. On bimanual examination, a pelvic mass, ranging in size from 5 to 15 cm, is palpable in about 20 percent of women. The mass is almost always either posterior or lateral to the uterus, and typically is soft and elastic. With extensive infiltration of blood into the tubal wall, however, the mass may be firm. Pain and tenderness often preclude identification of the mass by palpation. Overzealous and unnecessary bimanual examinations should be avoided so as to avert iatrogenic rupture.

Culdocentesis. This simple technique is used to identify hemoperitoneum. The cervix is pulled toward the symphysis with a tenaculum, and a long 16- or 18-gauge needle is inserted through the posterior fornix into the cul-de-sac. If present, fluid can be aspirated, however, failure to do so is interpreted only as unsatisfactory entry into the cul-de-sac and does not exclude an ectopic pregnancy, either ruptured or unruptured. Fluid containing fragments of old clots, or bloody fluid that does not clot, is compatible with the diagnosis of hemoperitoneum resulting from an ectopic pregnancy. If the blood subsequently clots, it may have been obtained from an adjacent blood vessel rather than from a bleeding ectopic pregnancy.

LABORATORY TESTS

Hemogram. After hemorrhage, depleted blood volume is restored toward normal by hemodilution over the course of a day or longer. Even after substantive hemorrhage, hemoglobin or hematocrit readings may at first show only a slight reduction. Hence, after an acute hemorrhage, a decrease in hemoglobin or hematocrit level over several hours is a more valuable index of blood loss than is the initial reading. In about half of women with ruptured ectopic pregnancies, varying degrees of leukocytosis up to 30,000/ μ L may be documented.

Chorionic Gonadotropin Assays. Ectopic pregnancy cannot be diagnosed by a positive pregnancy test alone. The key issue, however, is whether the woman is pregnant. Current serum and urine pregnancy tests that use enzyme-linked immunosorbent assays (ELISAs) are sensitive to levels of chorionic gonadotropin of 10 to 20 mIU/mL, and are positive in over 99 percent of ectopic pregnancies (Kalinski and Guss, 2002; Olshaker, 1996).

Serum Progesterone Levels. A single progesterone measurement can be used to establish that there is a normally developing pregnancy with high reliability. A value exceeding 25 ng/mL excludes ectopic pregnancy with 97.5-percent sensitivity (Lipscomb and co-workers, 1999a; Pisarska and colleagues, 1998). Values below 5 ng/mL occur in only 0.3 percent of normal pregnancies (Mol and colleagues, 1998). Thus, values this low suggest either an intrauterine pregnancy with a dead fetus or an ectopic pregnancy. In many cases, however, progesterone levels range from 5 to 25 ng/mL and are inconclusive (McCord and colleagues, 1996).

ULTRASOUND IMAGING. Ultrasonic imaging is indispensable to confirm the clinical diagnosis of suspected ectopic gestation, its size, and its location.

Abdominal Sonography. Identification of pregnancy products in the fallopian tube is difficult using abdominal sonography. If a gestational sac is clearly identified within the uterine cavity, ectopic pregnancy rarely coexists. Moreover, with sonographic absence of a uterine pregnancy, a positive pregnancy test result, fluid in the cul-de-sac, and an abnormal pelvic mass, ectopic pregnancy is almost certain (Romero and associates, 1988). Unfortunately, ultrasonic findings suggestive of early uterine pregnancy may be apparent in some cases of ectopic pregnancy. A small sac suggestive of a very early pregnancy or a collapsed sac suggesting a dead fetus may actually be a blood clot or decidual cast (Coleman and colleagues, 1985). A uterine pregnancy usually is not recognized using abdominal ultrasound until 5 to 6 menstrual weeks or 28 days after timed ovulation (Batzer and co-workers, 1983). Conversely, demonstration of an adnexal or cul-de-sac mass by sonography is not necessarily

helpful. Corpus luteum cysts and matted bowel can have the sonographic appearance of tubal pregnancies. Fetal heart action clearly outside the uterine cavity provides firm evidence of an ectopic pregnancy.

Vaginal Sonography. There has been much improvement in the early diagnosis of ectopic pregnancy using vaginal sonography. Its use results in earlier and more specific diagnoses of uterine pregnancy than abdominal sonography, and it has become the imaging method of choice in early pregnancy. Using a vaginal transducer allows ultrasonic detection of a uterine gestation as early as 1 week after missed menses. When serum chorionic gonadotropin (β -hCG) levels exceed 1000 mIU/mL, a gestational sac is seen half the time (De Cherney and Eichhorn, 1996). Criteria include identification of a 1- to 3-mm or larger gestational sac, eccentrically placed in the uterus, and surrounded by a decidual-chorionic reaction. A fetal pole within the sac is diagnostic, especially when accompanied by fetal heart action.

Vaginal sonography also is used to detect adnexal masses. An ectopic pregnancy may be missed, however, when a tubal mass is small or obscured by bowel (Cacciatore and colleagues, 1990). The reported sensitivity of vaginal sonography for the diagnosis of ectopic pregnancy ranges widely, from only 20 percent to as high as 80 percent (Brown and Doubilet, 1994). Fluid seen in the cul-de-sac increases the likely diagnosis of ectopic pregnancy, and depending on the amount, this likelihood may exceed 50 percent if the fluid is echogenic (Dart and colleagues, 2002).

DIAGNOSIS OF ECTOPIC PREGNANCY

MULTI-MODALITY DIAGNOSIS. During the past three decades, as methods of identifying ectopic pregnancy have evolved and been refined, the majority of ectopic pregnancies—perhaps 80 percent—are diagnosed before rupture. Concurrent with this evolution, the death rate from ectopic pregnancy has decreased appreciably (see [Fig. 10-2](#)).

Several algorithms for the diagnosis of ectopic pregnancy have been proposed (Barnhart, 1994, 1999; Kaplan, 1996; McCord, 1996; Stovall, 1989, 1990, 1992, and all their colleagues). All use five key components:

1. Vaginal sonography.
2. Serum β -hCG—both the initial level and the pattern of subsequent rise or decline.
3. Serum progesterone.
4. Uterine curettage.
5. Laparoscopy and, less frequently, laparotomy.

All diagnostic strategies for the unruptured ectopic pregnancy involve trade-offs. For example, strategies that maximize detection of ectopic pregnancy may result in the interruption of one normal pregnancy for every 100 women evaluated. Conversely, those that reduce the potential for interruption of a normal uterine pregnancy will miss more ectopic pregnancies (Gracia and Barnhart, 2001). Those that do not employ curettage result in unnecessary medical or surgical therapy for ectopic pregnancy (Barnhart and colleagues, 2002).

The choice of diagnostic algorithm applies only to hemodynamically stable women; those with presumed rupture should undergo prompt surgical therapy. In a woman in whom ectopic pregnancy is suspected because of pain, bleeding, and a positive pregnancy test, performance of vaginal sonography is a logical first step. If a live uterine gestation is present, ectopic pregnancy is extremely unlikely. A heterotypic pregnancy is, of course, the rare exception (Hirsch and associates, 1992). Alternatively, if the uterus is empty, an ectopic pregnancy can be diagnosed based on visualization of an adnexal mass separate from the ovaries ([Fig. 10-6](#)).

In the event of a nondiagnostic study, subsequent management can be based on serial serum β -hCG values and repeat vaginal sonography. A number of investigators have described *discriminatory β -hCG levels* (Bateman, 1990; Cacciatore, 1990; Fossum, 1988; Goldstein, 1988; Nyberg, 1987, and all their associates). Above these levels, failure to visualize a uterine pregnancy by transvaginal ultrasound indicates with high reliability that the pregnancy is either ectopic or nonviable. In a study by Barnhart and colleagues (1994), an empty uterus with a serum β -hCG concentration of 1500 mIU/mL or higher was 100-percent accurate in excluding a live uterine pregnancy. Thus, if the initial β -hCG exceeds the discriminatory level, and no live intrauterine pregnancy is identified by vaginal sonography, the differential diagnosis is narrowed to a uterine pregnancy with a dead fetus versus an ectopic pregnancy. Early multifetal gestation, of course, remains a possibility. Uterine curettage will distinguish an ectopic from a nonliving uterine pregnancy. If an embryo, fetus, or placenta is identified, the diagnosis is apparent. When none of these is identified, tubal pregnancy is a probability.

If the initial β -hCG level is below the discriminatory value, early uterine pregnancy is a possibility, and serial assays of β -hCG, in conjunction with repeat vaginal sonography, may prove useful. Kadar and Romero (1987) confirmed earlier work and demonstrated that in women with normal pregnancies, mean doubling time for β -hCG in serum was approximately 48 hours, and the lowest normal value for this increase was 66 percent ([Table 10-2](#)). In a series of 287 pregnant women, Barnhart and co-workers more recently (2004) reported a somewhat lower 48-hour minimum rise for a live intrauterine pregnancy of 53 percent, and a 24-hr minimum rise of 24 percent. Kadar and Romero concluded that failure to maintain this minimum rate of increased β -hCG production, along with an empty uterus, was suggestive of an ectopic pregnancy. Thus, appropriately selected women in whom ectopic pregnancy is suspected, but whose initial β -hCG is below the discriminatory level, may be followed expectantly. They are seen at 2- to 3-day intervals for further evaluation. If the β -hCG level rises inappropriately, plateaus, or exceeds the discriminatory level without evidence of a uterine pregnancy by vaginal sonography, a live uterine pregnancy can be excluded. Then, distinction between nonliving uterine versus an ectopic pregnancy is made by uterine curettage, or in some cases, by endometrial biopsy. Barnhart and associates (2003) reported that biopsy was less sensitive than curettage.

A single measurement of serum progesterone may clarify the diagnosis when ectopic pregnancy is suspected (McCord and colleagues, 1996; Stovall and associates, 1989, 1992). Its accuracy is crude, and customary thresholds of less than 5 ng/mL

and greater than 25 ng/mL neither absolutely refute nor confirm a living uterine pregnancy. Moreover, the capacity to expeditiously measure serum progesterone is not available at all institutions. Another pitfall is that pregnancy using assisted reproductive techniques may be associated with higher than usual serum progesterone levels (Perkins and associates, 2000). This being said, serum levels of at least 25 ng/mL after spontaneous conception provide reassurance that an ectopic pregnancy is *unlikely*. This finding may negate the need for vaginal sonography. Buckley and colleagues (2000), however, reported that serum progesterone was conclusive in only one fourth of women undergoing evaluation for ectopic pregnancy.

Figure 10-6. Vaginal sonogram of an ectopic pregnancy. **A.** The uterus (Ut) is seen with a normal endometrial stripe (ES). A small amount of free fluid (FF) is visible in the posterior cul-de-sac. **B.** The tubal ectopic pregnancy (EP) with its yolk sac (YS) is seen along with a corpus luteum (CL) cyst. SURGICAL DIAGNOSIS

Laparoscopy. Direct visualization of the fallopian tubes and pelvis by diagnostic laparoscopy offers a reliable diagnosis in most cases of suspected ectopic pregnancy, and a ready transition to definitive operative therapy. Compared with laparotomy, laparoscopy is more cost-effective, and there is a shorter postoperative recovery (Gray and colleagues, 1995).

At times, identification of an early unruptured tubal pregnancy may be difficult, even if the tube is fully visualized. In spite of the low morbidity and quick recovery time, laparoscopy is not without risks or cost. Thus laparoscopy usually is performed when, on the basis of noninvasive test or curettage results, the diagnosis of ectopic pregnancy is fairly certain and medical therapy is not planned.

Laparotomy. Open abdominal surgery is preferred when the woman is hemodynamically unstable, or when laparoscopy is not feasible. Laparotomy should not be delayed while laparoscopy is performed in a woman with obvious abdominal hemorrhage that requires immediate definitive treatment.

TREATMENT AND PROGNOSIS

Over the past two decades, earlier diagnosis and treatment have allowed definitive management of unruptured ectopic pregnancy even before the onset of symptoms. Importantly, early diagnosis, although contributing to a higher incidence, has made many cases of ectopic pregnancy amenable to medical therapy, which is more cost-effective than surgical therapy (Alexander and associates, 1996; Morlock and colleagues, 2000).

ANTI-D IMMUNOGLOBULIN. D-negative women with an ectopic pregnancy who are not sensitized to D-antigen should be given anti-D immunoglobulin.

SURGICAL MANAGEMENT. Higher subsequent pregnancy and lower recurrent ectopic pregnancy rates are observed in women in whom surgery is performed prior to rupture. Laparoscopy is preferred over laparotomy unless the woman is unstable (Tulandi and Saleh, 1999). Even though reproductive outcome is similar, including rates of uterine and recurrent ectopic pregnancies, laparoscopy is more cost-effective and has a shorter recovery time—1.3 versus 3.1 days (Tay and colleagues, 2000).

Tubal surgery for ectopic pregnancy is considered *conservative* when there is tubal salvage. Examples include salpingostomy, salpingotomy, and fimbrial expression of the ectopic pregnancy. *Radical surgery* is defined by salpingectomy. Conservative therapy may increase the subsequent rate of uterine pregnancy at the expense, however, of higher rates of persistently functioning trophoblast (Bangsgaard and colleagues, 2003).

Salpingostomy. This procedure is used to remove a small pregnancy that is usually less than 2 cm in length and located in the distal third of the fallopian tube (Fig. 10-7). A linear incision, 10 to 15 mm in length or less, is made on the antimesenteric border immediately over the ectopic pregnancy. The products usually will extrude from the incision and can be carefully removed or flushed out. Small bleeding sites are controlled with needlepoint electrocautery or laser, and the incision is left unsutured to heal by secondary intention. This procedure is readily performed through a laparoscope.

Salpingotomy. Seldom performed today, salpingotomy is essentially the same procedure as salpingostomy except that the incision is closed with 7-0 Vicryl or similar suture. According to Tulandi and Saleh (1999), there is no difference in prognosis with or without suturing.

Salpingectomy. Tubal resection can be performed through an operative laparoscope and may be used for both ruptured and unruptured ectopic pregnancies. When removing the oviduct, it is advisable to excise a wedge of the outer third (or less) of the interstitial portion of the tube. This so-called *cornual resection* is done in an effort to minimize the rare recurrence of pregnancy in the tubal stump. Even with cornual resection, however, a subsequent interstitial pregnancy may not be prevented (Kalchman and Meltzer, 1966).

Segmental Resection and Anastomosis. Resection of the ectopic mass and tubal reanastomosis is sometimes used for an unruptured isthmic pregnancy because salpingostomy may cause scarring and subsequent narrowing of the small isthmic lumen (Stangel and associates, 1976).

Persistent Trophoblast. Following salpingostomy, serum β -hCG levels usually fall quickly and are at about 10 percent of preoperative values by day 12 (Hajenius and colleagues, 1995; Vermesh and associates, 1988). Persistent ectopic pregnancy

is the result of incomplete removal of trophoblast and complicates 5 to 20 percent of salpingostomies (Graczykowski and Mishell, 1997). If the postoperative day 1 serum β -hCG value is less than 50 percent of the preoperative value, then persistent ectopic trophoblast rarely is a problem (Spandorfer and co-workers, 1997). According to Seifer (1997), factors that increase the risk of persistent ectopic pregnancy include:

1. Small pregnancies, viz., less than 2 cm.
2. Early therapy, viz., before 42 menstrual days.
3. β -hCG serum levels exceeding 3000 mIU/mL.
4. Implantation medial to the salpingostomy site.

In the face of persistent or increasing β -hCG, additional surgical or medical therapy is necessary.

Figure 10-7. Linear salpingostomy for ectopic pregnancy. **A.** Linear incision for removal of a small tubal pregnancy in the distal third of the fallopian tube. **B.** Hemostasis is by cautery or laser, and the incision is not sutured. If the incision is closed, the procedure is termed a *salpingotomy*.

MEDICAL MANAGEMENT

Systemic Methotrexate. This antineoplastic drug acts as a folic acid antagonist and is highly effective against rapidly proliferating trophoblast (see [Chap. 11](#), p. 282). Tanaka and associates (1982) were first to recommend use of methotrexate for an ectopic interstitial pregnancy. Since then, there have been numerous reports describing successful treatment of all varieties of ectopic pregnancy using a number of methotrexate regimens. In the largest single-center series, Lipscomb and colleagues (1999a) reported a 91-percent success rate in 350 women given methotrexate therapy. Of these, 283 women were given a single dose of methotrexate, 60 women received two doses, six women, three doses, and one woman, four doses.

Active intra-abdominal hemorrhage is a contraindication to chemotherapy. The size of the ectopic mass is also important, and Pisarska and colleagues (1998) recommend that methotrexate not be used if the pregnancy is more than 4 cm. Success is greatest if the gestation is less than 6 weeks, the tubal mass is not more than 3.5 cm in diameter, the fetus is dead, and the β -hCG is less than 15,000 mIU/mL (Lipscomb and colleagues, 1999a; Stovall, 1995). According to the American College of Obstetricians and Gynecologists (1998), contraindications include breast feeding, immunodeficiency, alcoholism, liver or renal disease, blood dyscrasias, active pulmonary disease, and peptic ulcer.

PATIENT SELECTION. Candidates for methotrexate therapy must be hemodynamically stable. They are instructed that:

1. Medical therapy fails in at least 5 to 10 percent of cases, and this rate is higher in pregnancies past 6 weeks' gestation or with a tubal mass greater than 4 cm in diameter.
2. Failure of medical therapy requires retreatment, either medically or with elective surgery. If tubal rupture occurs \mathfrak{R} — a 5- to 10-percent chance \mathfrak{R} — emergency surgery is necessary.
3. If the woman is treated as an outpatient, rapid transportation must be reliably available.
4. Signs and symptoms of tubal rupture such as vaginal bleeding, abdominal and pleuritic pain, weakness, dizziness, or syncope must be reported promptly.
5. Until the ectopic pregnancy is resolved, sexual intercourse is prohibited, alcohol avoided, and folic acid supplements \mathfrak{R} — including prenatal vitamins \mathfrak{R} — should not be taken.

DOSE AND ADMINISTRATION. The two general schemes used for methotrexate administration for ectopic pregnancy are shown in [Table 10-3](#). Although single-dose treatment is easier to administer and monitor than variable-dose methotrexate therapy, it is associated with a higher failure rate, defined as persistent ectopic pregnancy ([Table 10-4](#)). In most studies, the methotrexate dose was 50 mg/m².

MONITORING TOXICITY. Most regimens are associated with minimal laboratory changes and symptoms, although toxicity may be severe. Kooi and Kock (1992) reviewed 16 studies that reported side effects. All adverse effects were resolved by 3 to 4 days after methotrexate was discontinued. The most common were liver involvement (12 percent), stomatitis (6 percent), and gastroenteritis (1 percent). One woman had bone marrow depression. Case reports also describe life-threatening neutropenia and fever, transient drug-induced pneumonitis, and alopecia (Buster and Pisarska, 1999).

MONITORING EFFICACY OF THERAPY. Serum β -hCG levels are the most widely used marker to monitor response to both medical and surgical therapy. Saraj and colleagues (1998) reported serum β -hCG data for women enrolled in their randomized trial. After linear salpingostomy, serum β -hCG levels declined rapidly over days and then more gradually, with a mean resolution time of 20 days. In contrast, after a single intramuscular injection of methotrexate, mean serum β -hCG levels **rose** for the first 4 days, and then gradually declined, with a mean resolution time of 27 days ([Fig. 10-8](#)). Lipscomb and colleagues (1998) treated 287 women successfully with methotrexate and found the average time to resolution, defined as serum hCG level less than 15 mIU/mL, was 34 days. The longest time was 109 days.

As shown in [Table 10-3](#), monitoring single-dose therapy calls for serum β -hCG determinations at 4 and 7 days. With variable-

dose methotrexate, levels are measured at 48-hour intervals until they fall more than 15 percent. After successful treatment, weekly serum β -hCG determinations are measured until undetectable. Outpatient surveillance is preferred, but if there is any question of safety or compliance, the woman is hospitalized. Failure is judged when the β -hCG level plateaus or rises or tubal rupture occurs. Tubal rupture can occur in the face of declining β -hCG levels.

PERSISTENT ECTOPIC PREGNANCY. Conservative therapy carries with it the risk of initial treatment failure, which requires either additional methotrexate therapy or surgical removal. In three randomized trials, 5 to 14 percent of women treated initially with systemic methotrexate ultimately required surgery, whereas 4 to 20 percent of those treated with laparoscopy eventually received methotrexate for persistent trophoblast (Fernandez, 1998; Hajenius, 1997; Saraj, 1998, and their associates).

An important observation is that 65 to 75 percent of women initially given methotrexate will have increasing pain beginning several days after therapy. This *separation pain* generally is mild and relieved by nonnarcotic analgesics. In a series of 258 women treated with single-dose methotrexate, 53 (20 percent) had pain severe enough to require evaluation in the clinic or emergency room. Ultimately, 10 of these 53 underwent surgical exploration (Lipscomb and colleagues, 1999b). In women with worrisome pain after medical treatment for ectopic pregnancy, careful clinical observation \mathcal{R} — as an inpatient, if necessary \mathcal{R} — is warranted. Assessment of serial hematocrits and serum β -hCG levels coupled with vaginal sonography can be used to identify those who require surgical intervention.

Rupture of persistent ectopic pregnancy is the most catastrophic form of primary therapy failure. Its incidence is 5 to 10 percent in women initially treated medically. Lipscomb and associates (1998) described a 14-day mean time to rupture, but one woman had tubal rupture 32 days after single-dose methotrexate therapy.

Figure 10-8. Comparative pattern of resolution of serum human chorionic gonadotropin (β -hCG) levels after laparoscopic salpingostomy (LSC) and single-dose methotrexate (MTX) treatment of unruptured ectopic pregnancy. (From Saraj and colleagues, 1998, with permission.)

OTHER TREATMENTS

Direct Injection. Various cytotoxic drugs have been injected directly into the ectopic mass, either by laparoscopy or transvaginally by culdocentesis. However, because of the relative effectiveness of systemic therapy for ectopic pregnancy, its ease of delivery, and widespread experience, direct injection is infrequently employed.

Oral Methotrexate Therapy. Recently Lipscomb and colleagues (2002) evaluated oral methotrexate for the treatment of ectopic pregnancy in two divided doses 2 hours apart for a total dose of 60 mg/m^2 . They reported that the oral medication had a lower success rate and a greater necessity for repeated dosing compared with the single-dose intramuscular regimen.

Expectant Management. Some practitioners choose to observe very early tubal pregnancies that are associated with stable or falling serum β -hCG levels. As many as one third of women with ectopic pregnancies will present with declining β -hCG levels (Shalev and colleagues, 1995). Stovall and Ling (1992) restrict expectant management to women with these criteria:

1. Decreasing serial β -hCG levels.
2. Tubal pregnancies only.
3. No evidence of intra-abdominal bleeding or rupture as assessed by vaginal sonography.
4. Diameter of the ectopic mass not greater than 3.5 cm.

Trio and colleagues (1995) reported spontaneous resolution of ectopic pregnancy in 49 of 67 selected women (73 percent) treated expectantly. Resolution without treatment was more likely if the initial serum β -hCG level was less than 1000 mIU/mL. In another study of 60 women managed expectantly, Shalev and associates (1995) reported spontaneous resolution in 28 (48 percent). **The potentially grave consequences of tubal rupture, coupled with the established safety of medical and surgical therapy, require that expectant therapy be undertaken only in appropriately selected and counseled women.**

ABDOMINAL PREGNANCY

Almost all cases of abdominal pregnancy follow early rupture or abortion of a tubal pregnancy into the peritoneal cavity. The Centers for Disease Control and Prevention estimated that the incidence of abdominal pregnancy is 1 in 10,000 live births (Atrash and co-workers, 1987). At Parkland Hospital, where ectopic pregnancy is common, advanced abdominal pregnancy is rare and encountered in perhaps 1 in 25,000 births. Risk factors for abdominal pregnancy are the same as for ectopic pregnancy in general.

Typically, the growing placenta, after penetrating the oviduct wall, maintains its tubal attachment but gradually encroaches upon and implants in the neighboring serosa. Meanwhile, the fetus continues to grow within the peritoneal cavity. Occasionally, the placenta is found in the general region of the oviduct and over the posterior aspect of the broad ligament and uterus (Fig. 10-9). In other cases, after tubal rupture, the conceptus reimplants elsewhere in the peritoneal cavity.

Figure 10-9. Abdominal pregnancy at term. The placenta is implanted on the posterior wall of the uterus and broad ligament. The enlarged, flattened uterus is

located just beneath the anterior abdominal wall. The cervix and vagina are dislodged anteriorly and superiorly by the large fetal head in the cul-de-sac.

DIAGNOSIS. Because early rupture or abortion of a tubal pregnancy is the usual antecedent of an abdominal pregnancy, in retrospect, a suggestive history can usually be obtained. These include spotting or irregular bleeding along with abdominal pain that usually was most prominent in one or both lower quadrants (Costa and associates, 1991). Women with an established abdominal pregnancy are likely to be uncomfortable but not sufficiently so to warrant thorough evaluation. Nausea, vomiting, flatulence, constipation, diarrhea, and abdominal pain may each be present in varying degrees. Multiparas may state that the pregnancy does not "feel right." Late in pregnancy, fetal movements may cause pain.

Abnormal fetal positions frequently can be palpated, but the ease of palpating fetal parts is not a reliable sign. Fetal parts sometimes feel exceedingly close to the examining fingers even in normal pregnancies, especially in thin, multiparous women. As depicted in [Figure 10-9](#), the cervix is usually displaced, depending in part on the fetal position, and it may dilate, but appreciable effacement is unusual. The uterus may be outlined over the lower part of the pregnancy mass. Small parts or the fetal head may occasionally be palpated through the vaginal fornices and identified as clearly outside the uterus.

Laboratory Tests. An unexplained transient anemia early in pregnancy may accompany the initial tubal rupture or abortion. An otherwise unexplained increase in the serum alpha-fetoprotein value sometimes is found (Bombard, 1994; Costa, 1991; el Kareh, 1993; Jackson, 1993, and their associates).

Sonography. Ultrasonic findings with an abdominal pregnancy most often do not allow an unequivocal diagnosis to be made. Oligohydramnios is common but nonspecific. In some suspected cases, however, ultrasound findings may be diagnostic; for example, if the fetal head is seen to lie immediately adjacent to the maternal bladder with no interposed uterine tissue (Kurtz and associates, 1982). Even with ideal conditions, however, a sonographic diagnosis of abdominal pregnancy is missed in half of cases (Costa and associates, 1991).

Magnetic Resonance Imaging. This technique can be used to confirm abdominal pregnancy following a suspicious ultrasound examination. It has been described as very accurate and specific by some (Harris and associates, 1988; Wagner and Burchardt, 1995). Even so, in our institutions, abdominal pregnancy has been incorrectly diagnosed as a placenta previa, and an intrauterine pregnancy with degenerating fibroids has been misdiagnosed as an abdominal pregnancy.

Computed Tomography. Costa and associates (1991) maintain that computed tomography is superior to magnetic resonance imaging, but its use is limited because of the concern for fetal radiation. In cases of fetal demise, however, computed tomography may be diagnostic and should be considered (Glew and Sivanesaratnam, 1989).

FETAL OUTCOME. Fetal salvage in an abdominal pregnancy is much the exception rather than the rule, and surviving fetuses may be abnormal. However, in his extensive review of abdominal pregnancies, Stevens (1993) found that survival of infants born after 30 weeks was 63 percent. Moreover, fetal malformations and deformations were only 20 percent. The most common deformations were facial or cranial asymmetry, or both, and various joint abnormalities. The most common malformations were limb deficiency and central nervous system anomalies.

MANAGEMENT. An abdominal pregnancy is life-threatening, and clinical management depends on the gestational age at diagnosis. Some practitioners await fetal viability with in-hospital expectant management if pregnancy is diagnosed after 24 weeks (Cartwright and associates, 1986; Hage and colleagues, 1988). Such management carries a risk for sudden and life-threatening intra-abdominal bleeding. Because of this risk, termination generally is indicated when the diagnosis of abdominal pregnancy is made. In cases where amniotic fluid volume is minimal or absent, and in cases less than 24 weeks, conservative treatment rarely is justified because fetal survival is extremely poor.

The natural history was described in older literature: If the fetus died after reaching a size too large to be resorbed, it would undergo suppuration, mummification, or calcification. If bacteria gained access to the gestational products, particularly when they were adherent to the intestines, this resulted in suppuration. Eventually, the abscess would rupture, and if the woman did not die of peritonitis and septicemia, fetal parts would eventually be extruded through the abdominal wall or more commonly into the intestine or bladder (Emembolu, 1989). In some cases, mummification and lithopedion formation would ensue, and calcified products of conception would be carried for years (see [Fig. 10-4](#)). Much more rarely, the fetus would be converted into a yellowish, greasy mass to which the term *adipocere* is applied.

Surgery for abdominal pregnancy may precipitate torrential hemorrhage due to the lack of constriction of hypertrophied blood vessels after placental separation. Condition permitting, management of presumed abdominal pregnancy is best done in a facility with trauma center capabilities. It is essential to have adequate blood immediately available. Preoperatively, two intravenous infusion systems, each capable of delivering large volumes of fluid at a rapid rate, should be functioning. Techniques for monitoring the adequacy of the circulation should be employed, as described in [Chapter 35](#) (see p. 839). If time allows, a mechanical bowel preparation should be done. For optimal exposure, laparotomy generally is performed through a vertical midline incision. In general, the infant should be delivered, and the cord severed close to the placenta.

Management of the Placenta. Partial placental separation can develop spontaneously or, more likely, in the course of the operation while attempting to locate the exact site of placental attachment. Therefore, it is best to avoid unnecessary exploration of surrounding organs. If it is obvious that the placenta can be safely removed, or if there is already hemorrhage from its implantation site, then removal begins immediately. When possible, blood vessels supplying the placenta should be ligated first.

Often, leaving the placenta in place represents the lesser of two evils. This decreases the chance of immediate life-threatening hemorrhage, but at the expense of long-term sequelae. Unfortunately, when left in the abdominal cavity, the placenta commonly causes infection with abscesses, adhesions, intestinal obstruction, and wound dehiscence (Bergstrom and

colleagues, 1998; Martin and associates, 1988). Partial urethral obstruction with reversible hydronephrosis has been described (Weiss and Stone, 1994). In another report, Piering and colleagues (1993) described persistent preeclampsia for 99 days until the placenta was removed! In these cases, surgical removal becomes inevitable.

If the placenta is left, its involution may be monitored using ultrasound and serum β -hCG levels (France and Jackson, 1980; Martin and McCaul, 1990). We have used color Doppler ultrasound to follow changes in blood flow to the placenta. In some cases, and usually depending on its size, placental function rapidly declines, and the placenta is resorbed. In one case described by Belfar and associates (1986), placental resorption took over 5 years. Methotrexate use is controversial. It has been recommended to hasten involution but may cause accelerated placental destruction with accumulation of necrotic tissue and infection with abscess formation (Rahman and associates, 1982).

Arterial Catheterization and Embolization. Percutaneous femoral artery catheterization and pelvic angiography, followed by embolization of specific bleeding sites, is discussed in [Chapter 35](#) (see p. 836). This has been lifesaving in some instances of massive pelvic hemorrhage (Kivikoski and associates, 1988; Martin and colleagues, 1990). When the diagnosis is made preoperatively, Kerr and associates (1993) advocate transcatheter embolization of major feeder vessels immediately prior to surgical intervention.

Maternal Prognosis. Maternal mortality is increased substantively compared with normal pregnancy. With appropriate preoperative planning, however, maternal mortality has been reduced from approximately 20 percent to less than 5 percent in the past 20 years (Stevens, 1993).

OVARIAN PREGNANCY

Ectopic pregnancy implanted in the ovary is rare. Traditional risk factors for ovarian ectopic pregnancy are similar to those for tubal pregnancy. Use of an intrauterine contraceptive device seems to be disproportionately associated with ovarian pregnancy (Gray and Ruffolo, 1978; Pisarska and Carson, 1999). Although the ovary can accommodate itself more readily than the fallopian tube to the expanding pregnancy, rupture at an early period is the usual consequence. Nonetheless, there are recorded cases in which ovarian pregnancy went to term, and a few infants survived (Williams and associates, 1982).

DIAGNOSIS. Findings are likely to mimic those of a tubal pregnancy or a bleeding corpus luteum. Serious bleeding is seen in about one third of cases. At surgery, early ovarian pregnancies are likely to be considered corpus luteum cysts or a bleeding corpus luteum. Use of vaginal ultrasound has resulted in the more frequent diagnosis of unruptured ovarian pregnancies (Marcus and Brinsden, 1993; Sidek and colleagues, 1994). Such early diagnosis may allow for a medical approach.

MANAGEMENT. The classical management for ovarian pregnancies has been surgical. Early bleeding for small lesions has been managed by ovarian wedge resection or cystectomy (Schwartz and colleagues, 1993). In the presence of larger lesions, ovariectomy is most often performed. Recently, laparoscopy has been used to resect or to perform laser ablation of ovarian pregnancies (Carter and colleagues, 1993; Goldenberg and associates, 1994). Finally, methotrexate has been used successfully to treat unruptured ovarian pregnancies (Chelmow and associates, 1994; Raziell and Golan, 1993; Shamma and Schwartz, 1992).

CERVICAL PREGNANCY

In the past, cervical pregnancy was a rare form of ectopic gestation. Dees (1966) estimated the incidence to be 1 in 18,000 pregnancies. The incidence is increasing as a result of assisted reproduction, especially after in vitro fertilization and embryo transfer (Ginsburg, 1994; Pattinson, 1994; Peleg, 1994, and their associates). According to Pisarska and Carson (1999), prior dilatation and curettage precedes 70 percent of cases.

In a typical case, the endocervix is eroded by trophoblast, and the pregnancy proceeds to develop in the fibrous cervical wall ([Fig. 10-10](#)). The duration of pregnancy depends on the site of implantation. The higher the trophoblast is implanted in the cervical canal, the greater is its capacity to grow and cause hemorrhage.

Painless vaginal bleeding is present in 90 percent of cervical pregnancies, and one third of these have massive hemorrhage (Ushakov and colleagues, 1997). Only one fourth have abdominal pain with bleeding. As pregnancy progresses, a distended, thin-walled cervix with a partially dilated external os may be evident. Above the cervical mass, a slightly enlarged uterine fundus may be palpated. Cervical pregnancy rarely extends beyond 20 weeks and usually is surgically terminated because of bleeding. Identification of cervical pregnancy is based on a high degree of clinical suspicion coupled with sonography (Frates and colleagues, 1994; Kligman and associates, 1995). Findings include an empty uterus and a gestation filling the cervical canal ([Fig. 10-11](#)). Magnetic resonance imaging can be used to confirm the diagnosis (Bader-Armstrong and associates, 1989; Rafal and co-workers, 1990).

Figure 10-10. Cervical pregnancy in situ removed by hysterectomy nearly 3 months after the last normal menstrual period and 1 month after onset of vaginal bleeding. (Courtesy of Drs. D. Rubell and A. Brekken.)

Figure 10-11. Sonogram showing longitudinal view of an 11-week cervical pregnancy. (From Eblen and colleagues, 1999, with permission.)

SURGICAL MANAGEMENT. In the past, hysterectomy was often the only choice available because of profuse hemorrhage that accompanied attempts at removal of the cervical pregnancy. With hysterectomy, the risk of urinary tract injury is increased because of the enlarged barrel-shaped cervix. To avoid the morbidity of surgery, and in some cases to preserve fertility, other approaches have been developed.

Cerclage. Bernstein and associates (1981) and Bachus and colleagues (1990) successfully managed cervical pregnancy by placing a heavy silk ligature around the cervix, similar to a McDonald cerclage (see [Chap. 9](#), p. 238). More recently, Mashiach and colleagues (2002) described the successful management and resolution of four cervical pregnancies using a Shirodkar cerclage. In one of these cases, a concurrent uterine pregnancy progressed to term and a healthy infant was delivered vaginally.

Curettage and Tamponade. Nolan and associates (1989) and Thomas and co-workers (1991) recommend placement of hemostatic cervical sutures at 3 and 9 o'clock. Suction curettage is then performed, followed immediately by insertion of a Foley catheter into the cervical canal. The 30-mL catheter bulb is inflated, and the vagina is packed tightly with gauze to further tamponade bleeding. A suction catheter tip may be left above the vaginal packing to ensure adequate drainage and to monitor blood loss.

Arterial Embolization. Successful selective preoperative uterine artery embolization using Gelfoam has been described by Lobel and colleagues (1990), Saliken and co-workers (1994), and others. This technique, detailed in [Chapter 35](#) (see p. 836), also has been used successfully to control bleeding after medical therapy (Cosin and associates, 1997; Wong and colleagues, 1999). Kung and colleagues (2004) employed a combination of laparoscopically assisted uterine artery ligation followed by hysteroscopic endocervical resection to successfully treat six cervical pregnancies.

MEDICAL MANAGEMENT. To avoid the risks of uncontrolled hemorrhage, methotrexate and other drug treatments have been used successfully for treatment of cervical pregnancies. In many centers, including ours, chemotherapy is now the first line of therapy in the stable woman. The general guidelines for methotrexate use for ectopic pregnancy are as described earlier (see p. 263). The drug has been injected directly into the gestational sac, with or without potassium chloride to induce fetal death. It has been given systemically in single high-dose therapy with folinic acid rescue, in lower-dose prolonged courses, and as a single low-dose regimen. It also has been given in various combinations, for example, intra-amnionically, after failure of systemic therapy (Kaplan, 1990; Marcovici, 1994; Roussis, 1992; Timor-Tritsch, 1994; Wong, 1999, and their colleagues).

Pregnancies of more than 6 weeks' duration generally require induction of fetal death with potassium chloride or high-dose and prolonged methotrexate therapy. Kung and Chang (1999) reviewed 62 methotrexate-treated cases. The 35 women in whom the fetus was alive had a higher failure rate with single-dose methotrexate. Almost half of these required a surgical procedure compared with 4 percent in the group with a dead fetus.

OTHER SITES OF ECTOPIC PREGNANCY

Primary *splenic pregnancy* was reported by Mankodi and associates (1977). A similar case was reported by Cormio and associates (2003). A few cases of primary *hepatic pregnancy* have been described, including one with a lithopedion (Barbosa Junior Ade A and associates, 1991; Borlum and Blom, 1988; Schlatter and colleagues, 1988). At least four cases of *retroperitoneal pregnancy* have been reported. In the two described by Ferland and associates (1991) and Reid and Steel (2003), pregnancy followed in vitro fertilization and embryo transfer. Varma and co-workers (2003) described the live birth at 35 weeks of an infant whose placenta implanted exclusively on the omentum. Fishman and co-workers (1998) described implantation of a 6-week *diaphragmatic pregnancy* in a woman with abdominal and shoulder pain, dyspnea, and a hemothorax. Fylstra and colleagues (2002) recently described an ectopic *cesarean scar pregnancy*. We have also encountered these, and they are in many ways similar to a placenta increta with all of its proclivity to cause torrential hemorrhage (see [Chap. 35](#), p. 830).

11. Gestational Trophoblastic Disease

INTRODUCTION

The term *gestational trophoblastic disease* refers to pregnancy-related trophoblastic proliferative abnormalities. In the past, classification of these abnormalities was confusing because it was defined by histological criteria as well as by clinical findings. As experience accrued, it became evident that a histological diagnosis was not necessary to provide effective treatment. Thus, a system has been adopted based principally on clinical findings and serial measurement of serum human chorionic gonadotropin (hCG) levels (Hammond and colleagues, 1973).

In 1983, the World Health Organization Scientific Group on Gestational Trophoblastic Diseases published recommendations for the definition, classification, and staging of trophoblastic disease. This classification was recently updated by the International Federation of Gynecology and Obstetrics (FIGO Oncology Committee, 2002). Gestational trophoblastic disease is divided into two groups, *hydatidiform mole* and *postmolar gestational trophoblastic neoplasia* (Table 11-1). The latter is termed *malignant gestational trophoblastic disease* by the American College of Obstetricians and Gynecologists (2004).

HYDATIDIFORM MOLE (MOLAR PREGNANCY)

Molar pregnancy is characterized histologically by abnormalities of the chorionic villi that consist of trophoblastic proliferation and edema of villous stroma. Moles usually occupy the uterine cavity, however, occasionally they develop in the oviduct and even the ovary (Chauhan and colleagues, 2004; Stanhope and associates, 1983). The absence or presence of a fetus or embryonic elements has been used to describe them as *complete* and *partial moles* (Table 11-2). As emphasized by Benirschke and Kaufmann (2000), in many cases classification may be difficult.

COMPLETE HYDATIDIFORM MOLE. In complete hydatidiform mole, the chorionic villi transform into a mass of clear vesicles (Fig. 11-1). The vesicles vary in size from barely visible to a few centimeters and often hang in clusters from thin pedicles. The histological structure typically shows:

1. Hydropic degeneration and swelling of the villous stroma.
2. Absence of blood vessels in the swollen villi.
3. Proliferation of the trophoblastic epithelium to a varying degree (Fig. 11-2).
4. Absence of fetus and amnion.

Of note, *hydropic* or *molar degeneration*, which may be confused histologically with a true mole, is not considered trophoblastic disease (Berkowitz and associates, 1991).

The chromosomal composition in 85 percent of complete molar pregnancies is 46,XX, with both chromosomes being of paternal origin (Wolf and Lage, 1995). This phenomenon is termed *androgenesis*. Typically, the ovum has been fertilized by a haploid sperm, which then duplicates its own chromosomes after meiosis. The chromosomes of the ovum are either absent or inactivated. Occasionally, the chromosomal pattern in a complete mole may be 46,XY due to dispermic fertilization (Bagshawe and Lawler, 1982; Lawler and colleagues, 1991).

Lawler and colleagues (1991) described 200 hydatidiform moles—151 were complete and 49 partial moles (Table 11-3). Whereas almost 85 percent of complete moles are diploid, 85 percent of partial moles are triploid. Other variations also have been identified, such as 45,X. Thus, a morphologically complete mole can result from a variety of chromosomal patterns (Wolf and Lage, 1995).

Figure 11-1. A complete or classical hydatidiform mole is characterized grossly by an abundance of edematous enlarged chorionic villi but no fetus or fetal membranes. There are theca-lutein cysts in both ovaries (*arrows*).

Figure 11-2. Photomicrograph of a hydatidiform mole with slight to moderate trophoblastic hyperplasia confined to the syncytium and considered probably benign. (From Smalbraak, 1957.)

PARTIAL HYDATIDIFORM MOLE. When the hydatidiform changes are focal and less advanced, and some element of fetal tissue is seen, the term *partial hydatidiform mole* is used. There is slowly progressive swelling within the stroma of characteristically avascular chorionic villi, whereas other vascular villi with a functioning fetal-placental circulation are spared (Shapter and McLellan, 2001).

As shown in Table 11-3, the karyotype typically is triploid—69,XXX, 69,XXY, or 69,XYY—these are each composed of one maternal and two paternal haploid sets of chromosomes (Berkowitz and colleagues, 1986, 1991; Wolf and Lage, 1995). Although nontriploid partial moles have been reported, some have questioned whether they exist (Genest and colleagues, 2002). The nonviable fetus of a triploid partial mole typically has multiple malformations (Phillip and co-workers, 2004). Abnormal growth is also common, and in the review by Jauniaux (1999), 82 percent of fetuses had symmetrical growth restriction.

A twin gestation of a complete mole and a normal fetus and placenta is sometimes misdiagnosed as a diploid partial mole (Fig.

[11-3](#)). It is important to distinguish between the two, because twin pregnancies consisting of a normal fetus and a complete mole have a substantively increased risk of developing subsequent gestational trophoblastic neoplasia (Bruchim and associates, 2000). Generally, gestational trophoblastic neoplasia follows 20 percent of complete moles, whereas it develops in only 0.5 percent of women after a partial mole (Hancock and Tidy, 2000). In their recent review of 77 such cases, Sebire and colleagues (2002b) reported that 16 percent of women whose pregnancies were terminated, versus 21 percent of those with continued pregnancies, required chemotherapy for gestational trophoblastic neoplasia. In another review, Vejerslev (1991) found that of 113 pregnancies with a hydatidiform mole coexistent with a normal fetus, 45 percent of fetuses progressed to 28 weeks, and fetal survival was 70 percent. Thus, when providing counseling for women with a coexistent mole and a fetus, both cytogenetic and high-resolution ultrasonographic studies are of paramount importance. The risk of *choriocarcinoma* arising from a partial mole is also low (see [Table 11-2](#)). Seckl and associates (2000) described 3000 cases of partial mole and documented only three cases of choriocarcinoma.

Figure 11-3. Molar placenta on the left and normal placenta on the right (*white arrow*). The molar placenta was identified by ultrasonography late in pregnancy when the mother developed preeclampsia. She underwent cesarean delivery of a healthy fetus near term. Most likely, these were twins consisting of a placenta with a fetus from one ovum and a complete mole developing from the other ovum.

HISTOLOGICAL DIAGNOSIS OF HYDATIDIFORM MOLES. Attempts to relate the histological structure of individual complete hydatidiform moles to their subsequent malignant potential have generally been disappointing. For example, Novak and Seah (1954) could not precisely establish such a relationship in 120 cases of uncomplicated hydatidiform mole or in 26 cases of choriocarcinoma that developed after a molar pregnancy.

THECA-LUTEIN CYSTS. In many cases of hydatidiform mole, the ovaries contain multiple theca-lutein cysts. These may vary from microscopic size to 10 cm or more in diameter. Their surfaces are smooth, often yellowish, and lined with lutein cells. The incidence of obvious cysts in association with a mole is reported to be from 25 to 60 percent. They are thought to result from overstimulation of lutein elements by large amounts of hCG secreted by proliferating trophoblastic cells. Montz and colleagues (1988) reported that gestational trophoblastic neoplasia was more likely in women with theca-lutein cysts, especially if bilateral. Cysts, however, are not limited to cases of hydatidiform mole and may be associated with fetal hydrops and placental hypertrophy or with multifetal pregnancy. They may undergo torsion, infarction, and hemorrhage. Because the cysts regress after delivery, oophorectomy should not be performed unless the ovary is extensively infarcted. Large ovarian cysts may be decompressed by aspiration if symptomatic (Berkowitz and Goldstein, 1996).

INCIDENCE AND RISK FACTORS. Hydatidiform mole develops in approximately 1 in 1000 pregnancies in the United States and Europe. Although it has been reported to be more frequent in other countries, especially in parts of Asia, much of this information was obtained from hospital studies (Schorge and associates, 2000). When derived from population studies, the incidence in most of the world is probably similar to that in the United States (Miller and colleagues, 1989; Semer and Macfee, 1995). The role of gravidity, estrogen status, oral contraceptives, and dietary factors in the risk of gestational trophoblastic disease is unclear (Semer and Macfee, 1995).

Age. Sebire and colleagues (2002a) found the incidence of molar pregnancy highest in women aged 15 years or younger, and those aged 45 years or older. In the latter group, the relative frequency of the lesion is at least 10 times greater than that at ages 20 to 40 years (Schorge and colleagues, 2000).

Previous Mole. Women with molar pregnancies are at increased risk of developing either a complete or a partial mole in a future pregnancy (Garner and colleagues, 2002). In a review of 12 series totaling almost 5000 deliveries, the frequency of recurrent moles was 1.3 percent (Loret de Mola and Goldfarb, 1995). Garner and colleagues (2002) reported a 1.4 percent frequency of repeat moles in women with a prior complete mole and 2.4 percent in those with a prior partial mole. Repetitive hydatidiform moles in women with different partners would suggest that an oocyte problem leads to molar development (Garner and colleagues, 2002; Tuncer and colleagues, 1999).

CLINICAL COURSE. The clinical presentation of molar pregnancy has changed appreciably during the past 20 years (Coukos and colleagues, 1999; Hancock and Tidy, 2002). The availability of ultrasonography and quantitative measurement of serum hCG levels now allows earlier diagnosis. Symptoms are more likely to be dramatic with a complete mole than with a partial mole.

Bleeding. Uterine bleeding is almost universal, and may vary from spotting to profuse hemorrhage. It may begin just before abortion or, more often, these women may bleed intermittently for weeks and even months. At times there may be considerable hemorrhage concealed within the uterus. Iron-deficiency anemia is common, and a dilutional effect from appreciable pregnancy-induced hypervolemia is present in some women with larger moles.

Uterine Size. The growing uterus often enlarges more rapidly than usual, exceeding in about half of cases that expected from the gestational age. The uterus may be difficult to identify precisely by palpation because of its soft consistency. At times, ovarian theca-lutein cysts are difficult to distinguish from the enlarged uterus.

Fetal Activity. Even though the uterus is enlarged sufficiently to extend well above the symphysis, typically no fetal heart motion is detected. Infrequently, there may be extensive but incomplete molar degeneration in the placenta accompanied by a living fetus.

Gestational Hypertension. Because hypertension caused by pregnancy is rarely seen before 24 weeks, preeclampsia that develops before this gestational age may be from hydatidiform mole or extensive molar degeneration.

Hyperemesis. Significant nausea and vomiting may develop. Of interest, none of the 24 complete moles reported by Coukos

and colleagues (1999) were associated with preeclampsia, hyperemesis, or clinical hyperthyroidism.

Thyrototoxicosis. Plasma thyroxine levels in women with molar pregnancy are often elevated, but clinically apparent hyperthyroidism is unusual (see [Chap. 53](#), p. 1194). According to Amir (1984) and Curry (1975) and their colleagues, hyperthyroidism is identified in about 2 percent. In these cases, serum free thyroxine is elevated as the consequence of the thyrotropin-like effect of hCG (Mann and colleagues, 1986).

Embolization. Variable amounts of trophoblastic cells with or without villous stroma escape from the uterus into the venous outflow at the time of molar evacuation (Hankins and colleagues, 1987). The volume may be such as to produce signs and symptoms of acute pulmonary embolism or edema. Embolization with a large amount of trophoblastic tissue is probably uncommon, although fatalities have been described (Delmis and co-workers, 2000). This tissue, though, can subsequently invade the pulmonary parenchyma to establish metastases.

DIAGNOSTIC FEATURES. Spontaneous expulsion is most likely around 16 weeks and is rarely delayed beyond 28 weeks. The greatest diagnostic accuracy is obtained from the characteristic ultrasonographic appearance of hydatidiform mole ([Fig. 11-4](#)). Occasionally, other structures may have an appearance similar to that of a mole, including uterine myoma and multifetal pregnancy.

To summarize, the clinical and diagnostic features of a complete hydatidiform mole are:

1. Continuous or intermittent brown or bloody discharge evident by about 12 weeks and usually not profuse.
2. Uterine enlargement out of proportion to the duration of pregnancy in about half of the cases.
3. Absence of fetal parts and fetal heart motion.
4. Characteristic ultrasonographic appearance.
5. Serum hCG level higher than expected for the stage of gestation.
6. Preeclampsia-eclampsia developing before 24 weeks.
7. Hyperemesis gravidarum.

Figure 11-4. A. Longitudinal sonogram demonstrating a complete hydatidiform mole that fills a uterus enlarged to well above the umbilicus. A large theca-lutein cyst (tl) is seen above the uterus. **B.** Transverse sonogram of the same woman. (Courtesy of Dr. R. Santos.)

PROGNOSIS. Current mortality from molar pregnancies has been practically reduced to zero by prompt diagnosis and appropriate therapy. Earlier evacuation, however, has not reduced the 20 percent risk for gestational trophoblastic neoplasia (Schorge and co-workers, 2000). The report by Lurain and colleagues (1983) consisted of follow-up of 738 women from 1962 to 1978 after evacuation of a hydatidiform mole. Spontaneous regression was documented in 81 percent, while the remainder developed gestational trophoblastic neoplasia.

TREATMENT. As a result of greater awareness, and certainly of better technology for diagnosis, moles now are terminated more often when they are small. There is time for adequate evaluation of the woman who may be anemic, hypertensive, or hypovolemic. Hydatidiform mole treatment consists of two phases. The first is immediate evacuation of the mole, and the second is subsequent evaluation for persistent trophoblastic proliferation or malignant change. Unless there is other evidence of extrauterine disease, computed tomography or magnetic resonance imaging to evaluate the liver or brain is not performed routinely.

The rare circumstance of twinning with a complete hydatidiform mole plus a fetus and placenta presents an unusual therapeutic dilemma, especially in the absence of karyotypic aberrations or gross fetal anomalies. Neither the risks to the mother nor the likelihood of a healthy offspring have been established if pregnancy is continued (Suzuki and associates, 1980; Vejerslev, 1991).

Prophylactic Chemotherapy. The role of prophylactic chemotherapy for women with a hydatidiform mole is controversial (Bloss and Miller, 1995; Goldstein and Berkowitz, 1995). Such therapy does not improve the long-term prognosis. Moreover, the toxicity from prophylactic chemotherapy may be significant, including death (Bloss and Miller, 1995). Chemoprophylaxis may be considered in women with high-risk complete moles, particularly if serum hCG testing is unavailable or follow-up is impossible (Berkowitz and Goldstein, 1996).

Vacuum Aspiration. Suction evacuation is the treatment of choice for hydatidiform mole, regardless of uterine size (Bloss and Miller, 1995). For large moles, compatible blood should be available and an intravenous system established for its rapid infusion, if needed. Cervical dilating agents may be necessary (see [Chap. 9](#), p. 243). The cervix may be further dilated under anesthesia to a diameter sufficient to allow insertion of a 10- to 12-mm plastic suction curet. After most of the molar tissue has been removed by aspiration, oxytocin is given. After the myometrium has contracted, *thorough but gentle curettage* with a large sharp curet usually is performed. Intraoperative ultrasonographic examination may help document that the uterine cavity has been emptied.

Oxytocin, Prostaglandins, and Hysterotomy. In the United States, labor induction rarely is used for evacuation of hydatidiform moles. In fact, there are many who feel that medical termination and hysterotomy have no role in its management (Miller and co-workers, 1989).

Hysterectomy. If no further pregnancies are desired, then hysterectomy may be preferred to suction curettage. Hysterectomy is a logical procedure in women aged 40 and older, because at least one third develop gestational trophoblastic neoplasia (Tow, 1966; Xia and colleagues, 1980). Although hysterectomy does not eliminate recurrent disease, it appreciably reduces its likelihood.

FOLLOW-UP EVALUATION OF MOLAR PREGNANCY. Close and consistent follow-up for these women is imperative with the following aims:

1. Prevent pregnancy for a minimum of 6 months using hormonal contraception.
2. Monitor serum hCG levels every 2 weeks. Serial measurement of serum hCG is important to detect trophoblastic neoplasia, and even small amounts of trophoblastic tissue can be detected by the assay. These levels should progressively fall to an undetectable level (Fig. 11-5).
3. Chemotherapy is not indicated as long as these serum levels continue to regress. A rise or persistent plateau in the level demands evaluation for gestational trophoblastic neoplasia and usually treatment. An increase signifies trophoblastic proliferation that is most likely malignant unless the woman is again pregnant.
4. Once the hCG level falls to a normal level, test the patient monthly for 6 months; then follow-up is discontinued and pregnancy allowed.

Estrogen-progestin contraceptives or depot-medroxyprogesterone usually are used to prevent a subsequent pregnancy during the period of surveillance. Deicas and associates (1991) studied the effect of contraception on subsequent development of gestational trophoblastic neoplasia in 162 women with hydatidiform mole and 137 with trophoblastic tumor. Oral contraceptives were found to be superior to barrier methods or use of an intrauterine device in decreasing the risk of developing gestational trophoblastic neoplasia. During follow-up, 33 percent of oral contraceptive users developed gestational trophoblastic neoplasia compared with about half who used other methods.

Figure 11-5. The mean value and 95-percent confidence limits describing the normal postmolar β -subunit chorionic gonadotropin regression curve. (From Schlaerth and associates, 1981, with permission.)

GESTATIONAL TROPHOBLASTIC NEOPLASIA

Also called malignant gestational trophoblastic disease, this term refers to invasive mole, choriocarcinoma, and placental site trophoblastic tumor. Any of these may follow molar pregnancy or normal pregnancy, or develop after abortive outcomes, including ectopic pregnancy. The criteria for diagnosis of postmolar gestational trophoblastic neoplasia are shown in [Table 11-1](#).

ETIOLOGY. Gestational trophoblastic neoplasia almost always develops with or follows some form of pregnancy. Approximately half of cases follow a hydatidiform mole, 25 percent follow an abortion, and 25 percent develop after an apparently normal pregnancy. Of 48 fatal cases from the Brewer Trophoblastic Disease Center, only one third developed in association with a hydatidiform mole (Lurain and co-workers, 1982). The remainder were associated with term or near-term pregnancies, abortions, or ectopic pregnancies. Bailey and colleagues (2003) recently described choriocarcinoma arising from a primary abdominal pregnancy. Rarely, choriocarcinoma may arise from a teratoma.

Malignancy is rarely identified in the placenta of a seemingly normal pregnancy. In a case described by Brewer and Mazur (1981), widespread malignant trophoblastic invasion was evident at 18 weeks, and a primary choriocarcinoma of the placenta was detected. A case in which malignant trophoblastic tissue metastasized to the fetus also has been described (Kruseman and colleagues, 1977). Others have reported intraplacental choriocarcinoma associated with a live fetus (Aonahata and co-workers, 1998; Jacques and associates, 1998).

PATHOLOGY. The diagnosis of gestational trophoblastic neoplasia is made primarily by persistently elevated serum hCG levels. In most cases, there is no tissue to submit for pathological study. Thus, an unusual situation exists in that clinical management is not always dictated by histological findings.

Choriocarcinoma. This extremely malignant form of gestational trophoblastic neoplasia may be considered a carcinoma of the chorionic epithelium. In its growth and metastasis, however, it often behaves like a sarcoma. The characteristic gross picture is that of a rapidly growing mass invading both myometrium and blood vessels that causes hemorrhage and necrosis (Fig. 11-6A). The tumor is dark red or purple and ragged or friable. If it involves the endometrium, then bleeding, sloughing, and infection of the surface usually occur early. Masses of tissue buried in the myometrium may extend outward, appearing on the uterus as dark, irregular nodules that eventually penetrate the peritoneum.

Although cytotrophoblastic and syncytial elements are involved, one or the other may predominate. Microscopically, columns and sheets of these trophoblastic cells penetrate the muscle and blood vessels, sometimes in plexiform arrangement and at other times in complete disorganization, interspersed with clotted blood (Fig. 11-6B). An important diagnostic feature of choriocarcinoma, in contrast to hydatidiform mole or invasive mole, is absence of a villous pattern. Cellular anaplasia exists, but it is not a valuable criterion of malignancy. Factors involved in malignant transformation of the chorion are unknown. In choriocarcinoma, the predisposition of normal trophoblast to invasive growth and erosion of blood vessels is greatly exaggerated.

Metastases often develop early and are generally blood-borne because of the affinity of trophoblastic cells for blood vessels.

The most common sites of metastasis are the lungs, in more than 75 percent of cases, and the vagina, in about 50 percent. The vulva, kidneys, liver, ovaries, brain, and bowel also may contain metastases ([Fig. 11-7](#)). Ovarian theca-lutein cysts are identified in over one third of cases.

Invasive Mole. The distinguishing features of invasive mole are excessive trophoblastic overgrowth and extensive penetration by the trophoblastic cells, including whole villi. These structures penetrate into the depths of the myometrium, sometimes to involve the peritoneum, adjacent parametrium, or vaginal vault. Such moles are locally invasive, but generally lack the pronounced tendency to widespread metastasis typical of choriocarcinoma.

Placental Site Trophoblastic Tumor. Rarely, trophoblastic neoplasia arises from the placental implantation site following a normal term pregnancy, spontaneous or induced abortion, ectopic pregnancy, or molar pregnancy (Feltmate and colleagues, 2001; Moore-Maxwell and Robboy, 2004). The tumor is characterized histologically by predominantly cytotrophoblastic cells, and immunohistochemical staining reveals many prolactin-producing cells and few gonadotropin-producing ones (Miller and associates, 1989). Thus, serum hCG levels may be normal to elevated. Bleeding is the main presenting symptom. Brewer and colleagues (1992) described a placental site trophoblastic tumor associated with erythrocytosis that resolved after hysterectomy. Nigam and co-workers (2004) described a tumor in a postmenopausal woman.

A placental site trophoblastic tumor was detected by Ichikawa and colleagues (2003) at the time of hysterectomy for a large uterine arteriovenous fistula. In another unusual presentation, Wright and colleagues (2002) reported a case of placental site trophoblastic tumor in a woman at 37 weeks' gestation who presented with a pneumothorax caused by a bullous metastatic tumor.

Figure 11-6. A. Choriocarcinoma (*arrow*) invading the uterus. Persistent trophoblastic disease was demonstrated by curettage subsequent to the expulsion of a hydatidiform mole. When repeated courses of chemotherapy failed to destroy the malignancy, hysterectomy and bilateral salpingo-oophorectomy were performed. The woman was alive without detectable chorionic gonadotropin 10 years later. **B.** Histological characteristics of the same choriocarcinoma. Malignant syncytiotrophoblast and cytotrophoblast without villous stroma invade the myometrium and vascular spaces (*arrow*), accompanied by necrosis and hemorrhage.

Figure 11-7. Metastatic choriocarcinoma. A chest radiograph (**A**) and a computed tomographic (CT) scan (**B**) demonstrate a left lower lobe metastatic lesion having poorly defined, irregular borders ("alveolar type") thought to be secondary to peripheral hemorrhage. (**C**) Abdominal CT scan at the level of the liver shows multiple low-density hepatic metastasis. (**D**) Cranial CT scan of the brain performed without contrast shows a large hemorrhagic metastasis in the left parietal lobe. (From DeBaz and Lewis, 1995, with permission.)

CLINICAL COURSE. The most common finding is irregular bleeding associated with uterine subinvolution. The bleeding may be continuous or intermittent, with sudden and sometimes massive hemorrhage. Uterine perforation caused by invasive trophoblastic growth may cause intraperitoneal hemorrhage (Hancock and Tidy, 2002).

In some cases, the woman presents with a metastatic lesion of the vagina or vulva. Occasionally, it has been impossible to locate choriocarcinoma in the uterus or pelvis because the original lesion has disappeared, leaving only distant metastases. If untreated, choriocarcinoma is invariably fatal.

DIAGNOSIS. Recognition of the possibility of gestational trophoblastic neoplasia is the most important factor in diagnosis. Any case of unusual bleeding after term pregnancy or abortion should be investigated by curettage, and especially with measurements of serum hCG. Solitary or multiple nodules seen in the chest radiograph are suggestive of choriocarcinoma (see [Fig. 11-7](#)). Persistent or rising hCG levels in the absence of pregnancy also are indicative of gestational trophoblastic neoplasia.

Anatomical staging before treatment includes pelvic examination, chest radiograph, and computed tomography (CT) scanning of the abdomen and pelvis. CT scanning of the chest and head is recommended only if the chest radiograph is abnormal. Moodley and Moodley (2004) described three women with normal chest radiograph readings but who had lung metastases identified with CT-scanning.

PROGNOSTIC SCORING SYSTEM. The International Federation of Gynecology and Obstetrics recently revised the World Health Organization Prognostic Scoring System (FIGO Oncology Committee, 2002). Scores of 0 to 4 are given according to age; type of antecedent pregnancy and interval from it; serum hCG concentration; size of tumor, site, and number of metastases; and whether previous chemotherapy was given. Low-risk neoplasia generally includes scores of 0 to 6.

Several other prognostic scoring systems and at least one anatomical staging system have been described (Bagshawe, 1976; Kohorn, 2002; Lurain and associates, 1991; Pettersson and colleagues, 1985).

TREATMENT. Single-agent chemotherapy is given for nonmetastatic or low-risk metastatic neoplasia. Methotrexate and other agents effective against malignant tumors, especially actinomycin D, are usually curative. Several regimens have

been used with success. Methotrexate has been used with good results when given orally, by intravenous infusions, or by intramuscular injections (Garrett, 2002; Khan, 2003; Soper, 1994, and their colleagues). Single-dose actinomycin D is also highly effective in women with nonmetastatic disease (Lurain and Elfstrand, 1995; Petrilli and associates, 1987). In the ongoing Gynecological Oncology Group Protocol 174, women with low-risk disease are randomized to receive either methotrexate or actinomycin D. Suzuka and colleagues (2001) treated 37 women who had low-risk gestational trophoblastic neoplasia and reported that adjuvant hysterectomy decreased the total dose of chemotherapy needed to achieve primary remission. In some cases, such as with brain metastases, chemotherapy is given along with radiotherapy (Evans and associates, 1995).

High-Risk Trophoblastic Neoplasia. Patients are classified as high risk when the modified WHO prognostic score is 7 or greater. In these women, combination chemotherapy with its increased toxicity has produced the highest cure rates. According to Schorge and colleagues (2000) and Lurain (2002), the *EMA-CO regimen* results in response rates of about 90 percent and survival rates of 80 to 100 percent. This regimen is a combination of etoposide, methotrexate, actinomycin, cyclophosphamide, and Oncovin (vincristine). Similar results with EMA-CO were reported recently from the Netherlands by Houwen and associates (2004).

Placental Site Tumors. Hysterectomy is the most efficacious treatment for confirmed placental site trophoblastic tumor (Feltmate and associates, 2001; Miller and colleagues, 1989). It is not necessary to remove the ovaries if they appear normal (Ajithkumar and associates, 2003). Although chemotherapy is recommended for metastatic disease, it is not as effective as for other gestational trophoblastic neoplasias (Gillespie and colleagues, 2000).

Randall and colleagues (2000) described a woman with a 3-year prolonged remission following recurrent metastatic placental site tumor and chemotherapy. Gillespie and colleagues (2000) treated three women successfully with only hysterectomy for tumor confined to the uterus. Another four were given chemotherapy for metastases, and although two responded, the other two died. Papadopoulos and colleagues (2002) reviewed their 25-year experiences with 34 cases of placental site tumors. Half of these followed a normal pregnancy, 20 percent followed a molar pregnancy, and 15 percent developed after a missed abortion. Of these 34 women, 20 percent died. The two most common factors associated with death were metastatic lung disease and an interval of 4 years or longer between the antecedent pregnancy and diagnosis.

PROGNOSIS. The recent overall cure rate for gestational trophoblastic neoplasia of all severities is about 90 percent. Women with nonmetastatic tumors or low-risk gestational trophoblastic neoplasia are cured virtually 100 percent of the time if single-agent chemotherapy is started as soon as persistent disease is identified (Schorge and colleagues, 2000). Previously cited on page 277 were the remarkable results of Lurain and colleagues (1983) for women treated at the Brewer Trophoblastic Disease Center of Northwestern University. From 1962 to 1978, 738 women with molar pregnancy were managed as generally outlined above. Chemotherapy was given to 142 women (19 percent) for gestational trophoblastic neoplasia. Of this group, 17 percent had an invasive mole and 2 percent had choriocarcinoma. All were living and disease-free 4 to 18 years later.

Women with low-risk metastatic gestational trophoblastic neoplasia who are treated aggressively with single- or multiagent chemotherapy do almost as well as those with nonmetastatic disease (Hammond and colleagues, 1980; Jones, 1987). Women with high-risk metastatic neoplasia have appreciable mortality rates that depend on which factors placed them at high risk (Soper and associates, 1988). Remission rates vary from 45 to 65 percent. Lurain (1987) analyzed 53 deaths from the Brewer Trophoblastic Center and concluded that the three risk factors primarily responsible were: (1) extensive choriocarcinoma at initial diagnosis, (2) lack of appropriately aggressive initial treatment, and (3) failure of currently used chemotherapy to effect neoplasia regression.

PREGNANCY AFTER GESTATIONAL TROPHOBLASTIC DISEASE. Follow-up surveillance is minimally 6 months for molar pregnancy, 1 year for gestational trophoblastic neoplasia, and up to 2 years for cases with metastases other than to the lung. There is no difficulty with fertility or normal pregnancy outcome following successfully treated gestational trophoblastic disease (Schorge and associates, 2000; Woolas and co-workers, 1998). Women who have been given chemotherapy do not have an increased risk for anomalous fetuses in subsequent pregnancies (Rustin and colleagues, 1984; Song and associates, 1988). The primary concern is that women who had gestational trophoblastic disease are at increased risk for developing it again in a subsequent pregnancy. Berkowitz and colleagues (1987) reported that 1.3 percent of 1048 women treated at the New England Trophoblastic Disease Center developed a second molar pregnancy. Kim and associates (1998) reported that 4.3 percent of 115 Korean women had a second tumor.

12. Genetics

INTRODUCTION

Genetics is the study of biological variation. *Medical genetics* is the study of individual variation in the incidence of and susceptibility to medical disorders and birth defects. Disease mechanisms, response to therapy, and genetic testing also are included in this field.

Genetic disease is common. Between 2 and 3 percent of neonates are born with a recognized congenital structural defect, another 3 percent have a defect diagnosed by age 5, and another 8 to 10 percent are discovered to have one or more functional or developmental abnormalities by age 18. In addition, susceptibility to many common diseases often has a genetic basis, and most cancers develop as the result of cumulative mutations. Thus, two thirds of the population will experience a disease with a genetic component in their lifetime. If cancers are included, 91 percent will be affected (Rimoin and colleagues, 1997). The types and estimated frequencies of various categories of genetic conditions by age at diagnosis are listed in [Table 12-1](#). Tests available to diagnose some genetic diseases antenatally and the rationale accompanying their use in pregnancy are described throughout [Chapter 13](#).

The *Human Genome Project*, supported principally by the National Human Genome Research Institute, had the goal of mapping the complete human genome. Sequencing was essentially complete by 2000, and finalized in 2003. Mapping the approximately 40,000 genes that comprise the haploid human genome will no doubt aid studies of normal and abnormal gene function to provide the basis for future diagnosis and therapy. Within our professional lifetimes, it is likely that consideration of each patient's genetic background and specific traits and susceptibilities will become part of routine medical care. Knowledge of genetic principles will thus be essential for all practitioners.

ETIOLOGY OF BIRTH DEFECTS

Birth defects can arise in at least three ways. This is illustrated by [Figure 12-1](#), which shows three similar looking defects that actually arose by three different mechanisms. The first limb defect caused by fusion of the lower extremities is a *malformation*, meaning that the limb was "programmed" to develop abnormally and is thus intrinsically genetically abnormal. In contrast, a *deformation* occurs when a genetically normal structure develops an abnormal shape because of mechanical forces imposed by the uterine environment. An example is an otherwise normal limb that develops contractures because of prolonged oligohydramnios. A *disruption* is a more severe change in form or function that occurs when genetically normal tissue is modified as the result of a specific insult. An example is early amnion rupture causing limb deformities. There are some identical-appearing abnormalities, referred to as *phenocopies*, that have widely varying etiologies, which can make the diagnosis of even relatively simple defects difficult.

Multiple structural defects or developmental abnormalities can occur together in one individual. A cluster of several anomalies or defects can be a *syndrome*, meaning that all the abnormalities have the same cause—for example, trisomy 18. Anomalies also may comprise a *sequence*, meaning that all abnormalities developed sequentially as the result of one initial insult—for example, oligohydramnios leading to pulmonary hypoplasia, limb contractures, and facial deformities. Finally, a group of anomalies may be considered an *association*, meaning that these particular anomalies occur together frequently, but do not seem to be linked etiologically—for example, *CHARGE association*, which is a combination of coloboma, heart defects, atresia choanae, mental retardation, growth deficiency, and ear anomalies. It is readily apparent that classification of anomalies can be challenging, and reclassification often is required.

Figure 12-1. Examples of three major types of dysmorphogenesis. **A.** Malformation sequence: sirenomelia or fused lower extremities. **B.** Deformation sequence: clubbed feet from prolonged oligohydramnios. **C.** Disruption sequence: cephalocele, cleft lip, amputated right arm, and bilateral arm bands from amnionic bands (Photographs courtesy of Dr. Ron Ramus and Dr. Diane Twickler.)

CHROMOSOMAL ABNORMALITIES

STANDARD NOMENCLATURE. By convention, karyotypes are reported using nomenclature agreed upon by the genetics community and codified in 1985 by the International System for Human Cytogenetic Nomenclature (ISCN). The total number of chromosomes is listed first and corresponds to the number of centromeres present. This is followed by the sex chromosomes (XX or XY), and then by a description of any variation or abnormality detected. Specific abnormalities are indicated by standard abbreviations, such as *dup* (*duplicated*), *der* (*derivative*), *t* (*translocated*), and many more. Each chromosome has a short arm—the "p" or *petit* arm—and a long arm—the "q" arm—named for the next letter in the alphabet. The arms are separated by a centromere. These letters further identify the affected chromosomal components. The standard nomenclature for writing a karyotype is shown in [Table 12-2](#).

Chromosomal abnormalities figure prominently in assessments of the impact of genetic disease, accounting for 50 percent of embryonic deaths, 5 to 7 percent of fetal losses, 6 to 11 percent of stillbirths and neonatal deaths, and 0.9 percent of liveborn children (Hook, 1992; Tolmie, 1995).

ANEUPLOIDY. There are a total of 44 autosomes, arranged in pairs numbered from 1 to 22, and one pair of sex chromosomes. The most obvious or easily recognized chromosomal abnormalities are numerical. In these, the affected individual inherits an extra chromosome—*trisomy*; is missing a chromosome—*monosomy*; or has an abnormal number of haploid chromosomal complements—*polyploidy*. The estimated incidence of aneuploidy and other chromosomal abnormalities in newborns is shown in [Table 12-3](#).

Trisomy. Most trisomies and nonmosaic monosomies result from meiotic nondisjunction. Chromosomes fail to pair up initially, or they pair properly but then fail to separate or separate prematurely (Gardner and Sutherland, 1996; Sherman and colleagues, 1991). The risk of nondisjunction increases with maternal age (Table 12-4). Oocytes are held suspended in midprophase of meiosis I from birth until ovulation— in some cases for 50 years. Aging is thought to break down chiasmata that keep paired chromosomes aligned. When meiosis is completed at the time of ovulation, nondisjunction leads to one resulting gamete receiving two copies of the chromosome in question. This leads to trisomy if fertilized. The other gamete receives no copies and is thus monosomic when fertilized. Although 3 to 4 percent of sperm and 10 to 20 percent of oocytes are aneuploid as the result of meiotic errors, natural selection against these abnormal gametes makes them less likely to result in conception than normal gametes. If fertilization does occur, most aneuploid conceptuses die early.

Although each of the 23 chromosome pairs is equally likely to be involved in a segregation error, only a few trisomies are identified (Kamiguchi and associates, 1993). Some trisomies are associated with such severe abnormalities that they always result in loss before or shortly after implantation. For example, trisomy 1 has never been reported. Trisomy 16 accounts for 16 percent of all first-trimester deaths, but is never seen later. Only autosomal trisomies 13, 18, and 21 result in viable term pregnancies. Even so, the majority of these fetuses are lost before term (Table 12-5). In their review, McIntosh and colleagues (1995) confirmed that one third of Down syndrome fetuses in women aged 35 years and older are lost in the interval between chorionic villus sampling at 10 weeks and amniocentesis at 16 weeks, and half die before term.

Monosomy. Although nondisjunction leads to an equal number of nullisomic and disomic gametes, there is no clinically recognized association between maternal age and monosomy. The most likely explanation is that monosomy is almost universally incompatible with life, and monosomic conceptuses die prior to implantation (Garber and co-workers, 1996). As a rule, missing chromosomal material is much more devastating to the organism than having extra chromosomal material. One exception is *monosomy X*, or *Turner syndrome*, discussed later. Although it accounts for about 20 percent of first-trimester fetal deaths, a small proportion of cases survive until term.

Polyploidy. Abnormalities of ploidy account for about 20 percent of abortions and are rarely seen in later pregnancies. Two thirds of *triploidy* cases result from fertilization of one egg by two sperm. The remainder are caused by failure of one of the meiotic divisions, resulting in a diploid chromosomal complement in either the egg or, more frequently, the sperm. The origin of the extra set of chromosomes determines the phenotype. If the extra chromosomes are paternal (diandric), the result is usually a partial hydatidiform mole with abnormal fetal structures (see Chap. 11, p. 275). Rarely, a relatively normal-sized fetus develops but the placenta is abnormally large and cystic. These pregnancies frequently are complicated by midtrimester severe preeclampsia. If the extra set of chromosomes is maternal (digynic), a fetus and placenta develop but the fetus is severely growth restricted. Triploid fetuses of either kind are frequently dysmorphic. If a woman had a triploid pregnancy with a fetus that survived past the first trimester, the recurrence risk is 1 to 1.5 percent (Gardner and Sutherland, 1996). This risk justifies offering prenatal diagnosis in subsequent pregnancies (see Chap. 13, p. 315).

Tetraploidy always results in 92,XXXX or 92,XXYY, indicating a postzygotic failure to complete an early cleavage division (Thompson and colleagues, 1991). The recurrence risk for tetraploidy is minimal.

PATERNAL EFFECTS. There is no association between aneuploidy and paternal age, probably because aneuploid sperm cannot fertilize an egg. Advanced paternal age does, however, logarithmically increase the risk of spontaneous new mutations causing autosomal dominant diseases such as neurofibromatosis or achondroplasia (Friedman, 1981). These new mutations also may be a factor in early pregnancy loss. The incidence of new autosomal dominant mutations among newborns whose fathers are 40 years old is at least 0.3 percent. There is some evidence that paternal age also may affect the incidence of isolated structural abnormalities (McIntosh and colleagues, 1995).

Chromosome abnormalities are increased when conception is induced by *intracytoplasmic sperm injection (ICSI)*. A study including 2083 such pregnancies evaluated with fetal karyotyping identified 72 chromosomal abnormalities, a rate of 3.5 percent (Van Steirteghem and co-workers, 2002). Of these, 30 were inherited, 15 involved sex chromosome abnormalities, and 28 involved autosomes. In addition, these fetuses are at increased risk to have inherited Y chromosome deletions (In't Velt and colleagues, 1997).

AUTOSOMAL TRISOMIES

Trisomy 21. This trisomy also is called *Down syndrome* after J.L.H. Down, who described it in 1866. A trisomy 21 karyotype, shown in Figure 12-2, is found in 1 in 800 to 1000 newborns. Because it is the most common nonlethal trisomy, this condition is the focus of most genetic screening and testing protocols (see Chap. 13, p. 323). Approximately 95 percent of Down syndrome cases result from maternal nondisjunction of chromosome 21— 75 percent during meiosis I and 25 percent during meiosis II. The remaining cases result from mosaicism or translocation.

The Down syndrome phenotype includes marked hypotonia, tongue protrusion, a small head with flattened occiput, flat nasal bridge, and epicanthal folds with up-slanting palpebral fissures. There is frequently loose skin at the nape of the neck, short fingers, a single palmar crease, and absence or hypoplasia of the middle phalanx, causing clinodactyly (inward curving) of the fifth finger, and the "sandal toe" gap (Fig. 12-3). Associated major abnormalities include heart defects (particularly endocardial cushion defects) in 30 to 40 percent of cases and gastrointestinal atresias. These children also have a high incidence of neonatal or childhood leukemia and thyroid disease. The intelligence quotient (IQ) ranges from 25 to 50, with a few individuals testing higher, and most affected children have social skills averaging 3 to 4 years ahead of their mental age. The chromosome region responsible for the mental deficit is located at 21q22.13 to 22.2.

RECURRENCE RISK. Once a woman has had a pregnancy complicated by trisomy 21 resulting from nondisjunction, her risk to have another pregnancy with any trisomy is 1 percent until her age-related risk exceeds this; then her age-related risk predominates. This risk justifies offering invasive prenatal diagnosis. Parental chromosomal studies are not necessary unless the trisomy was due to a translocation (approximately 3 percent of cases). Females with Down syndrome are fertile, and approximately one third of their offspring will have Down syndrome (Scharrer and colleagues, 1975). Males are almost always sterile, and only a few cases of reproduction have been reported (Sheridan and associates, 1989; Zuhlke and co-workers, 1994).

Trisomy 18. Also known as *Edwards syndrome*, trisomy 18 occurs in 1 in 8000 newborns and is three to four times more common in females. The incidence is much higher in the first trimester, but 85 percent of fetuses with this syndrome die between 10 weeks and term. Moreover, trisomy 18 fetuses usually are growth restricted, with a mean birthweight of 2340 g (Snijders and colleagues, 1995).

Striking facial features include prominent occiput, rotated and malformed auricles, short palpebral fissures, and a small mouth. The hands are often held clenched with the second and fifth fingers overlapping the third and fourth (Jones, 1997). Virtually every organ system can be affected by trisomy 18. Almost 95 percent of affected individuals have cardiac defects, most commonly ventricular or atrial septal defect or patent ductus arteriosus. Horseshoe kidney, radial aplasia, hemivertebrae, hernias, diastasis, or imperforate anus may be evident. These infants are usually frail and have frequent apneic spells. In a recent report from the National Center on Birth Defects and Developmental Disabilities, Rasmussen and associates (2003) described a median survival of 14 days. Up to 10 percent survive to 1 year, and rare reports describe survivors to age 10 or older. Those who survive are profoundly retarded.

In view of the extremely poor outcome, prenatal diagnosis should prompt discussion of pregnancy termination. If the pregnancy is continued, the mode of delivery must be discussed. Fetuses with trisomy 18 commonly have fetal heart rate abnormalities during labor, and more than half of all undiagnosed cases are delivered by cesarean for "fetal distress" (Schneider and colleagues, 1981). Because it is extremely unlikely that cesarean delivery will change the outcome, it is reasonable to avoid unnecessary maternal operative morbidity by planning a vaginal delivery regardless of whether the fetus tolerates labor, recognizing that intrapartum fetal demise may occur.

Trisomy 13. Known as *Patau syndrome*, trisomy 13 occurs in approximately 1 in 20,000 births. Common abnormalities include cardiac defects in 80 to 90 percent of cases, and holoprosencephaly in 70 percent. Holoprosencephaly may be accompanied by microcephaly, hypotelorism, and pronounced abnormalities of the orbits, nose, and palate. Affected fetuses also may have abnormal ears, omphalocele, polycystic kidneys, radial aplasia, cutis aplasia, and polydactyly. Rasmussen and colleagues (2003) recently reviewed outcomes of 70 liveborn infants with trisomy 13. They found that the median survival for trisomy 13 liveborn neonates was 7 days. Up to 10 percent survived to 1 year. Counseling regarding prenatal diagnosis and delivery is approached as previously described with trisomy 18.

Other Trisomies. It is rare to see liveborn neonates with other autosomal trisomies, although mosaicism involving a few other autosomal chromosomes has been reported.

SEX CHROMOSOME ABNORMALITIES

XXX and XXY. There have been studies in which children with sex chromosome abnormalities are identified through early screening and then followed prospectively. These studies aid the identification of each specific phenotype. One such study between 1964 and 1974 identified 43 of 40,000 newborns—1 in 930—with sex chromosome aneuploidy (Robinson and colleagues, 1991). They were followed until age 24. Both females with 47,XXX and males with 47,XXY (*Klinefelter syndrome*) had very similar phenotypes. Both tended to be tall. XXX females displayed normal pubertal development and fertility. XXY males, however, did not virilize and required testosterone replacement therapy. They were more likely to be infertile as the result of gonadal dysgenesis and to have gynecomastia and small testicles.

Neither XXX nor XXY is strongly associated with mental retardation, but there is wide variability in intellectual function. The IQ scores ranged from 71 to 122; the mean IQ of XXY males was 95, whereas that of XXX females was 87—both within normal limits, but lower than controls. Most XXX and XXY study subjects had some type of developmental problem or speech disability, neuromotor, or learning disability.

Females with more than three X chromosomes—48,XXXX or 49,XXXXX—are likely to have physical abnormalities that are apparent at birth and to exhibit varying degrees of mental retardation. For both males and females, IQ drops with each additional X chromosome.

47,YYY. These males are phenotypically normal but tall. They generally have normal intelligence, although their IQs may be lower than those of their siblings, and they often have learning disabilities. Early reports indicating that YYY was associated with criminal or violent behavior suffered from ascertainment bias because prisoners or men with serious psychological dysfunction were tested preferentially. In their prospective study, Robinson and colleagues (1997) found only an increased risk of emotional difficulties, including mild depression and increased hyperactivity and aggressiveness in YYY men. Males with more than two Y chromosomes—48,YYYY—or with both additional X and Y chromosomes—48,XXYY or 49,XXXYY—have obvious physical abnormalities and significant mental retardation.

45,X. Called *Turner syndrome*, this is the only monosomy compatible with life. It is the most common aneuploidy in abortuses and accounts for 20 percent of chromosomally abnormal first-trimester abortions. Its prevalence in liveborn neonates is about 1 in 5000 births (Sybert and McCauley, 2004).

There are three distinct phenotypes seen with 45,X. At least 98 percent of conceptuses are so abnormal that they abort in the first trimester. In the majority of the remainder, abnormal ultrasonographic findings such as cystic hygromas (see [Fig. 16-8](#), p. 395) may be detected later, and these findings may be accompanied by hydrops and fetal demise. The third, least common phenotype comprises liveborn individuals, who may have only minor problems. Features of this last group include short stature, broad chest with widely spaced nipples, congenital lymphedema with puffy fingers and toes, low hairline with webbed posterior neck, and minor bone and cartilage abnormalities. Between 30 and 50 percent have a major cardiac malformation, usually aortic coarctation or bicuspid aortic valves. Intelligence is generally in the normal range. 45,X females, however, frequently have visual-spatial organization deficits and difficulty with nonverbal problem solving and with interpretation of subtle social cues (Jones, 1997). Over 90 percent also have ovarian dysgenesis and require life-long hormone replacement beginning just before adolescence.

The tremendous range of phenotypes of Turner syndrome may be explained by a high incidence of mosaicism, with two or more populations of cells identified. About half are 45,X nonmosaic which results from an error in meiosis. The mosaic Turner syndrome stems from an error in mitosis, with one or more populations of cells missing an X chromosome. The live-born infants will have karyotypes like 45,X/46,XX or 45,X/46,XY (Saenger, 1996; Sybert and McCauley, 2004). As many as half of women with Turner syndrome display mosaicism in peripheral blood cells; the remainder may have mosaicism expressed only in tissues that are not routinely tested (Fernandez, 1996; Kim, 1999; Nazarenko, 1999, and their colleagues). If ultimately the majority of cells are 45,X, that individual will have the Turner phenotype, but modified by the presence of the other cell populations (Koeberl and co-workers, 1995). The missing X chromosome does not appear to be lost randomly — the maternal X is retained in 80 percent of surviving cases (Cockwell and colleagues, 1991; Hassold and associates, 1991).

Figure 16-8. Large, septated cystic hygromas in a 17-week fetus with Turner syndrome. (Courtesy of Dr. Jodi Dashe.)

CHROMOSOMAL DELETIONS. A deletion means that a portion of a chromosome is missing. These errors usually are described by the location of the two break points within the chromosome or, if the deletion is common, by an eponym; for example, *del 5p* also is called *cri du chat syndrome*. Most deletions occur during meiosis and result from malalignment or mismatching during pairing of homologous chromosomes. If the two chromosomes are not aligned properly, the unaligned loop may be deleted ([Fig. 12-4](#)). If the mismatch remains and the two chromosomes recombine, the result may be a deletion in one and a duplication in the other. If a deletion is identified in a fetus or child, the parents should be tested to determine whether either carries a balanced translocation that would increase the recurrence risk.

Chromosome Banding. Recognition of a deletion during cytogenetic analysis is facilitated by various staining methods used to create light and dark chromosomal bands. These banding patterns are unique and allow identification of each chromosome and recognition of missing segments. Several genetic conditions have been identified that are caused by microdeletions — deletions too small to be detected by older methods.

Genes in a deleted chromosomal segment often control several different traits. Thus, *contiguous gene deletion syndromes* usually involve serious but unrelated phenotypic and functional abnormalities. Deletions can occur in any area of any chromosome. Several specific deletions, however, are found more frequently than expected by chance alone, probably because certain regions are predisposed to breakage.

Deletion 4p. Known as *Wolf-Hirschhorn syndrome*, this deletion involves material from the short arm of chromosome number 4. It is characterized by fetal growth restriction, hypotonia, a unique facial appearance, severe mental deficiency, polydactyly, and cutis aplasia. Affected children often have severe seizures and seldom survive childhood. Approximately 85 percent of 4p deletions occur de novo, and in 80 percent the deleted chromosomal material is paternal.

Deletion 5p. Partial deletion of the short arm of chromosome 5 causes *cri du chat syndrome*. Affected infants are growth restricted, hypotonic, and severely retarded. They are sometimes identified by their mewing, high-pitched, catlike cry, attributed to abnormal laryngeal development.

Shprintzen and DiGeorge Phenotypes. These phenotypes both result from the same 22q11.2 microdeletion (Driscoll and colleagues, 1993). Botto and colleagues (2003) recently described a population-based study from the National Center on Birth Defects and Developmental Disabilities. They found the prevalence of 22q11.2 microdeletion to be about 1 in 6000 among whites, blacks, and Asians, and 1 in 3800 among Hispanics. More than 80 percent had heart defects, and one third had major extracardiac anomalies. The deletion accounted for at least 1 in 68 cases of a major heart defect. Shprintzen phenotype also is called *velo-cardio-facial syndrome*. Individuals with this deletion may have cleft palate, velopharyngeal incompetence, prominent nose, a long face with retruded mandible, cardiac defects, learning difficulties, and short stature. By contrast, the DiGeorge phenotype is characterized by thymus hypo- or aplasia, parathyroid hypo- or aplasia, and aortic arch malformations. Typical facies includes short palpebral fissures, micrognathia with a short philtrum, and ear anomalies. Mental development is usually normal.

It has been hypothesized that DiGeorge and Shprintzen phenotypes represent two extremes of a spectrum of abnormalities associated with the identical deletion. It is also possible that each condition represents a separate contiguous gene deletion syndrome of genes located at 22q11.2, but that current cytogenetic methods cannot distinguish differences between the two. Recent data indicate that the 22q11.2 microdeletion also accounts for a large proportion of heart defects in individuals without the extracardiac features of either DiGeorge or Shprintzen syndromes. These include interrupted aortic arch, truncus

arteriosus, and Fallot tetralogy.

Figure 12-4. One mechanism to produce a duplication and a deletion. Similar sequences (crosshatched segments) exist at numerous places along the chromosome. Misalignment of two nonhomologous sequences, followed by illegitimate recombination within these two sequences (X), produces recombinant products that are reciprocally imbalanced: one with a duplication of the chromatin between the two sequences, and the other with a deficiency. (From Gardner and Sutherland, 1996, with permission.)

CHROMOSOMAL TRANSLOCATIONS

Reciprocal Translocations. A reciprocal or double-segment translocation is a rearrangement of chromosomal material in which breaks occur in two different chromosomes, and the fragments are exchanged before the breaks are repaired. The rearranged chromosomes are called *derivative (der) chromosomes*. If no chromosomal material is gained or lost in this process, it is a *balanced translocation*. Although the transposition of chromosomal segments can cause abnormalities due to repositioning of specific genes, in most cases gene function is not affected and the balanced carrier is phenotypically normal. Offspring who inherit either the two normal chromosomes or the two translocated chromosomes also usually have a normal phenotype. Fryns and associates (1992) reported a 6.4 percent total risk (including background) for anomalies with a balanced translocation.

Carriers of a balanced translocation can produce unbalanced gametes that result in abnormal offspring. As shown in [Figure 12-5](#), if one of the translocated chromosomes and one of the normal co-chromosomes are included in the oocyte or sperm, following fertilization, the result is monosomy for part of one chromosome and trisomy for part of another. The observed risk of many specific translocations can be estimated by a genetic counselor, but in general, translocation carriers identified after the birth of an abnormal child have a 5 to 30 percent risk of having unbalanced liveborn offspring. Carriers identified for other reasons, for example, during an infertility workup, only have up to 5 percent risk, probably because their gametes and thus conceptions are so abnormal as to be nonviable.

Robertsonian Translocations. These translocations result when the long arms of two individual acrocentric chromosomes X —for example, chromosomes 13 and 14 X —fuse at the centromere to form one. Translocations may involve any of the acrocentric chromosomes shown in [Figure 12-2](#). These include chromosomes 13, 14, 15, 21, and 22, but almost all involve chromosome 14 (Levitan, 1988). Fusion at the centromeres results in the loss of one centromere and the *satellite regions* which comprise the short arms of each chromosome. These regions contain only genes coding for ribosomal RNA, which also are present in multiple copies on other acrocentric chromosomes. As long as the fused q arms are intact, the translocation carrier is usually phenotypically normal. Because the number of centromeres determines the chromosome count, the typical carrier of a Robertsonian translocation will have only 45 chromosomes.

Robertsonian carriers have reproductive difficulties. If the fused chromosomes are homologous X —from the same chromosome pair X —the carrier makes only unbalanced gametes. Each egg or sperm contains either both copies of the translocated chromosome, which would result in trisomy if fertilized, or no copy, which would result in monosomy. If the fused chromosomes are nonhomologous, four of the six possible gametes (66 percent) would be abnormal. Because some of these abnormal gametes would be nonviable, however, the actual observed incidence of abnormal offspring is only 15 percent if the translocation is carried by the mother, and 2 percent if carried by the father.

Robertsonian translocations are common. Their incidence in newborns is approximately 1 in 1000, which is equal to all other translocations combined. Robertsonian translocations, however, are not a major cause of miscarriage and occur in fewer than 5 percent of couples with recurrent pregnancy loss (Smith and Gaha, 1990). Still, identification of these translocations has tremendous impact on reproductive plans and may have implications for other family members. When a fetus or child is found to have a translocation trisomy, chromosomal studies of both parents should be performed. If neither parent is a carrier and the translocation occurred spontaneously, the recurrence risk is low.

Isochromosomes. These abnormal chromosomes are composed of either two q arms or two p arms of one chromosome fused together. Isochromosomes are thought to arise when the centromere breaks transversely instead of longitudinally during meiosis II or mitosis. They also may result from a meiotic error in a chromosome with a Robertsonian translocation. An isochromosome made of the q arms of an acrocentric chromosome behaves like a homologous Robertsonian translocation, because no important genetic material is lost. However, such a carrier could produce only abnormal unbalanced gametes. When an isochromosome involves nonacrocentric chromosomes that have p arms containing functional genetic material, the fusion and abnormal centromere break results in two isochromosomes X —one composed of both p arms and one composed of both q arms. Because one of these isochromosomes is likely to be lost during cell division, resulting in the deletion of all the genes located on the lost chromosome arm, the carrier is usually phenotypically abnormal and produces abnormal gametes. An example is isochromosome X, which causes the full Turner syndrome phenotype.

Figure 12-5. Gametes produced by a balanced translocation carrier. (From Greenwood Genetics Center, 1995, with permission.)

CHROMOSOMAL INVERSIONS. Inversions result when two breaks occur in the same chromosome, and the intervening genetic material is inverted before the breaks are repaired. Although no genetic material is lost or duplicated, the rearrangement may alter gene function. *Paracentric inversions* are those in which the inverted material is from only one

arm, and the centromere is not within the inverted segment ([Fig. 12-6](#)). The carrier makes either normal (balanced) gametes or gametes that are so abnormal as to preclude fertilization. Thus, although infertility may be a problem, the risk of abnormal offspring is extremely low.

Pericentric inversions occur when the breaks are in each arm of the chromosome, so that the inverted chromosome material includes the centromere. Because such inversions cause problems in chromosomal alignment during meiosis, the carrier is at high risk to produce abnormal gametes and thus abnormal offspring. The risk can be calculated for each unique inversion, but in general, the observed risk is 5 to 10 percent if ascertainment was prompted after the birth of an abnormal child, and 1 to 3 percent if ascertainment was prompted by some other reason (Gardner and Sutherland, 1996).

Figure 12-6. Meiosis in chromosomes with pericentric and paracentric inversions. (Adapted from Greenwood Genetics Center, 1995, with permission.)

RING CHROMOSOMES. When there are deletions from both ends of a chromosome, the ends may unite, forming a ring chromosome. If the deletions are substantial, the carrier is phenotypically abnormal. For example, *ring X chromosome* is associated with the Turner syndrome phenotype.

Telomeres are the physical ends of linear chromosomes. They are specialized nucleoprotein complexes that have important functions, primarily in the protection, replication, and stabilization of the chromosomal ends. If only the telomeres are lost, all important genetic material is retained and the carrier is essentially balanced. The ring, however, prevents normal chromosome alignment during meiosis and thus produces abnormal gametes. It also disrupts cell division, causing abnormal growth of many tissues and leading to small stature, borderline to moderate mental deficiency, and minor dysmorphisms (Gardner and Sutherland, 1996).

A ring chromosome may form *de novo* or may be inherited from a carrier parent. In all cases of parent-to-child transmission, the mother is the carrier, possibly because a ring chromosome somehow compromises spermatogenesis.

CHROMOSOMAL MOSAICISM. This finding is defined as two or more cytogenetically distinct cell lines in the same individual. In many cases, mosaicism is a cell-culture artifact that must be differentiated from true mosaicism (Claussen and co-workers, 1984). The phenotypic expression of mosaicism depends on many factors, including whether the cytogenetically abnormal cells involve the placenta, the fetus, parts of the fetus, or some combination. Although true mosaicism rarely is encountered in either a fetus or amniocytes, chorionic villus sampling has shown that 2 percent of placentas are mosaic, even though the associated fetus is usually normal (Henderson and associates, 1996). This finding is called *confined placental mosaicism*, and it likely results from nondisjunction during early mitotic divisions in one or more cells destined to become the placenta. It could also result from partial "correction" of a trisomy resulting from a meiotic error, with the extra chromosome lost from all cells destined to become the fetus, but retained in some cells destined to become the placenta. The mechanism causing mosaicism seems to be chromosome specific. Mosaicism involving chromosomes 2, 7, 8, 10, and 12 is usually caused by a mitotic error, whereas that involving chromosomes 9, 16, and 22 tends to result from partial correction of a meiotic error (Robinson and colleagues, 1997).

Confined placental mosaicism may have either positive or negative effects. It may play a role in the survival of some cytogenetically abnormal fetuses. For example, trisomy 13 and 18 fetuses who survive to term may do so only because of early trisomic "correction" in some cells that become trophoblasts. This would favor more normal placental function (Kalousek and co-workers, 1989). Conversely, some cytogenetically normal fetuses may have severe growth restriction because the placenta contains a population of aneuploid cells that impair function (Kalousek and Dill, 1983). It now appears that growth restriction also is influenced by *which* chromosome is lost during the trisomic "correction." If the fetus retains two normal copies of the chromosome in question, but both copies came from the same parent, growth also may be impaired. This event is referred to as *uniparental disomy* and is discussed later.

Gonadal mosaicism is confined to the gonads. It likely arises as the result of a mitotic error in cells destined to become the gonad, resulting in a population of abnormal germ cells. Because spermatogonia and oogonia divide throughout fetal life, and spermatogonia continue to divide throughout adulthood, gonadal mosaicism also could occur as the result of a meiotic error in previously normal dividing germ cells. Gonadal mosaicism may explain *de novo* autosomal dominant mutations in the offspring of normal parents, causing such diseases as achondroplasia or osteogenesis imperfecta, or X-linked diseases such as Duchenne muscular dystrophy. It also explains the recurrence of such diseases in more than one child in a previously unaffected family. It is because of the potential for gonadal mosaicism that the recurrence risk after the birth of a child with a disease caused by a "new" mutation is approximately 6 percent.

SINGLE-GENE (MENDELIAN) DISORDERS

A mendelian disorder is caused by a mutation or alteration in a single locus or gene, in one or both members of a gene pair. Approximately 0.4 percent of the population has a genetic abnormality caused by a single-gene mutation discovered by age 25, and 2 percent will have a single-gene disorder diagnosed during their lifetime (see [Table 12-1](#)). As of 2004, 15,566 monogenic disorders had been identified. Although they are classified according to their mode of inheritance—14,589 autosomal, 868 X-linked, 54 Y-linked, and 61 mitochondrial—it must be emphasized that it is the *phenotype* that is dominant or recessive, not the genes. In some dominant diseases, for example, the normal gene may still be directing the production of normal protein, but the phenotype is determined by protein produced by the abnormal gene. Likewise, the heterozygous carrier of some recessive diseases may produce detectable levels of the abnormal gene product, but he or she does not display features of the disease because the phenotype is directed by the product of the normal co-gene. Some common "single-gene disorders" affecting adults are listed in [Table 12-6](#).

Although transmission patterns of these diseases are consistent with mendelian inheritance, their phenotypes are strongly

influenced by modifying genes and environmental factors. Ironically, although single-gene (mendelian) disorders were the first genetic conditions identified, diseases caused solely by single genes are actually relatively rare.

AUTOSOMAL DOMINANT. If only one member of a gene pair determines the phenotype, that gene is considered to be dominant. Likewise, a gene with a dominant mutation specifies the phenotype in preference to the normal gene. The carrier of a gene causing an autosomal dominant disease has a 50-percent chance of passing on the affected gene with each conception.

Penetrance. This term describes whether or not the mutant gene is expressed at all. A dominant gene with some kind of recognizable phenotypic expression in all individuals who carry the gene has 100 percent penetrance. If the carrier of the abnormal gene displays *no* features of the associated disease, the gene is not penetrant. Incomplete penetrance, the situation in which some gene carriers express the gene but some do not, is quantitatively expressed by the ratio of gene carriers who have any phenotypic characteristics associated with the altered gene to the total number of gene carriers. A gene that is expressed in some way in 80 percent of individuals who have that gene is 80-percent penetrant. Incomplete or reduced penetrance may explain why some autosomal dominant diseases appear to "skip" generations.

Some mechanisms responsible for reduced penetrance have been identified. For example, in retinoblastoma, reduced penetrance is explained by the fact that an individual carrying the abnormal allele must also acquire a somatic mutation affecting the normal retinoblastoma allele in order to develop the disease. If the normal allele is not mutated, the disease is not penetrant. Another mechanism is delayed onset of disease. For example, because symptoms of Huntington disease may not become apparent until age 40, if the individual carrying the gene died before it had been expressed, the gene would appear to have skipped that generation.

Expressivity. This term refers to the degree to which the phenotypic features are expressed. If all individuals carrying the affected gene do not have identical phenotypes, the gene has *variable expressivity*. Expressivity of a gene can range from complete or severe manifestations to only mild features of the disease. An example of a disease with variable expressivity is neurofibromatosis.

Anticipation. This term describes a phenomenon observed in certain chromosomal diseases such as fragile X syndrome and myotonic dystrophy. Disease symptoms seem to be more severe and to appear at an earlier age in each successive generation. In these cases, the progressively more severe phenotype corresponds to progressively larger gene mutations (discussed later). Other cases of apparent anticipation likely result from ascertainment bias. When an individual with a severe phenotype is identified, the search for other affected family members often reveals milder cases in previous generations.

AUTOSOMAL RECESSIVE. These traits usually are expressed only when both copies of the gene function identically. Thus, autosomal recessive diseases develop only when both gene copies are abnormal. Phenotypic alterations in gene carriers \mathfrak{R} —that is, *heterozygotes* \mathfrak{R} —usually are undetectable clinically but may be recognized at the biochemical or cellular level. For example, many enzyme deficiency diseases are autosomal recessive. The enzyme level in a carrier will be about half of normal, but because enzymes are made in great excess, this reduction usually does not cause disease. It does, however, represent a phenotypic alteration and can be used for screening purposes (see [Chap. 13](#), p. 318). Other recessive conditions do not produce any phenotypic changes in the carrier and can be identified only by molecular methods.

Unless they are screened for a specific disease, such as cystic fibrosis, carriers usually are recognized only after the birth of an affected child or the diagnosis of an affected family member (see [Chap. 13](#), p. 317). A couple whose child has an autosomal recessive disease has a 25-percent recurrence risk with each conception. The likelihood that a normal sibling of an affected child is a carrier of the gene is two out of three; 1/4 of offspring will be homozygous normal, 2/4 will be heterozygote carriers, and 1/4 will be homozygous abnormal \mathfrak{R} —thus, three of four children will be phenotypically normal and two of these three will be carriers.

The carrier child will not have affected children, unless his or her partner is also a carrier (heterozygous) or has the disease (homozygous). Because genes leading to rare autosomal recessive conditions have a low prevalence in the general population, the chance that a partner will be a gene carrier is low unless the couple is related or part of an isolated population (American College of Obstetricians and Gynecologists, 2004).

Inborn Errors of Metabolism. Most of these autosomal recessive diseases result from the absence of a crucial enzyme leading to incomplete metabolism of proteins, sugars, or fats. The metabolic intermediates that build up are toxic to a variety of tissues, resulting in mental retardation or other abnormalities.

PHENYLKETONURIA (PKU). This classical example of an autosomal recessive defect results from diminished or absent phenylalanine hydroxylase activity. Homozygotes are unable to metabolize phenylalanine to tyrosine. If the diet is unrestricted, incomplete protein metabolism leads to abnormally high phenylalanine levels that cause neurological damage and mental retardation. There also is hypopigmented hair, eyes, and skin because phenylalanine competitively inhibits tyrosine hydrolase, which is essential for melanin production. The disease is rare and affects 1 in 10,000 to 15,000 white newborns. There is tremendous geographical and ethnic variation, with incidences ranging from 5 to 190 cases per million.

PKU is notable for two reasons. First, it is one of the few metabolic disorders for which treatment exists. Homozygotes who ingest a phenylalanine-free diet can avoid many of the clinical consequences of the disease. Early diagnosis and limitation of dietary phenylalanine beginning in infancy are essential to prevent neurological damage. Accordingly, all states and many countries now mandate newborn screening for PKU, and about 100 cases per million births have been identified worldwide. The special diet should be continued indefinitely, as patients who abandon the phenylalanine-free diet may have some decline in IQ.

Women with PKU who plan to conceive and are not already on a phenylalanine-restricted diet should be counseled to adhere to the diet before conception and throughout pregnancy. Phenylalanine readily crosses the placenta, and high maternal serum levels can result in damage to the fetus or pregnancy loss (National Institutes of Health, 2000). Hyperphenylalaninemia causes microcephaly with mental retardation and cardiac defects in the heterozygote fetus who otherwise would not be affected. Importantly, these defects can be prevented with maternal dietary treatment (Williamson and associates, 1981). The Maternal

Phenylketonuria Collaborative Study, which enrolled nearly 600 women during 12 years, found that maintenance of serum phenylalanine levels in the 160 to 360 $\mu\text{mol/L}$ (2 to 6 mg/dL) range significantly reduced the risk of fetal abnormalities (Platt and colleagues, 2000).

CONSANGUINITY. Two individuals are considered consanguineous if they have at least one ancestor in common. The term usually refers to an individual mating with a third-degree relative such as a first cousin, a half-uncle or aunt, or a half-niece or nephew, or a more distantly related individual. First-degree relatives share half, second-degree relatives share one fourth, and third-degree relatives (cousins) share one eighth of their genes. Because of the potential for shared deleterious genes, consanguineous unions are at increased risk to produce children with autosomal recessive or multifactorial diseases.

First-cousin marriages, the most frequent consanguineous mating, carry a twofold increased risk of abnormal offspring (4 to 6 percent risk instead of the 2 to 3 percent background risk) if there is no family history of genetic disease. If one of the partners has a sibling with an autosomal recessive disease, the risk of affected offspring is many times higher than if he or she had chosen an unrelated partner. First-cousin marriage is legal in 30 states and is actually preferred in some countries, for example, some parts of the Middle East (Bennett, 1987; Shami and colleagues, 1991). Despite this, there are significant medical, societal, and legal ramifications to first-cousin marriages in the United States. All of these should be addressed by the couple before childbearing with each other.

Incest is defined as a sexual relationship between first-degree relatives such as parent and child or brother and sister and is universally illegal. Progeny of such unions carry the highest risk of abnormal outcome, and up to 40 percent of offspring are abnormal as a result of both recessive and multifactorial disorders (Friere-Maia, 1984; Nadiri, 1979).

CO-DOMINANT GENES. If alleles in a gene pair are different from each other, but both are expressed in the phenotype, they are considered to be co-dominant. An example is the genes responsible for hemoglobinopathies. The individual with one gene directing production of sickle hemoglobin and the other directing production of hemoglobin C produces both S and C hemoglobins. Genes determining human blood type are also co-dominant; both A and B red-cell antigens can be expressed simultaneously in one individual.

X-LINKED AND Y-LINKED GENES. X-linked diseases are usually recessive. The best known X-linked recessive diseases are color blindness, hemophilia A, and Duchenne muscular dystrophy. Women carrying an X-linked recessive gene generally are unaffected, unless unfavorable lyonization X^{in} —inactivation of one X chromosome in every cell X^{in} —results in the majority of cells expressing the abnormal gene. When a woman carries a gene causing an X-linked recessive condition, there is a 50 percent chance of passing the gene with each conception. Thus, each son has a 50 percent risk of being affected and each daughter has a 50 percent chance of being a carrier.

Men carrying an X-linked recessive gene usually are affected because they lack a second X chromosome to express the normal dominant gene. When a man has an X-linked disease, none of his sons will be affected because they cannot receive the abnormal X-linked gene from him. As subsequently discussed, for complex reasons, fragile X syndrome does not conform to these rules of X-linked inheritance.

X-linked dominant disorders affect females predominantly because they tend to be lethal in male offspring. Examples include focal dermal hypoplasia, vitamin D-resistant rickets, and incontinentia pigmenti.

The Y chromosome carries genes important for sex determination and a variety of cellular functions such as spermatogenesis and bone development. Deletion of genes on the long arm of the Y chromosome results in severe spermatogenic defects, whereas genes at the tip of the short arm are critical for chromosomal pairing during meiosis and for fertility.

NONMENDELIAN PATTERNS OF INHERITANCE

HEREDITARY UNSTABLE DNA. Mendel's first law states that genes are passed unchanged from parent to progeny. Barring the occurrence of new mutations, that law still applies to many genes or traits. Certain genes, however, are unstable, and their size and consequently their function may be altered as they are transmitted from parent to child.

Fragile X Syndrome. Also called *Martin-Bell syndrome*, fragile X syndrome is the most common form of *familial* mental retardation. By contrast, Down syndrome is the most common *genetic* cause of mental retardation, but it is usually not familial. Fragile X syndrome accounts for 4 to 8 percent of all retardation in males and females in all ethnic and racial groups. The incidence of the full fragile X syndrome is generally cited as 1 in 1000 males and 1 in 2000 females (Rousseau and co-workers, 1995; Turner and colleagues, 1996).

The fragile X mutation is a region of unstable DNA on the X chromosome. The region is best described as a series of CGG (cytosine-guanine-guanine) triplet repeats at Xq27. If the number of repeats and thus the region reaches a critical size, it can be methylated and thus inactivated (Migeon, 1993). When the gene is inactivated, *fragile X mental retardation-1 (FMR-1) protein* is not produced. Although the function of this protein is unknown, it is highly conserved in all species and is most active in brain and testes.

The number of repeats and the degree of methylation determine whether or not an individual is affected (Cutillo, 1994). The absolute number of repeats is less important than whether the number exceeds either of two important thresholds. Individuals carrying 2 to 49 repeats are usually phenotypically normal. Those carrying 50 to 199 repeats have a *premutation*, and although they were previously considered to be normal, three distinct phenotypes have recently been characterized (Hagerman and Hagerman, 2004). These include mild cognitive and behavioral deficits, premature ovarian failure, and a neurodegenerative disorder that affects older adults and has been termed the *fragile X-associated-tremor/ataxia syndrome (FXTAS)*. Those with more than 230 repeats have the *full* mutation and, if methylation occurs, are usually affected.

The number of repeats usually remains stable when the gene is transmitted by a male. When transmitted by a female with a premutation, however, the gene can expand during meiosis. The risk of expansion with maternal transmission generally

correlates with the number of repeats in the maternal premutation. Thus, if a woman carries a premutation that increases in size as she transmits it to her offspring, it is possible for her child to manifest fragile X syndrome (Cutillo, 1994).

Approximately 80 percent of males and 50 to 70 percent of females carrying the full mutation are mentally handicapped (de Vries and co-workers, 1996; Jones, 1997). Males are moderately to severely affected, with an IQ of 35 to 45, whereas the IQ in females is generally higher (Nelson, 1995). Affected individuals also may have autistic behavior, attention-deficit/hyperactivity disorder, and speech and language problems. The physical phenotype includes a narrow face with large jaw, long prominent ears, and macroorchidism in postpubertal males. Surprisingly, 20 percent of males and 10 percent of females carrying the expanded gene either are unaffected or have a mild phenotype. This phenotypic variability is caused by lyonization (in females) or mosaicism for the size of the expansion, the degree of methylation, or both (Cutillo, 1994).

With the use of restriction endonuclease digestion and Southern blot analysis, as discussed on page 308, the number of CGG repeats and the methylation status of the gene can be accurately determined. Amniocentesis may be preferred for prenatal diagnosis because methylation status may be difficult to determine in chorionic villus cells. It is reasonable to refer individuals with a history of mental retardation, developmental delay of unknown etiology, or autism for genetic evaluation because 2 to 6 percent will be determined to have fragile X (Curry and colleagues, 1997; Wenstrom and associates, 1999). Screening rationale is discussed further in [Chapter 13](#) (see p. 326).

Myotonic Dystrophy. This is the most common form of adult myopathy (Jones, 1997). Affected family members tend to have successively earlier and more severe symptoms with each generation. The affected gene on the long arm of chromosome 9 contains a region of unstable trinucleotide (cytosine-thymine-guanine; CTG) repeats (Buxton and co-workers, 1992). Normal individuals have 3 to 30 repeats, and although they can expand up to 3000, an increase to as few as 40 has been associated with myotonic dystrophy.

There are three distinct myotonic dystrophy phenotypes, depending on the number of repeats. The severity of the phenotype increases as the number of repeats increases from generation to generation, thus accounting for "anticipation." With about 100 repeats there is mild disease, characterized by mild facial muscle weakness and wasting, frontal balding, and cataract formation. With 1300 repeats there is a 90-percent chance of having the full syndrome, which includes proximal muscle weakness, cardiomyopathy, mental retardation, endocrine dysfunction, abnormal facies, and cataract development. Individuals with an intermediate number of repeats, from 200 to 800, have an intermediate phenotype (Gennarelli and colleagues, 1996). The most severe manifestations develop in the congenital form of the disease, which is associated with huge expansions of at least 10 kb. Affected infants are thin and have hypotonia, facial muscle weakness, decreased cry and suck, and respiratory insufficiency, and rarely survive to adulthood. Hydramnios, which results from decreased fetal swallowing, and decreased fetal movement in a patient with facial muscle weakness or frontal balding should arouse suspicion. In contrast to fragile X syndrome, the number of repeats can increase with transmission by either parent and also can decrease when transmitted by a male.

Huntington Disease. This disorder is characterized by progressive chorea, bradykinesia, and rigidity with an insidious deterioration of intellectual function. The mean age at diagnosis is about 40 years. The gene on chromosome 4 contains a region of CAG (cytosine-adenine-guanine) triplet repeats. Normal individuals have 10 to 35 CAG repeats, whereas those with the disease have 36 to 121 repeats. Like myotonic dystrophy, there is a significant correlation between the number of repeats and the age of onset (Andrew and colleagues, 1993). Interestingly, there is also a correlation between *paternal* inheritance and early disease (Clarke, 1990). Thus, the gene appears to be most unstable when transmitted by the father.

Other DNA-Triplet Repeat Diseases. These include Friedreich ataxia, X-linked spinal and bulbar muscular atrophy (Kennedy disease), spinocerebellar ataxia types 1 and 2, dentato-rubro-pallido-luysian atrophy, and Machado-Joseph disease.

IMPRINTING. This term describes the process by which certain genes are inherited in an inactivated or *transcriptionally silent* state (Hall, 1990). This type of gene inactivation is determined by the gender of the transmitting parent and may be reversed in the next generation. Imprinting affects gene expression by *epigenetic control*, that is, it changes the phenotype by altering gene expression and not by permanently altering the genotype. When a gene is inherited in an imprinted state, gene function is necessarily directed entirely by the co-gene inherited from the other parent. Thus, imprinting exerts an effect by controlling the "dosage" of specific genes.

Certain important genes appear to be *monoallelic*. Thus, under normal circumstances only one member of the gene pair is functioning — as opposed to most genes in the genome, which are biallelic. Most of the monoallelic genes identified so far regulate tissue growth. Genes normally expressed only from the paternal allele, such as insulin growth factor 2, tend to be associated with tissue overgrowth and tumor formation, whereas genes normally expressed exclusively from the maternal allele, such as *H19*, result in growth suppression (Tycko, 1994).

The genes inherited from each parent express the parental imprinting in all fetal cells. Then, in the immediate post-zygote period, the inherited methylation pattern in the fetal *germ cells only* is erased, and a new imprinting pattern, corresponding to the gender of the fetus, is imposed. When the fetus reaches adulthood, during reproduction it will pass on the imprinting pattern unique to its own gender.

One example of the effect of imprinting concerns a chromosome deletion at 15q11-13, which causes two very different diseases:

1. *Prader-Willi syndrome* is characterized by obesity and hyperphagia; short stature; small hands, feet, and external genitalia; and mild mental retardation.
2. *Angelman syndrome* includes normal stature and weight, severe mental retardation, absent speech, seizure disorder, ataxia and jerky arm movements, and paroxysms of inappropriate laughter.

Both syndromes are associated with the same deletion, but which of the two different phenotypes occurs depends on whether the missing genetic material was inherited from the mother or the father. If the deleted genetic material was maternal in origin, the result is Angelman syndrome, but if the deleted material was paternally derived, Prader-Willi syndrome results.

There are a number of other examples of imprinting important to obstetricians-gynecologists. *Complete hydatidiform mole*, which has a paternally derived, diploid chromosomal complement, is characterized by the abundant growth of placental tissue, but no fetal structures (see [Chap. 11](#), p. 274). Conversely, *ovarian teratoma*, which has a maternally derived, diploid chromosomal complement, is characterized by the growth of various fetal tissues but no placental structures (Porter and Gilks, 1993). It thus appears that paternal genes are vital for placental development and maternal genes are essential for fetal development, but both must be present in every cell for normal fetal growth and development. Imprinting also is operative in some growth disorders and malignancies.

UNIPARENTAL DISOMY. In this situation, both members of one pair of chromosomes are inherited from the same parent ([Fig. 12-7](#)). This appears to result from the "correction" of a trisomic zygote by loss of a chromosome. The chromosome transmitted by one parent is lost, and the two chromosomes transmitted by the other parent are retained.

Isodisomy is the unique situation in which an individual receives two identical copies of one chromosome in a pair from one parent. This mechanism explains some cases of cystic fibrosis, in which only one parent was a carrier but the fetus inherited two copies of the same abnormal chromosome from that parent (Spence and co-workers, 1988; Spotila and colleagues, 1992). It also has been implicated in abnormal growth related to placental mosaicism (Robinson and colleagues, 1997).

Figure 12-7. Diagrammatic representation of how uniparental disomy may arise.

MITOCHONDRIAL INHERITANCE. Each human cell contains hundreds of mitochondria, each containing its own genome and associated replication systems. In this sense, mitochondria behave autonomously. Interestingly, these organelles are derived exclusively from the mother. Whereas human oocytes contain approximately 100,000 mitochondria, sperm contain only 100, and these are destined for destruction after fertilization. Each mitochondrion contains multiple copies of a 16.5-kb circular DNA molecule. This DNA encodes 13 peptides that are subunits of proteins required for oxidative phosphorylation, as well as ribosomal and transfer RNAs.

Because mitochondria contain genetic information, mitochondrial inheritance allows the transmission of genes from mother to offspring without the possibility of recombination. If a mitochondrial mutation occurs, it may segregate into a daughter cell during cell division and thus be propagated. Over time, the percentage of mutant mitochondrial DNAs in different cell lines can drift toward either normal or pure mutant (Wallace, 1995). If an oocyte containing largely mutant mitochondrial DNAs is fertilized, the offspring might have a mitochondrial disease. These have a characteristic transmission pattern—individuals of both sexes can be affected, but transmission is only through females. Mitochondrial genetic diseases include *myoclonic epilepsy with ragged red fibers (MERRF)*, *Leber hereditary optic neuropathy*, *Leigh syndrome*, and *pigmentary retinopathy*.

POLYGENIC AND MULTIFACTORIAL INHERITANCE. *Polygenic traits* are determined by the combined effects of many genes. *Multifactorial traits* are determined by multiple genes and environmental factors. It is now believed that the majority of inherited traits are multifactorial or polygenic. Birth defects caused by such inheritance are recognized by their tendency to recur in families, but not according to a mendelian inheritance pattern. The empirical recurrence risk for first-degree relatives usually is quoted as 2 to 3 percent (Thompson and colleagues, 1991). Multifactorial traits can be classified in several ways, but the most logical is to categorize them as continuously variable traits, threshold traits, or complex disorders of adult life.

Continuously Variable Traits. These traits have a normal distribution in the general population. By convention, abnormality is defined as a trait or measurement greater than two standard deviations above or below the population mean. These are typically measurable or quantitative traits such as height or head size and are believed to result from the individually small effects of many genes combined with environmental factors. Such traits tend to be less extreme in the offspring of affected individuals, because of the statistical principle of regression to the mean.

Threshold Traits. These traits do not appear until a certain threshold of liability is exceeded ([Fig. 12-8](#)). Factors creating liability to the malformation are assumed to be continuously distributed, and only individuals at the extreme of this distribution exceed the threshold and have the trait or defect. The phenotypic abnormality is thus an all-or-none phenomenon. Individuals in high-risk families have enough abnormal genes or environmental influences that their liability is close to the threshold. Usually for unknown reasons, some factor(s) further increase the liability for certain family members, and the threshold is crossed. Cleft lip and palate and pyloric stenosis are examples of threshold traits.

Certain threshold traits have a predilection for one gender, indicating that males and females have a different liability threshold. An example is pyloric stenosis, which is more common in males. If a female has pyloric stenosis, she or her parents have even more abnormal genes or predisposing factors than is usually necessary to produce pyloric stenosis in males. The recurrence risk for her siblings or for her future children is thus higher than the expected 2 to 3 percent. Male siblings or offspring would have the highest liability, because they not only will inherit more than the usual number of predisposing genes, but also are the more susceptible sex.

Finally, the recurrence risk of threshold traits is also higher if the defect is severe, again suggesting the presence of more abnormal genes or influences. For example, the recurrence risk after the birth of a child with bilateral cleft lip and palate is 8 percent, compared with only 4 percent associated with unilateral cleft lip without cleft palate (Melnick and associates, 1980).

Complex Disorders of Adult Life. These are traits in which many genes determine the susceptibility to environmental

factors, with disease resulting from the most unfavorable combination of both. Examples include common disorders such as heart disease or hypertension. These disorders are usually familial and behave as threshold traits, but with environmental influence as an important cofactor. The genetic mechanisms of many common adult diseases have not yet been elucidated, although in most cases, several associated genes have been identified. In some diseases, the identity of the associated gene provides a clue to pathogenesis, whereas in others the related gene may simply serve as a disease marker. For example, premature cardiovascular disease is associated with the gene for apolipoprotein E, which likely influences the pathology of the disease. In contrast, the association of type 1 diabetes mellitus with HLA-DR3/4 is less clear. Some multifactorial adult-onset diseases and associated genes are listed in [Table 12-7](#).

Examples of Multifactorial or Polygenic Defects. Various isolated structural birth defects and common diseases exhibit multifactorial or polygenic inheritance. All of these traits have certain characteristics that help to distinguish them from disorders with other modes of inheritance, which can be cited in counseling ([Table 12-8](#)). When counseling patients regarding risks for a familial multifactorial trait, it is important to consider the degree of relatedness of the affected relative to the *fetus*, not the parents. An affected first-degree relative (the parents or siblings of the fetus) results in a substantial risk increase, but risk declines exponentially with successively more distant relationships. Two examples are neural-tube and cardiac defects.

NEURAL-TUBE DEFECTS. The neural plate extends down the dorsum of the 18-day embryo. It folds and closure is believed to occur in five separate regions, which then fuse ([Fig. 12-9](#)). Neural-tube defects likely result from either failure of closure at one or more sites, or failure of two sites to fuse (Golden and Chernoff, 1995).

Isolated or nonsyndromic neural-tube defects are the second most common congenital structural abnormalities after cardiac defects. Worldwide their incidence is 1.4 to 2 per 1000 live births. They also can develop as part of a genetic syndrome or constellation of abnormalities. They are a major cause of stillbirth and neonatal and infant death. With treatment, 80 to 90 percent of infants with isolated spina bifida survive with varying degrees of handicap. Factors that influence eventual neurological function include the size and location of the defect, trauma to exposed neural tissue, timing of surgical closure, degree of associated ventriculomegaly, and occurrence of complications such as infection.

Anencephaly is the most severe defect ([Fig. 12-10](#)). It is always lethal and results in stillbirth or early neonatal demise. *Spina bifida* occurs when one or more vertebral arches fail to fuse, so that meninges (*meningocele*) or neural tissue plus meninges (*meningomyelocele*) are exposed ([Fig. 12-11](#)). *Rachischisis* describes the lethal situation in which none of the vertebral arches fuse, and the entire spine is open. These lesions, as well as some of their ultrasonographic appearances, are discussed in [Chapter 16](#) (see p. 393).

Neural-tube defects are classical examples of multifactorial inheritance. Their development is influenced by environment, diet, physiological abnormalities such as hyperthermia or hyperglycemia, teratogen exposure, family history, ethnic origin, fetal gender, amniotic fluid nutrients, and various genes. The fact that certain defects are associated with specific risk factors suggests that many genes are likely to be involved in neural-tube development. For example, those associated with type 1 diabetes mellitus are likely to be cranial or cervical-thoracic defects; hyperthermia has been associated with anencephaly; and valproic acid exposure with lumbosacral defects (Becerra and colleagues, 1990; Hunter, 1984; Lindhout and associates, 1992).

Although Hibbard and Smithells (1965) postulated more than 30 years ago that abnormal folate metabolism was responsible for many neural-tube malformations, a specific gene defect only recently has been implicated. A thermolabile variant of the enzyme 5,10-methylene tetrahydrofolate reductase (MTHFR), which plays a key role in folate metabolism, has been associated with neural-tube defects. This enzyme transfers a methyl group from folic acid to convert homocysteine to methionine. One abnormal form of MTHFR carries a mutation at position 677 and has reduced enzymatic activity. Folic acid supplementation likely works by overcoming this relative enzyme deficiency. Because some defects develop in fetuses with normal 677 C₆₇₇→T alleles, and because folic acid supplementation does not prevent all cases, other unknown genes or factors are presumed to be involved. Without folic acid supplementation, the empirical recurrence risk after one affected child is 3 to 4 percent, and after two affected children it is 10 percent. With supplementation, the risk after one affected child decreases by 70 percent to less than 1 percent (Czeizel and Dudas, 1992; MRC Vitamin Study Research Group, 1991).

Importantly, folic acid supplementation may also significantly decrease the incidence of first occurrences of neural-tube defects. Since 1998 the Food and Drug Administration has required fortification of cereal grain products calculated so that the average woman ingests daily an extra 200 µg of folic acid (American College of Obstetricians and Gynecologists, 2003). In the United States, the incidence of neural-tube defects has decreased by one fourth following folic acid fortification (Centers for Disease Control and Prevention, 2004; De Wals and associates, 2003). This relatively small decrease is probably the result of inadequate fortification. Wald (2004) estimates that folic acid supplementation with 5 mg per day would decrease the incidence of neural-tube defects by 85 percent.

CARDIAC DEFECTS. Cardiac anomalies are the most common birth defects worldwide, with an incidence of 8 per 1000 births. They outnumber all other isolated structural defects combined (Burn and Goodship, 1996). The majority of isolated cardiac malformations have traditionally been considered multifactorial, with genetic aspects that were difficult to evaluate. In the past, women with severe heart defects often did not reproduce, and many parents whose child had a serious heart defect chose not to have more children. Certain cardiac defects are much more likely to recur than others, and first-degree relatives with heart defects are likely to have the same or similar defect regardless of environmental exposures (see [Chap. 13](#), p. 316).

More than 100 genes believed to be involved in cardiovascular morphogenesis have been identified, including those directing production of various transcription factors, secreted proteins, extracellular proteins, and protein receptors (Chin, 1998). These gene products are likely involved in the development of specific cardiac tissues and structures. For example, clinical and laboratory data indicate that folic acid and the same MTHFR 677 C₆₇₇→T mutation associated with neural-tube defects influence the development of cardiac defects (Wenstrom and co-workers, 2001). As discussed, folic acid provides methyl groups for a number of important cellular processes. One study showed that myocyte DNA in hypoplastic left ventricles was significantly hypomethylated compared with that of normal controls (Wenstrom and co-workers, 2002). Moreover, preconceptional folic acid supplementation appears to reduce their incidence (Czeizel, 1996).

Many other genes likely to be involved in normal and abnormal cardiac development have not yet been identified. Gene deletion syndromes that include cardiac defects provide clues to the function and location of some of these unknown genes. For example, an association between the DiGeorge deletion and conotruncal cardiac defects has prompted a search for the

causative genes within a small region of chromosome 22q11.2.

Observed recurrence risks, which likely reflect both genetic and environmental influences, for some common congenital heart defects are shown in [Table 12-9](#). For counseling, if the exact nature of the defect is known, the most specific risk should be quoted. Otherwise, couples can be informed of the empirical risk of having a child with a cardiac defect. This is 5 to 6 percent if the mother has the defect, and 2 to 3 percent if the father has the defect (Burn and associates, 1998). Specific defects, which have recurrence risks four- to sixfold higher, include hypoplastic left heart, bicuspid aortic valve, and aortic coarctation (Lin and Garver, 1988; Nora and Nora, 1988).

MOLECULAR GENETICS

The complexity of the human genome and the billion DNA base pairs that make it up were discussed earlier. What follows is a cursory review of molecular genetics as related to obstetrics as well as to prenatal diagnosis, which is discussed in [Chapter 13](#).

ORGANIZATION OF THE GENOME. The 2 meters of DNA in every cell must be packaged in an elaborate system to be maintained and transmitted without interruption. The DNA is wrapped compactly around basic proteins called histones to form nucleosomes. These are then organized into solenoid structures and looped around a nonhistone protein scaffold to form chromatin ([Fig. 12-12](#)). As the cell enters prophase, the chromatin begins to condense until it assumes the familiar structure of metaphase chromosomes. Each chromosome is composed of densely packed nontranscribed DNA near the centromeres, called *heterochromatin*, and less densely packed transcribed DNA called *euchromatin*.

In humans about 75 percent of the genome is unique, single-copy DNA, and the rest consists of various classes of repetitive DNA. Surprisingly, virtually all of the repetitive DNA and a large portion of the single-copy DNA has no apparent or recognized function. Less than 10 percent of the genome encodes genes! Single-copy DNA is intensely studied because it contains all the genes necessary to make and sustain the organism, and repetitive DNA is of interest because it contains unique markers that identify each individual and can be used to study genetic variation.

Figure 12-12. Schematic representation of the structural organization of DNA. (Adapted from Elsa and Patel, 1998, with permission.)

CODING DNA: GENES. A gene is a unique series of four types of purine and pyrimidine bases—more generally called *nucleotides*—that specifies the amino acid sequence for a single polypeptide chain of a protein molecule. Within a gene, nucleotide triplets, called *codons*, either code for placement of a specific amino acid within the polypeptide chain or signal the starting or stopping of protein assembly. In the nucleus, *codons* are *transcribed* from DNA into a single-stranded RNA that corresponds in sequence with one of the strands of the DNA helix. The RNA is processed and transported into the cytoplasm, where it is *translated* into the amino acid sequence that constitutes a protein. A gene is not one continuous

segment of coding DNA, but rather is typically composed of multiple coding sequences called *exons*, interrupted by noncoding regions called *introns* that must be excised prior to translation. Each gene also has a regulatory region called a *promoter*, which is a 5'^{3'} untranslated region, and a 3'^{5'} untranslated region containing the signal for messenger RNA maturation and function. Posttranslational processing of the protein follows, and the polypeptide chain is folded into a unique three-dimensional structure. Two or more polypeptide chains may combine, or the structure may be chemically modified by the addition of carbohydrate or other moieties.

The vast majority (99.8 percent) of DNA is identical in all humans. There are, however, minor differences that distinguish one person from another. These differences, called *polymorphisms*, generally consist of a single nucleotide substitution present roughly once in every 200 to 500 base pairs. These changes are primarily in noncoding regions of the genome.

Many genes exist in several alternate but normal forms called *alleles*. For example, the Rh and major blood group genes all have several normal alleles. A mutation is an alteration of DNA sequencing within a coding region of a gene that results in an adverse change in protein structure or function. Mutations can be visible chromosomal alterations, such as deletions or insertions, or may involve a substitution in one or more of the purine or pyrimidine bases. Single nucleotide substitutions that result in the wrong amino acid being coded for and selected are called *missense mutations*. Those that create a premature "stop" codon are called *nonsense mutations*. Some mutations cause an error in RNA splicing at the intron-exon splice sites. Diseases caused by a single mutation, such as sickle cell disease, are rare. Because genes coding for the proteins involved in physiological processes are highly redundant, a single mutation located in the coding region of a gene may be clinically silent. Most frequently, pathological phenotypic changes develop only when multiple genes are affected or when specific environmental influences are present.

When newly discovered genes are being analyzed, it can be difficult to distinguish polymorphism in a normal allele from a mutation. For example, more than 6300 variations of the *BRCA1* gene, one of the major genes associated with familial breast and ovarian cancer, have been identified (Hohenstein and Fodde, 2003). It is not currently known whether all of these variations are actually mutations associated with disease, or if some could be polymorphisms or allelic variants (Collins, 1996). The ability to distinguish alleles from mutations is obviously essential to any molecular screening program.

CONTROL OF GENE EXPRESSION: METHYLATION. Genomic DNA methylation is a reversible form of DNA modification that permits control of many aspects of gene expression (Thompson and colleagues, 1991). Its most important function is to control the tissue-specific activation of certain genes. Even though every cell contains the entire genome, genes that are not essential for each specific tissue type are methylated and thus "turned off." The only nucleotide that is methylated is the cytosine of CpG dinucleotide repeats CpG — "p" represents the phosphate backbone of the base pairing. Most CpG dinucleotides are located in gene regulatory regions, where methylation prevents transcription and thus effectively turns off the gene. An example is the globin genes, which are methylated (turned off) in all nonerythroid tissues; thus, only erythrocytes produce hemoglobin (Barsh and Epstein, 1996).

It is likely that both maintenance of methylation and its reversal require the actions of specific enzymes. Methyltransferases capable of adding a methyl group have been identified, but an enzyme capable of removing methyl groups has not (Reik and associates, 2001).

NEW MUTATIONS AND GENE REGULATION. New mutations also are linked to DNA methylation. Although most CpG dinucleotides appear to be located primarily in gene regulatory regions, they are also found within gene coding regions. The function of the CpGs within gene coding regions is not completely understood, but cytosine methylation here does not prevent gene transcription. Once it is methylated, however, the cytosine residue can be deaminated, either spontaneously or as the result of an exogenous mutagen, to become the nucleotide thymine. This thymine may not be recognized as a mutation, and thus not repaired. During DNA replication, this thymine will result in the addition of adenine instead of guanine in the complementary strand. Thus, cytosine methylation can ultimately result in a G to A point mutation (Wajed and Laird, 2001). This specific mutation is extremely common. Methylated CpGs are the single most mutated dinucleotides in the genome, and cause one third of all germline point mutations leading to genetic disease (Mancini and associates, 1997; Ollila and colleagues, 1996; Tornaletti and Pfeifer, 1995). Certain regions of the human genome, termed *hot spots*, have an abundance of CpGs and are especially vulnerable.

CpG dinucleotides have been associated with mutations in a variety of genes. New mutations causing hemophilia A, achondroplasia, mucopolysaccharidosis type II, and some retinoblastomas frequently involve CpG doublets (Mancini and collaborators, 1997; Rathmann and associates, 1996). Other genes with high mutation rates are those causing neurofibromatosis, polycystic kidney disease, and aniridia.

Certain lethal autosomal dominant diseases such as osteogenesis imperfecta or thanatophoric dwarfism *always* result from new mutations. These affected individuals have "reduced reproductive fitness" and are "genetic lethals" who die before they can reproduce.

Other Forms of Gene Regulation. In a small number of genes, the mRNA sequence is modified mRNA — termed *mRNA editing* mRNA — before it is transcribed, so that it is no longer complementary to its original DNA template (Barsh and Epstein, 1996). The initiation of mRNA translation also can be regulated, controlling the quantity of gene product produced. Finally, rearrangement of DNA can occur and produce a unique functional protein, such as an immunoglobulin (Harriman and colleagues, 1993).

Restriction Fragment Length Polymorphisms (RFLPs). Genomic DNA can be broken into manageable fragments for analysis by bacterial enzymes termed *restriction endonucleases*. Each endonuclease locates and cleaves a specific sequence of base pairs, wherever it occurs along the genome. As shown in [Figure 12-13](#), some enzymes recognize sequences of four nucleotides, some six, and others seven. More than 200 different restriction enzymes have been identified. The number and size of fragments produced by enzyme digestion are determined by the frequency or location of the particular sequences recognized by the enzyme. Each enzyme thus produces its own unique pattern of DNA fragments.

Certain restriction endonuclease sites are the same in all humans. Others, however, are unique to each individual. These unique endonuclease sites, leading to unique DNA fragment lengths, are called *restriction fragment length polymorphisms*

(RFLPs). These are not mutations or abnormalities, but are merely individual differences in nucleotide sequences that are present roughly once in every 250 base pairs throughout the genome (Marian, 1995). Each RFLP generally has two alleles and is inherited in mendelian fashion. Because of this, RFLPs can be used for identification purposes, for diagnostic testing, or to confirm or rule out transmission of a specific DNA segment from parent to child.

Repetitive DNA. These segments are characterized by short nucleotide sequences that are repeated many times throughout the genome. These regions are of interest because they include polymorphisms that can be used as markers. They also can be useful for following alleles through a family.

Clustered repetitive DNA makes up 10 to 15 percent of the genome (Elsa and Patel, 1998). These segments are called *simple sequence DNA* or *satellite DNA* because of their physical properties. These segments of DNA include several distinct classes of repeated sequences. One class is characterized by a *variable number of tandem repeats (VNTRs)*, consisting of multiple copies of short DNA sequences. *Short tandem repeats (STRs)*, also called *CA dinucleotides* or *GT repeats*, are areas of dinucleotide or trinucleotide repeats scattered throughout the genome. STRs are also highly polymorphic, with 4 to 10 alleles typically identified at each site. VNTRs and STRs are termed more *informative* than RFLPs because their allelic variation makes them more useful for DNA identification.

Interspersed repetitive DNA also occurs randomly and accounts for 15 percent of the genome. These sequences include *short interspersed sequences (SINES)* and *long interspersed sequences (LINES)*. All these repetitive sequences can be used to determine the relative locations of markers to each other and to the gene(s) of interest. Thus, they can be used to generate a DNA map.

Figure 12-13. Restriction endonucleases. *Hae III* (*H influenzae III*) cleaves a four-base sequence. *Mst II* (*Microcoleus*) cleaves a seven-base sequence, the center of which is a nonspecific nucleotide, shown here as N.

GENETIC TESTS

Cytogenetic Analysis. Any tissue containing dividing cells or cells that can be stimulated to divide is suitable for cytogenetic analysis. The dividing cells are arrested in metaphase, and the chromosomes are stained to reveal light and dark bands. The unique banding pattern of each chromosome facilitates its identification and detection of any deleted, duplicated, or rearranged segments. The accuracy of cytogenetic analysis increases along with the number of bands produced. Most laboratories now routinely perform high-resolution metaphase banding, which yields 350 to 550 visible bands per haploid chromosome set. Banding of prophase chromosomes generally yields 850 bands.

Because only dividing cells can be evaluated, the rapidity with which results are obtained correlates with the rapidity of cell growth in culture. Using bone marrow cells, results are usually available in less than 1 day, and adult blood cells yield results in 3 to 4 days. Fetal blood cells often produce results in 1 to 2 days. Amniocytes, which are fetal fibroblasts, sloughed gastrointestinal mucosal cells, and amnion cells, require 7 to 14 days. Skin fibroblasts usually require 3 to 6 weeks, but this is often because the sample is obtained postmortem and stimulation of growth is difficult.

Fluorescence In Situ Hybridization (FISH). This technique provides a rapid method for determining ploidy of select chromosomes or confirming the presence or absence of a specific gene or large DNA sequence (Fig. 12-14). It is not comparable to cytogenetic evaluation because the chromosomes appear squat and the banding patterns are much less distinctive. Chromosome duplications, deletions, and rearrangements often cannot be detected by FISH.

Cells are fixed onto a glass slide, and fluorescently labeled chromosome or gene probes are allowed to hybridize to the fixed chromosomes. Each probe is complementary to a unique area of the chromosome or gene being investigated, thus preventing cross reaction with other chromosomes. If the chromosome or gene of interest is present, hybridization is detected as a bright signal visible by microscopy. The number of signals indicates the number of chromosomes or genes of that type in the cell being analyzed.

The FISH technique usually is used when ploidy status would change clinical management and time constraints prohibit cytogenetic analysis. It also is used to provide fast but preliminary results in order to reduce parental anxiety. The Test and Technology Transfer Committee of the American College of Medical Genetics (2000) recommends that a full karyotype be performed along with all FISH analyses to confirm the ploidy status and to rule out structural chromosomal alterations.

Spectral Karyotype Analysis. This technique is a FISH procedure in which a labeled probe for every chromosome is used simultaneously. Chromosomes can be distinguished from each other because each probe emits a unique color. The results are analyzed by computer, making it a rapid and accurate test. It is currently available for research only.

Linkage Analysis. RFLPs, STRs, and other markers can be used to locate a specific gene for research or diagnostic purposes if certain criteria are met (Beaudet and Ballabio, 1994). First, a large family with multiple members affected by the disease in question must be identified. Next, specific markers scattered throughout the genome are selected for study or, if the gene is believed to be located on a specific chromosome, markers on that chromosome are chosen. DNA from each family member is then analyzed to determine whether any of the selected markers are transmitted along with the disease gene. If individuals with the disease have the marker and individuals without the disease do not, the gene causing the disease is said to be linked to the marker, suggesting that they are close to each other on the same chromosome. *Linkage analysis* allows the locations of different genes to be determined, along with their approximate distances from each other.

In cases in which the specific gene has not been identified, linkage analysis can sometimes be used to estimate the likelihood that an individual, for example, a fetus, has inherited the abnormal trait. Linkage analysis, however, is imprecise and depends on family size, availability of family members for testing, and presence of informative markers near the gene.

Complementary DNA (cDNA). When the nucleic acid sequence of a gene or DNA region of interest is known, it can be

studied directly using complementary DNA (cDNA), a laboratory-made copy of RNA corresponding to a DNA segment or gene. Many isolated genes or DNA fragments have been collected in cDNA libraries for research and diagnostic use. They are synthesized using reverse transcriptase, an enzyme isolated from tumor viruses, which can synthesize a complementary DNA copy (hence the term *cDNA*) of a nuclear messenger RNA. cDNA is usually single stranded. Importantly, because messenger RNA is the template, it does not contain the introns, which are removed during processing of mRNA. cDNA can be used to locate its corresponding gene. The cDNA is made using radioactive bases and is then allowed to anneal with the DNA being studied. The radioactive bases allow the DNA probe to be visualized if it bonds successfully, indicating that a matching sequence or identical gene is present.

Fluorescence-Activated Chromosome Sorting (FACS). Large quantities of a specific chromosome can be obtained by FACS. Chromosomes are stained with fluorescent dyes and then passed through a laser beam, which deflects off each chromosome according to its unique intensity. Chromosomes are distinguished from each other by this intensity.

Gel Separation. Once a desired chromosome has been isolated, it can be fragmented with a restriction endonuclease. These fragments can be separated using electrophoresis. Smaller fragments move faster and farther along the gel than larger fragments. The DNA fragments can then be removed from the gel and screened for the gene or DNA sequence of interest.

Polymerase Chain Reaction (PCR). This technique enables the rapid synthesis of large amounts of a specific DNA sequence or gene (Beaudet and Ballabio, 1994). Using PCR, 1 million copies of the original gene or DNA segment can be made in a few hours using minute quantities of DNA. Either the entire gene sequence or the sequences at the beginning and end of the gene, however, must be known. PCR involves three steps that are repeated many times. First, double-stranded DNA is denatured by heating. Then, oligonucleotide primers corresponding to the target sequence on each separated DNA strand are added and anneal to either end of the target sequence. Finally, a mixture of nucleotides and heat-stable DNA polymerase is added to elongate the primer sequence, and new complementary strands of DNA are synthesized. In just a few minutes, the original DNA has been duplicated. The procedure is repeated over and over with exponential amplification of the DNA segment.

Southern Blotting. Named for its inventor, Edward Southern, this technique allows identification of one or several DNA fragments of interest from among the million or so typically obtained by enzyme digestion of the entire human genome. As illustrated in [Figure 12-15](#), it applies the principles of gel separation and cDNA hybridization discussed earlier, but on a much larger scale. The cDNA probe may be a copy of a normal gene, in which case hybridization confirms the presence of the normal gene while lack of hybridization indicates a mutation. Hybridization can occur, however, even with incomplete sequence homology. Therefore, only relatively large mutations or changes such as deletions can be detected by cDNA probes.

The probe could also be a fragment of DNA produced by endonuclease digestion. In this case, individuals with a normal gene would have fragments of a different size from individuals carrying a mutated gene. Basic principles of the Southern blot technique also can be applied to RNA, in which case it is called *Northern blotting*, and to proteins — *Western blotting*.

Allele-Specific Oligonucleotide (ASO) Probes. If a mutation of interest consists of a change in only one or two base pairs, a cDNA probe will not detect it, as discussed earlier. For single-nucleotide mutations, an ASO probe must be used instead. An ASO is a short DNA probe, 15 to 25 bases in length, that is homologous to a specific DNA sequence (Layman, 1992). ASOs can be used instead of cDNA in the Southern blotting technique shown in [Figure 12-15](#). They are useful for testing family members at risk for a small, well-characterized familial mutation.

Multiplex Polymerase Chain Reaction. PCR can be used to amplify any DNA segment, including genes with deletions or mutations, as long as primers spanning the DNA region of interest are available. If various mutations in one gene have been identified in association with a certain disorder, they can all be amplified simultaneously using multiplex PCR.

Oligonucleotide Ligation Assay (OLA). This technique provides great sensitivity in detecting single-base insertions, deletions, or substitutions. Two probes, each corresponding to an adjacent region of the gene in question, are allowed to hybridize to these regions. If the nucleotide sequences of the two probes correspond exactly, they will link together when exposed to DNA ligase, releasing the label attached to one probe. This procedure provides a higher degree of accuracy than can be achieved with single-probe assays (Winn-Deen, 1996).

Ligase Chain Reaction (LCR). This technique is the amplification counterpart of OLA and may be used to screen for many different small or single-gene mutations simultaneously. In a single tube, the specimen is submitted to multiplex PCR and then evaluated with simultaneous OLA analysis for multiple different mutations. LCR is used by many laboratories for cystic fibrosis screening, because it allows simultaneous testing for the entire panel of 25 common mutations (see [Chap. 13](#), p. 325).

Cloning. A clone is a large number of molecules or cells all identical to one ancestral molecule or cell (Lewin, 1997). Cloning refers to the replication of genetic material, although a new definition created by the popular media includes replication of whole animals. Most commonly, cloning involves several laboratory techniques that enable pieces of DNA to be copied in large quantities by vectors within bacteria. These vectors are DNA molecules that replicate autonomously. Restriction enzymes are used to cleave both the DNA sequence of interest and the vector DNA at appropriate sites, and DNA ligase is used to insert the DNA segment into the vector DNA. The inserted DNA is replicated along with the vector DNA, and large quantities of the DNA insert can then be retrieved for study. The first vectors used for cloning were bacterial plasmids, which are circular, double-stranded DNA molecules that replicate separately from bacterial chromosomes.

Plasmids are used for small DNA inserts, usually less than 5 to 10 kb. DNA fragments were later cloned in bacteriophages with inserts up to 20 kb, and in modified plasmids called *cosmids* with inserts up to 50 kb. Burke and colleagues (1987) developed a method to insert 100 to 1000 kb of DNA into a *yeast artificial chromosome (YAC)*. These chromosomes have centromeres and telomeres and replicate like normal yeast chromosomes. YAC libraries, with each YAC containing a different fragment of the genome, have been established to greatly simplify gene isolation.

Positional Cloning. This technique is sometimes referred to as *reverse genetics*, because it involves an attempt to clone the gene responsible for a specific disease based on its location, without knowing the nature of the gene product. This attempt is only possible once the gene has been localized to a specific part of a given chromosome, which usually involves narrowing the search to a sequence of over 1 million base pairs (Gelehrter and Collins, 1990). Positional cloning is easier if the affected individual also has a cytogenetic abnormality such as a chromosomal deletion to mark the most likely location. Examples of

genes that have been cloned using this technique include those causing cystic fibrosis, Duchenne muscular dystrophy, retinoblastoma, colonic polyposis, neurofibromatosis, and Huntington disease (Beaudet and Ballabio, 1994).

DNA Chips. These chips take advantage of the principles of PCR and nucleic acid hybridization to screen DNA for many genes or mutations simultaneously. Many cDNA probes or ASOs, each representing a different gene mutation, are tagged with differently colored fluorescent dyes and arrayed on a tiny chip. DNA from the tested individual is amplified by PCR and exposed to the probes fixed on the chip. Hybridization to any of the probes is recognized by the color pattern and indicates that the individual carries the mutation represented by that particular cDNA. It is anticipated that this technology will revolutionize genetic screening. For example, although more than 900 mutations causing cystic fibrosis have been identified, patient samples are currently tested only for a panel of 25 of the most common mutations. Using a DNA chip, the patient could be screened for all 900 mutations simultaneously.

Microarrays. DNA chip technology can also be used as a research tool to investigate patterns of gene expression. A microarray platform contains hundreds of oligonucleotides or cDNAs generated from cDNA libraries. Messenger RNA is extracted from the tissue of interest, converted to DNA, labeled with a fluorescent probe, and applied to the microarray. Hybridization to any of the cDNAs is detected and quantified by fluorescence scanning. This technique facilitates analysis and comparison of patterns of gene expression, for example, the genes expressed by the amnion and chorion during preterm versus term labor (Marvin and colleagues, 2002).

Figure 12-14. Steps in fluorescence in situ hybridization (FISH). (Adapted from Greenwood Genetics Center, 1995, with permission.)

Figure 12-15. Southern blotting analysis. Genomic DNA is isolated from leukocytes or amniocytes and digested with a restriction enzyme. This procedure yields a series of reproducible fragments that are separated by agarose gel electrophoresis. The separated DNA fragments are then transferred ("blotted") to a nitrocellulose membrane that binds DNA. The membrane is treated with a solution containing a radioactive single-stranded nucleic acid probe, which forms a double-stranded nucleic acid complex at membrane sites when homologous DNA is present. These regions are then detected by autoradiography.

13. Prenatal Diagnosis and Fetal Therapy

INTRODUCTION

The incidence of major abnormalities discovered at birth is 2 to 3 percent. These anomalies cause a significant portion of neonatal deaths, and more than one fourth of all pediatric hospital admissions result from genetic disorders (Lee and colleagues, 2001). Prenatal diagnosis is the science of identifying these structural or functional abnormalities in the developing fetus. With this information, clinicians hope to alter the severity of congenital disease by offering an ever-expanding number of fetal treatments or surveillance as well as optimal delivery for some or consideration of pregnancy termination for others. Diagnostic evaluation typically involves three major categories:

1. Fetuses at high risk for a genetic or congenital disorder.
2. Fetuses at unknown risk for common congenital abnormalities.
3. Fetuses discovered ultrasonographically to have structural or developmental abnormalities.

Current fetal therapy includes optimizing the intrauterine environment and delivery, blood transfusion, administration of medication, amnioreduction, placement of shunts, and surgery. In the near future, hemopoietic stem cell transplantation and other methods for gene therapy likely will be added to this list.

FETUSES AT HIGH RISK FOR GENETIC OR CONGENITAL DISORDERS

FETAL ANEUPLOIDY. At least 8 percent of conceptuses are aneuploid, accounting for 50 percent of first-trimester abortions and 5 to 7 percent of all stillbirths and neonatal deaths (see [Chap. 12](#), p. 288). Chromosomal defects compatible with life but causing significant morbidity are found in 0.65 percent of newborns. Another 0.2 percent have structural chromosomal rearrangements that will eventually affect reproduction (Milunsky, 1992).

Several safe, accurate, and well-established procedures to obtain fetal cells for karyotyping are currently available. The challenge is to determine which women are at high risk for carrying aneuploid fetuses and should be offered one of these tests. Most commonly, "high risk" describes a risk greater than the chance of fetal death associated with the diagnostic procedure being considered. The postamniocentesis pregnancy loss rate is approximately 1 in 200, therefore, amniocentesis for fetal karyotyping would not typically be offered unless the risk of fetal aneuploidy was estimated to be greater than 1 in 200. Women with a risk of carrying an aneuploid fetus high enough to prompt an invasive diagnostic procedure ([Table 13-1](#)) include the following:

1. *Women who will be at least 35 years old at the delivery of their singleton pregnancy.* The midtrimester risk, or incidence, of fetal Down syndrome among 35-year-old gravidas is 1 in 250 and rises rapidly with increasing maternal age ([Fig. 13-1](#)). The risk of any numerical aneuploidy is 1 in 132 ([Table 13-2](#)). The midtrimester incidence is greater than that at term because a large proportion of aneuploid fetuses die spontaneously before reaching term. Consequently, for women aged 35 or older, the risk of fetal Down syndrome at term is 1 in 384 and that of any numeric aneuploidy is 1 in 204.
2. *Women aged at least 31 years at the delivery of their dizygotic twin gestation.* The chance that a pregnancy will be complicated by fetal Down syndrome is greater if there are two fetuses than if there is only one. The risk of trisomy 21 in a twin pregnancy can be calculated by considering the maternal age-related Down syndrome risk, the maternal race- and age-related incidence of dizygotic twinning, and the probability that either or both fetuses could be affected. The analysis by Meyers and colleagues (1997) shows that for both white and African-American 31-year-old women, the midtrimester risk of Down syndrome in a dizygotic twin pregnancy is approximately 1 in 190 ([Table 13-3](#)). Counseling in this situation should include a discussion of options for pregnancy management if only one fetus is affected, as this may influence the desire for prenatal diagnosis. These options include aborting the twin pregnancy, selective second-trimester reduction of the affected fetus, continuing the pregnancy with monitoring of only the normal fetus, or continued monitoring of both fetuses.
3. *Women who have previously carried a fetus with an autosomal trisomy.* After having one trisomic fetus, the chance of having another is approximately 1:100 (or 1 percent) until the maternal age-related risk exceeds 1 percent. After that, the age-related risk predominates (Warburton and associates, 1987).
4. *Women who have previously carried a fetus with triple X (47,XXX) or Klinefelter syndrome (47,XXY).* The extra X chromosome in these disorders may be maternal or paternal in origin. As with autosomal trisomies, the recurrence risk is 1:100 until the maternal age-related risk exceeds 1:100, after which the age-related risk predominates (Gardner and Sutherland, 1996). Women whose previous child was 47,XYY are not at high risk for recurrence, because the extra chromosome in this situation is paternal in origin, and paternal errors have minimal chance of recurring. Likewise, 45,X has a very low recurrence risk.
5. *Women or their partners who have a chromosomal translocation.* The risk of having abnormal offspring must be estimated individually, accounting for the chromosomes involved, the gender of the transmitting parent, and the testing method used. For most translocations, the observed risk of an abnormal liveborn neonate is less than the theoretical risk, because a portion of gametes are so abnormal as to either preclude conception or produce only nonviable conceptions. In general, however, translocation carriers identified after the birth of an abnormal neonate have a 5- to 30-percent risk of having another fetus with an unbalanced translocation. In contrast, carriers identified during an infertility evaluation have a much lower risk (0 to 5 percent) because their translocation most likely results in nonviable gametes or embryos (Gardner and Sutherland, 1996).
6. *Women or their partners who are carriers of chromosomal inversions.* The risk for each carrier is individually determined by considering the testing method used, the chromosome involved, and the size of the inversion. In general, the observed risk is

approximately 5 to 10 percent if the inversion was detected after the birth of an abnormal neonate and 1 to 3 percent if identified by some other means (Gardner and Sutherland, 1996).

7. *History of triploidy.* Over 99 percent of triploid conceptions are lost in the first or second trimesters. Rarely, a fetus develops. If the triploidy involved a fetus surviving past the first trimester, the recurrence risk is 1 to 1.5 percent, and thus sufficient to prompt prenatal testing (Gardner and Sutherland, 1996).

8. *Repetitive spontaneous first-trimester abortions.* The majority of first-trimester miscarriages result from aneuploidy. A history of one early aneuploid loss does not increase the maternal age-related risk of a second aneuploid pregnancy. Importantly, the majority of conceptuses from repetitive early abortions are euploid (Morton and associates, 1987; Warburton and colleagues, 1987). In fact, as the number of first-trimester abortions increases, the proportion caused by karyotypic abnormalities decreases (Ogasawara and colleagues, 2000). Accordingly, the value of karyotyping abortuses is unclear. Karyotyping the *parents* may be more helpful, because the few repetitive early abortions associated with a chromosomal abnormality are caused by maternal or paternal inversions or translocations. Identification of such a parental abnormality would allow counseling about the recurrence risk (Warburton and associates, 1987).

9. *Parental aneuploidy.* Women with trisomy 21 or 47,XXX and men with 47,XYY are usually fertile and have a 30-percent risk of having trisomic offspring. In contrast, men with trisomy 21 or 47,XXY are usually sterile.

10. *A fetus with a major structural defect identified by ultrasonography.* This increases the risk of aneuploidy sufficiently to warrant fetal karyotyping, regardless of maternal age or parental karyotypes (Williamson and Pringle, 1987; Wladimiroff and co-workers, 1988).

Figure 13-1. Maternal age-related incidence of fetal trisomy. (Data from Ferguson-Smith and Yates, 1984.)

ISOLATED STRUCTURAL ANOMALIES. Structural malformations that are multifactorial or polygenic in origin have a 2- to 3-percent recurrence risk. Thus, a fetus who is a first-degree relative of an affected individual \mathfrak{R} —usually because it is the sibling of an affected child or the child of an affected parent \mathfrak{R} —has a 2- to 3-percent risk of being similarly affected. Therefore, any parent who is affected or has an affected child should be offered prenatal counseling and diagnostic evaluation. Although the risk conferred by an affected *second-degree* relative of the fetus (i.e., aunt, uncle, grandparent, or half-sibling) is much lower, many of these patients request counseling and testing. In most multifactorial disorders, the risk resulting from affected third-degree relatives (i.e., cousins) is not substantively different from the general population (Thompson and colleagues, 1991). For severe malformations, the evaluation should be completed early in the pregnancy to allow pregnancy termination to be considered. Several kinds of structural defects can be identified by an ultrasonographic examination performed using high-resolution equipment ([Table 13-4](#)).

Congenital Heart Defects. These abnormalities are the most common isolated structural defects, with an incidence of 0.7 percent (Burn and colleagues, 1998). Certain specific heart defects or heart defect categories, if present in one fetus, may recur in subsequent pregnancies. Gill and colleagues (2003) studied 6640 pregnancies at risk of recurrent congenital cardiac defect and found that the same defect recurred in 37 percent and a similar defect developed in 44 percent of subsequent fetuses. The abnormalities most likely to be associated with recurrence of the same defect were atrioventricular septal defect, which recurred in 80 percent, and laterality defects, which recurred in 64 percent. Recurrence of a *similar* defect was most likely for left heart defects (47 percent), outflow tract defects (47 percent), and septal defects (60 percent), all of which involve abnormal blood flow patterns.

Prenatal diagnosis typically involves careful evaluation of the heart, usually including echocardiography, at approximately 20 to 22 weeks (see [Chap. 16](#), p. 396). At this gestational age, all cardiac structures can usually be seen, and time remains for a complete evaluation and consideration of pregnancy termination if an anomaly is found. One caveat is that defects associated with abnormal blood flow \mathfrak{R} —generally defects characterized by hypoplasia or atresia \mathfrak{R} —may develop as late as the third trimester (Hornberger and associates, 1996). For this reason, if the initial lesion was in this category (e.g., hypoplastic right or left heart, coarctation of the aorta, or pulmonary or aortic stenosis), then ultrasonographic examinations should be scheduled at 20 to 22 weeks and again in the third trimester.

Neural-Tube Defects. These defects are the second most common congenital malformation in the United States, with an incidence of 1.4 to 2 per 1000 pregnancies (American College of Obstetricians and Gynecologists, 2003). They are also discussed in [Chapter 12](#) (see p. 302). Women at increased risk of carrying a fetus with a neural-tube defect (NTD) are counseled and offered alpha-fetoprotein testing and targeted ultrasonographic examination as part of the diagnostic evaluation. If the ultrasonographic examination is incomplete or a defect is seen, amniocentesis may be performed to confirm the presence of the defect and to determine the fetal karyotype. Some factors listed in [Table 13-5](#) that are known to increase the risk of NTD include:

1. *Family history of NTDs.* This is the most commonly recognized risk factor, although only 5 percent of all NTDs are familial. The chance of recurrence for a multifactorial NTD is 2 to 3 percent if one first-degree relative is affected and is higher if more than one is affected. The level of risk should be estimated individually for each family, by calculating the number of affected relatives and their degree of relatedness to the fetus (Bonaiti-Pellie and Smith, 1974).

2. *Exposure to certain environmental agents.* A few of these have been implicated in NTD formation. Exposure must occur during the first 28 days of gestation, when the neural tube is developing. *Hyperglycemia*, usually from type 1 diabetes mellitus, increases the risk of NTDs (Becerra and colleagues, 1990). The exact mechanism is unknown, but may involve

inhibition of fetal glycolysis, a functional deficiency of arachidonic acid or myoinositol in the developing embryo, or alterations in the yolk sac (Reece and Hobbins, 1986). *Hyperthermia* during neural-tube formation also appears to cause defects. A prolonged increase in maternal core temperature has been reported to increase the relative risk up to sixfold. The duration and intensity of core temperature elevation necessary to produce an effect and the pathophysiology are unknown (Milunsky, 1992). Certain drugs, especially those that disturb folic acid metabolism, are thought to be causative (see [Chap. 14](#), p. 345). *Anticonvulsants*, most notably *valproic acid* and *carbamazepine*, significantly increase malformation risk. *Aminopterin* and *isotretinoin* have been associated with a constellation of abnormalities that can include anencephaly or encephalocele.

3. History of a genetic syndrome or anatomical anomalies associated with NTDs. Some inherited syndromes known to contain NTDs include Meckel-Gruber, Roberts-SC phocomelia, Jarco-Levin, and HARDE (hydrocephalus-agyria-retinal dysplasia-encephalocele) syndromes. These are all autosomal recessive with a 25-percent recurrence risk. Trisomies 13 and 18 and triploidy can include NTDs, and all have a 1 percent chance of recurrence (Jones, 1997). Cloacal exstrophy and sacroccygeal teratoma may be associated with spina bifida. Amniotic bands may cause spina bifida or anencephaly but are believed to occur sporadically and have minimal recurrence risk.

4. Belonging to a high-risk racial or ethnic group, living in a high-risk geographical region, or both. The United Kingdom has the highest frequency of NTDs, with a population incidence of almost 1 percent. China, Egypt, and India also have a high frequency. In contrast, the incidence in the United States is 0.2 percent. The frequency of defects in high-risk populations is probably related to both the ethnic (genetic) background of the inhabitants and environmental influences such as diet (see [Chap. 12](#), p. 302). For example, individuals of Celtic origin living in the United States and consuming a vitamin-fortified American diet are at lower risk than those living in the United Kingdom (Main and Mennuti, 1986; Thompson and co-workers, 1991). Moreover, since the fortification of breads and grains was begun in 1998 in this country, there has been a decrease in NTDs (Evans and collaborators, 2004).

5. Production of anti-folate receptor antibodies. Rothenberg and colleagues (2004) reported that 9 of 12 women who had a pregnancy complicated by a fetal NTD produced anti-folate receptor antibodies, compared with only 2 of 20 control women. Although cause and effect were not established, these data suggest another mechanism by which periconceptual folic acid supplementation could prevent NTD recurrence.

FAMILIAL GENETIC DISEASE. Couples with a personal or family history of a heritable genetic disorder should be offered genetic counseling and provided with a calculated risk of having an affected fetus. Specific molecular tests for a variety of common genetic diseases are now available (see [Chap. 12](#), p. 307). The risk of a disease for which the responsible gene has not been identified can sometimes be estimated by comparing fetal DNA with that of affected and unaffected family members using *restriction fragment length polymorphism analysis*. The risk of disease for which no laboratory test has been developed may, in some cases, be refined by ultrasonographic examination if the disease is associated with fetal structural abnormalities, or by determination of fetal gender if the disease is X-linked.

A major issue that remains unresolved for many genetic disorders is phenotype prediction. Because of variable penetrance and expressivity, and modification of phenotype by pre- and postnatal environmental influences, identification of a specific disease gene often is not sufficient to allow the phenotype of an affected fetus to be predicted, even when there have been other affected siblings or family members. The phenotype of cystic fibrosis, for example, can vary widely within a family (see [Chap. 12](#), p. 295). Phenotype prediction is especially difficult when there are no living affected family members, or when the disease gene is identified as the result of population screening (see [Chap. 12](#), p. 296).

Ethnic Groups at High Risk. Some otherwise rare recessive genes are found with increased frequency in certain racial or ethnic groups. This increased frequency results from generations who procreate only within their own groups because of religious or ethnic prohibitions or geographical isolation. A phenomenon called the *founder effect* occurs when an otherwise rare gene that is found with increased frequency within a certain population can be traced back to a single family member or small group of ancestors. This effect accounts for the high rate of tyrosinemia in the Lac Saint Jean region of Quebec. Some autosomal recessive diseases are found with increased frequency in ethnic groups living in the United States ([Table 13-6](#)).

AFRICAN, MEDITERRANEAN, CARIBBEAN, LATIN AMERICAN, OR MIDDLE EASTERN DESCENT. Several clinically significant hemoglobin gene mutations are more prevalent in patients with ancestry from these areas (see [Chap. 51](#), p. 1150). African-Americans are at increased risk of having sickle cell anemia, which is the most common hemoglobinopathy in the United States. Southeast Asians are at increased risk of carrying hemoglobin E, the second most common abnormal hemoglobin in the world.

MEDITERRANEAN OR ASIAN ORIGIN. These individuals are at increased risk of having α - or β -thalassemia (see [Chap. 51](#), p. 1154).

JEWISH ANCESTRY. These individuals are at increased risk for several diseases, each caused by a different enzyme deficiency. For example, Tay-Sachs, Canavan, and Gaucher diseases are caused by deficiencies of hexosaminidase A, aspartoacylase, and glucocerebrosidase, respectively. Carrier rates and screening protocols for these diseases are discussed subsequently.

CAUCASIANS OF NORTHERN EUROPEAN DESCENT. Cystic fibrosis is the most common monogenic disorder in this population. Carrier and fetal screening protocols are discussed on page 325.

SCREENING FOR COMMON CONGENITAL ABNORMALITIES

The vast majority of cases of NTDs, Down syndrome, and many other fetal abnormalities are found in families with no prior history of birth defects. Prenatal evaluation of only women at high risk for these complications would thus fail to identify most affected pregnancies. Couples with no family history of genetic abnormalities can now be offered prenatal screening tests for certain fetal disorders. Screening tests by design do not provide a diagnosis, but rather identify individuals with risk high enough to benefit from a definitive diagnostic test. According to Wald and associates (1997), genetic screening tests should meet criteria generally accepted for other types of screening tests:

1. The disorder is well defined and serious.
2. Treatment or prevention is available but not possible without the screening test.
3. The screening test is cost effective and reliable.
4. The subsequent diagnostic test is reliable. That said, Caughey and collaborators (2004) interviewed 447 women of all ages with undetermined genetic risk. They reported that half were willing to undergo invasive prenatal diagnostic testing. One third of women aged 35 years or older expressed a willingness to pay partially or completely for such testing. Such requests present a conundrum for prenatal diagnostic centers and each should have a protocol to cover these exigencies.

NEURAL-TUBE DEFECTS (NTDS). At least 95 percent of children with NTDs are born into families with no prior history. Prior to the late 1970s, identification of affected pregnancies was not possible. At that time, Brock and associates (1972, 1973) reported that both amniotic fluid and maternal serum alpha-fetoprotein (AFP) levels were much higher in pregnancies complicated by fetal anencephaly and other NTDs. The first large prospective trial of maternal serum screening was the UK Collaborative Study on Alpha-fetoprotein in Relation to Neural-tube Defects (1977). The utility of maternal serum AFP screening for NTDs was subsequently confirmed by others and adopted in the United States and Europe (Burton and associates, 1983; Haddow and colleagues, 1983; Milunsky and co-workers, 1980).

Alpha-Fetoprotein (AFP). This glycoprotein is synthesized early in gestation by the fetal yolk sac and later by the fetal gastrointestinal tract and liver (see [Chap. 4](#)). It normally circulates in fetal serum and passes into fetal urine and thus into amniotic fluid. Although its function is unknown, AFP is the major serum protein in the embryo-fetus, analogous to albumin. Its concentration increases steadily in both fetal serum and amniotic fluid until 13 weeks, after which these levels rapidly decrease (Burton, 1988). AFP passes into the maternal circulation by diffusion across the placental membranes and also may be transported via the placental circulation (Brumfield and colleagues, 1990). AFP is found in steadily increasing quantities in maternal serum after 12 weeks ([Fig. 13-2](#)). Open fetal body wall defects uncovered by integument permit additional AFP to leak into the amniotic fluid, and maternal serum AFP levels are increased.

Maternal Serum AFP Screening. Maternal screening is offered between 14 and 22 weeks. Maternal serum AFP is measured in nanograms per milliliter and reported as a multiple of the median (MoM) of the unaffected population. Converting the results to MoM normalizes the distribution of AFP levels and permits comparison of results from different laboratories and populations. Factors that influence the maternal serum AFP level include weight, race, and diabetic status, as well as the gestational age and number of fetuses. Using a maternal serum AFP level of 2.0 or 2.5 MoM as the upper limit of normal, most laboratories report a screen-positive rate of 3 to 5 percent, a sensitivity of at least 90 percent, and a positive-predictive value of 2 to 6 percent (Milunsky and associates, 1989).

Evaluation of an elevated maternal serum AFP begins with a basic ultrasonographic examination to determine fetal age and viability and the number of fetuses ([Fig. 13-3](#)). Underestimating gestational age accounts for a large proportion of abnormal test results. In such cases, the laboratory can usually generate a corrected report when given accurate pregnancy dating criteria. If the initial specimen was obtained prior to 14 weeks, a repeated specimen is necessary. The distributions of maternal serum AFP levels in affected and unaffected pregnancies overlap considerably ([Fig. 13-4](#)). If the level falls within the range of the overlap—the *indiscriminate zone* of 2.5 to 3.5 MoM—then repeating the measurement may determine whether the pregnancy is really at risk. Because repeated measurements tend to regress toward the mean of the population to which they belong, a truly elevated maternal serum AFP level will remain so in the repeated sample, whereas levels from an unaffected pregnancy have a tendency to normalize.

Maternal serum AFP levels greater than 3.5 MoM need not be repeated, because levels this high are outside the AFP distribution of unaffected pregnancies and clearly indicate increased fetal risk. In general, the likelihood that the fetus is affected increases in proportion to the AFP level. In a study of 773 women with elevated serum AFP levels, Reichler and colleagues (1994) reported that there was a progressive increase in the frequency of NTDs, ventral wall defects, and other anomalies as maternal serum AFP levels rose ([Fig. 13-5](#)). About 40 percent of pregnancies were abnormal when the AFP level was greater than 7 MoM.

Other Causes of Elevated Maternal Serum AFP Levels. Other causes of elevated levels that can be determined by ultrasonography include fetal death, multiple gestations, structural defects, and placental abnormalities ([Table 13-7](#)).

RECOMMENDATIONS FOR SCREENING. The American College of Obstetricians and Gynecologists (2003) recommends that all pregnant women be offered second-trimester maternal serum AFP screening. It should be performed within a protocol that includes quality control, counseling, follow-up, and high-resolution ultrasonography. Because only 1 in 16 to 1 in 33 women with an elevated serum AFP level actually has an affected fetus, women should be counseled regarding the high false-positive rates, the risks of amniocentesis, and the rationale for the screening program.

Ultrasonographic Examination. After confirming the gestational age and establishing fetal number and viability, the fetus is evaluated by targeted ultrasonography. Anencephaly, other major cranial defects, and most spine defects can be readily identified ([Figs. 13-6](#) and [13-7](#)). In 99 percent of cases, open spine lesions are associated with one or more of five specific cranial anomalies detected by ultrasonography (Watson and associates, 1991). As detailed in [Chapter 16](#) (see p. 394), these include frontal notching, also called the *lemon sign*; small biparietal diameter; ventriculomegaly; obliteration of the cisterna magna; and elongated cerebellum, the *banana sign* ([Fig. 13-8](#)). These cranial anomalies are most clearly visible in the second trimester, and some, such as the lemon sign, may resolve later in pregnancy.

In the early days of AFP screening, an elevated maternal serum AFP level prompted amniocentesis to determine the amniotic fluid AFP level. If the AFP level was elevated, then an assay for acetylcholinesterase was done. These tests were considered diagnostic for fetal NTD. Today, however, nearly 100 percent of NTDs are identified by ultrasonography used alone (Nadel and colleagues, 1990; Sepulveda and associates, 1995). Citing this high detection rate, several authorities conclude that a woman with an elevated maternal serum AFP level and a normal ultrasonographic examination need not undergo amniocentesis for amniotic fluid AFP measurement. Instead, she could be counseled that the risk of an NTD is reduced by 95 percent when no spine defects or cranial findings are seen ultrasonographically (Hogge, 1989; Morrow, 1991; Van den Hof, 1990, and their

colleagues).

By contrast, a number of other studies report considerably less than a 100-percent ultrasonographic detection rate for structural fetal anomalies, especially before 22 weeks. For example, only 17 percent of all fetal anomalies were identified in the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial ([Chap. 16](#), p. 390). VanDorsten and colleagues (1998) reported only a 48-percent ultrasonographic detection rate for all fetal anomalies diagnosed. Platt and co-workers (1992) reported that 6 of 161 cases of open spina bifida were not recognized in a screening program. Accordingly, many recommend that an amniocentesis for amniotic fluid AFP be offered to all women with elevated maternal serum AFP levels. Women considering amniocentesis should be informed that amniotic fluid AFP measurement will detect only open spine defects, and not the 3 to 5 percent of defects that are covered by skin (Crandall and Matsumoto, 1984).

Amniocentesis. Amniotic fluid AFP levels are measured if an NTD is suspected, if the maternal serum AFP is elevated and the ultrasonographic examination is nondiagnostic, or simply because the maternal serum AFP is elevated, as discussed previously. An elevated amniotic fluid AFP level prompts assay of the same sample for acetylcholinesterase. After ruling out blood contamination, the presence of this enzyme verifies that exposed neural tissue or another open fetal defect is present.

Because NTDs carry a small associated risk of aneuploidy, and aneuploidy would change the prognosis and likely pregnancy management, ultrasonographic identification of a fetal NTD should prompt fetal karyotyping. In a review of more than 17,000 prenatal diagnosis cases, Hume and associates (1996) observed a 2-percent rate of aneuploidy in the 106 fetuses with an isolated NTD. Harmon and colleagues (1995) found that 7 of 43 fetuses with isolated NTDs were aneuploid.

Some clinicians determine the fetal karyotype whenever both maternal serum and amniotic fluid AFP levels are elevated, even if the amniotic fluid acetylcholinesterase assay is negative and an open NTD has thus been ruled out. Gonzalez and associates (1996) reported that in women with elevated serum and amniotic fluid AFP levels and normal ultrasonographic examinations, the incidence of chromosomal abnormalities was elevated fivefold above background risk.

INCIDENTAL FETAL KARYOTYPE. If a woman with a normal targeted ultrasonographic examination has undergone amniocentesis for amniotic fluid AFP just because her maternal serum AFP level was elevated, and the amniotic fluid AFP level is normal, fetal karyotyping is controversial. Thiagarajah and colleagues (1995) studied 658 such women and concluded that there was no justification for routine fetal karyotyping. In contrast, Feuchtbaum and associates (1995) reviewed 8097 pregnancies complicated by elevated maternal serum AFP levels. In the pregnancies in which the elevated maternal serum AFP level was "unexplained" because there was no fetal NTD or ventral wall defect and the amniotic fluid AFP level was normal, the rate of chromosomal anomalies was 1.1 percent, or twice as high as that of the general population.

INCIDENTAL AMNIONIC FLUID AFP MEASUREMENT. When amniocentesis is performed primarily for genetic analysis, amniotic fluid AFP is often routinely measured. This practice may not be cost-effective. Shields and colleagues (1996) reviewed almost 7000 women who underwent second-trimester amniocentesis for fetal karyotyping. They reported that measurement of amniotic fluid AFP did not increase the detection of anomalies. Similarly, Silver and associates (2001) performed a retrospective analysis of 2769 amniotic fluid specimens and reported that incidental amniotic fluid AFP measurement identified only one NTD not detected by ultrasonography. They estimated that routine amniotic fluid AFP measurement cost \$219,000 per informative case.

Unexplained Elevated Abnormal Maternal Serum AFP Levels. Even if there are no obvious fetal abnormalities, several large studies have shown that unexplained high maternal serum AFP levels often forecast a poor pregnancy outcome. These outcomes include low birthweight, oligohydramnios, placental abruption, and fetal death (Katz, 1990; Simpson, 1991; Waller, 1991, each with their associates). According to Wenstrom and co-workers (1992), the first maternal serum AFP level is the most predictive, and serial measurements are not helpful. Simpson and colleagues (1991) reported that second-trimester, but not third-trimester, maternal serum AFP elevation levels were associated with preterm ruptured membranes, preterm birth, and low-birthweight infants. Ramus and associates (1996) studied 241 women with unexplained serum AFP elevations and reported that they had a higher incidence of preterm delivery than women who had normal levels—22 versus 11 percent. The incidence of preterm delivery was highest (47 percent) in the 38 women who had both unexplained elevated serum levels and placental sonolucencies on ultrasonographic examination.

Although elevated maternal serum AFP levels in these cases are assumed to result from placental damage or dysfunction, neither the etiology of the elevated maternal serum values nor the most appropriate management for these women is clear. In these cases, no specific program of maternal or fetal surveillance favorably affects pregnancy outcomes (American College of Obstetricians and Gynecologists, 1996; Cunningham and Gilstrap, 1991).

Management of the Fetus with an NTD. Other than termination of pregnancy, options for pregnancies complicated by an NTD have traditionally been limited. Anencephaly, exencephaly, and iniencephaly are lethal, but some women elect to continue these pregnancies. Routine prenatal care is given, but interventions for fetal indications are not recommended as they will not change fetal outcome.

Counseling and decision making in the case of an isolated fetal spine defect are more difficult. Such women may benefit from counseling by a pediatric neurosurgeon, neurologist, or other specialists in pediatric development. The fully informed couple is more likely to make their best decision and to be prepared for the range of possible pregnancy outcomes. With continued pregnancy, antenatal care is designed to detect changes in fetal status that might alter the timing or route of delivery. Generally, the goal is delivery at term, but rapidly increasing ventriculomegaly may prompt delivery before term so that a shunt can be placed. Fetal heart rate testing is problematic because heart rate patterns in anomalous fetuses can be difficult to interpret (Vindla and associates, 1997).

The optimal timing and method of delivery remain controversial. All studies of delivery methods for fetuses with NTDs are retrospective and suffer from various biases. That said, an equal number of reports support cesarean versus vaginal delivery (Bensen and co-workers, 1988; Luthy and colleagues, 1991; Sakala and Andree, 1990). Theoretically, cesarean delivery might reduce the risk of mechanical trauma and infection of the fetal spine and also allow precise timing of delivery so that appropriate consultants can be available. Optimally, the delivery time and method should be determined on a case-by-case basis by the team that ultimately will care for the woman and her neonate. Team members should include maternal-fetal medicine specialists, neonatologists, neurosurgeons, and others. Fetal surgical repair of meningomyelocele is discussed later

(see p. 334).

DOWN SYNDROME. Before the mid-1980s, amniocentesis for fetal karyotyping was generally offered only to women aged 35 years and older. After Merkatz and colleagues (1984) reported that pregnancies with fetal Down syndrome were characterized by low maternal serum AFP levels, prenatal NTD screening was expanded to include Down syndrome screening in women aged younger than 35 years. Cuckle (1984) and Haddow (1983) and their associates confirmed this finding, and most NTD screening programs now include Down syndrome screening.

Screening program results show that detection rates are highest when maternal age-related risk is incorporated because it is the most powerful predictor of aneuploidy. Ultimately, the Down syndrome risk for each woman is estimated by multiplying her maternal age-related risk by a likelihood ratio determined by her serum AFP level (New England Regional Genetics Group, 1989). Women with a calculated Down syndrome risk greater than a predetermined threshold are offered amniocentesis for fetal karyotyping. This screening threshold is typically equal to the midtrimester or term Down syndrome risk of a 35-year-old woman.

Multiple-Marker Screening. Fetal aneuploidy alters serum analytes other than AFP. If a fetus has Down syndrome, second-trimester serum levels of chorionic gonadotropin (hCG) are usually higher and those of unconjugated estriol are lower than expected (Bogart and colleagues, 1987; Wald and associates, 1988a, 1988b). The individual predictive values of hCG, estriol, and AFP for detecting Down syndrome are low, but when combined they can frequently distinguish euploid fetuses from those with Down syndrome.

The most common second-trimester screening protocol in current use, variously called the *expanded AFP test*, *AFP plus*, *triple screen*, or *multiple-marker screening test*, is based on a composite likelihood ratio determined by levels of all three analytes. The maternal age-related risk is then multiplied by this ratio. The screening threshold chosen may be the midtrimester risk of a 35-year-old woman. More frequently, a threshold is chosen because it results in the optimal combination of a high detection rate with a low screen-positive rate. The risk threshold of about 1:200 is selected most often because, at a 5-percent screen-positive rate, the Down syndrome detection rate is 60 percent in women younger than 35 years. In women older than 35 years, the multiple-marker test detects more than 75 percent of fetuses with Down syndrome and a portion of other aneuploidies as well, although at a detection rate close to 25 percent (Haddow and co-workers, 1994). The multiple-marker test has been validated and has become the preferred second-trimester Down syndrome screening test in most centers (Burton, 1993; Cheng, 1993; Wenstrom, 1993, and their colleagues).

There are several permutations of the multiple-marker test in current use. Some centers offer AFP and hCG testing alone, and others use estriol measurement as a third marker. Some prefer to measure the free β -subunit of hCG (β -hCG) instead of the intact hCG molecule, and others add inhibin as a fourth analyte (Wald and colleagues, 1996; Wenstrom and associates, 1999b). Other multiple-marker screening tests have been used that combine maternal serum analytes, ultrasonographic measurement of the nuchal fold, long bone measurements, and other parameters (Bahado-Singh and colleagues, 2001; Morris and co-workers, 2001). Several investigative protocols are subsequently discussed.

In most series, only 6 percent of all screen-positive samples are associated with an affected fetus. Thus, a positive screening test indicates increased risk but not necessarily fetal Down syndrome. Conversely, a negative screening test indicates *no increased risk*, but does not mean that the fetus is normal. Once gestational age is confirmed by ultrasonography, women with a positive screening test should be offered amniocentesis for karyotyping (American College of Obstetricians and Gynecologists, 1996).

Serum Screening in Women Older than 35 Years. The basis of any multiple-marker algorithm is the maternal age-related risk. Thus, the multiple-marker screening test identifies a higher proportion of fetal Down syndrome cases \approx — at least 80 percent \approx — in women aged 35 years and older than in younger women (Haddow and co-workers, 1994). Although the detection rate increases along with maternal age, so does the screen-positive rate. For example, about 25 percent of women aged 35 years and older will have a test result indicating increased risk. Although some older women will opt for empirical amniocentesis regardless of screening results, others find that serum screening facilitates the decision to undergo invasive testing.

First-Trimester Down Syndrome Screening. Early identification of fetal aneuploidy is desirable for many reasons, including the availability of more options for pregnancy termination. First-trimester screening protocols in current use include maternal serum analyte screening, ultrasonographic evaluation, or a combination of both. Urinary screening has been studied, but the results were disappointing. The most discriminatory first-trimester maternal serum analytes appear to be free β -hCG and pregnancy-associated plasma protein A (PAPP-A) (Haddow and associates, 1998; Wald and colleagues, 1998). Measurement of the nuchal translucency (NT), an echolucent area seen in longitudinal views of the back of the neck, is also highly discriminatory (Snijders and colleagues, 1998). If the NT measurement is expressed as an MoM, it can be combined with serum analytes to calculate a composite risk.

Two large trials of combined first-trimester ultrasonographic and serum screening have documented its efficacy. First Trimester Maternal Serum Biochemistry and Fetal Nuchal Translucency Screening Study, referred to as the "BUN study," reported by Wapner and co-workers (2003) was a multicenter trial that enrolled 8514 women who underwent screening between 74 and 97 days of gestation. Individual risks of fetal Down syndrome and trisomy 18 were calculated based on age, first-trimester levels of free β -hCG and PAPP-A, and NT measurement. Women determined to be screen positive were offered fetal karyotyping. Using a Down syndrome risk cutoff of 1:270, 85 percent of Down syndrome cases were identified at a false-positive rate of 9.4 percent. When the false-positive rate was held at 5 percent, the detection rate was 79 percent. Importantly, 91 percent of trisomy 18 cases were identified at a false-positive rate of 2 percent. Because of the high incidence of spontaneous pregnancy loss in aneuploid pregnancies, performing fetal karyotyping after first-trimester screening likely resulted in the identification of some aneuploid pregnancies that would otherwise have been lost spontaneously. This outcome can be viewed either positively or negatively.

The FASTER (First- and Second-Trimester Evaluation of Risk) trial was reported by Malone and colleagues (2003a, 2003b). This multicenter trial included 33,557 women, and it took a slightly different approach. All women participating in the trial underwent both first-trimester screening \approx — which included free β -hCG, PAPP-A, NT measurement, and maternal age \approx — and second-trimester screening with hCG, AFP, estriol, and inhibin, along with maternal age. If either test was positive, fetal karyotyping was offered. The investigators then evaluated the screen-positive and detection rates for first-, second-, and combined first- and second-trimester screening. They found that the best results were obtained when women had combined both first- and second-trimester screening \approx — the Fully Integrated Test \approx — and then underwent definitive testing if its result was positive. The integrated test yielded a Down syndrome detection rate of 90 percent at a screen-positive rate of 5.4 percent. Importantly, the investigators determined that NT measurement was difficult to do accurately and reproducibly (D'Alton and associates, 2003). Further, not only did NT measurement medians vary from center to center and operator to operator, but NT medians obtained by a single operator varied over time. The authors therefore concluded that NT measurement should be performed only by operators with specific training and that measurement medians for individual operators should be monitored carefully and adjusted as necessary.

In addition to drifting NT medians, problems with first-trimester screening include a relatively narrow gestational age window for screening \approx — approximately 10 to 13 weeks \approx — and variability in NT measurement resulting from poor visibility, suboptimal fetal position, or inconsistent measurement technique. Accurate assessment of gestational age is essential. The American College of Obstetricians (2004) emphasizes that appropriate training, monitoring systems, and counseling must be provided.

ELECTIVE GENETIC AMNIOCENTESIS IN WOMEN YOUNGER THAN 35 YEARS. Some women younger than 35 years may request amniocentesis for fetal karyotyping despite reassuring maternal serum screening and ultrasonographic findings. Caughey and colleagues (2004) interviewed 447 women of all ages with undetermined genetic risk and reported that half were willing to undergo invasive prenatal diagnostic testing. One third of

women aged 35 years or older expressed a willingness to pay partially or completely for such testing. These investigators concluded that guidelines should be expanded to offer testing for a genetic diagnosis, not only for screening. Others believe that each case must be evaluated individually, and each center must develop its own protocol to handle such requests (Pauker and Pauker, 1994).

SCREENING FOR HERITABLE GENETIC DISEASES

The development of molecular tests for various genetic diseases has raised the possibility of population screening. Current debate centers on screening for cystic fibrosis and fragile X syndrome but will no doubt extend to other conditions as more disease-specific genes are identified.

CYSTIC FIBROSIS (CF). This autosomal recessive disorder is caused by a mutation in the *CFTR* gene that is on the long arm of chromosome 7. The gene encodes a protein called the *cystic fibrosis conductance transmembrane regulator* (*CFTR*). As of 2003, over 1300 mutations in this large gene had been described (Cystic Fibrosis Mutation Database, 2004). The CF carrier frequency is about 1 in 29 in Caucasian Americans, 1 in 30 in Native Americans, and 1 in 50 in Hispanics. It ranges from 1 in 90 to 1 in 29 in individuals of Ashkenazi Jewish heritage (National Institutes of Health, 1997). The classical form is marked by abnormal sweat chloride levels, chronic pulmonary disease, pancreatic insufficiency, liver disease, and obstructive azoospermia (Freedman and associates, 2004; Rosenstein and Zeitlin, 1998). Some individuals with CF, however, have mild disease or only a single affected organ—such as chronic pancreatitis (see [Chap. 46](#), p. 1066). This tremendous range of clinical expression likely reflects both the degree to which protein function is changed by the mutation, and variation in exposure and susceptibility to environmental factors. Diagnosing CF prenatally offers little advantage other than to make termination of affected pregnancies possible. Accordingly, CF testing is not included in newborn screening in most states (Wagener and co-workers, 2003).

Carrier Screening. Current technology does not yet allow routine carrier screening for all known mutations. The American College of Obstetricians and Gynecologists and the American College of Medical Genetics (2001) recommend that all couples either planning a pregnancy or seeking prenatal care be counseled about CF screening. Screening should be *offered to* individuals who have an affected first- or second-degree relative or whose reproductive partners have CF, and to couples in whom both partners are Caucasian. Because their CF carrier rate and thus risk of CF is significantly lower, screening should be *made available to* couples of other racial or ethnic backgrounds.

These organizations further recommend that screening include all CF mutations with at least a 0.1 percent incidence in the United States. The $\Delta F508$ mutation, which accounts for 75 percent of cases in Caucasians, and the 5T and W1282X mutations, which account for 50 percent of cases in Ashkenazi Jews, are included. This mutation panel will identify 97 percent of all CF carriers of Ashkenazi Jewish descent, 90 percent of Caucasian carriers of northern European heritage, and 80 percent of Caucasian carriers of European background. It probably will not identify the majority of CF mutations in individuals of other ethnic or racial backgrounds, because the mutations most common in these populations are unknown. Although a negative test does not preclude the possibility of carrying another of the more than 1300 known mutations, it does reduce the risk substantively from the background rate ([Table 13-8](#)).

Because CF is a recessive disorder, a fetus must inherit an affected gene from each parent to have the disease. If only one partner undergoes CF screening, the risk of having a child with CF can be calculated assuming that the other partner has the 1 in 29 background risk. Some patients will be reassured by this analysis, especially if the only goal is to determine the risk to the fetus. Testing both partners is more expensive but also more accurate.

Fetal Testing. If both parents are carriers, the fetus can be tested to determine whether it inherited either or both parental mutations. Phenotype prediction is fairly accurate if the mutations are $\Delta F508$ or W1282X. Other mutations are less closely associated with disease symptoms, making phenotype prediction and decisions about the pregnancy difficult. Prognosis is determined primarily by pulmonary status, and there is poor genotype-phenotype correlation between these other mutations and the severity of pulmonary disease.

FRAGILE X SYNDROME. This is the most common cause of *familial* mental retardation, and it is discussed further in [Chapter 12](#) (see p. 298). Although fragile X syndrome is an X chromosome-linked anomaly, inheritance of this syndrome does not conform to the usual rules governing X-linked traits. This is because the fragile X mutation is an unstable region of repeated CGG trinucleotides that can expand when transmitted by a female. When the expansion reaches a critical size—more than 230 repeats—the gene can become methylated and thus turned off. Female carriers of a *premutation*, who have 56 to 229 CGG repeats, are at risk to pass on an expanded gene, and the individual inheriting the expanded gene is at high risk to exhibit fragile X phenotype (Fisch and colleagues, 1995). Premutation carriers are also at risk of developing one of three disorders: carrier females may have mild cognitive or psychological problems; 20 percent of female carriers may have premature ovarian failure; and carrier males older than 50 may develop *fragile-X-associated tremor/ataxia syndrome* (Hagerman and Hagerman, 2004).

Carrier Screening. Based on current knowledge, fragile X syndrome does not meet established criteria for a good screening test. The prevalence of the premutation in the general population is unknown, so it is not clear who should be offered testing. The carrier rate is estimated to be approximately 1 in 700, an incidence that is much lower than that of other genetic diseases for which screening is usually considered (Hagerman and co-workers, 1991). In addition, it is not always possible to predict whether a female carrier will pass on an expanded gene. Studies of Scandinavian kindreds have demonstrated that even large premutations can be passed unchanged through several generations (Holmgren and co-workers, 1988). Finally, phenotype prediction in both male and female fetuses carrying the full mutation is imprecise. Because of favorable lyonization, as many as half of females inheriting the full fragile X mutation will be intellectually normal (de Vries and colleagues, 1996). Mosaicism for either gene size or methylation status results in wide phenotypic variation in both males and females inheriting the gene (see [Chap. 12](#), p. 298).

Testing. It is currently recommended that any individual with unexplained mental retardation be tested for the fragile X mutation, especially if there are clinical findings consistent with the syndrome or a family history (Cuttillo, 1994). In this setting, approximately 2 to 6 percent of males and 2 to 4 percent of females will be determined to carry the full mutation

(Curry and associates, 1997). Family members of patients with documented fragile X syndrome also should be offered testing. The goal is to identify premutation carriers and allow them to make informed reproductive choices. Based on available data, however, it seems unlikely that it will be cost effective to test relatives of patients with unexplained mental retardation not known to be due to fragile X mutation (Curry and co-workers, 1997; Wenstrom and collaborators, 1999a). Likewise, testing of women without a family history of neurodevelopmental disorders is not recommended by the American College of Obstetricians and Gynecologists (1995).

TAY-SACHS, CANAVAN, AND GAUCHER DISEASES. The carrier rate among individuals of Ashkenazi Jewish heritage is 1 in 30 for Tay-Sachs disease, 1 in 40 for Canavan disease, and 1 in 12 to 1 in 25 for Gaucher disease. Carrier screening for Tay-Sachs and Canavan diseases should be considered for patients of Jewish heritage because these diseases are relatively common, the phenotypes of individuals inheriting the abnormal genes are consistently severe and predictable, and prenatal diagnosis is possible for both. Gaucher disease is more complex because diagnosis requires molecular analysis, but molecular testing cannot determine which of three phenotypes ranging from mild to severe the fetus will have (Azuri and associates, 1998).

ULTRASONOGRAPHIC SCREENING

INCIDENTAL FINDING OF A MAJOR STRUCTURAL DEFECT. Major structural fetal anomalies or minor dysmorphic features often are discovered during ultrasonographic examinations performed for other indications in pregnancies otherwise at low risk for complications. An isolated malformation may be multifactorial— as in isolated cardiac defects or NTDs— or may be part of a genetic syndrome. If the defect is part of a syndrome, the fetus may have other abnormalities that are undetectable by ultrasonography but that affect the prognosis— for example, mental retardation. Fetal aneuploidy commonly is associated with major anatomical malformations and minor dysmorphic features. The specific aneuploidy risk associated with most major anomalies is high enough to prompt invasive fetal testing ([Table 13-9](#)).

The finding of two or more minor structural abnormalities in the same fetus also indicates a risk of aneuploidy sufficient to warrant fetal karyotyping (Williamson and colleagues, 1987; Wladimiroff and associates, 1988). Although some combinations of anomalies may indicate a genetic syndrome not resulting from aneuploidy, fetal karyotyping is still indicated because aneuploidy-associated abnormalities can mimic other syndromes.

ULTRASONOGRAPHIC SCREENING FOR MAJOR STRUCTURAL ANOMALIES.

Early second-trimester ultrasonography performed specifically to look for structural fetal abnormalities in women at low risk is controversial. Before this issue can be resolved, the detection and false-negative rates for such screening examinations need to be determined. The largest study to date addressing these issues is the RADIUS trial, reported by Ewigman and colleagues (1993). In this study, the fetuses of almost 16,000 women at low risk for perinatal complications were examined ultrasonographically. Only 17 percent of all major congenital anomalies were detected before 24 weeks, and only 35 percent were detected before delivery (see [Chap. 16](#), p. 390). Others, such as VanDorsten and associates (1998), have reported higher detection rates at tertiary centers (48 percent). Still, it appears that, even under ideal circumstances, the detection rate for major anomalies may not be high enough to warrant screening low-risk women.

ULTRASONOGRAPHIC SCREENING FOR MINOR ABNORMALITIES. By themselves, minor abnormalities or dysmorphisms usually do not affect the fetal prognosis in any substantive way. They can, however, provide important clues that suggest chromosomal abnormalities. To date, dysmorphisms have been studied mostly in women at high risk for fetal aneuploidy. Controversy surrounds whether ultrasonographic evaluation for fetal dysmorphisms should be offered as a Down syndrome screening test to women at low risk for aneuploidy instead of or as a supplement to maternal serum screening (Souter and colleagues, 2004). Down syndrome risks resulting from some dysmorphisms detected sonographically in the second trimester are listed in [Table 13-10](#). NT is a first-trimester finding, and a thickened nuchal fold is identified in the second trimester. Other findings include absent nasal bone and a space between the first and second toes— the *sandal gap*.

Nuchal Translucency (NT). This appears to be the best first-trimester discriminator of affected and unaffected pregnancies. It is best seen in the midsagittal plane as a sonolucency at the back of the fetal neck. Although its precise etiology and prognosis are unknown, NT is believed to represent one end of the spectrum of *lymphatic obstruction sequence*. Most data indicate that, even under optimal circumstances, first-trimester NT measurements by themselves typically identify fewer than half of all Down syndrome cases (Brambati and colleagues, 1995; Haddow and Palomaki, 1996). As previously discussed (see p. 324), when NT measurements are expressed as an MoM and incorporated into an algorithm that includes serum analytes and maternal age-related risks, screening efficacy appears to be substantially improved.

Normal measurements are between 0 and 5 mm, with an overlap of 2 to 3 mm between affected and unaffected populations. Accurate measurement requires special training and ongoing monitoring of performance, as discussed earlier. Flexion or extension of the head can change measurements by as much as 0.62 mm, and an unfavorable fetal position or maternal obesity may prevent measurement. Roberts and colleagues (1995) and Haddow and Palomaki (1996) have reported that first-trimester measurement is technically impossible in up to 20 percent of women. In the FASTER trial, NT measurement was not possible in 6 percent of cases (D'Alton and colleagues, 2003).

Nasal Bone. Cicero and colleagues (2001) examined 701 women at 11 to 14 weeks prior to scheduled routine amniocentesis for advanced maternal age or abnormal fetal NT measurements. In this high-risk population, the nasal bone was absent in 73 percent of Down syndrome fetuses but in only 0.5 percent of genetically normal fetuses. In the FASTER trial reported by Malone and colleagues (2003b), which included over 6300 women of average risk who completed first-trimester nasal bone ultrasonography, absence of the nasal bone did not identify any Down syndrome cases.

Modification of Age-Related Risk. Analogous to screening with serum analytes, some investigators believe that certain ultrasonographic markers can be used to modify the maternal age-associated Down syndrome risk (Wald and colleagues,

1998). As an example, Vintzileos and Egan (1995) advocate a second-trimester ultrasonographic screening protocol that includes evaluation for both major structural anomalies and minor dysmorphisms. If no abnormalities are detected, the maternal age-related risk is reduced substantively. For example, a 35-year-old woman with a normal-appearing fetus on a second-trimester ultrasonographic examination would have a Down syndrome risk reduced from 1:274 based on age alone to a risk of 1:4200.

Thus, the primary benefit of ultrasonographic screening appears to be its negative-predictive value. It is problematic that failure to identify a fetal anomaly or dysmorphism, which is used to lower the maternal age-related risk of fetal aneuploidy, also makes this screening test ineffective.

Effect of Maternal Age. As with maternal serum analytes, the aneuploidy risk associated with one ultrasonographic marker can be estimated more accurately by incorporating the age-related risk. Gupta and colleagues (1997) used data from 200,000 ultrasonographic examinations to modify aneuploidy risk in pregnancies with fetal choroid plexus cysts. In women who had multiple-marker screening tests indicating no increased risk, who had otherwise normal-appearing fetuses, and who were younger than 32 years, isolated choroid plexus cysts did not increase the risk of trisomy 18 sufficiently to prompt fetal karyotyping.

DIAGNOSTIC TECHNIQUES

SECOND-TRIMESTER AMNIOCENTESIS. Amniocentesis for genetic diagnosis usually is performed between 14 and 20 weeks. A number of multicenter studies have confirmed its safety and its more than 99-percent diagnostic accuracy for Down syndrome (Canadian Early and Mid-Trimester Amniocentesis Trial Group, 1998; NICHD National Registry for Amniocentesis Study Group, 1976). Typically, ultrasonographic guidance is used to pass a 20- to 22-gauge spinal needle into the amniotic sac while avoiding the placenta, umbilical cord, and fetus. Because the initial 1 or 2 mL of fluid aspirate may be contaminated with maternal cells, it is either discarded or used for amniotic fluid AFP testing. Another approximately 20 mL of fluid is then collected for fetal karyotyping, and the needle is removed. The uterine puncture site is observed for bleeding, and the woman is shown fetal heart motion and the remaining amniotic fluid at the conclusion of the procedure. The incidence of bloody taps, amniotic fluid leakage, and multiple punctures is inversely related to operator experience (Leschot and co-workers, 1985; Romero and colleagues, 1985).

Complications are infrequent and include transient vaginal spotting or amniotic fluid leakage in 1 to 2 percent and chorioamnionitis in less than 0.1 percent. Needle injuries to the fetus are rare when ultrasonographic guidance is used. Fetal cells obtained during amniocentesis rarely fail to grow in culture, but this is more likely if the fetus is abnormal (Persutte and Lenke, 1995). Fetal loss of 0.5 percent or less has been reported by many investigators, and it does not appear possible to reduce this further (Simpson, 1990; Wilson and colleagues, 1984). Some losses likely result from preexisting abnormalities, such as placental abruption, abnormal placental implantation, uterine anomalies, and infection, and were destined to occur whether or not amniocentesis was performed. For example, Wenstrom and colleagues (1996) analyzed 66 fetal deaths following nearly 12,000 second-trimester amniocenteses, and found that 12 percent were caused by preexisting intrauterine infection. Other postprocedural deaths have no apparent etiology.

EARLY AMNIOCENTESIS. This procedure is performed between 11 and 14 weeks and has been widely studied (Johnson, 1996; Nicolaides, 1994; Shulman, 1994; Sundberg, 1997, and all their associates). The technique is the same as for traditional amniocentesis, although if done before membrane fusion to the uterine wall, puncture of the sac may be difficult. Less fluid can be withdrawn—usually 1 mL for each week of gestation.

For reasons that are not yet clear, early amniocentesis appears to result in significantly higher rates of postprocedural pregnancy loss and other complications than traditional amniocentesis. In the multicenter randomized study by the Canadian Early and Mid-Trimester Amniocentesis Trial Group (1998), the spontaneous abortion rate following early amniocentesis was 2.5 percent compared with that of 0.7 percent after traditional amniocentesis. In an Italian single-center study of 475 early and 3294 midtrimester amniocenteses, Centini and co-workers (2003) reported a miscarriage rate of only 0.4 and 0.3 percent, respectively. In the recently reported randomized trial by the NICHD Early Amniocentesis Trial Group, 3775 women were randomized to either amniocentesis or chorionic villous sampling at 11 to 14 weeks (Philip and colleagues, 2004). The spontaneous loss rate before 20 weeks was 0.9 and 1.5 percent, respectively.

Early amniocentesis has been associated with significantly more positional foot deformities than traditional amniocentesis (Fig. 13-9). A number of large studies cited by Philip and collaborators (2004) report that 0.75 to 1.6 percent of fetuses have talipes equinovarus (clubfoot) after early amniocentesis. This rate is compared with 0.1 percent following traditional amniocentesis and a background rate of 0.1 to 0.3 percent. The Canadian study group also found that membrane rupture was more likely after early amniocentesis, and that the incidence of talipes was 15 percent in cases with early postprocedural fluid leakage. Because oligohydramnios was transitory in most cases, at least some of the foot deformities likely resulted from damage to the vascular supply of the developing limb, rather than from oligohydramnios causing positional deformities. Finally, after early amniocentesis, significantly more cell cultures failed, necessitating an additional amniocentesis in some cases. For all these reasons, many centers no longer perform amniocentesis before 14 weeks.

Figure 13-9. Clubfoot or talipes equinovarus. (Courtesy of Dr. Jodi Dashe.)

CHORIONIC VILLUS SAMPLING (CVS). This procedure generally is performed at 10 to 13 weeks. Villi may be obtained transcervically or transabdominally, depending on which route allows easiest access to the placenta (Fig. 13-10). Relative contraindications include vaginal bleeding or spotting, active genital tract infection, extreme uterine ante- or

retroflexion, or body habitus precluding easy uterine access or clear ultrasonographic visualization of its contents.

The indications for CVS and amniocentesis are essentially the same, except for a few analyses that specifically require either amniotic fluid or placental tissue. The primary advantage of CVS is that results are available earlier in pregnancy, which lessens parental anxiety when results are normal. It also allows earlier and safer methods of pregnancy termination when they are abnormal.

Complications of CVS are similar to those of amniocentesis. Several randomized and case-control trials have compared the safety of CVS with that of early and midtrimester amniocentesis as well as the safety of transabdominal versus transcervical CVS. Wald and colleagues (1998) summarized eight randomized trials and found that transcervical CVS has a procedure-related fetal death rate 3.7 percent greater than that of either transabdominal CVS or traditional amniocentesis. This rate is similar to that for early amniocentesis. In the randomized trial reported by Philip and co-workers (2004), the fetal loss rate associated with transabdominal CVS before 20 weeks was 1.5 percent, compared with that of 0.9 percent for early amniocentesis. In their review of 14 randomized trials, Alfievic and collaborators (2003) found that midtrimester amniocentesis was safer than either transcervical CVS or early amniocentesis. They recommend transabdominal CVS if early diagnosis is required.

Early reports of an association between CVS and limb-reduction defects, oromandibular defects, and cavernous hemangiomas have been disproved (Burton, 1992; Firth, 1991, 1994; Hsieh, 1995, and their colleagues). When CVS is performed after 9 weeks, Kuliev and colleagues (1996) reported the incidence of limb-reduction defects to be 6 per 10,000— the same as the background incidence. The frequency of oromandibular-limb hypogenesis, however, was increased after CVS when the procedure was performed before 9 weeks (Bianchi and associates, 1993; Kalousek and Dill, 1983).

Laboratory Results. Midtrimester amniocentesis is associated with the lowest incidence of *uninformative results*, which are found in up to 8 percent. This compares with 0.8 to 1.5 percent for transcervical CVS and 0.7 to 1.9 percent for transabdominal CVS (Canadian Collaborative CVS-Amniocentesis Clinical Trial Group, 1989; Philip and co-workers, 2004; Rhoads and colleagues, 1989). Uninformative data usually are the result of an inadequate sample or the detection of *mosaicism*, that is, more than one distinct cell line in a single chorionic villus sample. Such mosaicism rarely represents true fetal mosaicism but usually indicates *confined placental mosaicism*, or *pseudomosaicism* (see [Chap. 12](#), p. 295).

Figure 13-10. Transcervical chorionic villus sampling.

PERCUTANEOUS UMBILICAL CORD BLOOD SAMPLING (PUBS). Also called *cordocentesis*, this procedure was first described by Daffos and colleagues (1983). Cordocentesis currently is performed primarily for the assessment and treatment of confirmed red cell or platelet alloimmunization and for the analysis of nonimmune hydrops (Fisk and Bower, 1993). If anemia is suspected, Pereira and colleagues (2003) recommended that fetal cerebral artery velocimetry be considered before direct fetal blood sampling. PUBS also can be used to obtain fetal blood cells for genetic analysis when CVS or amniocentesis results are confusing or when rapid diagnosis is necessary. Karyotyping of fetal blood usually can be accomplished within 24 to 48 hours. The sample can also be analyzed as necessary for metabolic and hematological studies, acid-base analysis, viral cultures, polymerase chain reaction and other genetic techniques, and immunological studies.

In this procedure, the operator punctures the umbilical vein, usually at or near its placental origin, with a 22-gauge spinal needle under direct ultrasonographic guidance, and blood is withdrawn ([Fig. 13-11](#)). A free loop of cord also can be accessed. Arterial puncture should be avoided because it can result in vasospasm and fetal bradycardia.

Complications. The complications of PUBS are similar to those of amniocentesis. Additionally, cord vessel bleeding (50 percent), cord hematoma (17 percent), fetal-maternal hemorrhage (66 percent with an anterior placenta and 17 percent with a posterior placenta), and fetal bradycardia (3 to 12 percent) may result (Ghidini and colleagues, 1993). Most complications are transitory and followed by complete fetal recovery. Some, however, result in fetal death. The overall procedure-related fetal death rate is about 1.4 percent, but varies according to the indication for the procedure and the fetal status at the time of the procedure (Ghidini and colleagues, 1993; Maxwell and associates, 1991).

Figure 13-11. Umbilical cord blood sampling. Access to the umbilical artery or vein varies, depending on both the placental location and the position of cord insertion into the placenta. **A.** With an anterior placenta, the needle may traverse the placenta. **B.** With posterior implantation, the needle usually passes through the amniotic fluid before penetrating an umbilical vessel.

FETAL TISSUE BIOPSY. There are many genetic conditions for which there is no specific molecular genetic test. Linkage analysis has been used for the diagnosis of familial disorders, but it is possible only if there are living, informative, affected family members (see [Chap. 12](#), p. 308). Prenatal diagnosis of a few conditions sometimes can be accomplished by direct analysis of fetal tissue obtained by ultrasonographically guided biopsy. The technique has been used by Evans and colleagues (1994) for muscle biopsy to diagnose muscular dystrophy or mitochondrial myopathy. Elias and co-workers (1994) used skin biopsy to diagnose epidermolysis bullosa.

PREIMPLANTATION GENETIC DIAGNOSIS. Identification of the genes responsible for certain severe hereditary diseases and in vitro fertilization techniques allow diagnosis of a few such disorders prior to implantation. As a result, only healthy embryos are selected for implantation, and pregnancy termination can be avoided. The technique has been performed to diagnose single-gene disorders such as CF, sickle-cell disease, or thalassemia; determine gender in X-linked diseases; identify aneuploidy associated with advanced maternal age; and detect parentally derived chromosomal rearrangements (Flake, 2003; Grewal and associates, 2004; Jiao and colleagues, 2003; Xu and co-workers, 2004).

Several variations in technique have been reported. Some clinicians favor polar body analysis because the first and second polar bodies normally are expelled, and their removal should not affect fetal development. Because the majority of biopsied polar bodies are in metaphase, the chromosomes in these cells also are suitable for fluorescence in situ hybridization (FISH) analysis (Munne, 2001). A second technique uses the 3-day-old embryo at the 6- to 10-cell stage. It involves *blastomere biopsy* through a hole made in the zona pellucida. Loss of one totipotent cell at this stage supposedly has little or no effect on the developing embryo, although in the report by El-Toukhy and co-workers (2003), there was a lower implantation rate when previously biopsied frozen embryos were thawed and transferred. This technique is still under development and currently is quite complex.

FETAL CELLS IN THE MATERNAL CIRCULATION. Since the 1950s, various types of fetal cells have been identified in the maternal circulation (Douglas and colleagues, 1959). Virtually all pregnant women have at least a small number of fetal cells in their bloodstream (Goldberg, 1997). Isolation of these cells for prenatal analysis might obviate the need for more invasive procedures. Most research in this area focuses on cell sorting techniques, which take advantage of unique cell surface proteins and other characteristics that distinguish fetal from maternal cells. These techniques include *density gradient or protein separation, fluorescence-activated cell sorting, and magnetic-activated cell sorting*. Nucleated red blood cells are most easily isolated. Fetal cells obtained this way have been evaluated for genetic diseases such as β -thalassemia (Camaschella and associates, 1990) as well as for fetal red cell D-antigen typing (Gelfman-Holtzman and colleagues, 1996). Karyotyping using FISH also is possible (Poon and co-workers, 2000; Price and colleagues, 1991). With an aneuploid fetus, Bianchi and colleagues (1997) have reported a sixfold increase in the number of fetal cells in the maternal blood.

Several problems must be resolved before these techniques can be used clinically. Currently, it is difficult to isolate a quantity of fetal cells sufficient for analysis and to isolate a pure sample that does not contain maternal cells. One unique problem is that fetal lymphocytes or stem cells persist in the maternal circulation indefinitely. Thus, it is difficult to determine whether isolated cells come from the current pregnancy or a past one. Indeed, there is evidence that these persistent fetal cells cause certain maternal autoimmune diseases, such as scleroderma and other connective-tissue diseases and thyroiditis (see [Chap. 53](#), p. 1191 and [Chap. 54](#), p. 1210).

FETAL THERAPY

PREGNANCY TERMINATION. It is unfortunate that antenatal therapy is not available for most congenital anomalies. Despite this, the woman and her family may still benefit from prenatal diagnosis because it allows for psychological preparation and for an informed decision about pregnancy termination. In addition to a maternal-fetal medicine or genetics referral, consultation with the appropriate pediatric subspecialist may be helpful. A complete summary of the counseling session should be placed in the medical record. Techniques for singleton pregnancy termination are discussed in [Chapter 9](#) (see p. 242). In some cases, only one fetus of a twin or higher-order multiple gestation is affected, and pregnancy termination in this setting is discussed in [Chapter 39](#) (see p. 941).

TWIN-TO-TWIN TRANSFUSION SYNDROME. This syndrome is a unique problem that complicates about 15 percent of monochorionic twin pregnancies. It occurs as the result of unbalanced vascular anastomoses that connect the two fetal circulations. In the extreme case, one twin is severely growth restricted with no amniotic fluid—the *stuck twin*—while the co-twin is larger, often plethoric, and has hydramnios. The pathophysiology is discussed in greater detail in [Chapter 39](#) (see p. 929). Management options for twin-to-twin transfusion syndrome are limited. They include therapeutic amniocentesis, septostomy, laser occlusion of placental vascular anastomoses, and selective feticide of the donor twin. Unfortunately, with or without therapy, the perinatal death rate is high, and long-term studies indicate severe neurodevelopmental abnormalities in some survivors (Lopriore and colleagues, 2003).

FETAL TRANSFUSION

Isoimmunization. Various techniques for red blood cell transfusion have been used in the treatment of fetal anemia. Ultrasonographically directed transfusion into the umbilical cord vein currently is favored because it has proved effective and safe (Berkowitz, 1986; Nicolaidis, 1986; Weiner, 1991, and their colleagues). The fetal-placental volume allows the relatively rapid infusion of a large quantity of blood. Direct ultrasonographic guidance minimizes trauma to the umbilical cord and allows direct fetal monitoring. Prior to the blood infusion, pancuronium and furosemide can be administered directly into the umbilical vein. Pancuronium minimizes trauma by stopping fetal movement and protecting against vagally mediated fetal bradycardia. Furosemide relaxes the capacitance vessels and aids the clearance of excess plasma. The latter is important if there is heart failure with fetal hydrops and hydramnios.

Parvovirus Infection. Some fetuses affected by parvovirus B19 infection, especially those infected before 20 weeks, develop severe transient aplastic anemia with heart failure and hydrops (see [Chap. 58](#), p. 1279). Although an unknown number spontaneously recover, others are severely compromised and die. Some of these moribund fetuses can be rescued with blood transfusion (Peters and Nicolaidis, 1990; Sahakian and colleagues, 1991). The hydropic fetus can be evaluated with cordocentesis or cerebral artery Doppler velocimetry and transfusion performed if anemia is confirmed. For confirmation of the diagnosis, parvovirus DNA can be detected in fetal and maternal blood by polymerase chain reaction (Dieck and associates, 1999). Although a single transfusion is all that is required to aid recovery in many cases, fetuses who develop viral myocarditis do not respond to this therapy.

Other Indications. Transfusion may be considered after a severe but not ongoing fetal-maternal hemorrhage. It also has been described in a case of fetal hemoglobin Bart disease (see [Chap. 51](#), p. 1154). Copel and co-workers (1991) have administered platelet transfusion for severe alloimmune thrombocytopenia using the same technique (see [Chap. 29](#), p. 677).

FETAL MEDICAL THERAPY. Sometimes fetal disease can be treated pharmacologically by giving the mother medication that then crosses the placenta. For example, women with Graves disease who have been rendered euthyroid by radioiodine ablation may continue to produce immunoglobulin G thyroid-stimulating antibodies, which cross the placenta and cause *fetal thyrotoxicosis* (see [Chap. 53](#), p. 1193). Fetal thyroid status can be assessed by cordocentesis and, if hyperthyroidism is confirmed, propylthiouracil administered to the mother crosses the placenta to suppress the fetal thyroid (Wenstrom and associates, 1990).

Another example is the fetus at risk of *congenital adrenal hyperplasia*, an autosomal recessive condition that results in virilization of a female fetus. This outcome can be prevented with maternally administered corticosteroids, which suppress fetal adrenal function (David and Forest, 1984).

A third example is *fetal arrhythmia*, which complicates up to 1 percent of pregnancies (Copel and associates, 2000). Most fetal arrhythmias are tolerated without compromise, or resolve spontaneously (Simpson and colleagues, 1997). The fetus with sustained tachyarrhythmia, however, may experience cardiac decompensation, which can progress to hydrops. Treatment is accomplished by maternal administration of antiarrhythmic agents that cross the placenta in therapeutic doses. Digoxin, verapamil, propranolol, procainamide, quinidine, flecainide, sotalol, and amiodarone have all been used to treat fetal arrhythmias with good results in nonhydropic fetuses (Edwards and colleagues, 1999; Sonesson and associates, 1998). If the fetus is hydropic, some of these drugs may not enter the fetal circulation in sufficient amounts. Strasburger and co-workers (2004), however, found amiodarone effective in most cases. In other cases, medication can be administered directly to the fetus through the umbilical cord or by intramuscular injection in the buttock (Mangione and co-workers, 1999; Parilla and colleagues, 1996).

Congenital Infection. A number of infectious agents can cross the placenta and cause fetal infection with serious consequences. Prompt and effective maternal treatment can improve some or all of the most severe associated fetal morbidity. Treatment of maternal infections that could cause pregnancy complications also constitutes fetal therapy. Diagnosis and treatment of sexually transmitted and other infectious diseases are discussed in [Chapters 58](#) and [59](#).

FETAL SURGERY. With only a few exceptions, fetal surgery is still in the pioneering stages and is performed in only a few centers. Because it entails substantial fetal and maternal risks, surgery should be considered only when it will improve fetal outcome with certainty, barring unforeseen complications, and when withholding it would be catastrophic. It is important that appropriate selection criteria be established and verified. The procedure must be perfected and tested successfully in experimental animals, preferably primates (Harrison and colleagues, 1980; Moise and associates, 1995). Finally, the efficacy of the technique in humans should be rigorously evaluated prior to its widespread use.

Urinary Shunts. In many cases, the presence of a major urinary tract malformation indicates aneuploidy or another genetic syndrome usually associated with a poor prognosis. Malformations such as cystic dysplasia or renal agenesis cannot be corrected and are associated with oligohydramnios, which prevents development of the fetal lungs (see [Chap. 21](#), p. 530). In contrast, fetuses with certain types of isolated urinary tract obstructive lesions may have the potential for a good prognosis following correction.

Lesions such as posterior urethral valves, urethral atresia, and ureteropelvic junction obstruction often occur with relatively normal kidneys capable of producing normal amounts of urine and thus amniotic fluid. These obstructions, however, can cause renal damage due to prolonged increases in intrarenal pressure and can prevent normal lung development because of oligohydramnios (Adzick and Harrison, 1994). Placement of a double-pigtail catheter \Re — with one end in the fetal bladder and the other in the amniotic cavity \Re — shunts urine into the uterine cavity with restoration of amniotic fluid volume and reduction of intrarenal pressure. In experienced hands, fetal survival after shunt placement is 70 percent (Holzgreve and Evans, 1993). One case in which the catheter was placed transurethrally has been described (Hofmann and co-workers, 2004).

Survivors still may have serious renal pathology because either there is intrinsic renal dysplasia or significant renal damage had already developed by the time obstruction was recognized (Johnson and associates, 1995). Accordingly, the greatest problem with this procedure is selecting appropriate fetuses. Before shunt placement, serial vesicocenteses with urine chemistry analyses can be performed to help determine whether sufficient renal function remains (Johnson and Freedman, 1999). The use of fetal endoscopic cystotomy has been evaluated by Quintero and associates (2000) for complicated cases in which shunting alone is not sufficient.

Thoracic Shunts. Accumulation of thoracic fluid also can cause pulmonary hypoplasia by compressing the developing lung. Some causes include chylothorax, infection, and chest tumors. Survival after thoracic shunt placement for isolated fetal hydrothorax has been reported, but one third of such fetuses will have a poor outcome whether or not a shunt is placed (Hagay and colleagues, 1993).

Intrathoracic masses leading to pulmonary hypoplasia include pulmonary sequestration, congenital cystic adenomatoid malformation, and nonspecific cysts (Harrison and co-workers, 1990). Their diagnosis is considered in [Chapter 16](#) (see p. 396). Fetal goiter or tracheal atresia also may prevent egress of pulmonary fluid. Thoracic shunt placement with variable success has been described for all these entities. Although fluid drainage immediately following the procedure is usually adequate, obstruction or displacement of the shunt can rapidly lead to reaccumulation. Shunt placement in the presence of hydrops is generally not curative, probably because the fetus has already suffered damage, or is moribund at the time of the procedure, or because hydrops itself indicates a more serious abnormality (Adzick and co-workers, 1993; Weiner and colleagues, 1986).

Congenital Diaphragmatic Hernia (CDH). The incidence of this defect in the general population is about 1 in 3700 (Wenstrom and colleagues, 1991). Up to half of these fetuses have genetic syndromes or other associated defects that may be lethal. Approximately 70 percent of those with isolated malformations survive with normal physical and mental function following postnatal surgery and specialized neonatal care (Reickert and colleagues, 1998). Antenatal surgery is presumed to

prevent mortality in the 30 percent of fetuses who typically would not survive. Although CDH was one of the first malformations for which ex-utero fetal surgery was performed, the surgical technique has not yet been perfected (Harrison and colleagues, 2003). Importantly, both maternal and fetal surgical outcomes remain suboptimal, whereas the survival rate in neonates treated postnatally continues to improve (Harrison and colleagues, 2003; Wenstrom, 2003). At least three major problems must be overcome:

1. Despite the development of a variety of diagnostic tests, the fetuses with isolated CDH who would not survive despite optimal postnatal care cannot be reliably identified.
2. None of several different antenatal surgical procedures studied has consistently improved neonatal outcome.
3. Virtually all fetuses subjected to antenatal surgery have been delivered preterm, and many before 30 weeks. Such fetuses are thus subjected to the morbidity associated with preterm birth and that associated with surgery itself.

Until these problems can be overcome, antenatal repair of CDH is considered investigational.

Sacrocoxygeal Teratoma. This congenital tumor is composed of tissues representing all three germ layers and arises from the totipotent cells in the Hensen node or from ectopic primordial germ cells in the sacral area. These teratomas are vascular, with numerous arteriovenous shunts that can lead to vascular steal syndromes or hemorrhage. Perinatal morbidity and mortality is great due to the associated fetal anemia, heart failure, and hydrops (Altman and colleagues, 1974). Tumors detected early are usually aggressive. Survival is less than 10 percent in fetuses whose tumors are identified before 30 weeks, compared with 75 percent in those whose tumors are discovered later (Malone and co-workers, 1990).

In view of the very poor prognosis for early aggressive lesions, prenatal surgical excision has been attempted, but largely without success (Langer and colleagues, 1989). An alternative approach is to attempt palliative debulking surgery to prevent hydrops, and to defer definitive repair until after birth (Graf and colleagues, 1998).

Congenital Cystic Adenomatoid Malformation and Pulmonary Sequestration. These two pulmonary lesions may be amenable to fetal surgical therapy. Congenital cystic adenomatoid malformations (CCAMs) are pulmonary hamartomas consisting of overgrown terminal bronchioles. Type I has large cysts, type II has multiple small cysts measuring less than 1.2 cm, and type III is full of microcysts, giving the tissue an essentially solid appearance. Type III lesions have the worst prognosis. Pulmonary sequestration occurs when a mass of pulmonary tissue develops completely separated from normal lung and receives its blood supply from the systemic circulation. The intralobar variety is located inside the pleura adjacent to normal lung, whereas the extralobar variety has its own separate pleura, similar to an accessory lobe.

Both of these lesions may enlarge and eventually cause mediastinal shift, pleural effusions, hydramnios, and perinatal death from hydrops or pulmonary hypoplasia. Alternatively, either may regress spontaneously, although this is more likely with sequestration. Hydropic fetuses with either lesion are ideal candidates for fetal surgery because (1) the natural history of these lesions is known, (2) those with a poor prognosis can be readily identified because they are hydropic, and (3) such fetuses do not survive even with aggressive neonatal therapy. Adzick and colleagues (1993) offered fetal surgery to mothers of hydropic fetuses with CCAMs, and reported that the 25 fetuses with large cystic CCAMs and hydrops who were managed expectantly died. In contrast, 13 hydropic fetuses survived after open fetal lobectomy, and 5 of 6 survived with thoracoamniotic shunting.

Neural-Tube Defects. Isolated open spine defects usually result in permanent neurological damage (see [Chap. 12](#), p. 302). The damage likely results from two insults—the "two-hit" hypothesis. The first hit is the defect itself, and the second is neurological damage resulting from chronic exposure of the spine defect to amniotic fluid (Hefez and colleagues, 1990). Several investigators have theorized that antenatal closure or coverage of the spine defect might avert some of the damage. Fetal surgery for this indication is controversial because spina bifida is not a lethal defect, but results in morbidity, including reduced mobility, lack of bowel and bladder control, and need for a ventricular shunt.

The American College of Obstetricians and Gynecologists (2003) cites about 220 fetal surgeries for open spina bifida in the United States from 1997 through 2002. The studies were not randomized, and outcomes were not overly impressive given the risks of surgery. Thus, prenatal surgical closure of a fetal spine defect is currently available only as part of a National Institutes of Health (2003) multicenter research trial entitled *Management of Myelomeningocele Study (MoMS)*. The hypothesis of the study is that fetal surgery results in a decreased incidence of Arnold-Chiari malformation, and thus a reduced need for shunt placement if performed before 25 weeks (Bruner and colleagues, 1999; Tulipan and co-workers, 2003). Unfortunately, fetal surgical repair does not appear to improve lower extremity function (Tubbs and associates, 2003). In addition, there is substantive maternal morbidity that includes preterm labor and preterm rupture of the membranes, infection, pulmonary edema, and a scar in the contractible portion of the uterus. These complications, along with its uncertain benefit, make it unlikely that fetal surgery for spina bifida will be offered any time soon outside of a research trial.

STEM CELL TRANSPLANTATION

Because immunocompetence in the human fetus does not develop until 18 weeks, it is theorized that the fetus would be tolerant to foreign antigens introduced before that time. For this reason, fetal hemopoietic stem cell transplantation might treat a variety of hematological diseases or serve as a delivery vehicle for gene transfer for the treatment of other genetic conditions. Several animal models have been developed to study fetal bone marrow transplantation. Studies to date have focused on identifying the optimal time interval for transplantation and the best source of hematopoietic stem cells, including fetal liver, umbilical cord blood, and adult bone marrow. Therapeutic fetal bone marrow transplantation has been attempted in the human fetus for such diseases as bare lymphocyte syndrome, severe combined immunodeficiency syndrome, thalassemia, metachromatic leukodystrophy, and D-antigen isoimmunization. Despite limited success, however, research efforts continue (Crombleholme and Bianchi, 1994; Westgren and co-workers, 1996).

GENE TRANSFER

With advances in genetic technologies and progress in the identification of genes responsible for inherited disease, the

possibility of gene transfer as definitive therapy for a variety of genetic conditions is being explored. An excellent review by Pergament and Fiddler (1995) provides a detailed summary of fetal gene transfer. Early therapy by gene transfer would be ideal for certain inherited metabolic conditions in which tissue damage begins shortly after or even before birth. In Tay-Sachs disease, for example, central nervous system cells exhibit the characteristic pathology as early as 9 weeks after conception (Grabowski and colleagues, 1984). Early gene therapy also has the potential of requiring only one treatment, which would be definitive and would have a lifetime impact. Finally, healthy children would be assured without having to choose termination of affected pregnancies.

A number of criteria are considered requisite for the development of therapeutic gene transfer. These criteria, which have not yet been met, include that:

1. The normal gene can be inserted into the target cells and remain there long enough to have the desired effect.
2. The level of gene expression in the new gene will be appropriate.
3. The new gene will not harm the cell or the individual (Anderson, 1984). For example, it was recently reported that infants receiving gene therapy for X-linked severe combined immunodeficiency disease developed T-cell leukemia 3 years later (Berns, 2004).

Other unresolved issues include the timing of the procedure, viz., preconceptional, at the time of fertilization, prior to implantation, or during embryogenesis or fetal development; the best DNA vectors to use; the ideal recipient or target cells; and the safest methods. Efficient techniques for in vivo gene targeting have yet to be developed, and the possibility of ex vivo gene transfer raises ethical considerations. Other ethical questions remaining to be resolved include whether or not to target fetal gonadal tissues—which would affect future generations—and how to prevent gene transfer from being used for enhancement of phenotype rather than disease prevention—*eugenics*. Gene transfer is in its earliest experimental stages, and it must be thoroughly investigated in animals and adult humans before it can be extended to fetuses.

14. Teratology, Drugs, and Other Medications

INTRODUCTION

A birth defect is defined as a major deviation from normal morphology or function that is congenital in origin. Birth defects are common. Three percent of all newborns born in the United States have a major structural malformation detectable at birth. By 1 year of age, malformations or developmental disorders have been identified in 7 percent. This number increases to 12 to 14 percent by the time children enter school, and to 17 percent before they reach age 18 (Boyle and associates, 1994; Kimmel and colleagues, 1993). Most malformations are not inherited, and less than one third of patients seeking counseling for birth defects have a genetic condition (Hanson, 1996). A smaller proportion—about 10 percent—of congenital abnormalities are caused by teratogens. Only a small number of teratogens have been confirmed ([Table 14-1](#)).

TERATOLOGY

A *teratogen* is any agent that acts during embryonic or fetal development to produce a permanent alteration of form or function (Shepard, 1998). Teratology is the study of all environmental contributions to abnormal development. Currently recognized teratogens include chemicals, viruses, environmental agents, physical factors, and drugs. Women commonly ingest medications or drugs while pregnant. In a study of almost 9000 Medicaid prenatal patients in Michigan, Piper and colleagues (1987) reported that each woman received an average of 3.1 prescriptions for drugs other than vitamins. In a more contemporaneous study, Lacroix and colleagues (2000) found that pregnant women each took an average of 13.6 medications. Commonly used drugs include antiemetics, antacids, antihistamines, analgesics, antimicrobials, antihypertensives, tranquilizers, hypnotics, and diuretics. A substantial number of pregnant women also abuse recreational drugs during pregnancy. A study by Vega and colleagues (1993) found that 5.2 percent of 29,494 women presenting for delivery in 202 California hospitals were using one or more illicit drugs, including amphetamines, barbiturates, benzodiazepines, cannabis, cocaine, methadone, opiates, or phencyclidine. Another 6.7 percent were using alcohol, and 8.8 percent smoked cigarettes prior to delivery.

The word *teratogen* is derived from the Greek *teras*, meaning monster. Because this derivation implies obvious, visible defects, a teratogen is most properly defined as an agent that produces structural abnormalities. Many if not most major structural anomalies are easily recognized at birth, and an association with a specific prenatal exposure is likely to be suspected. Many congenital abnormalities, however, do not become apparent until later. A *hadegen*—after Hades, the god who possessed a helmet conferring invisibility—is an agent that interferes with normal maturation and function of an organ. A *trophogen* is an agent that alters growth. Hadegens and trophogens generally affect processes occurring after organogenesis or even after birth. Chemical or physical exposures that act as hadegens or trophogens are much harder to document. For simplification, most authors use the word *teratogen* to refer to all three types of agents.

EVALUATION OF POTENTIAL TERATOGENS. A birth defect in a newborn exposed prenatally to a certain drug, chemical, or environmental agent naturally arouses concern that the agent was a teratogen. The two approaches used currently to identify teratogenicity after a drug is released for clinical use include follow-up studies and case-control surveillance (Mitchell, 2003). Before such culpability is established, specific criteria, as shown in [Table 14-2](#), must be met:

The Defect Must Be Completely Characterized. This task preferably is done by a geneticist or dysmorphologist. Many genetic and environmental factors produce similar anomalies. For example, although cleft lip and palate are associated with antenatal hydantoin exposure, there are also more than 200 known genetic causes (Murray, 1995). Identical defects with different etiologies are called *phenocopies* (see [Chap. 12](#), p. 286). Determining the origin of a defect with many known phenocopies can be difficult. In general, it is easiest to prove causation when a rare exposure produces a rare defect, when at least three cases with the same exposure have been identified, and when the defect is relatively severe. For example, it was not difficult to show that isotretinoin is a teratogen because relatively few pregnant women have taken it during pregnancy, and one associated defect—agenesis of the ears—is an otherwise rare and severe abnormality.

The Agent Must Cross the Placenta. It must do so in sufficient quantity to directly influence fetal development or alter maternal or placental metabolism to exert an indirect fetal effect. Placental transfer depends on both maternal metabolism and specific characteristics of the drug, such as protein binding and storage, molecular size, electrical charge, and lipid solubility. Additionally, placental tissue contains an array of enzymes, including cytochrome P₄₅₀, which may metabolize offending substances. In the first trimester, the placenta also has a relatively thick membrane that slows diffusion (Leppik and Rask, 1988).

Exposure Must Occur During a Critical Developmental Period. Gestation is divided into three periods, and syndromes resulting from teratogen exposure are named accordingly. Exposures within the first 8 weeks result in an *embryopathy*, and after 8 weeks, a *fetopathy*.

1. The *preimplantation period* is the 2 weeks from fertilization to implantation and has traditionally been called the "all or none" period. The zygote undergoes cleavage, and cells divide into an outer and inner cell mass. An insult damaging a large number of cells usually causes death of the embryo. If only a few cells are injured, compensation is usually possible with continued normal development (Clayton-Smith and Donnai, 1996). Animal research studies have shown that some insults, namely those that appreciably diminish the number of cells in the inner cell mass, can produce a dose-dependent diminution in body length or size (Iahnaccone and co-workers, 1987).

2. The *embryonic period*, from the second through the eighth week following conception, encompasses organogenesis and is thus the most crucial with regard to structural malformations. [Figure 14-1](#) illustrates the critical developmental period for each organ system.

3. Maturation and functional development continue after 9 weeks, and during this *fetal period*, certain organs remain vulnerable. For example, the brain remains susceptible throughout pregnancy to environmental influences such as alcohol

exposure. Alteration in cardiac blood flow during the fetal period can result in deformations such as hypoplastic left heart or aortic coarctation (Clark, 1984).

There Must Be a Biologically Plausible Association. After consideration of its pharmacology and maternal and fetal metabolism, is it biologically plausible that the suspected agent caused the defect? Because both birth defects and drug or environmental exposures are common, it is always possible that an exposure and a defect are temporally but not causally related. For example, pregnant women frequently express concern about ingesting food or drinks containing aspartame. This compound, however, is metabolized to aspartic acid, which does not cross the placenta; to phenylalanine, which is metabolized; and to methanol, which is produced from aspartame in quantities lower than those released from an equal amount of metabolized fruit juice. Thus, it is not biologically plausible that aspartame is a teratogen.

Epidemiological Findings Must Be Consistent. Recurrent findings of certain abnormalities in association with a possible environmental exposure should prompt suspicion. A current example is first-trimester exposure to some cholesterol-lowering lipophilic statin drugs (Edison and Muenke, 2004). Characteristic abnormalities include fetal wastage, fetal growth restriction, structural abnormalities, and altered neurological function (Hanson, 1996). The initial evaluation of teratogen exposure is usually retrospective, and thus is likely to be hampered by recall bias, inadequate reporting, and incomplete assessment of the exposed population. The investigation is often further confounded by a variety of doses, concomitant drug therapy, and maternal disease(s). Familial and environmental factors can also influence development of birth defects. Thus, an important criterion for proving teratogenicity is that two or more high-quality epidemiological studies report similar findings.

High-quality epidemiological studies are those that are controlled for confounding factors, exclude positive and negative biases, include a sufficient number of cases, and are carried out prospectively. Additionally, a relative risk greater than three is generally necessary to support the hypothesis; a lesser risk should be interpreted with caution (Khouri and colleagues, 1992). An illustration of the advantages of prospective evaluation is the Canadian multicenter study of lithium exposure (Jacobson and colleagues, 1992). Case reports had linked lithium to the rare *Ebstein anomaly*. But when 138 exposed women were carefully evaluated prospectively, there was no increased incidence of birth defects.

Suspected teratogens rarely are evaluated epidemiologically, and as a result, drug safety information frequently is derived from case reports and small series. Nonscientific and biased reporting has contributed to assertions, subsequently proven false, about the safety of many widely used drugs. In many cases these assertions prompted litigation and cessation of manufacture of some very useful drugs. An example is *Bendectin*, a drug that was safe and effective for the treatment of nausea and vomiting in early pregnancy. More than 30 million women used this drug worldwide, and the 3 percent congenital anomaly rate among exposed fetuses was not different from the background rate (McKeigue and associates, 1994). Despite scientific evidence that Bendectin was not teratogenic, it was the subject of numerous lawsuits, and the financial burden of defending these suits forced its withdrawal. Thereafter, hospitalizations for hyperemesis gravidarum increased twofold (Koren and co-workers, 1998).

The Suspected Teratogen Causes a Defect in an Animal. If a drug or environmental exposure causes birth defects in experimental animals, it may be harmful to the human fetus (Brent, 2004a,b). Human teratogenicity is more likely if the agent produces an adverse effect in many different species, especially subhuman primates. That said, drugs under development often are tested in only a few animal species and at the equivalent of toxic human doses, making fetal outcomes difficult to interpret. The problems associated with reliance solely on animal data are illustrated by thalidomide and corticosteroids. Although thalidomide is one of the most potent teratogens ever prescribed, this was not immediately recognized because it produced no defects in mice and rats (Shepard, 1998). Conversely, corticosteroids have been withheld in pregnancy because they cause cleft lip in rodents, even though there is no evidence that they cause human structural malformations (Czeizel and Rockenbauer, 1997).

Figure 14-1. Timing of organogenesis during the embryonic period. (From Sadler, 1990, with permission.)

FOOD AND DRUG ADMINISTRATION CLASSIFICATIONS. To provide therapeutic guidance, a system for rating drug safety in pregnancy was developed by the Food and Drug Administration (FDA). The current FDA system is problematic because many drug ratings have been based on case reports or limited animal data. Moreover, update of these ratings is sometimes slow; for example, oral contraceptives continued to be listed as category X, even after teratogenicity was disproved. Because of these problems, this rating system eventually will be replaced by an evidence-based rating system, currently under development. The most current and accurate information can be obtained from the drug information services offered by many academic centers or through an on-line reproductive toxicity service such as *Reprotox*.

GENETIC AND PHYSIOLOGICAL MECHANISMS OF TERATOGENICITY

Teratogens likely act by disturbing specific pathogenetic processes, leading to cell death, altered tissue growth, or abnormal cellular differentiation. Some teratogens disrupt one or more of these processes, and the effects of combinations of drugs may be additive. Because abnormal physiological processes may be induced in many different cells or tissues, teratogenic exposure commonly results in multiple effects. In addition, different drugs can produce similar phenotypes if they disturb similar pathophysiological processes. The *fetal hydantoin syndrome* illustrates these concepts (see p. 348). Exposure may cause any combination of growth deficiency, borderline mental deficiency, craniofacial abnormalities, hypoplasia of the distal phalanges, and widely spaced nipples. This phenotype also results from prenatal exposure to carbamazepine and is similar to fetal alcohol syndrome (Vorhees and associates, 1988).

Two major mechanisms of teratogenesis are disruption of folic acid metabolism and production of toxic oxidative intermediates.

DISRUPTION OF FOLIC ACID METABOLISM. Several congenital anomalies, including neural-tube defects, cardiac defects, cleft lip and palate, and even Down syndrome, are thought to arise, at least in part, from disturbance of folic acid metabolic pathways. Folic acid is essential for the production of methionine, which is required for methylation reactions and thus production of proteins, lipids, and myelin (Scott and associates, 1994). It is essential for normal meiosis and mitosis. Hydantoin, carbamazepine, valproic acid, and phenobarbital all impair folate absorption or act as antagonists. They can lead to decreased periconceptional folate levels in women with epilepsy and to fetal malformations (Dansky and colleagues, 1987; Hiilesmaa and co-workers, 1983). A recent study by Hernandez-Diaz and colleagues (2000), including 5832 infants with birth defects and 8387 control infants, showed that fetuses who were exposed during embryogenesis to antiseizure medications known to act as folic acid antagonists had a two- to threefold increased risk for oral clefts, cardiac defects, and urinary tract defects. Although periconceptional folate supplementation lowers the malformation rate, women with epilepsy should be given the fewest number of drugs possible during pregnancy as well as folic acid supplementation (Lewis and co-workers, 1998; Zhu and Zhou, 1989).

OXIDATIVE INTERMEDIATES. Hydantoin, carbamazepine, and phenobarbital are metabolized by microsomes to arene oxides or epoxides. These oxidative intermediates normally are detoxified by cytoplasmic *epoxide hydrolase*, but because fetal epoxide hydrolase activity is weak, oxidative intermediates accumulate in fetal tissue (Horning and colleagues, 1974). These free oxide radicals have carcinogenic, mutagenic, and other toxic effects (Buehler and associates, 1990). These effects are dose related and increase with multidrug therapy (Lindhout and co-workers, 1984).

EFFECTS OF MATERNAL DISEASES. The interaction of maternal disease and maternal and fetal genetic composition will determine some drug effects. For example, alcoholic women often have poor nutrition and abuse other drugs. Fetuses exposed to these combined adverse influences are at higher risk of malformation than those exposed to excessive alcohol alone.

FETAL GENETIC COMPOSITION. It is likely that many anomalies now categorized as multifactorial are caused by the interaction of environment and certain altered genes. The most well-known example is the MTHFR 677 C→T mutation, which is associated with neural-tube defects and other malformations, but only when the mother has inadequate folic acid intake. As another example, fetuses exposed to hydantoin are most likely to develop anomalies if they are homozygous for a gene mutation resulting in abnormally low levels of epoxide hydrolase (Buehler and associates, 1990). There is also a reported association between cigarette smoking and isolated cleft palate, but only in individuals with an uncommon polymorphism in the gene for transforming growth factor-1. The risk of clefts in individuals with this allele is increased two- to sevenfold (Hwang and colleagues, 1995; Shaw and co-workers, 1996).

HOMEBOX GENES. Certain genes are found in all humans and confer equal susceptibility to specific agents. For example, all vertebrates carry groups of highly conserved genes—*homeobox genes*—that share a region of homology. These regulatory genes encode nuclear proteins that act as transcription factors to control the expression of other developmentally important genes (Boncinelli, 1997). They are essential for establishing positional identity of various structures along the body axis from the branchial area to the coccyx. The arrangement of the genes along the chromosome corresponds to the arrangement of the body areas they control and the order in which they are activated. Genes at the 3-prime end control the cranial region and are expressed before those at the 5-prime end, which control the caudal region (Faiella and collaborators, 1994).

During normal embryogenesis, retinoids such as vitamin A activate some of these genes essential for normal growth and tissue differentiation. The potent teratogen, retinoic acid, can activate these genes prematurely, resulting in chaotic gene expression at sensitive stages of development (Soprano and Soprano, 1995). This mechanism has been linked to abnormalities in the hindbrain and limb buds. Valproic acid is believed to preferentially alter the expression of homeobox genes called *Hox genes*. Disregulation of Hox-gene expression by valproic acid may prevent normal closure of the posterior neuropore (Faiella and colleagues, 1994). Interestingly, the affected Hox genes, *Hox d8*, *d10*, and *d11*, all control posterior structures. This corresponds with clinical observations that most neural-tube defects caused by valproic acid are in the lumbosacral area.

PATERNAL EXPOSURES. There are some paternal exposures to drugs or environmental influences that may increase the risk of adverse fetal outcome (Robaire and Hales, 1993). Several mechanisms have been postulated. One is the induction of a gene mutation or chromosomal abnormality in sperm. Because the process by which germ cells mature into functional spermatogonia takes 64 days, drug exposure at any time during the 2 months prior to conception could result in a mutation. A second possibility is that during intercourse a drug in seminal fluid could directly contact the fetus. Third, paternal germ cell exposure to drugs or environmental agents may alter gene expression (Trasler and Doerksen, 1999).

Some studies support these hypotheses. For example, ethyl alcohol, cyclophosphamide, lead, and certain opiates have been associated with an increased risk of behavioral defects in the offspring of exposed male rodents (Nelson and colleagues, 1996). In humans, paternal environmental exposure to mercury, lead, solvents, pesticides, anesthetic gases, or hydrocarbons has been associated with early pregnancy loss, although the data are of varying quality (Savitz and associates, 1994). Offspring of men employed in the art or textile industries have been reported to be at increased risk for stillbirth, preterm delivery, and growth restriction. Others who may have an increased risk of having anomalous offspring include janitors, woodworkers, firemen, printers, and painters (Olshan and co-workers, 1991; Schnitzer and associates, 1995). There have been no adverse outcomes associated with paternal therapeutic or recreational drug exposure, atomic radiation exposure, or Agent Orange (Centers for Disease Control and Prevention, 1998; Trasler and Doerksen, 1999).

COUNSELING FOR TERATOGEN EXPOSURE

Questions regarding medication and illicit drug use should be part of routine preconceptional and prenatal care (American College of Obstetricians and Gynecologists, 1999). Often women who request genetic counseling for prenatal drug exposure have misconceptions regarding their risk. Koren and colleagues (1989) reported that one fourth of women exposed to

nonteratogenic drugs thought they had a 25-percent risk of fetal anomalies — that is, a risk equivalent to thalidomide exposure. Women also may underestimate the background risk of birth defects in the general population. Such misconceptions can be amplified by the referral source, who may exaggerate risk — and even offer pregnancy termination — or by inaccurate reports in the lay press.

Counseling should include possible fetal risks from drug exposure, as well as possible teratogenic risks or genetic implications of the condition for which the drug was prescribed. Importantly, the manner in which information is presented affects the perception of risk. Jasper and colleagues (2001) showed that women given *negative information* — such as a 1 to 3 percent chance of having a malformed newborn — are more likely to perceive an exaggerated risk than women given *positive information* — the 97 to 99 percent chance of having a normal child. Ideally, women should be counseled preconceptionally as discussed throughout [Chapter 9](#). In reality, however, patients often report possible adverse exposures only *after* conception.

With a few notable exceptions, most commonly prescribed drugs and medications can be used with relative safety during pregnancy. For the few drugs believed to be teratogenic, counseling should emphasize *relative risk*. All women have about a 3-percent chance of having a neonate with a birth defect, and although exposure to a confirmed teratogen may increase this risk, it is usually increased by only 1 or 2 percent, or at most doubled or tripled. The concept of *risk versus benefit* also should be introduced. Some untreated diseases pose a more serious threat to both mother and fetus than any theoretical risks from medication exposure.

KNOWN TERATOGENS

Fortunately, the number of drugs or medications strongly suspected or proven to be human teratogens is small (see [Table 14-1](#)). In addition, in nearly every clinical situation potentially requiring therapy with a known teratogen, there are several alternate drugs that can be given with relative safety. New or infrequently used drugs for which there is inadequate safety information should be given in pregnancy only if the benefits clearly outweigh any theoretical risks.

ALCOHOL. Ethyl alcohol is one of the most potent teratogens known. As many as 70 percent of Americans imbibe alcohol socially, and use during pregnancy varies by population. Data from the most recent Behavioral Risk Factor Surveillance System survey indicate an average use of 12.8 percent during pregnancy (Sidhu and Floyd, 2002). Furthermore, although some decline in alcohol use since 1999 has been reported, the amount of binge drinking has not changed. The fetal effects of alcohol abuse have been recognized at least since the 1800s and were first described in a medical journal in 1900 by Sullivan. In 1968, Lemoine and associates reported the wide spectrum of alcohol-related fetal defects, culminating in what is now called *fetal alcohol syndrome* ([Table 14-3](#)). According to data from the Birth Defects Monitoring Program, the incidence of fetal alcohol syndrome increased from 1 per 10,000 births in 1979 to more than 6 per 10,000 births in 1993 (Centers for Disease Control and Prevention, 1995). It is one of the most frequent recognizable causes of mental retardation in the United States, a tragedy that could be avoided (Hanson, 1996).

Clinical Characteristics. The affected child may have congenital heart and joint defects, as well as failure to thrive and persistent irritability in early years. This is followed by developmental delay, growth deficiency, and poor coordination. Other comorbid conditions include mental retardation, attention deficit/hyperactivity disorder, learning disorders, sensory impairment, cerebral palsy, and epilepsy (Burd and colleagues, 2003). The distinctive facial features are shown in [Figure 14-2](#).

Dose Effect. A safe threshold dose for alcohol use during pregnancy has never been established. Current data indicate that women at highest risk to have affected children are those who chronically ingest large quantities and those who engage in binge drinking. This information can be used to reassure women who have inadvertently exposed their fetuses to low levels of alcohol. Although some studies show that fetal injury can result from consuming as little as one to two drinks per day, these studies typically report only the average daily dose and not the dose per occasion, and thus may have obscured the effects of binge drinking. For example, although Jacobson and co-workers (1993) reported that the threshold below which no alcohol-related effects occurred was an average of 0.5 ounce of absolute alcohol per day, they also found that most women with affected children actually drank four to six drinks per occasion. Alcoholic women ingesting eight or more drinks daily throughout pregnancy have a 30- to 50-percent risk of having a child with all the features of fetal alcohol syndrome.

Wass and colleagues (2001) showed that this level of exposure produces anatomical brain abnormalities that may account for some features of the syndrome. They monitored fetal brain growth ultrasonographically in 167 pregnant women and found that 23 percent of the fetuses whose mothers drank an average of 8 ounces of alcohol per day had a frontal cortex measurement below the 10th percentile for size, compared with only 4 percent of the nonexposed fetuses. Despite these findings, fetal alcohol syndrome cannot be diagnosed prenatally.

Prenatal alcohol exposure also increases the risk of pregnancy complications such as intraventricular hemorrhage and white matter brain damage in preterm neonates (Holzman and colleagues, 1995). Virtually all neonates with the syndrome have significant growth restriction (American College of Obstetricians and Gynecologists, 2000). Maternal age may contribute independently to increased fetal risk. Jacobson and co-workers (1998) have speculated that this susceptibility may be the result of age-related increases in the body fat-to-water ratio and a faster rate of alcohol metabolism in older women.

Fortunately, early cessation of alcohol use may result in amelioration of some of its teratogenic effects. In a prospective study of 60 fetuses exposed to heavy alcohol consumption, Autti-Ramo and colleagues (1992) found no abnormalities in language or mental development in children exposed to heavy drinking only in the first trimester. Those exposed to heavy drinking throughout pregnancy, however, had significantly lower scores in these two areas. Despite this, even low levels of alcohol consumption cannot be recommended during pregnancy. Besides individual variation of "threshold dose," there are confounding effects of maternal age, other drug and environmental exposures, and pregnancy complications.

Figure 14-2. Fetal alcohol syndrome. **A.** At 2 1/2 years. **B, C.** At 12 years. Note persistence of short palpebral fissures, epicanthal folds, flat midface, hypoplastic philtrum, and thin upper vermilion border. This individual also has the short, lean prepubertal stature characteristic of young males with fetal alcohol syndrome.

(From Streissguth and colleagues, 1985, with permission.)

ANTICONVULSANT MEDICATIONS. Women with epilepsy have an increased risk of fetal malformations. Although some studies suggest increased risk even when the mother is not taking anticonvulsants, others indicate that drug exposure is responsible for most fetal anomalies identified (Holmes and colleagues, 2001; Yerby, 1993). The most frequently reported defects, whether or not the mother takes medication, are orofacial clefts and cardiac malformations. Clefts develop almost 10 times more frequently than in the general population.

Malformations of all types are more prevalent with high serum anticonvulsant concentrations, and polytherapy imposes a higher risk than monotherapy (Dansky and associates, 1980; Omtzigt and colleagues, 1992). A Japanese collaborative study reported that the rate of major fetal malformations was 1.9 percent if women with epilepsy took no anticonvulsants during pregnancy, 5.5 percent if two drugs were taken, 11 percent if three were used, and 23 percent if four were taken (Nakane and colleagues, 1980; Okuma and associates, 1980). Because the need for drug therapy, high serum levels, and multiple medications also reflect severity of maternal disease, it is also possible that at least part of the increased risk is related to the epilepsy itself or some other aspect of the maternal condition.

The most commonly used potentially teratogenic anticonvulsants and their fetal effects are listed in [Table 14-4](#). Several of these medications produce a similar constellation of malformations, typified by the *fetal hydantoin syndrome* shown in [Figure 14-3](#). As discussed earlier, this syndrome results from the accumulation in fetal tissues of free oxide radicals, which have carcinogenic, mutagenic, and other toxic effects. Data from a Finnish provincial study indicated that monotherapy with carbamazepine did not impair intelligence in offspring who were evaluated when beginning school (Gaily and co-workers, 2004). Other medications, such as *phenobarbital* or *lamotrigine*, act by lowering fetal folate levels and thereby cause defects associated with impaired folic acid metabolism, such as neural-tube defects, oral clefts, cardiac anomalies, and urinary tract malformations (see [Chap. 12](#), p. 302).

Figure 14-3. Fetal hydantoin syndrome. Upper facial features including upturned nose, mild midfacial hypoplasia, and long upper lip with thin vermilion border. Lower distal digital hypoplasia. (From Buehler and colleagues, 1990, with permission.)

WARFARIN COMPOUNDS. These coumarin anticoagulants have a low molecular weight, readily cross the placenta, and can cause significant adverse teratogenic and fetal effects. Hall and co-workers (1980) estimated that one sixth of exposed pregnancies result in an abnormal liveborn neonate, and one sixth result in abortion or stillbirth. Ginsberg and Hirsh (1989) reviewed 186 studies involving 1325 exposed pregnancies and reported that 9 percent of exposed fetuses suffered permanent deformity or disability, and 17 percent of these fetuses died.

Distinct defects with two different etiologies result from exposure during two different developmental periods. If exposed between the sixth and ninth week, the fetus is at increased risk of *warfarin embryopathy*. This is characterized by nasal and midface hypoplasia ([Fig. 14-4](#)) and stippled vertebral and femoral epiphyses. Because vitamin K clotting factors are not demonstrable in the embryo at this age, warfarin derivatives are thought to exert their teratogenic effect by inhibiting posttranslational carboxylation of coagulation proteins (Hall and associates, 1980). These proteins are called osteocalcins because of their role in embryonic control of calcification, and their deficiency could result in many features of warfarin embryopathy. The syndrome is a phenocopy of *chondrodysplasia punctata*, a group of genetic diseases thought to be caused by inherited defects in osteocalcin ([Fig. 14-5](#)). Recent data suggest that the risk of warfarin embryopathy is dose dependent. In a study of 43 women with mechanical heart valves treated with warfarin during 58 pregnancies, Vitale and colleagues (1999) found that warfarin embryopathy and fetal wastage occurred only when a dose exceeding 5 mg was taken throughout the first trimester. In these women, the incidence of embryopathy was 8 percent and the incidence of spontaneous abortion was 72 percent.

During the second and third trimester, the defects associated with fetal exposure to warfarin likely result from hemorrhage leading to disharmonic growth and deformation from scarring in any of several organs (Warkany, 1976). Defects may be regionally extensive and include dorsal midline central nervous system dysplasia, such as agenesis of the corpus callosum, Dandy-Walker malformation, and midline cerebellar atrophy; ventral midline dysplasia such as microphthalmia, optic atrophy, and blindness; and developmental delay and mental retardation (Hall and colleagues, 1980).

Figure 14-5. Fetal radiograph demonstrating the main features of *chondrodysplasia punctata*: bone stippling of vertebrae; rib ends; iliac, ischial, and pubic bones; epiphyses of the long tubular bones; and patellae. Stippling results from aberrant

calcification of cartilage and premature calcification of bone. (From Wessels and Willems, 2002, with permission.)

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS. These

antihypertensive agents have been associated with many reports of fetal damage. The most frequently associated agent is *enalapril*, although *captopril* and *lisinopril* have been implicated. These drugs disrupt the renin-angiotensin system, which has been shown to be essential for normal renal development. Interruption of angiotensin II type-1 receptor-mediated effects during embryogenesis in experimental animals results in renal papillary and tubular atrophy and a significant impairment in urinary concentrating ability (Guron and Friberg, 2000). ACE inhibitors appear to have similar effects on human fetuses. In addition, they may provoke prolonged fetal hypotension and hypoperfusion, thus initiating a sequence of events leading to renal ischemia, renal tubular dysgenesis, and then anuria (Pryde and colleagues, 1993; Schubiger and associates, 1988). The resulting oligohydramnios prevents normal lung development and causes limb contractures. Reduced perfusion also causes growth restriction, relative limb shortening, and maldevelopment of the calvarium (Barr and Cohen, 1991). Because these changes occur during the fetal period, they are termed *ACE inhibitor fetopathy* (see [Chap. 14](#), p. 343).

There have been reports of cases in which embryonic exposure to an ACE inhibitor has not caused apparent renal abnormalities (Barr, 1994; Lip and colleagues, 1997). One possible explanation for this variable fetal response may be variation in the ACE gene. For example, homozygotes for a 50-base pair deletion in the ACE gene have high serum ACE activity, whereas those homozygous for an insertion of the same fragment have low activity (Lee, 1994; Rigat and associates, 1990). The relationship between ACE exposure and the fetal ACE gene is not yet understood, and ACE exposure during pregnancy should be avoided.

RETINOIDS. Retinoids, especially vitamin A, are essential for normal growth, tissue differentiation, reproduction, and vision (Gudas, 1994). As discussed earlier, retinoids are believed to activate four clusters of homeobox genes during embryogenesis (Soprano and Soprano, 1995).

Vitamin A. There are two forms of vitamin A in nature. *Beta-carotene* is a precursor of provitamin A. It is found in fruits and vegetables and has never been shown to cause birth defects (Oakley and Erickson, 1995). *Retinol* is preformed vitamin A. Many foods contain vitamin A, but animal liver contains the most. It is uncertain whether high doses of vitamin A are teratogenic. Although several reports concerning vitamin A supplementation have associated high doses with congenital anomalies, they have been hampered by small patient numbers, unknown daily dose, and absence of any recognizable pattern of observed defects. Two cohort studies have also been inconclusive (Conway, 1958; Rothman and co-workers, 1995).

In the largest prospective study, 423 women contacted European Teratology Services to report exposure (Mastroiacovo and associates, 1999). They had ingested from 10,000 to 300,000 IU of vitamin A daily during the first 9 weeks. Only three newborns had birth defects, and there was no relationship between vitamin dose and outcome. Although these data suggest that vitamin A supplements may be safe during pregnancy, vitamin A deficiency is rare in the United States and there is no scientific basis for supplementation. Doses higher than the recommended daily allowance of 5000 IU should be avoided (American College of Obstetricians and Gynecologists, 1995).

ISOTRETINOIN. Some isomers of vitamin A are used chiefly for dermatological disorders because they stimulate epithelial cell differentiation (see [Chap. 56](#), p. 1255). *Isotretinoin*, which is 13-*cis*-retinoic acid, is effective for treatment of cystic acne. It is also considered one of the most potent teratogens in common use. First-trimester exposure is associated with a high rate of fetal loss, and the 26-fold increased malformation rate in survivors is similar to that for thalidomide (Lammer and co-workers, 1985). Abnormalities have been described only with first-trimester use. Because it is rapidly cleared—the mean serum half-life is 12 hours—the anomalies are not increased in women who discontinue therapy before conception (Dai and colleagues, 1989).

Any organ system can be affected by isotretinoin exposure, but malformations typically involve the cranium and face, heart, central nervous system, and thymus. The otherwise extremely rare craniofacial malformation most strongly associated with isotretinoin, microtia or anotia, is bilateral, but often asymmetrical. These defects frequently appear in conjunction with agenesis or stenoses of the external ear canal ([Fig. 14-6](#)). Other defects include cleft palate and maldevelopment of the facial bones and cranium. The most frequent cardiac anomalies are conotruncal or outflow tract defects, and hydrocephalus is the most common central nervous system defect. Thymic abnormalities include aplasia, hypoplasia, or malposition.

Dai and colleagues (1992) summarized 433 exposed pregnancies reported to the drug manufacturer. Elective abortion was chosen in half. Of the others exposed before 12 weeks, one third spontaneously aborted and one third resulted in a neonate with at least one major malformation. Importantly, there did not appear to be any safe first-trimester exposure period or dose.

Despite the well-publicized hazards associated with prenatal isotretinoin use, as well as efforts by the manufacturer to highlight these reproductive risks, exposures continue to be reported. A pregnancy test before initiating the drug and a mistake-proof method of birth control such as *Norplant* are now required by many clinics prior to beginning therapy.

Etretinate. This orally administered retinoid is used to treat psoriasis. It is associated with severe anomalies similar to those with isotretinoin. One important difference is that anomalies are observed with etretinate even when conception occurs after discontinuation of therapy. It is lipophilic, has a half-life of 120 days, and has been detected in serum almost 3 years after therapy (DiGiovanna and colleagues, 1984; Thomson and Cordero, 1989). It is unknown how long the teratogenic effects persist, but Lammer (1988) reports that malformations have been described up to 51 weeks after its discontinuation! If possible, women who plan future childbearing should not use this drug. If etretinate is used, Geiger and associates (1994) suggest that women wait at least 2 years after concluding treatment before conceiving.

Tretinoin. This is all-*trans*-retinoic acid, usually prepared as a gel, which is prescribed for treatment of acne vulgaris. It is also available in an oral form, which is used as antineoplastic therapy for acute promyelocytic leukemia at doses 9000 to 14,000 times greater than those used topically. When the gel is used, the skin metabolizes most of the drug with minimal apparent

absorption. Jick and colleagues (1993) found no increase in rates of congenital anomalies in 215 neonates born to women who used topical tretinoin during early pregnancy. Four cases have been reported in which first-trimester topical use resulted in fetal defects similar to those associated with isotretinoin (Reprotox, 2003b). In all, however, the doses were unknown and in one case another medication was concurrently used. The oral medication, like other retinoids, is likely to be highly teratogenic although no affected fetuses have been reported to date (Briggs and colleagues, 2002).

HORMONES. The primordial structures that will become the external genitalia are bipotential for the first 9 weeks (see Chap. 4, p. 113). Between 9 and 14 weeks, the testis secretes androgen and the male fetus develops a male perineal phenotype. Because the ovaries do not secrete androgens, the female fetus continues to develop a female phenotype, which is completed by 20 weeks (Speroff and colleagues, 1994). Exposure to exogenous sex hormones before 7 completed weeks generally has no effect on external structures. Between 7 and 12 weeks, however, female genital tissue is responsive to exogenous androgens and exposure can result in full masculinization. The tissue continues to exhibit some response until 20 weeks, with exposure causing partial masculinization or genital ambiguity.

Those areas of the brain with high concentrations of estrogen and androgen receptors are also influenced by hormonal exposure. Hormones program the central nervous system for gender identity, sexual behavior, levels of aggression, and gender-specific play behaviors. The critical period for hormonal influence on behavior is much later than that for the external genitalia, with the degree of behavioral alteration proportional to dose and length of exposure.

Androgens. An example of the fetal effects from early exposure to androgens is autosomal recessive *congenital adrenal hyperplasia*. Fetal adrenal glands ordinarily begin functioning by 12 weeks, but in this condition, specific enzyme deficiencies prevent the glands from hydroxylating cortisol precursors. Androgenic intermediates accumulate, masculinizing female external genitalia and producing abnormal male genital growth (Chrousos and associates, 1985). Female fetuses exposed early to androgens also develop a more masculine orientation and increased male gender identity (Dittman and co-workers, 1990, 1992; Meyer-Bahlburg and collaborators, 1996; Zucker and associates, 1996). Exposure to exogenous androgens can induce similar fetal effects. In contrast to congenital adrenal hyperplasia, masculinization from exogenous androgens does not progress after birth (Stevenson, 1993b).

TESTOSTERONE AND ANABOLIC STEROIDS. Androgen exposure in reproductive-aged women occurs primarily as the result of anabolic steroid use by athletes to increase lean body mass and muscular strength. The most effective agents are synthetic testosterone, which are taken in doses 10 to 40 times higher than those used therapeutically. In women, these agents cause extreme and irreversible virilization, liver dysfunction, and mood and libido disorders. Exposure of a female fetus results in varying degrees of virilization, including labioscrotal fusion after first-trimester exposure and phallic enlargement with later fetal exposure (Grumbach and Ducharme, 1960; Schardein, 1985). Normal female maturation usually occurs at puberty, although surgery may be necessary to give a more feminine appearance to the virilized genitalia.

ANDROGENIC PROGESTINS. These testosterone derivatives currently are used as contraceptives. In studies of rats and nonhuman primates, antenatal exposure to *medroxyprogesterone acetate*, an intramuscular depot contraceptive, has been associated with virilization of female fetuses and feminization of male fetuses. Fortunately, no association between this agent and any congenital defects in humans has been established. *Norethindrone*, a progesterone-only contraceptive, is estimated to cause female fetus masculinization in 1 percent of exposures (Schardein, 1985).

DANAZOL. This ethinyl testosterone derivative has weak androgenic activity that inhibits the pituitary-ovarian axis. It is prescribed primarily for endometriosis but also is used to treat immune thrombocytopenic purpura, migraine headaches, premenstrual syndrome, and some breast diseases. In a review of its inadvertent use during early pregnancy, Brunskill (1992) reported that 40 percent of 57 exposed female fetuses were virilized. There was a dose-related pattern of clitorimegaly, fused labia, and urogenital sinus malformation, most of which required surgical correction.

Estrogens. There are many estrogen compounds, and most do not affect fetal development. Oral contraceptives are discussed on page 361.

DIETHYLSTILBESTROL (DES). From 1940 to 1971, between 2 and 10 million pregnant women took DES to "support" high-risk pregnancies (Giusti and co-workers, 1995). The drug later was shown to have no beneficial effects, and its use for this purpose was abandoned. Herbst and colleagues (1971) subsequently reported a series of eight prenatally exposed women who developed vaginal clear-cell adenocarcinoma. Subsequent studies showed that the absolute cancer risk in prenatally exposed women is substantially increased to about 1 per 1000. The Registry for Research on Hormonal Transplacental Carcinogenesis reported that half of 384 cancer patients were exposed before 12 weeks and 70 percent before 17 weeks (Melnick and colleagues, 1987). Malignancy was not dose related, and there was no relationship between location of the tumor and timing of exposure. For these reasons and because its absolute risk is low, some authors categorize DES as an *incomplete carcinogen*.

DES also produces both structural and functional abnormalities (Salle and colleagues, 1996). By 18 weeks, the müllerian-derived cuboidal-columnar epithelium lining the vagina should be replaced by squamous epithelium originating from the urogenital sinus. DES interrupts this transition in up to half of exposed female fetuses, resulting in excess cervical eversion (ectropion) and ectopic vaginal glandular epithelium (adenosis). The Diethylstilbestrol Adenosis Project showed that these lesions have malignant potential, and DES-exposed women have a twofold increase in vaginal and cervical intraepithelial neoplasia (Vessey, 1989).

One fourth of exposed females have structural abnormalities of the cervix or vagina (Robboy and associates, 1984). The embryological mechanism is unknown (Kaufman and co-workers, 1980). The most commonly reported abnormalities include a hypoplastic, T-shaped uterine cavity; cervical collars, hoods, septa, and coxcombs; and "withered" fallopian tubes (Goldberg

and Falcone, 1999). As discussed in [Chapter 40](#) (see p. 957), these women are at increased risk for poor pregnancy outcomes related to uterine malformations, decreased endometrial thickness, and reduced uterine perfusion (Kaufman and colleagues, 2000). Exposed men have normal sexual function and fertility, but are at increased risk for epididymal cysts, microphallus, cryptorchidism, and testicular hypoplasia (Stillman, 1982). Recently, Klip and associates (2002) reported that sons of women exposed in utero had an increased risk of hypospadias.

ANTINEOPLASTIC AGENTS

Cyclophosphamide. In the first trimester, this alkylating agent inflicts a chemical insult on developing fetal tissues, resulting in cell death and heritable DNA alterations in surviving cells. Fetal anomalies have been described after exposure during early pregnancy. The most commonly reported are missing and hypoplastic digits on hands and feet. These anomalies are believed to be caused by necrosis of limb buds and DNA damage in surviving cells (Manson and associates, 1982). Other defects include cleft palate, single coronary artery, imperforate anus, and fetal growth restriction with microcephaly (Kirshon and colleagues, 1988). Nurses who administer cyclophosphamide may be at increased risk for fetal loss, but the data are unclear and there are no adequate epidemiological studies (Glantz, 1994). Alkylating agents should be avoided during early pregnancy if possible, but can be given during the second and third trimesters.

Methotrexate and Aminopterin. These drugs alter normal folic acid metabolism, which is essential for cell replication (Sutton and co-workers, 1998). Methotrexate commonly is prescribed as an abortifacient for ectopic pregnancy, and for psoriasis and some connective tissue diseases. Principal features of fetal methotrexate-aminopterin syndrome are growth restriction, failure of calvarial ossification, craniosynostosis, hypoplastic supraorbital ridges, small posteriorly rotated ears, micrognathia, and severe limb abnormalities (Del Campo and associates, 1999). After a review of 20 first-trimester exposures, Feldcamp and Carey (1993) calculated that a dosage of 10 mg/week is necessary to produce abnormalities. This dosage is exceeded during standard therapy for ectopic pregnancy or elective abortion. Ongoing pregnancies after methotrexate treatment, especially if used in conjunction with misoprostol, thus raise concerns about fetal malformations (Creinin and Vittinghoff, 1994).

ANTIMICROBIALS

Tetracyclines. These drugs, including doxycycline and minocycline, may cause yellow-brown discoloration of deciduous teeth or be deposited in fetal long bones (Kutscher and associates, 1966). One acceptable use is treatment of maternal syphilis in penicillin-allergic women for whom desensitization is impractical (see [Chap. 59](#), p. 1304).

Aminoglycosides. Maternal administration can result in toxic fetal blood levels, but this can be avoided by using lower divided doses (Regev and colleagues, 2000). Although both nephrotoxicity and ototoxicity have been reported in preterm newborns and adults treated with *gentamicin* or *streptomycin*, congenital defects resulting from prenatal exposure have not been confirmed.

Sulfonamides. Although these agents readily cross the placenta, fetal blood levels are lower than maternal levels. These drugs can displace bilirubin from protein binding sites, raising theoretical concerns about hyperbilirubinemia in the preterm neonate if used near delivery. There have been no studies documenting an association between sulfonamides and congenital anomalies, even when used in combination with trimethoprim, a folate antagonist (Briggs and colleagues, 2002).

ANTIFUNGALS

Griseofulvin. This oral fungicide is used for treatment of mycotic infections of the skin, nails, and scalp. Animal studies indicate increased anomalies of the central nervous system and skeleton. There have been conflicting reports of a possible association with conjoined twins (Knudsen, 1987; Rosa and associates, 1987a, 1987b).

Fluconazole and Itraconazole. These antifungal agents commonly are used in immunocompromised patients. There have been several reports of congenital malformations associated with fluconazole use during pregnancy. Exposed newborns had skull abnormalities, cleft palate, humeral-radial fusion, and other arm abnormalities, collectively resembling Antley Bixler syndrome (Aleck and Bartley, 1997). The FDA has received reports associating itraconazole with limb defects and other adverse outcomes. Despite this, large cohort studies indicate that neither of these drugs is teratogenic (Bar-Oz and colleagues, 2000; Sorenson and collaborators, 1999).

ANTIVIRALS. *Ribavirin* is given by aerosol inhalation to treat respiratory syncytial virus infections in infants and young children. Pregnant women may be exposed to the drug while working in intensive care nurseries. The drug is highly teratogenic in all animal species studied and consistently produces hydrocephalus and limb abnormalities in rodent models (Johnson, 1990). Although human exposures are rare, the Centers for Disease Control and Prevention and the manufacturers consider it contraindicated for use in pregnancy.

ANTIMALARIALS. *Chloroquine* is valuable as a first-line antimalarial treatment and for chemoprophylaxis. In high doses it is also effective against rheumatoid arthritis and systemic lupus erythematosus. *Quinine* and *quinidine* are reserved for severely ill women with chloroquine-resistant malaria. There has been no increased rate of congenital anomalies in the offspring of mothers given any of these antimalarial drugs during pregnancy (McGready and co-workers, 2001, 2002). Daily use of chloroquine for lupus and other connective tissue diseases has been shown to cause maternal retinopathy but no adverse fetal effects (Araiza-Casillas and colleagues, 2004; Costedoat-Chalumeau and co-workers, 2003). Second- or third-trimester use of *mefloquine* for asymptomatic malaria treatment has been associated with a fivefold increased risk of stillbirth (Nosten and colleagues, 1999). According to Briggs and colleagues (2002), however, accumulated evidence supports its safety.

TOBACCO. Cigarette smoke contains a number of potential teratogens, including nicotine, cotinine, cyanide, thiocyanate, carbon monoxide, cadmium, lead, and various hydrocarbons. In addition to being fetotoxic, many of these substances have vasoactive effects or reduce oxygen levels.

The most well-documented reproductive outcome related to smoking is a direct dose-response reduction in fetal growth. Newborns of mothers who smoke weigh an average of 200 g less than those of nonsmokers, and heavy smoking results in more severe weight reduction (D'Souza and associates, 1981). Smoking doubles the risk of low birthweight, and increases the risk of a small-for-gestational aged newborn 2.5-fold (Werler, 1997). Women who stop smoking early in pregnancy generally have neonates with normal birthweights (Cliver and co-workers, 1995). Smoking also may cause a slightly increased incidence of subfertility, spontaneous abortion, placenta previa and abruption, and preterm delivery. These effects are discussed in more detail in [Chapters 35](#) (see p. 814), [36](#) (see p. 859), and [38](#) (see p. 899).

It is plausible that the vasoactive properties of tobacco smoke could produce congenital defects related to vascular disturbances. Martinez-Frias and colleagues (1999) observed in smokers a twofold risk of Poland sequence, which is caused by an interruption in the vascular supply to one side of the fetal chest and ipsilateral arm. Smoking at least 20 cigarettes a day combined with the use of vasoconstrictive drugs such as amphetamines and decongestants also appears to result in a fourfold risk of gastroschisis and small intestinal atresia (Werler and associates, 2003).

Smoking has been associated with cleft lip and palate in individuals heterozygous or homozygous for an uncommon polymorphism in the transforming growth factor gene (Shaw and colleagues, 1996). When exposed prenatally to cigarette smoke, these individuals have twice the risk of combined cleft lip and palate, and four to seven times the risk for cleft palate alone (Hwang and associates, 1995; Shaw and co-workers, 1996). A study that used the National Vital Statistics System natality data from more than 6 million live births in the United States found an association between maternal smoking and hydrocephaly, microcephaly, omphalocele, gastroschisis, cleft lip and palate, and hand abnormalities (Honein and colleagues, 2001).

COCAINE. This alkaloid is derived from the leaves of the South American tree *Erythroxylon coca*. It is a highly effective topical anesthetic and local vasoconstrictor. It is also a central nervous system stimulant through sympathomimetic action via dopamine. Cocaine is currently one of the most widely abused drugs in the United States. The National Household Survey on Drug Use, reported by Ebrahim and Gfroerer (2003), found that 6.4 percent of women of childbearing age and 2.8 percent of pregnant women used illicit drugs. Marijuana accounted for 75 percent of drug use, and cocaine for 10 percent. In 1996, the Centers for Disease Control and Prevention determined that 1 in 20 pregnancies was associated with cocaine use.

Most of the adverse outcomes associated with cocaine result from its vasoconstrictive and hypertensive effects. Maternal complications include myocardial infarction, arrhythmias, aortic rupture, stroke, seizure, bowel ischemia, and sudden death. As discussed in [Chapter 35](#) (see p. 814), placental abruption is the most frequently cited cocaine-related pregnancy complication in cocaine abusers, and its incidence is fourfold greater than in nonusers (Chasnoff and colleagues, 1985; Shiono and colleagues, 1995).

The risk of vascular disruption within the embryo, fetus, or placenta is highest *after* the first trimester, and likely accounts for the increased incidence of stillbirth (Hoyme and associates, 1990). A number of cocaine-related congenital anomalies resulting from vascular disruption have been described. These include skull defects, cutis aplasia, porencephaly, subependymal and periventricular cysts, ileal atresia, cardiac anomalies, and visceral infarcts (Cohen and associates, 1994; Little and colleagues, 1989; Stevenson, 1993a). Results from the population-based Atlanta Birth Defects Case-Control Study showed that cocaine use increased the risk of urinary tract defects fourfold (Chavez and colleagues, 1988). Prune-belly anomaly also has been reported (Bingol and co-workers, 1986; Chasnoff and colleagues, 1985, 1988).

Although cocaine has been associated with microcephaly and behavioral abnormalities, there are few prospective studies of its effect on psychomotor development. Singer and colleagues (2002) reported a well-designed, prospective blinded study of 218 cocaine-exposed infants and 197 unexposed controls followed until 2 years. Compared with control infants, the cocaine-exposed infants had significantly more cognitive defects and twice the rate of developmental delay. Cognitive impairments were persistent at age 4 years (Singer and associates, 2004).

Not all studies, however, support the concept of cocaine as a major teratogen. Reports of cocaine-induced limb-reduction defects have been disputed (Hume and co-workers, 1997). One prospective longitudinal cohort study of 272 offspring of crack-cocaine users found no increase in the number or pattern of birth defects (Behnke and co-workers, 2001). Because few reports address dosage or total fetal exposure during pregnancy, it is difficult to estimate the ultimate fetal risk associated with antenatal cocaine use.

THALIDOMIDE. This anxiolytic and sedative drug is likely the most notorious human teratogen. It produces malformations in approximately 20 percent of fetuses exposed during the specific time window from 34 to 50 days menstrual age. Defects primarily are limited to structures derived from the mesodermal layer, such as limbs, ears, cardiovascular system, and bowel musculature. A wide variety of limb-reduction defects have been associated with thalidomide, with upper limbs usually more severely affected. Bone defects range from abnormal shape or size to total absence of a bone or limb segment. Limb-reduction defects may be the result of dysmorphogenesis (as occurs with thalidomide, warfarin, and phenytoin) or of vascular disruption of a normally formed limb (as occurs with misoprostol, chorionic villus sampling, and phenytoin) (Holmes, 2002).

Thalidomide was available from 1956 to 1960 before its teratogenicity, along with several teratological principles, were forcefully demonstrated. Prior to this time, the placenta was believed to be a perfect barrier that was impervious to toxic substances unless given in such high doses as to be lethal to the mother (Dally, 1998). The extreme variability in species susceptibility to drugs and chemicals also had not yet been appreciated. Thus, because thalidomide produced no defects in experimental mice and rats, it was assumed to be safe for humans. The thalidomide experience also demonstrated the close relationship between the timing of exposure and the type of defect (Knapp and co-workers, 1962). For example, upper limb phocomelia developed after exposure occurred during days 27 to 30—coincidental with appearance of the upper limb buds at 27 days. Lower limb phocomelia was associated with exposure during days 30 to 33, gallbladder aplasia with 42 to 43 days, duodenal atresia with 40 to 47 days, and so on for a vast number of malformations.

In the past decade, a number of immunomodulating uses have been found for thalidomide (Franks and associates, 2004). It was approved in 1999 in the United States for the treatment of erythema nodosum leprosum (Ances, 2002). It also has been

effective in the treatment of cutaneous lupus erythematosus, chronic graft-versus-host disease, prurigo nodularis, and certain malignancies (Maurer and co-workers, 2004; Pro and associates, 2004). It is recommended that reproductive-aged women taking thalidomide use two highly effective forms of birth control, because thalidomide-affected children continue to be born in countries where the drug is available, despite ample warnings (Castilla and co-investigators, 1996).

METHYL MERCURY. Although not a drug, methyl mercury is a known teratogen. Reports from Minimata, Japan, and from rural Iraq, the sites of two major methyl mercury spills, indicate that the developing nervous system is particularly susceptible to the effects of mercury. Prenatal exposure appears to cause a disturbance in neuronal cell division and migration, resulting in a range of defects from developmental delay and mild neurological abnormalities to microcephaly and severe brain damage (Choi and colleagues, 1978).

Although there have been no recent episodes of large-scale methyl mercury contamination in the United States, pregnant women worldwide are currently at increased risk of exposure. Mercury enters the ecosystem through industrial pollution, which joins surface water and eventually reaches the ocean. Several varieties of older large fish, notably tuna, shark, king mackerel, and tilefish, absorb and retain mercury from the water or ingest it when they eat smaller fish and aquatic organisms. Women who eat these fish ingest mercury as well. Methyl mercury is metabolized to inorganic mercury by intestinal microflora and eliminated by demethylation and fecal excretion. The process is slow, with an elimination half-time of 45 to 70 days (Clarkson, 2002). Women who ingest large quantities of contaminated fish during pregnancy may therefore expose their fetuses to unsafe levels of mercury with the attendant risk of neurological abnormalities. The FDA (2004) currently recommends that pregnant women not eat shark, swordfish, king mackerel, or tilefish. They should also limit ingestion of albacore tuna to 6 ounces per week or to 12 ounces per week of fish and shellfish varieties thought to be low in mercury.

DRUGS COMMONLY USED IN PREGNANCY

Fortunately, as discussed on page 346, only a few drugs taken by pregnant women have adverse fetal effects.

ANALGESICS

Salicylates and Acetaminophen. Almost half of pregnant women use salicylates and acetaminophen. There is some evidence that early spontaneous abortion may be increased with their use (Nielsen and colleagues, 2001). Although two case-control studies have reported an association between first-trimester salicylate use and fetal gastroschisis, most investigators have found no association with any fetal anomalies (CLASP Collaborative Group, 1994; Martinez-Frias and colleagues, 1997).

Because *aspirin* is a potent prostaglandin inhibitor, there is a theoretical concern that fetal exposure could lead to premature closure of the ductus arteriosus. Despite this, and with the massive number of exposures, premature closure has not been reported. DiSessa and colleagues (1994) performed echocardiography from 15 to 40 weeks in 63 fetuses exposed to 60 mg of aspirin given daily to prevent preeclampsia. They consistently found normal ductus flow velocity and cardiac output. *Acetaminophen* also has not been associated with an increased risk of anomalies (Pastore and colleagues, 1999; Thulstrup and associates, 1999).

Other Nonsteroidal Anti-Inflammatory Drugs (NSAIDs). Various NSAIDs have analgesic action, and *ibuprofen*, *naproxen*, and *ketoprofen* are used most often. *Indomethacin* has been employed as a tocolytic agent (see [Chap. 36](#), p. 871). These drugs are not considered to be teratogenic but they have largely reversible fetal effects when used short term in the third trimester (Parilla, 2004).

In contrast to salicylates, indomethacin can result in constriction of the fetal ductus arteriosus and subsequent pulmonary hypertension in the neonate (Marpeau and associates, 1994; Rasanen and Jouppila, 1995). It also decreases fetal urine output and reduces amniotic fluid volume after prolonged use, presumably by increasing vasopressin levels and responsiveness to it (van der Heijden and colleagues, 1994; Walker and associates, 1994). For these reasons, the drug is used to treat hydramnios (see [Chap. 21](#), p. 530). Most studies have shown that these effects are reversible if the drug is discontinued after 34 weeks (Niebyl, 1991). Case reports have associated indomethacin with other adverse fetal effects such as intraventricular hemorrhage, bronchopulmonary dysplasia, and necrotizing enterocolitis. Some reports indicate that low-birthweight neonates delivered preterm within 48 hours of instituting therapy are at highest risk (Major and associates, 1994; Norton and Vargas, 1993). Studies conducted after neonatal surfactant treatment became available have not confirmed this association (Gardner and colleagues, 1996).

Narcotic Analgesics. Commonly used opioids include meperidine, morphine, codeine, propoxyphene, oxycodone, and hydrocodone. These agents have not been associated with congenital anomalies in humans (Bracken and Holford, 1981; Norton and Vargas, 2003). As with all narcotics, chronic maternal ingestion may be associated with a neonatal withdrawal syndrome (see [Chap. 14](#), p. 364). Butorphanol has been associated with neonatal respiratory depression and withdrawal, and 20 percent of exposed fetuses exhibit a sinusoidal heart rate pattern in utero (Hatjis and Meis, 1986; Welt, 1985).

Migraine Headache Medications. Most medications used to acutely treat migraine headaches cause vasoconstriction. Although ergotamine could theoretically cause anomalies in exposed fetuses, there are conflicting reports about its possible teratogenicity. The case-control study by Czeizel (1989) included 9460 newborns exposed in utero to various medications. This study found an association between first-trimester use and neural-tube defects, but this has not been confirmed by others (Briggs and colleagues, 2002). Third-trimester ergotamine use has been associated with fetal bradycardia, presumably resulting from uterine contractions and decreased uterine blood flow.

Sumatriptan also averts headache by causing vasoconstriction, but in contrast to ergotamine, it does not appear to affect uterine vessels. A study by Kallen and Lygner (2001) of 658 neonates exposed to sumatriptan antenatally found no increased incidence of anomalies. The Sumatriptan and Naratriptin Pregnancy Registries (2002) established by the manufacturer include 316 exposed pregnancies with a 3.8 percent incidence of diverse congenital defects. This rate is similar to the commonly reported background rate.

ANESTHETIC AGENTS

General Anesthesia. All agents used for general anesthesia cross the placenta to some degree. Some local analgesics have the potential for systemic absorption. None of the currently used anesthetic agents is a known teratogen, and exposure during pregnancy is generally brief and at nontoxic levels (Kuczkowski, 2004). A Swedish study that included 720,000 pregnant women who underwent 5405 nonobstetrical operations found no association between anesthesia exposure and adverse fetal outcome (Mazze and Kallen, 1989).

Specific agents that have been evaluated and found to be safe in small studies include *nitrous oxide*, *halothane*, *ketamine*, *methohexital*, *thiamylal*, *etomidate*, *alphaxalone*, *sodium oxylate*, and *thiopental*. The two most commonly used muscle relaxants, *curare* and *succinylcholine*, likewise have not been associated with teratogenic effects in humans (Friedman, 1988; Heinonen and co-workers, 1977). There have been no epidemiological studies regarding use during pregnancy of *isoflurane*, *enflurane*, or *methoxyflurane*. Chronic exposure of mouse and rabbit embryos to isoflurane and enflurane at doses resulting in maternal toxicity caused impaired development, but similar effects have not been found in humans (Reprotox, 2000b, 2000c). Older reports suggested that women with an occupational exposure to inhalation agents (e.g., anesthesiologists, surgeons, nurse anesthetists, operating room nurses, dental hygienists) had an increased risk of pregnancy loss or decreased fertility (see [Chap. 9](#), p. 235). Most of these studies had various biases and were conducted before nitrous oxide scavenging equipment was routinely utilized (Boivin, 1997; Friedman, 1988; Rowland and associates, 1992). Exposure is now limited by stringent ventilation and scavenging equipment.

Local Anesthesia. Various local anesthetic agents are used for spinal or epidural analgesia. Fetal malformations have not been associated with exposure to *lidocaine* or the other "-caine" anesthetics (Heinonen and colleagues, 1977). The main concern with these agents is the possibility of associated fetal bradycardia from their effect on diastolic depolarization, or of hyperthermia from maternal malignant hyperthermia. Both could be detrimental to the fetus but would likely not produce structural anomalies (Macaulay and co-workers, 1992; Stavrous and colleagues, 1990).

ANTICOAGULANTS. Deep-vein thrombosis or pulmonary embolus complicates about 1 in 1000 pregnancies (see [Chap. 47](#), p. 1079). As discussed on page 349, warfarin and other *coumarin* derivatives cause embryo-fetal defects and should not be used in pregnancy. Thus, *heparin* is the anticoagulant of choice. It is a group of large (molecular weight 4000 to 30,000), highly polar molecules that do not cross the placenta and thus are not associated with fetal anomalies. Although there are less data regarding the newer low-molecular-weight heparins (molecular weight 4000 to 6000), such as *enoxaparin*, they likewise are not believed to cross the placenta. They have not been associated with fetal malformations, low birthweight, or stillbirth (Fejgin and Lourwood, 1994; Sarsen and colleagues, 2000). Both preparations, however, can cause maternal osteopenia (see [Chap. 53](#), p. 1199).

A number of *thrombolytic agents* have been used during pregnancy. *Urokinase* normally is produced by the ovary and cytotrophoblast, and case reports suggest it can be used safely in pregnancy (Kramer and colleagues 1995; Turrentine and associates, 1995). In two reports of 166 pregnancies, *streptokinase* was not associated with adverse fetal effects (Ludwig, 1973). *Alteplase*, *tissue plasminogen activator (t-PA)*, is a high-molecular-weight enzyme that likely has no teratogenic risk (Briggs and colleagues, 2002).

ANTIEMETICS. Many agents have been used to treat nausea and vomiting in pregnancy (see [Chap. 49](#), p. 1113). *Bendectin*, a combination of doxylamine and pyridoxine, is the most widely studied, but for reasons discussed on page 344, it is no longer available in the United States. It is, however, available in Canada as *Diclectin*. It also can be reconstituted by combining pyridoxine (vitamin B₆) and *doxylamine*, an over-the-counter sleep aid, neither of which is teratogenic (Niebyl, 2000). The piperazines (*meclizine* and *cyclizine*) and the phenothiazines (*chlorpromazine*, *prochlorperazine*, *promethazine*, and *metoclopramide*) are also commonly used antiemetics, and none is associated with anomalies (Berkovitch and associates, 2000; Heinonen and colleagues, 1977). *Ondansetron hydrochloride* is highly effective for nausea associated with cancer chemotherapy but it has not been studied during pregnancy. It can be given intravenously or orally and usually is reserved for treatment of hyperemesis refractory to other medications.

ANTIPILEPTIC DRUGS. Many commonly used anticonvulsants are teratogenic, as discussed on page 347. Ethosuxamide and methsuximide are succinimide derivatives used for petit mal seizures. There are no human reproductive studies available and there are no case reports of malformations attributed solely to either of these agents. Information about the safety of newer anticonvulsants, including *felbamate*, *gabapentin*, *oxcarbazepine*, *tiagabin*, and *vigabatrin*, is limited (Briggs and associates, 2002). Based on what is known about the likely mechanisms of teratogenesis of traditional anticonvulsants, some of these newer drugs may prove to be safer for the fetus. For example, none of these new agents has antifolate effects, nor do they result in arene oxide metabolites, and most have minimal or no effect on the cytochrome P₄₅₀ system (Morrell, 1996).

Lamotrigine is from a different drug class but it inhibits dihydrofolate reductase and thus increases the risk for neural-tube defects and other folate-associated anomalies. The interim 2000 report of the Lamotrigine Pregnancy Registry indicated that the drug has a lower teratogenicity risk than other antifolate anticonvulsants (Briggs and co-workers, 2002). A population-based study from Denmark also was reassuring that the drug is likely safe (Sabers and associates, 2004). *Topiramate* is another new anticonvulsant that readily crosses the placenta and causes fetal defects in all animals tested, even at relatively low doses. Human data are lacking, but the drug should be avoided in pregnancy at this time.

ANTIHYPERTENSIVES. Almost 1 percent of pregnant women have some form of cardiovascular disease for which they are given a myriad of drugs and medications. Fortunately, most of these are safe during pregnancy. The majority of these are discussed also in [Chapter 45](#) (see p. 1048).

Undoubtedly *methyl dopa* is the agent most widely used during pregnancy for the treatment of chronic hypertension, and its many years of use attest to its safety. *Hydralazine* commonly is used to treat hypertension in women in the latter half of pregnancy without apparent adverse fetal effects. There are no human reproductive studies of *sodium nitroprusside*. It readily

crosses the placenta, which could result in the accumulation of cyanide in the fetal liver (Lewis and colleagues, 1977). *Clonidine* is an α -adrenergic antagonist that has been used to treat hypertension in pregnant women without adverse fetal effects (Horvath and co-workers, 1985).

Beta-Adrenergic Antagonists. A number of β -adrenergic blocking agents are used primarily for the treatment of chronic hypertension. These include *propranolol*, *labetalol*, *atenolol*, *metoprolol*, *nadolol*, and *timolol*. Several are also useful for the chronic treatment of angina pectoris and certain cardiac arrhythmias, and for treatment of hyperthyroidism. Although there is little information regarding their use in early gestation, there appear to be few adverse effects of β -blockers used in the second or third trimesters. There are conflicting reports about a possible association between β -blockers and fetal growth restriction and neonatal hypoglycemia. There are also some reports of transient mild hypotension and symptomatic β -blockade in exposed newborns (Crooks and co-workers, 1998; Reprotox, 2003a; Stevens and Guillet, 1995). Beta-blockers have not been linked to structural fetal anomalies or persistent physiological abnormalities.

Calcium-Channel Blockers. These agents also are used to treat chronic hypertension during pregnancy. Many embryonic processes are calcium dependent and theoretically could also be blocked (Bilozur and Powers, 1982; Lee and Nagel, 1986). *Verapamil* is used to treat hypertension, angina, and supraventricular tachycardias. There has been a report of first-trimester use in association with limb defects in two children, but cause and effect were not established (Magee and associates, 1996). Animal data suggest that second- or third-trimester verapamil use may decrease uterine blood flow (Murad and colleagues, 1985). An association with hypertrophic cardiomyopathy in exposed offspring has been reported (Shen and associates, 1995). Finally, verapamil has been associated with fetal cardiac depression and arrest when used in combination with digoxin for treatment of fetal supraventricular tachycardia (Owen and associates, 1988).

Nifedipine has been associated with pregnancy loss and fetal limb defects, but most reports note no adverse fetal effects (Magee and colleagues, 1996; Sibai and associates, 1992). Other calcium channel antagonists include *diltiazem* and *nifedipine*.

Diuretics. These drugs are prescribed during pregnancy for some women with chronic hypertension and also are given acutely or chronically to treat pulmonary edema. Neither *chlorothiazide* nor *hydrochlorothiazide* has been associated with congenital anomalies (Heinonen and co-workers, 1977; Jick and colleagues, 1981). Thiazide diuretics have been associated with neonatal thrombocytopenia, bleeding, and electrolyte disturbances when given near the time of delivery.

Acetazolamide is a carbonic anhydrase inhibitor used as a diuretic. It also is used to treat glaucoma and epilepsy and to prevent high-altitude sickness. Although the drug has consistently been associated with an unusual type of limb abnormality in rodents, similar defects could not be induced in primates and have not been observed in humans (Heinonen and co-workers, 1977; Hirsch and colleagues, 1983).

Spirolactone is a commonly used potassium-sparing diuretic that has not been widely studied in pregnancy. Acting as an anti-androgen, it causes feminization of male rat fetuses and delayed sexual maturation of female rat fetuses, but these effects have not been observed in humans (Messina and colleagues, 1979).

Ethacrynic acid and *furosemide* are loop diuretics that are not commonly used during pregnancy. Furosemide crosses the placenta and increases fetal urine production. There is some evidence that it stimulates renal synthesis of prostaglandin E_2 , which increases the incidence of patent ductus arteriosus in preterm newborns (Green and colleagues, 1983). No adverse fetal effects have been associated with its acute administration. Ethacrynic acid has ototoxic effects in vitro, but there is only one report of associated ototoxicity in vivo (Jones, 1973).

ANTIMICROBIALS. Several bacterial, viral, fungal, and parasitic infections are encountered during pregnancy, and virtually all antimicrobial and chemotherapeutic medications readily cross the placenta.

Antibacterial Agents. As a group, *penicillins* are probably the safest antimicrobials used during pregnancy. They include agents with broad-spectrum activity such as piperacillin and mezlocillin, as well as those combined with the β -lactamase inhibitors, namely, clavulanic acid, sulbactam, and tazobactam. Numerous oral and parenteral *cephalosporins* all cross the placenta, although their half-life is decreased because of increased renal clearance during pregnancy (Gilstrap and colleagues, 1988). No adverse embryo-fetal effects have been reported after many years of use.

Erythromycin is a macrolide often given to penicillin-allergic patients, especially for community-acquired pneumonia (see [Chap. 46](#), p. 1057). Macrolides do not cause fetal anomalies because only small amounts of these drugs reach the fetus. For this reason the erythromycins are not used to treat maternal syphilis (see [Chap. 59](#), p. 1304). *Azithromycin* effectively treats community-acquired pneumonias and chlamydial cervicitis (Peipert, 2003). It also has not been associated with fetal anomalies. *Clindamycin* readily crosses the placenta and may result in significant fetal blood levels (Gilstrap and associates, 1988). There have been few studies of its use during pregnancy, but clinical experience suggests that it is relatively safe. *Vancomycin* is used primarily for bacterial endocarditis prophylaxis in penicillin-allergic patients or for *Clostridium difficile* pseudomembranous colitis. Like the related aminoglycosides, vancomycin is associated with maternal nephrotoxicity and ototoxicity but has not been associated with congenital defects (Hermans and Wilhelm, 1987).

It Aztreonam is a monolactam used primarily as an aminoglycoside alternative. It is not associated with either renal or ototoxicity, and although there are no well-controlled human studies, it is not teratogenic in rodents. *Imipenem* is a carbapenem that is effective against aerobic and anaerobic organisms commonly isolated from intra-abdominal and female pelvic infections as well as multiresistant organisms. There are no data regarding its safety during human pregnancy, but it does not appear to be teratogenic in mice, rats, or rabbits.

Chloramphenicol readily crosses the placenta and results in significant fetal blood levels. The incidence of congenital anomalies does not appear to be increased in exposed fetuses (Heinonen and associates, 1977). The *gray baby syndrome*, manifested by cyanosis, vascular collapse, and death, has been reported with large doses of chloramphenicol given to the preterm neonate. It seems unlikely that fetal serum levels obtained from maternal administration would cause this syndrome.

Nitrofurantoin commonly is used for urinary infections during pregnancy. A prospective study of 100 women treated with this

drug found no increase in the rate of congenital anomalies (Lenke and colleagues, 1983). Although nitrofurantoin has been associated with hemolytic anemia in women with glucose-6-phosphate dehydrogenase deficiency, we have not observed this in more than 20,000 pregnant women given this drug for asymptomatic bacteriuria.

The quinolones *— ciprofloxacin, norfloxacin, ofloxacin, and enoxacin —* are especially useful for treatment of urinary infections. Although there are no well-controlled studies in pregnant women, no teratogenic effects have been demonstrated in animal studies. Fluoroquinolones have an affinity for bone and are reported to be associated with irreversible arthropathy and cartilage erosion in dogs, mice, and rats (Linseman and co-workers, 1995; Lozo and colleagues, 1996). Accordingly, they have not been recommended for use during pregnancy except for the treatment of multiresistant infections. Recently, the American College of Obstetricians and Gynecologists (2001) has recommended ciprofloxacin, 500 mg orally every 12 hours, for maternal prophylaxis after exposure to anthrax (see [Chap. 58](#), p. 1294).

Commonly used tuberculostatic drugs include *rifampicin, isoniazid, and ethambutol* (see [Chap. 46](#), p. 1065). *Rifabutin* also is used to treat *Mycobacterium avium complex (MAC)* disease in patients with human immunodeficiency virus (HIV) infection. Snyder and co-workers (1980) reviewed studies of several hundred pregnant women given these drugs and reported no increase in the rate of congenital anomalies.

Antifungal Agents. Vaginal candidiasis is common during pregnancy. Three commonly used agents for its treatment are *clotrimazole, miconazole, and nystatin*. There have been no congenital malformations reported in association with their use (Czeizel and co-workers, 2003; Rosa and associates, 1987a). There are no human studies of *butoconazole* use during early pregnancy, however, it is not teratogenic in rodents. *Amphotericin B* is used primarily to treat systemic histoplasmosis, coccidioidomycosis, cryptococcosis, and candidiasis (see [Chap. 46](#), p. 1060). In more than 30 exposed fetuses, there were no congenital anomalies (Dean and associates, 1994).

Antiviral Agents. Experience with use of antiviral medications during pregnancy is growing along with the increasing burden of HIV infections. These agents inhibit host intracellular viral replication through their action on RNA or DNA substrates. A registry chronicling the maternal and fetal effects of these drugs has been established by several drug manufacturers. This registry can be accessed for current information on safety or risks (www.apregistry.com).

Zidovudine, previously called *azidothymidine* or *AZT*, is a thymidine analogue that decreases DNA synthesis by reverse transcriptase inhibition. It is used specifically to treat HIV infections. It has been given to delay the onset of clinical disease in asymptomatic seropositive persons and is used prophylactically following accidental HIV exposure. Transplacental passage of the drug has been documented (Pons and colleagues, 1991). The Antiretroviral Pregnancy Registry Steering Committee (2003) has now acquired information regarding first-trimester exposures, but no increase in anomalies has been seen. The incidence of birth defects was 2.8 percent in zidovudine-exposed newborns compared with that of 3.1 percent in the unexposed control population.

Zalcitabine (ddC), didanosine (ddI), stavudine (d4T), lamivudine (3TC), and abacavir, along with zidovudine, are the six currently approved nucleoside (analog reverse) transcriptase inhibitors (NRTIs). These agents do not appear to cause malformations in animals given nontoxic doses, and there are no reports of defects in exposed human fetuses (Antiretroviral Pregnancy Registry Steering Committee, 2003). These drugs are recommended for use in pregnant women. When combined with protease inhibitors and given along with zidovudine, NRTIs dramatically lower serum viral concentrations, reverse HIV-related complications, and reduce the perinatal transmission rate to 1 percent (Public Health Service Task Force, 2002). This is discussed in detail in [Chapter 59](#) (p. 1313).

The other major class of drugs used to treat HIV infection is the protease inhibitors, including *amprenavir, indinavir, lopinavir, ritonavir, nelfinavir, and saquinavir*. There have been no reports of congenital anomalies developing after fetal exposure to these agents. The European Collaborative Study (2000) and the Swiss Mother and Child HIV-1 Cohort Study reported by Mandelbrot and colleagues (2001) found an association between combination therapy and preterm birth. Conversely, a meta-analysis of several studies involving more than 2100 HIV-positive pregnant women did not find such a link (Tuomala and colleagues, 2002).

Enfuvirtide inhibits binding or fusion of HIV to host cells. The drug was recently approved for use in combination therapy for adults and children older than 6 years. No teratogenicity was demonstrated in rats or rabbits.

Acyclovir, ganciclovir, and valacyclovir are purine nucleoside analogues that inhibit ribonucleotide production. They are effective for treating primary herpes and varicella infections. The Acyclovir Pregnancy Registry (1998) reported the outcome of 1129 pregnancies in which acyclovir was given, including 712 with first-trimester exposure. There was no increase in anomalies and no distinctive pattern of defects. Topical administration of acyclovir results in minimal systemic absorption. There is limited information on ganciclovir, with only 25 first-trimester exposures reported by the Valacyclovir Pregnancy Registry (1998).

Amantadine is used in pregnancy to prevent, modify, or treat influenza infections (see [Chap. 46](#), p. 1059). This drug is embryotoxic and teratogenic in animals at high doses, but data regarding its safety in pregnancy are limited (Centers for Disease Control and Prevention, 2003). Several case reports and case series in which amantadine was given during the first trimester suggest a possible association with cardiac defects, but the information provided is too limited to allow risk assessment (Pandit and colleagues, 1994; Rosa, 1994).

Oseltamivir is a viral neuraminidase inhibitor used to treat influenza. No data on its safety in humans are available. In animals, doses producing blood levels 50 to 100 times higher than those achieved therapeutically caused maternal toxicity and minor fetal skeletal malformations (Reprotox, 2000d).

Interferons are a family of naturally occurring proteins and glycoproteins with antiviral, antineoplastic, and immunomodulating actions. Interferon- α is used during pregnancy for maintenance therapy of chronic myeloid leukemia and essential thrombocytopenia and is effective against some viral infections. Interferons- β 1b and - γ 1b also are used therapeutically. Because interferons- α and - γ 1b inhibit testicular steroidogenesis and may affect ovarian function, they are classified as reproductive hormones (Roberts and colleagues, 1992). Animal studies indicate that interferons have a low potential for teratogenesis. Experience in pregnant women is very limited (Briggs and associates, 2002).

Idoxuridine is a nucleoside analogue that is effective against adenovirus, cytomegalovirus, varicella, and vaccinia viral infections. It has not been investigated in human pregnancy. When tested in rodents, idoxuridine was associated with embryotoxicity and malformations of the eye, palate, head, and limbs (Chaube and Murphey, 1968). *Trifluridine* and *vidarabine*, which were developed originally as antineoplastics, are effective in treating herpesvirus infections, and *vidarabine* is also effective against poxvirus infections.

Antiparasitic Agents. Parasitic infections during pregnancy are common, are usually asymptomatic, and in general do not need to be treated until after delivery. *Metronidazole* is a nitroimidazole that is effective for treatment of vaginal trichomoniasis and bacterial vaginosis. Although carcinogenic in rodents and mutagenic in certain bacteria, there was no increase in the rate of congenital anomalies in more than 1700 fetuses exposed to metronidazole during the first trimester (Piper and associates, 1993; Rosa and colleagues, 1987a). In a meta-analysis, Burtin and colleagues (1995) found no increased teratogenic risk. Metronidazole is recommended by the Centers for Disease Control and Prevention (2002) for treatment of trichomoniasis and bacterial vaginosis in pregnancy (see [Chap. 59](#), p. 1319).

Lindane is used topically for the treatment of pediculosis pubis and scabies. It is not teratogenic in a variety of animal species. Approximately 10 percent of the topical adult dose is absorbed systemically, and a portion of this crosses the placenta or accumulates in maternal and fetal tissues (Pompa and associates, 1994; Saxena and colleagues, 1980). Lindane has mild estrogenic qualities, but no fetal effects have been observed. Maternal intoxication from excessive use can lead to maternal restlessness, muscle spasms, and seizures (Meinking and co-workers, 1986). Because of this and its suboptimal effectiveness, some recommend a combination of *pyrethrins* and *piperonyl butoxide* as initial treatment of pediculosis pubis during pregnancy. *Crotamiton* in 10-percent lotion or cream or 6-percent *sulfur in petrolatum* also can be used as first-line treatment for scabies during pregnancy.

Chloroquine, quinine, and mefloquine are first-line antimalarial agents used for treatment and chemoprophylaxis and are discussed on page 353. *Pyrimethamine* is an antiparasitic folic acid antagonist also used to treat malaria. Hengst (1972) reported no increased frequency of malformations in 64 newborns exposed in early pregnancy to pyrimethamine given with sulfadiazine to treat toxoplasmosis. *Spiramycin* also has been used to treat toxoplasmosis, without evidence of adverse embryo-fetal effects. Unfortunately, these agents neither prevent nor ameliorate all the embryo-fetal effects of toxoplasmosis. Despite antenatal therapy, infected newborns may have chorioretinitis, hydrocephalus, and intracranial calcifications (see [Chap. 58](#), p. 1289).

Mebendazole is effective for treatment of a variety of helminths, including enterobiasis (pinworm), trichuriasis (whipworm), ascariasis (roundworm), and uncinariasis (hookworm), and is used to treat neurocysticercosis. When given at several times the human adult dose, it is teratogenic in animals. In several studies, however, there did not appear to be increased human teratogenic risks (Briggs and co-workers, 2002). *Thiabendazole* is a similar antihelmintic used primarily to treat strongyloidiasis, trichinosis, and cutaneous larval migrans. It also is used as second-line therapy to treat pinworm, whipworm, roundworm, and hookworm infections. There are no adequate human studies, but thiabendazole has not been reported to be teratogenic in animals. *Pyrantel pamoate* is used primarily in the treatment of ascariasis and enterobiasis. It has not been reported as teratogenic in animals, and there are no human studies.

ASTHMA MEDICATIONS. Most medications for treatment of asthma can be used with safety during pregnancy (see [Chap. 46](#), p. 1062). For acute asthma, *epinephrine* and *terbutaline* may be given subcutaneously, as there is little evidence that these agents cause adverse fetal effects. Metaproterenol and albuterol are self-administered by inhalation. There is little information regarding their possible teratogenicity following first-trimester use. Theophylline salts are commonly used bronchodilators and appear to be safe for pregnancy use. *Aminophylline* is the only salt available for parenteral use, but there are numerous oral forms of it that may contain other bronchodilators such as *ephedrine*.

Cromolyn inhibits mast cell histamine release and is given chronically for asthma prophylaxis. A number of studies in pregnant women indicate that first-trimester use does not increase the incidence of congenital anomalies (Briggs and associates, 2002).

Glucocorticoids have long been used for asthma treatment. Inhaled agents, including *beclomethasone* and *triamcinolone*, are now used commonly for maintenance. For flares, oral prednisone may be given as a dose pack, or *methylprednisolone* may be given intravenously. Beclomethasone has not been associated with defects in humans. Two clinical studies that included 101 pregnant women treated with beclomethasone or prednisone or both for severe asthma found no increase in congenital malformation rates (Fitzsimons and colleagues, 1986; Greenberger and Patterson, 1983). Triamcinolone is a more potent teratogen in animals than either hydrocortisone or cortisone, but it has not been associated with adverse human fetal effects (Dombrowski and co-investigators, 1996).

CARDIAC MEDICATIONS. Cardiac glycosides are prescribed for heart failure, atrial fibrillation or flutter, and other supraventricular tachycardias. Although *digoxin* rapidly crosses the placenta, there is no evidence of adverse fetal effects. Antiarrhythmic drugs have been administered both maternally and directly to the fetus in attempts to control fetal tachycardias (Harrigan and associates, 1981; Kerenyi and colleagues, 1980; Weiner and Thompson, 1988). This is discussed in [Chapter 13](#) (see p. 332). *Quinidine* is used to treat supraventricular tachycardias and some ventricular arrhythmias. It readily crosses the placenta and has been given to the mother to treat fetal supraventricular tachycardias (Killeen and Bowers, 1987). The dose used to treat arrhythmias is one tenth the dose used to treat severe malaria and has not been associated with fetal abnormalities.

Several β -blockers may be used to treat supraventricular and ventricular tachycardias, as well as chronic hypertension and hyperthyroidism. As previously discussed, these agents are not believed to be teratogenic. Other drugs used to treat cardiac arrhythmias include *disopyramide*, *amiodarone*, *adenosine*, *bretylum*, *diltiazem*, local anesthetics (*procainamide*, *lidocaine*, and *tocainide*), and calcium antagonists (*nifedipine* and *verapamil*). All cross the placenta, and many have been used to treat fetal arrhythmias without adverse effects (Dumesic and colleagues, 1982; Rey and associates, 1985). *Amiodarone* is structurally similar to thyroxine. It readily crosses the placenta at levels that are 10 to 30 percent of maternal serum levels, and because it has been associated with fetal and neonatal hypothyroidism, its use in pregnancy should be avoided (De Catte and co-workers, 1994; Grosso and colleagues, 1998).

HERBAL REMEDIES. It is difficult to estimate the risk or safety of various herbal remedies because they are not regulated as prescription or over-the-counter drugs. Often, the identity and quantity of all ingredients are unknown. Virtually no human or animal studies of their teratogenic potential have been reported, and knowledge of complications has essentially been limited to reports of acute toxicity (Hepner and co-workers, 2002; Sheehan, 1998). Some herbal preparations with physiological and pharmacological effects that could significantly complicate surgery are listed in [Table 14-5](#). Others that have adverse effects when used long term are shown in [Table 14-6](#). Because it is not possible to assess the effects of herbal remedies on the developing fetus, pregnant women should be counseled to avoid these substances.

Several herbal products contain substances with pharmaceutical properties that could theoretically have adverse fetal effects. *Echinacea*, which is believed to have anti-inflammatory properties at high concentrations, causes fragmentation of hamster sperm (Ondrizek and associates, 1999). *Black cohosh*, used to speed labor and treat premenstrual symptoms, contains a chemical that acts similarly to estrogen. *Garlic* and *willow bark* have anticoagulant properties that may intensify the effects of anticoagulant drugs. *Ginkgo*, touted as an aid to memory and mental clarity, can interfere with the effects of monoamine oxidase (MAO)-inhibiting drugs and has anticoagulant properties. Real *licorice* contains *glycyrrhizin*, which has hypertensive and potassium-wasting effects. *Valerian* intensifies the effects of prescription sleep aids and anesthetic agents and may cause withdrawal symptoms. *Ginseng*, which is ingested to increase energy, interferes with MAO-inhibiting drugs and promotes hypoglycemia. *Soy* products contain phytoestrogen. *Ephedra*, one of the most dangerous herbal drugs, has both direct and indirect sympathomimetic effects and has been associated with myocardial ischemia and stroke.

Certain herbal remedies are used as abortifacients. For example, *blue* and *black cohosh* appear to directly stimulate uterine musculature. *Pennyroyal* appears to work by irritating the bladder and uterus and causing strong uterine contractions. The drug also can cause liver damage, renal failure, and disseminated intravascular coagulation and has been associated with several maternal deaths (Black, 1985).

HORMONES. Some hormones are teratogenic, as discussed on page 351. *Oral contraceptives* have not been associated with congenital anomalies (Raman-Wilms and colleagues, 1995). A proposed new formulation that includes folic acid may actually reduce the incidence of fetal defects if conception occurs. In 1988, the Food and Drug Administration approved the removal of the package insert rejoinder that warned of birth defects. *Gonadotropin-releasing hormone (GnRH) agonists* have been used to treat infertility and other gynecological conditions. There is little information regarding their use during pregnancy. In a review of five women who were exposed to GnRH agonists during the first trimester, Young and colleagues (1993) reported two abortions and three term pregnancies.

IMMUNOSUPPRESSIVE AGENTS. These agents are given primarily for the treatment of autoimmune disease and for organ transplantation maintenance. Corticosteroids such as prednisone and dexamethasone are discussed on page 360.

Azathioprine is used primarily to prevent reinfection after organ transplantation or to treat inflammatory bowel disease and is not believed to be teratogenic (Briggs and colleagues, 2002). Exposed neonates have an increased risk of growth restriction as well as immune suppression and pancytopenia (Davidson and co-workers, 1985; DeWitte and associates, 1984).

Relatively new immunosuppressants have been isolated from soil fungi. *Cyclosporine* is an immunosuppressant antimicrobial used to prevent rejection of heart, liver, and kidney allografts. The drug causes significant maternal toxicity, especially nephrotoxicity, but it appears to be safe for the fetus (Briggs and co-workers, 2002). Its benefits appear to outweigh any theoretical risks. *Tacrolimus*, also known as *FK506*, is a macrolide antimicrobial that is more potent than cyclosporine and is used after organ transplantation. It causes abortions and anomalies in some laboring animals, but this has not yet been reported in humans. Documented fetal problems include preterm delivery, growth restriction, hyperkalemia, and nephrotoxicity.

PSYCHOTROPIC DRUGS. Medications used to treat psychiatric illness include sedatives, hypnotics, tranquilizers, antidepressants, and antipsychotics. Some of these are discussed in [Chapter 55](#).

Benzodiazepines. These minor tranquilizers may be required for women who have severe and debilitating anxiety disorders or who are psychotic and violent or agitated. *Diazepam* is the most widely used. It has been associated with an increased risk of cleft palate, limb malformations, and other defects in rodents. Whether or not it has teratogenic effects in human fetuses is controversial, but any effects are likely to be minimal (Briggs and colleagues, 2002; Dolovich and associates, 1998). Other less well-studied agents like *lorazepam* and *midazolam* have not been linked to birth defects. These drugs can cause neonatal depression and somnolence as well as withdrawal symptoms with long-term maternal use or abuse. Also, when used concomitantly with alcohol and other abused substances, there may be adverse fetal effects. In a study of 104,000 pregnant Swedish women, 10 percent of the offspring of women who abused benzodiazepines during pregnancy had birth defects thought to be caused by the additive effects of heavy alcohol use and exposure to other substances (Bergman and colleagues, 1992). *Alprazolam* is a benzodiazepine commonly used for panic disorder. Two studies examining 778 first-trimester exposures found no increase in the incidence of anomalies after antenatal exposure (Schick-Boschetto and Zuber, 1992; St. Clair and Schirmer, 1992). Exposed neonates should be watched for transient withdrawal symptoms.

Lithium salts, especially lithium carbonate, are used for the treatment of manic-depression and other affective illnesses. Reports initially suggested an association between maternal lithium exposure and a cardiac defect called Ebstein anomaly. Subsequent studies found that lithium is not a major teratogen (Cohen and associates, 1994; Jacobson and colleagues, 1992). Lithium can have toxic fetal effects, including diabetes insipidus, hypothyroidism, and hypoglycemia (Pinelli and co-workers, 2002). These can be minimized by monitoring maternal serum levels. It would seem prudent to avoid lithium exposure until at least 6 to 8 weeks' gestation, when organogenesis is completed and cardiac structures have formed (Briggs and colleagues, 2002).

MAO inhibitors are used less frequently today because patients must follow a low tyramine diet and hypertensive crises can develop after dietary indiscretion, as well as after administration of meperidine and some other anesthetic agents. Because such severe adverse reactions are especially undesirable in pregnant women, this class of medication is generally avoided

during pregnancy (Mortola, 1989).

Antidepressant Drugs. The most commonly used antidepressants are the *selective serotonin reuptake inhibitors (SSRIs)*. The older compounds, *fluoxetine* and *sertraline*, have not been reported to cause birth defects in animals or humans. A summary of almost 800 fluoxetine-exposed pregnancies reported to the manufacturer described rates of early pregnancy loss and congenital abnormalities not different from those in controls. Moreover, there was no specific pattern of defects or a predilection for any particular organ system in the small number of affected offspring (Goldstein and associates, 1993, 1997). In a study evaluating treatment with fluoxetine, there were no differences in rates of malformations or fetal losses (Pastuszak and colleagues, 1993). Because these agents have few side effects compared with other antidepressants, they are a good choice for pregnant women.

Bupropion is not an MAO inhibitor nor is it an SSRI. The interim report by the Bupropion Pregnancy Registry (2000) reported no unusual effects in 90 exposed pregnancies. *Venlafaxine* is another commonly prescribed antidepressant. There are few published data on its fetal effects, but it has not been associated with adverse outcomes (Briggs and colleagues, 2002). *Tricyclic antidepressants* have a long record of use in pregnancy. In the largest study investigating the rate of malformations in more than 1 million fetuses exposed to these antidepressants during pregnancy, no increase in the rate of fetal malformation was found (Rowe, 1973).

Antipsychotic Medications. Many of these agents are *phenothiazines*, which have been used in pregnancy to treat both psychotic disorders and hyperemesis. Most safety information has been derived from their use as antiemetics. Data collected as part of the Collaborative Perinatal Project indicate that *chlorpromazine* and other phenothiazines taken intermittently at low doses for hyperemesis do not increase the risk of fetal malformations (Slone and colleagues, 1977). When taken at high continuous doses for antipsychotic therapy, the safety of these agents is difficult to assess. This is because many affected women take a number of other prescription medications as well as known teratogens such as alcohol, and certain illnesses such as schizophrenia independently increase fetal risk (Elia and colleagues, 1987). Widespread and long-term use of these agents without serious fetal effects suggests that their teratogenic potential is minimal (Briggs and associates, 2002).

RECREATIONAL DRUGS. It has been estimated that from 350,000 to more than 700,000 fetuses may be exposed to illicit substances in utero each year (Chasnoff, 1991; Gomby and Shiono, 1991). *Cocaine* and *alcohol* (see pp. 354 and 346) are potent and commonly used teratogenic substances, but solid data about the risks of other abused substances are lacking (American College of Obstetricians and Gynecologists, 1997). Available information usually is confounded by factors that include poor maternal health, malnutrition, infectious diseases, and polydrug abuse. Several different drugs may be used at the same time, with the combination resulting in a worse outcome than expected with any of the drugs used alone. Furthermore, many illegal substances contain contaminants such as lead, cyanide, cellulose, herbicides, and pesticides. Moreover, substances commonly added as diluents include fine glass beads, powdered sugar, finely ground sawdust, strychnine, arsenic, antihistamines, and even coumadin. Many of these diluents and impurities independently have serious adverse effects on both the mother and her fetus.

Marijuana or *hashish* is used by nearly 15 percent of pregnant women (Abel and Sokol, 1988; Chasnoff and colleagues, 1990). The active ingredient is *delta-9-tetrahydrocannabinol (THC)*, which in high doses is teratogenic for animals. However, there is no evidence that marijuana is associated with human anomalies. The birthweight of exposed fetuses has been reported to be lower in some studies but not others (Greenland, 1983; Linn, 1983; Shiono, 1995, and all their colleagues).

Amphetamines are sympathomimetic agents used as central nervous system stimulants, as anorectics, or as treatment for narcolepsy. Various amphetamines are teratogenic at very high doses in mice and rabbits (Reprotox, 2000a). In four cohort studies of 818 women who took amphetamines during early pregnancy, however, the frequencies of major and minor congenital anomalies were no greater than controls (Heinonen and colleagues, 1983; Little and associates, 1988; Milkovich and van den Berg, 1977). *Methamphetamines* are used medically to treat obesity and narcolepsy in adults and hyperkinetic children. These drugs often are used to dilute other illicit drugs. Methamphetamine use has been associated with symmetrical fetal growth restriction but does not appear to increase the frequency of congenital anomalies (Little and colleagues, 1988; Ramin and associates, 1992). Methylamphetamine, known as *speed*, *ice*, *crank*, and *crystal meth*, produces defects in mice, rats, and rabbits, but has not been associated with defects in humans.

In most studies, the frequency of congenital anomalies is not higher among neonates born to mothers addicted to heroin (Little and associates, 1990b). In one cohort study of 830 exposed neonates, the frequency of anomalies was 2.4 percent, similar to the background risk (Ostrea and Chavez, 1979). Other types of morbidity, such as fetal growth restriction, perinatal death, and several perinatal complications, are common in the offspring of narcotic-addicted mothers (Lifschitz and colleagues, 1983; Little and co-workers, 1990b). It is not clear whether these complications are due to fetal heroin exposure or to generally poor maternal health. Postnatal growth of these children appears to be normal in most cases, although the average head circumference is smaller than that of unexposed children, and there may be mild developmental delay or behavioral disturbances (Chasnoff and colleagues, 1986; Lifschitz and co-workers, 1983). Withdrawal symptoms such as tremors, irritability, sneezing, vomiting, fever, diarrhea, and occasionally seizures are observed in 40 to 80 percent of newborns born to heroin-addicted women (Alroomi and colleagues, 1988). Although these symptoms may be prolonged, they usually persist for fewer than 10 days. Abnormal respiratory function during sleep often persists and may be a factor in the increased incidence of sudden infant death syndrome in exposed newborns (Kandall and associates, 1993).

Methadone, a synthetic opiate narcotic that structurally resembles propoxyphene, is used primarily as maintenance therapy for narcotic addiction. Although large doses are teratogenic in rodents, congenital anomalies were not increased above background in cohort studies and clinical series of neonates born to women on methadone maintenance (Stimmel and Adamsons, 1976). Withdrawal symptoms, however, are frequent and birthweights are often lower than expected (Briggs and colleagues, 2002). Chasnoff and co-workers (1987) compared 52 cocaine-using pregnant women with 73 women who were former heroin addicts maintained on methadone and found a significantly higher rate of preterm labor, rapid labor, abruptio placentae, and meconium staining among cocaine users. Withdrawal from methadone is more severe than from heroin and more protracted—up to 3 weeks—due to the much longer half-life of methadone.

Lysergic acid amides, classically known as *lysergic acid diethylamide (LSD)*, are amine alkaloids obtained only through chemical synthesis. There is no evidence that this drug is a human teratogen. Some investigators have found increased

frequencies of chromosomal breakage in somatic cells of mothers who used lysergic acid as well as in their prenatally exposed newborns, but such breakage does not appear to correlate with an increased risk for congenital anomalies.

Phencyclidine (PCP), known as *angel dust*, is not associated with congenital anomalies. Neonatal withdrawal, characterized by tremors, jitteriness, and irritability, is observed in more than half of exposed newborns. Golden and colleagues (1987) reported that the incidence of structural malformations was not increased in 94 phencyclidine-exposed infants, but confirmed an increased incidence of newborn behavioral and developmental abnormalities.

"*T's and blues*" is a street mixture of the narcotic analgesic *pentazocine (Talwin)* and the over-the-counter antihistamine *tripelennamine (Pyribenzamine)*. It has not been associated with an increased incidence of congenital anomalies (Little and co-workers, 1990a; von Almen and Miller, 1984).

15. Antepartum Assessment

INTRODUCTION

In this chapter, the evolution of techniques employed to forecast fetal well-being is considered. The focus is on testing procedures that depend on fetal physical activities, including movement, breathing, amniotic fluid production, and heart rate. According to the American College of Obstetricians and Gynecologists (1999), the goal of antepartum fetal surveillance is to prevent fetal death. In most cases, a normal test result is highly reassuring, because fetal deaths within 1 week of a normal test are rare. Indeed, negative-predictive values — a true negative test — for most of the tests described are 99.8 percent or higher. In contrast, estimates of the positive-predictive values — a true positive test — for abnormal test results are quite low and range between 10 and 40 percent. Importantly, the widespread use of antepartum fetal surveillance is primarily based on circumstantial evidence because there have been no definitive randomized clinical trials.

FETAL MOVEMENTS

Passive unstimulated fetal activity commences as early as 7 weeks and becomes more sophisticated and coordinated by the end of pregnancy (Vindla and James, 1995). Indeed, beyond 8 menstrual weeks, fetal body movements are never absent for time periods exceeding 13 minutes (DeVries and co-workers, 1985). Between 20 and 30 weeks, general body movements become organized and the fetus starts to show rest-activity cycles (Sorokin and co-workers, 1982). In the third trimester, fetal movement maturation continues until about 36 weeks, when behavioral states are established in 80 percent of normal fetuses. Nijhuis and colleagues (1982) studied fetal heart rate patterns, general body movements, and eye movements and described four fetal behavioral states:

State 1F is a quiescent state (quiet sleep), with a narrow oscillatory bandwidth of the fetal heart rate.

State 2F includes frequent gross body movements, continuous eye movements, and wider oscillation of the fetal heart rate. This state is analogous to rapid eye movement (REM) or active sleep in the neonate.

State 3F includes continuous eye movements in the absence of body movements and no accelerations of the heart rate. The existence of this state is disputed (Pillai and James, 1990a).

State 4F is one of vigorous body movement with continuous eye movements and fetal heart rate accelerations. This state corresponds to the awake state in infants. unnumlist

Fetuses spend most of their time in states 1F and 2F. For example, at 38 weeks, 75 percent of time is spent in states 1F and 2F (Nijhuis and colleagues, 1982).

These behavioral states — particularly 1F and 2F, which correspond to quiet sleep and active sleep — have been used to develop an increasingly sophisticated understanding of fetal behavior. Oosterhof and co-workers (1993) studied fetal urine production in normal pregnancies in states 1F or 2F. As shown in [Figure 15-1](#), bladder volumes increased during quiet sleep (state 1F). During state 2F, the fetal heart rate baseline bandwidth increased appreciably, and bladder volume was significantly diminished. The latter occurred due to fetal voiding as well as decreased urine production. These phenomena were interpreted to represent reduced renal blood flow during active sleep. Boito and colleagues (2004) recently reported increasing umbilical vein distention during state 2F, which they interpret to be caused by increased venous pressure from increased flow.

An important determinant of fetal activity appears to be sleep-awake cycles, which are independent of the maternal sleep-awake state. *Sleep cyclicality* has been described as varying from about 20 minutes to as much as 75 minutes. Timor-Tritsch and associates (1978) reported that the mean length of the quiet or inactive state for term fetuses was 23 minutes. Patrick and associates (1982) measured gross fetal body movements with real-time ultrasound for 24-hour periods in 31 normal pregnancies and found the longest period of inactivity to be 75 minutes. Amniotic fluid volume is another important determinant of fetal activity. Sherer and colleagues (1996) assessed the number of fetal movements in 465 pregnancies during biophysical profile testing in relation to amniotic fluid volume estimated using ultrasound. They observed decreased fetal activity with diminished amniotic volumes and suggested that a restricted intrauterine space might physically limit fetal movements.

Sadovsky and colleagues (1979b) studied fetal movements in 120 normal pregnancies and classified the movements into three categories according to both maternal perceptions and independent recordings using piezoelectric sensors. Weak, strong, and rolling movements were described, and their relative contributions to total weekly movements throughout the last half of pregnancy were quantified. As pregnancy advances, weak movements decrease and are superseded by more vigorous movements, which increase for several weeks and then subside at term. Presumably, declining amniotic fluid and space account for diminishing activity at term. [Figure 15-2](#) shows fetal movements during the last half of gestation in 127 pregnancies with normal outcomes. The mean number of weekly movements calculated from 12-hour daily recording periods increased from about 200 at 20 weeks to a maximum of 575 movements at 32 weeks. Fetal movements then declined to an average of 282 at 40 weeks. Normal weekly maternal counts of fetal movements ranged between 50 and 950, with large daily variations that included counts as low as 4 to 10 per 12-hour period in normal pregnancies.

Figure 15-1. Fetal bladder volume measurements together with fetal heart rate variation record in relation to 1F or 2F behavior states. State 1F fetal heart rate has a narrow bandwidth consistent with quiet sleep. State 2F heart rate shows wide oscillation of the baseline consistent with active sleep. (Modified from Oosterhof and co-workers, 1993, with permission.)

Figure 15-2. Weekly average fetal movements calculated from daily fetal

movement records during normal pregnancy (means $\bar{x} \pm$ SEM). (From Sadovsky and associates, 1979a, with permission.)

CLINICAL APPLICATION. Since 1973, when Sadovsky and Yaffe described seven case reports of pregnancies with decreased fetal activity that preceded fetal death, various methods have been described to quantify fetal movement as a way of prognosticating well-being. Methods include use of a tocodynamometer, visualization with real-time ultrasound, and maternal subjective perceptions. Most investigators have reported excellent correlation between maternally perceived fetal motion and movements documented by instrumentation. For example, Rayburn (1980) found that 80 percent of all movements observed during ultrasonic monitoring were perceived by the mother. In contrast, Johnson and colleagues (1992) reported that beyond 36 weeks, mothers perceived only 16 percent of fetal body movements recorded by a Doppler device. Fetal motions lasting more than 20 seconds were identified more accurately by the mother than shorter episodes.

Although several fetal movement counting protocols have been used, neither the optimal number of movements nor the ideal duration for counting them has been defined. For example, in one method, perception of 10 fetal movements in up to 2 hours is considered normal (Moore and Piaquadio, 1989). In another, women are instructed to count fetal movements for 1 hour a day, and the count is accepted as reassuring if it equals or exceeds a previously established baseline count (Neldam, 1983).

A particularly bothersome clinical situation occurs when women present in the third trimester complaining of subjectively reduced fetal movement. Harrington and colleagues (1998) reported that 7 percent of 6793 women delivered at a London hospital presented with a complaint of decreased fetal movement. Fetal heart rate monitoring tests were employed if ultrasound scans for fetal growth or Doppler velocimetry were abnormal. The pregnancy outcomes for women who complained of decreased fetal movement were not significantly different from those for women without this complaint. Nonetheless, the authors recommended evaluation to reassure the mother.

Grant and co-workers (1989) performed an unparalleled investigation of maternally perceived fetal movements and pregnancy outcome. More than 68,000 pregnancies were randomly assigned between 28 and 32 weeks. Women in the fetal movement arm of the study were instructed by specially employed midwives to record the time needed to feel 10 movements each day. This required an average of 2.7 hours of each day. Women in the control group were informally asked about movements during prenatal visits. Reports of decreased fetal motion were evaluated with tests of fetal well-being. Antepartum death rates for normally formed singletons were similar in the two study groups regardless of prior risk status. Despite the counting policy, most stillborn fetuses were dead by the time the mothers reported for medical attention. Importantly, these investigators did not conclude that maternal perceptions of fetal activity were meaningless. Conversely, they concluded that informal maternal perceptions were as good as formally counted and recorded fetal movement.

FETAL BREATHING

After decades of uncertainty as to whether the fetus normally breathes, Dawes and co-workers (1972) showed small inward and outward flows of tracheal fluid, indicating fetal thoracic movement in sheep. These chest wall movements differed from those following birth in that they were discontinuous. Another interesting feature of fetal respiration was *paradoxical chest wall movement*. As shown in [Figure 15-3](#), during inspiration the chest wall paradoxically collapses and the abdomen protrudes (Johnson and co-authors, 1988). In the newborn or adult, the opposite occurs. One interpretation of the paradoxical respiratory motion might be coughing to clear amniotic fluid debris. Although the physiological basis for the breathing reflex is not completely understood, such exchange of amniotic fluid appears to be essential for normal lung development.

Dawes (1974) identified two types of respiratory movements. The first are *gasps or sighs*, which occurred at a frequency of 1 to 4 per minute. The second, *irregular bursts of breathing*, occurred at rates up to 240 cycles per minute. These latter rapid respiratory movements were associated with REM. Badalian and co-workers (1993) studied the maturation of normal fetal breathing using color flow and spectral Doppler analysis of nasal fluid flow as an index of lung function. They suggested that fetal respiratory rate decreased in conjunction with increased respiratory volume at about 33 to 36 weeks and coincidental with lung maturation.

Many investigators have examined fetal breathing movements using ultrasound to determine whether monitoring chest wall movements might be of benefit to evaluate fetal health. Several variables in addition to hypoxia were found to affect fetal respiratory movements. These included labor \bar{x} — during which it is normal for respiration to cease \bar{x} — hypoglycemia, sound stimuli, cigarette smoking, amniocentesis, impending preterm labor, gestational age, and the fetal heart rate itself.

Because fetal breathing movements are episodic, interpretation of fetal health when respirations are absent may be tenuous. Patrick and associates (1980) performed continuous 24-hour observation periods using real-time ultrasonography in an effort to characterize fetal breathing patterns during the last 10 weeks of pregnancy. A total of 1224 hours of fetal observation was completed in 51 pregnancies. [Figure 15-4](#) shows the percentage of time spent breathing near term. Clearly, there is diurnal variation, because breathing substantively diminishes during the night. In addition, breathing activity increases somewhat following maternal meals. Total absence of breathing was observed in some of these normal fetuses for up to 122 minutes, indicating that fetal evaluation to diagnose absent respiratory motion may require long periods of observation.

The potential for breathing activity to be an important marker of fetal health is unfulfilled because of the multiplicity of factors that normally affect breathing. Most clinical applications have included assessment of other fetal biophysical indices, such as heart rate. As will be discussed, fetal breathing has become a component of the *biophysical profile*.

Figure 15-3. Paradoxical chest movement with fetal respiration. (From Johnson and co-workers, 1988, with permission.)

Figure 15-4. The percentage of time spent breathing ($\bar{x} \pm$ SEM) by 11 fetuses at 38

to 39 weeks demonstrated a significant increase in fetal breathing activity after breakfast. Breathing activity diminished over the day and reached its minimum between 1900 and 2400 hours. There was a significant increase in the percentage of time spent breathing between 0400 and 0700 hours, when mothers were asleep. (From Patrick and co-workers, 1980, with permission.)

CONTRACTION STRESS TESTING

As amniotic fluid pressure increases with uterine contractions, myometrial pressure exceeds collapsing pressure for vessels coursing through uterine muscle, ultimately decreasing blood flow to the intervillous space. Brief periods of impaired oxygen exchange result, and if uteroplacental pathology is present, these elicit late fetal heart rate decelerations (see [Chap. 18](#), p. 452). Contractions also may produce a pattern of variable decelerations as a result of cord compression, suggesting oligohydramnios, which is often a concomitant of placental insufficiency.

Ray and colleagues (1972) used this concept in 66 complicated pregnancies and developed what they termed the *oxytocin challenge test* and later called the *contraction stress test*. Contractions were induced using intravenous oxytocin, and the fetal heart rate response was recorded using standard monitoring. The criterion for a positive (abnormal) test was uniform repetitive fetal heart rate decelerations. These reflected the uterine contraction waveform and had an onset at or beyond the acme of a contraction. Such late decelerations could be the result of uteroplacental insufficiency. The tests were generally repeated on a weekly basis, and the investigators concluded that negative (normal) contraction stress tests forecast fetal health. One disadvantage cited was that the average contraction stress test required 90 minutes to complete.

Fetal heart rate and uterine contractions are recorded simultaneously with an external monitor. If at least three spontaneous contractions of 40 seconds or longer are present in 10 minutes, no uterine stimulation is necessary (American College of Obstetricians and Gynecologists, 1999). Contractions are induced with either oxytocin or nipple stimulation if there are fewer than three in 10 minutes. If oxytocin is preferred, a dilute intravenous infusion is initiated at a rate of 0.5 mU/min and doubled every 20 minutes until a satisfactory contraction pattern is established (Freeman, 1975). The results of the contraction stress test are interpreted according to the criteria shown in [Table 15-1](#).

Nipple stimulation to induce uterine contractions is usually successful for contraction stress testing (Huddleston and associates, 1984). One method recommended by the American College of Obstetricians and Gynecologists (1999) involves the woman rubbing one nipple through her clothing for 2 minutes or until a contraction begins. She is instructed to restart after 5 minutes if the first nipple stimulation did not induce three contractions in 10 minutes. Advantages include reduced cost and shortened testing times. Although Schellpeffer and associates (1985) reported unpredictable uterine hyperstimulation with fetal distress, others did not find excessive activity to be harmful (Frager and Miyazaki, 1987).

NONSTRESS TESTS

Freeman (1975) and Lee and colleagues (1975) introduced the *nonstress test* to describe fetal heart rate acceleration in response to fetal movement as a sign of fetal health. This test involved the use of Doppler-detected fetal heart rate acceleration coincident with fetal movements perceived by the mother. By the end of the 1970s, the nonstress test had become the primary method of testing fetal health. The nonstress test was much easier to perform, and normal results were used to further discriminate false-positive contraction stress tests. Simplistically, the nonstress test is primarily a test of *fetal condition*, and it differs from the contraction stress test, which is a test of *uteroplacental function*. Currently, nonstress testing is the most widely used primary testing method for assessment of fetal well-being and has also been incorporated into the biophysical profile testing system (see later discussion).

FETAL HEART RATE ACCELERATION. The fetal heart rate normally is increased or decreased by autonomic influences mediated by sympathetic or parasympathetic impulses from brainstem centers. Beat-to-beat variability is also under the control of the autonomic nervous system (Matsuura and colleagues, 1996). Consequently, pathological loss of acceleration may be seen in conjunction with significantly decreased beat-to-beat variability of the fetal heart rate (see [Chap. 18](#), p. 447). Loss of such reactivity, however, is most commonly associated with sleep cycles, discussed earlier, and it also may be caused by central depression from medications or maternal cigarette smoking (Oncken and colleagues, 2002).

The nonstress test is based on the hypothesis that the heart rate of a fetus who is not acidotic as a result of hypoxia or neurological depression will temporarily accelerate in response to fetal movement. Fetal movements during testing are identified by maternal perception and recorded. An example is shown in [Figure 15-5](#). Similarly, Smith and colleagues (1988) observed a decrease in the number of accelerations in preterm fetuses subsequently found to have lower umbilical artery blood PO_2 values.

Gestational age influences acceleration or reactivity of fetal heart rate. Pillai and James (1990b) studied the development of fetal heart rate acceleration patterns during normal pregnancy. The percentage of body movements accompanied by acceleration and the amplitude of these accelerations increased with gestational age ([Fig. 15-6](#)). Guinn and colleagues (1998) studied nonstress test results between 25 and 28 weeks in 188 pregnancies that ultimately had normal outcomes. Only 70 percent of these normal fetuses demonstrated the required 15 bpm or more of heart rate acceleration. Lesser degrees of acceleration (i.e., 10 bpm) occurred in 90 percent of the tested pregnancies.

The National Institute of Child Health and Human Development fetal monitoring workshop (1997) has defined acceleration based on gestational age. The acme of acceleration is 15 bpm or more above the baseline rate, and the acceleration lasts 15 seconds or longer but less than 2 minutes in fetuses at or beyond 32 weeks. Before 32 weeks, accelerations are defined as having an acme 10 bpm or more above baseline for 10 seconds or longer.

Figure 15-5. Antepartum fetal heart rate tracings at 28 weeks' gestation in a woman with diabetic ketoacidosis. Tracing **A**, obtained during maternal and fetal acidemia, shows absence of accelerations, diminished variability, and late decelerations with weak spontaneous contractions. Tracing **B** shows return of normal accelerations and variability of the fetal heart rate following correction of maternal acidemia.

Figure 15-6. Percentage of fetuses with at least one acceleration of 15 beats/min sustained for 15 sec with fetal movement. (From Pillai and James, 1990b, with permission.)

NORMAL NONSTRESS TESTS. There have been many different definitions of normal nonstress test results. They vary as to the number, amplitude, and duration of acceleration, as well as the test duration. The definition currently recommended by the American College of Obstetricians and Gynecologists (1999) is two or more accelerations that peak at 15 bpm or more above baseline, each lasting 15 seconds or more, and all occurring within 20 minutes of beginning the test (Fig. 15-7). It was also recommended that accelerations with or without fetal movements be accepted, and that a 40-minute or longer tracing be performed to account for fetal sleep cycles should be performed before concluding that there was insufficient fetal reactivity. Miller and colleagues (1996b) reviewed fetal outcomes after nonstress tests considered as nonreactive because there was only one acceleration. They concluded that one acceleration was just as reliable in predicting healthy fetal status as were two.

Although a normal number and amplitude of accelerations seems to reflect fetal well-being, "insufficient acceleration" does not invariably predict fetal compromise. Indeed, some investigators have reported false-positive nonstress test rates in excess of 90 percent when acceleration was considered insufficient (Devoe and colleagues, 1986). Because healthy fetuses may not move for periods of up to 75 minutes, Brown and Patrick (1981) considered that a longer duration of nonstress testing might increase the positive-predictive value of an abnormal, or nonreactive test. They concluded that either the test became reactive during a period of time up to 80 minutes, or the test remained nonreactive for 120 minutes, indicating that the fetus was very ill.

Not only are there many different definitions of normal nonstress test results, but the reproducibility of interpretations is problematic. For example, Hage (1985) mailed five nonstress tests, blinded to specific patient clinical data, to a national sample of obstetricians for their interpretations. He concluded that although nonstress testing is very popular, the reliability of test interpretation needs improvement. Such problems with subjective interpretation have prompted efforts to computerize analysis of nonstress tests. Pardey and colleagues (2002) developed a computerized system, *Sonicaid Fetal Care*, that they claim is superior to visual subjective interpretation of nonstress tests.

Figure 15-7. Reactive nonstress test. Notice increase of fetal heart rate to more than 15 beats/min for longer than 15 sec following fetal movements, indicated by the vertical marks on the lower part of the recording.

ABNORMAL NONSTRESS TESTS. There are abnormal nonstress test patterns that reliably forecast severe fetal jeopardy. Hammacher and co-workers (1968) described tracings with what they termed a *silent oscillatory pattern*. This pattern consisted of a fetal heart rate baseline that oscillated less than 5 bpm and presumably indicated absent acceleration and beat-to-beat variability. Hammacher considered this pattern ominous.

Visser and associates (1980) described a "terminal cardiotocogram," which included (1) baseline oscillation of less than 5 bpm, (2) absent accelerations, and (3) late decelerations with spontaneous uterine contractions. These results were very similar to experiences from Parkland Hospital in which absence of accelerations during an 80-minute recording period in 27 fetuses was associated consistently with evidence of uteroplacental pathology (Leveno and associates, 1983). The latter included fetal growth restriction (75 percent), oligohydramnios (80 percent), fetal acidosis (40 percent), meconium (30 percent), and placental infarction (93 percent). Thus, the lack of fetal heart rate acceleration, when not due to maternal sedation, is an ominous finding (Fig. 15-8). Similarly, Devoe and co-workers (1985) concluded that nonstress tests that were nonreactive for 90 minutes were almost invariably (93 percent) associated with significant perinatal pathology.

Interval Between Testing. The interval between tests, originally rather arbitrarily set at 7 days, appears to have been shortened as experience evolved with nonstress testing. According to the American College of Obstetricians and Gynecologists (1999), more frequent testing is advocated by some investigators for women with postterm pregnancy, type 1 diabetes mellitus, fetal growth restriction, or gestational hypertension. In these circumstances, some investigators perform twice-weekly tests, with additional testing performed for maternal or fetal deterioration regardless of time elapsed since the last test. Others perform nonstress tests daily or even more frequently. For example, Chari and co-workers (1995) recommend daily fetal testing in women with severe preeclampsia remote from term.

Decelerations During Nonstress Testing. Fetal movements commonly produce heart rate decelerations. Timor-Tritsch and co-authors (1978) reported this during nonstress testing in half to two thirds of tracings, depending on the vigor of the fetal motion. Such a high incidence of decelerations inevitably makes interpretation of their significance problematic. Indeed, Meis and co-workers (1986) reported that variable fetal heart rate decelerations during nonstress tests were not a sign of fetal

compromise. The American College of Obstetricians and Gynecologists (1999) has concluded that variable decelerations, if nonrepetitive and brief \leq less than 30 seconds \leq do not indicate fetal compromise or the need for obstetrical intervention. In contrast, repetitive variable decelerations \geq at least three in 20 minutes \geq even if mild, have been associated with an increased risk of cesarean delivery for fetal distress. Decelerations lasting 1 minute or longer have been reported to have an even worse prognosis (Bourgeois and colleagues, 1984; Druzin and colleagues, 1981; Pazos and colleagues, 1982).

Hoskins and associates (1991) attempted to refine interpretation of testing that shows variable decelerations by adding ultrasonic estimation of amniotic fluid volume. The incidence of cesarean delivery for intrapartum fetal distress progressively increased coincidentally with the severity of variable decelerations and diminished amniotic fluid volume. Severe variable decelerations during a nonstress test plus an amniotic fluid index of 5 cm or less resulted in a 75-percent cesarean delivery rate. Fetal distress in labor, however, also frequently developed in those pregnancies with variable decelerations but with normal amounts of amniotic fluid. Similar results were reported by Grubb and Paul (1992).

False-Normal Nonstress Tests. Smith and associates (1987) performed a detailed analysis of the causes of fetal death within 7 days of normal nonstress tests. The most common indication in this study for testing was postterm pregnancy. The mean interval between testing and death was 4 days, with a range of 1 to 7 days. The single most common autopsy finding was meconium aspiration, often associated with some type of umbilical cord abnormality. They concluded that an acute asphyxial insult had provoked fetal gasping. They also concluded that nonstress testing was inadequate to preclude such an acute asphyxial event and that other biophysical characteristics might be beneficial adjuncts. For example, assessment of amniotic fluid volume was considered to be of value. Other ascribed frequent causes of fetal death included intrauterine infection, abnormal cord position, malformations, and placental abruption.

Figure 15-8. Nonreactive nonstress test followed by contraction stress test showing mild, late decelerations. Cesarean delivery was performed, and the severely acidemic fetus could not be resuscitated.

ACOUSTIC STIMULATION TESTS

Loud external sounds have been used to startle the fetus, provoking acceleration of the heart rate \geq an acoustic stimulation nonstress test. Eller and associates (1995) used a commercially available acoustic stimulator (Corometrics model 146) and measured intrauterine sound levels. Sound intensity between 100 and 105 dB \geq equivalent to sounds generated by a jet plane at takeoff \geq was maintained until the stimulator was moved more than 20 cm from the maternal abdomen. The acoustic stimulator is positioned on the maternal abdomen and a stimulus of 1 to 2 seconds is applied. This may be repeated up to three times for up to 3 seconds (American College of Obstetricians and Gynecologists, 1999). Perez-Delboy and colleagues (2002) randomized 113 women to nonstress testing with and without vibroacoustic stimulation. Such stimulation shortened the average time for nonstress testing from 24 to 15 minutes.

BIOPHYSICAL PROFILE

Manning and colleagues (1980) proposed the combined use of five fetal biophysical variables as a more accurate means of assessing fetal health than any one used alone. They hypothesized that consideration of five variables could significantly reduce both false-positive and false-negative tests. Required equipment includes a real-time ultrasound device and Doppler ultrasound to record fetal heart rate. Typically, these tests require 30 to 60 minutes of examiner time. Shown in [Table 15-2](#) are the five biophysical components assessed, which include (1) fetal heart rate acceleration, (2) fetal breathing, (3) fetal movements, (4) fetal tone, and (5) amniotic fluid volume. Normal variables were assigned a score of two each and abnormal variables, a score of zero. Thus, the highest score possible for a normal fetus is 10. Kopecky and colleagues (2000) observed that 10 to 15 mg of morphine sulfate administered to the mother caused a significant decrease in the biophysical score by suppressing fetal breathing and heart rate acceleration.

Manning and colleagues (1987) tested more than 19,000 pregnancies using the biophysical profile interpretation and management shown in [Table 15-3](#). They reported a false-normal test rate, defined as an antepartum death of a structurally normal fetus, of approximately 1 per 1000. More than 97 percent of the pregnancies tested had normal test results. The most common identifiable causes of fetal death after normal biophysical profiles include fetomaternal hemorrhage, umbilical cord accidents, and placental abruption (Dayal and colleagues, 1999). Manning and co-authors (1993) published a remarkable description of 493 fetuses in which biophysical scores were performed immediately before measurement of umbilical venous blood pH values obtained via cordocentesis. Approximately 20 percent of tested fetuses had growth restriction and the remainder had alloimmune hemolytic anemia. As shown in [Figure 15-9](#), a biophysical score of zero was invariably associated with significant fetal acidemia, whereas normal scores of 8 or 10 were associated with normal pH. An equivocal test result \geq a score of 6 \geq was a poor predictor of abnormal outcome. A decrease from an abnormal result \geq a score of 2 or 4 \geq to a very abnormal score (zero) was a progressively more accurate predictor of abnormal outcome. Salvesen and colleagues (1993) correlated the biophysical profile with umbilical venous blood pH obtained at cordocentesis in 41 pregnancies complicated by diabetes. They also found that abnormal pH was significantly associated with abnormal biophysical profile scores. They concluded, however, that the biophysical profile was of limited value in the prediction of fetal pH, because nine mildly acidemic fetuses had normal antepartum tests. Weiner and colleagues (1996) assessed the meaning of antepartum fetal tests in 135 overtly growth-restricted fetuses and came to a similar conclusion. They found that morbidity and mortality in severe fetal growth restriction were determined primarily by gestational age and birthweight and not by abnormal fetal tests.

Figure 15-9. Mean umbilical vein pH ($\bar{x} \pm 2$ SD) in relation to fetal biophysical profile score category. (From Manning and associates, 1993, with permission.)

MODIFIED BIOPHYSICAL PROFILE. Because the biophysical profile is labor intensive and requires a person trained in ultrasonic visualization of the fetus, Clark and co-workers (1989) used an abbreviated biophysical profile as their first-line antepartum screening test in 2628 singleton pregnancies. Specifically, a vibroacoustic nonstress test was performed twice weekly along with determination of the amniotic fluid index (see [Chap. 16](#), p. 392). An amniotic fluid index of less than 5 cm was considered abnormal. This abbreviated biophysical profile required about 10 minutes to perform, and they concluded that it was a superb method of antepartum surveillance because there were no unexpected fetal deaths.

Nageotte and colleagues (1994) also combined biweekly nonstress tests with the amniotic fluid index and considered 5 cm or less to be abnormal. They performed 17,429 modified biophysical profiles in 2774 women and concluded that such testing was an excellent method of fetal surveillance. They randomized women with abnormal test results to backup testing with either a complete biophysical profile or a contraction stress test. Contraction stress testing increased intervention for a false-abnormal test. Miller and associates (1996a) reported results with more than 54,000 modified biophysical profiles performed in 15,400 high-risk pregnancies. They described a false-negative rate of 0.8 per 1000 and a false-positive rate of 1.5 percent. Young and co-workers (2003) randomized 683 women to the original biophysical profile or to two modified testing procedures and found no differences in effectiveness between three various methods.

The American College of Obstetricians and Gynecologists (1999) has concluded that the modified biophysical profile test is an acceptable means of antepartum fetal surveillance.

AMNIOTIC FLUID VOLUME

Assessment of amniotic fluid has become an integral component in the antepartum assessment of pregnancies at risk for fetal death. This is based on the rationale that decreased uteroplacental perfusion may lead to diminished fetal renal blood flow, decreased urine production, and ultimately, oligohydramnios. As discussed in [Chapter 16](#) (see p. 392), the amniotic fluid index, the deepest vertical pocket, and the 2 × 2 cm pocket used in the biophysical profile are some ultrasonic techniques used to estimate amniotic fluid volume (Chamberlain, 1984; Manning, 1984; Rutherford, 1987, and their colleagues).

In their review of 42 reports on the amniotic fluid index published between 1987 and 1997, Chauhan and colleagues (1999) concluded that an index of 5.0 cm or less significantly increased the risk of either cesarean delivery for fetal distress or a low 5-minute Apgar score. Similarly, in a retrospective analysis of 6423 pregnancies managed at Parkland Hospital, Casey and colleagues (2000) found that an amniotic fluid index of 5 cm or less was associated with significantly increased perinatal morbidity and mortality. Locatelli and associates (2004) reported excessive low-birthweight infants if there was oligohydramnios so defined.

Not all investigators agree with the concept that an index of 5 cm or less portends more adverse outcomes. Magann and colleagues (1999, 2004) concluded that the index was a poor diagnostic test and that it better predicted normal than abnormal volumes. Driggers and co-workers (2004) and Zhang and collaborators (2004) did not find a correlation with bad outcomes in pregnancies in which the index was below 5 cm. In the only randomized trial reported to date, Conway and colleagues (2000) concluded that nonintervention to permit spontaneous onset of labor was as effective as induction in term pregnancies with amniotic fluid index values of 5 cm or less.

UMBILICAL ARTERY DOPPLER VELOCIMETRY

Doppler ultrasonography is a noninvasive technique to assess blood flow by characterizing downstream impedance (see [Chap. 16](#), p. 400). The umbilical artery systolic-diastolic (S/D) ratio, the most commonly used index, is considered abnormal if it is above the 95th percentile for gestational age or if diastolic flow is either absent or reversed. Absent or reversed end-diastolic flow signifies increased impedance to umbilical artery blood flow ([Fig. 15-10](#) and [Fig. 16-20](#), p. 403). It is reported to result from poorly vascularized placental villi and is seen in the most extreme cases of fetal growth restriction (Todros and co-authors, 1999). Zelop and colleagues (1996) found that perinatal mortality for absent end-diastolic flow was about 10 percent, and for reversed end-diastolic flow, it was approximately 33 percent.

Doppler ultrasonography has been subjected to more extensive assessment with randomized controlled trials than has any previous test of fetal health. Williams and colleagues (2003) randomized 1360 high-risk women to either nonstress testing or Doppler velocimetry. They found a significantly increased incidence of cesarean delivery for fetal distress in the nonstress test group compared with that for those tested with Doppler—8.7 versus 4.6 percent. One interpretation of this finding is that the nonstress test more frequently identified fetuses in jeopardy. The utility of umbilical artery Doppler velocimetry was reviewed by the American College of Obstetricians and Gynecologists (1999, 2000). It was concluded that no benefit has been demonstrated other than in pregnancies with suspected fetal growth restriction. No benefit has been demonstrated for velocimetry for other conditions, such as postterm pregnancy, diabetes mellitus, systemic lupus erythematosus, or antiphospholipid antibody syndrome. Similarly, velocimetry has not proved of value as a screening test for detecting fetal compromise in the general obstetrical population.

It is possible to evaluate blood flow in other vessels in addition to the umbilical vessels (see [Chap. 16](#), p. 401). In the mother, these include velocimetry of the uterine artery (Lees and colleagues, 2001; Vergani and colleagues, 2003). In the fetus, the middle cerebral artery has received particular attention because of observations that the hypoxic fetus achieves *brain sparing* through reduced cerebrovascular impedance and thus increased blood flow. Such brain sparing in growth-restricted fetuses has been documented to undergo reversal in less than 24 hours by Konje and colleagues (2001). They reported that 8 of 17 fetuses with this finding died. Ott and colleagues (1998) randomized 665 women undergoing modified biophysical profiles to either this test alone or combined with middle cerebral to umbilical artery velocity flow ratios. There were no significant differences in pregnancy outcomes between these two study groups. This technique currently is considered investigational by the American College of Obstetricians and Gynecologists (1999).

CURRENT ANTENATAL TESTING RECOMMENDATIONS

According to the American College of Obstetricians and Gynecologists (1999), there is no "best test" to evaluate fetal well-being. Three testing systems—contraction stress test, nonstress test, and biophysical profile—have different end points that are considered, depending on the clinical situation. The American College of Obstetricians and Gynecologists (2002) patient education pamphlet describes these tests of fetal well-being and summarizes as follows: "Monitoring helps you and your doctor during your pregnancy by telling more about the well-being of the baby. If a test result suggests that there may be a problem, this does not always mean that the baby is in trouble. It simply may mean that you need special care or more tests. Discuss any questions you have about monitoring with your doctor."

The most important consideration in deciding when to begin antepartum testing is the prognosis for neonatal survival. The severity of maternal disease is another important consideration. In general, with the majority of high-risk pregnancies, most authorities recommend that testing begin by 32 to 34 weeks. Pregnancies with severe complications might require testing as early as 26 to 28 weeks. The frequency for repeating tests has been arbitrarily set at 7 days, but more frequent testing is often done.

At Parkland Hospital, antepartum fetal heart rate recordings have been limited to about 700 women admitted to the High-Risk Pregnancy Unit each year. Such recordings are often obtained several times throughout the week—for example, Monday, Wednesday, and Friday—in these pregnancies. The primary focus of fetal heart rate assessments is detection of decelerations, and delivery is not withheld simply because accelerations are witnessed. Clinical and ultrasonic estimations of amniotic fluid volume also may be used to assess fetal health. Outpatients do not undergo fetal heart rate testing. If there is concern about fetal movement or amniotic fluid volume, then the woman may be observed in the labor suite with fetal heart rate monitoring. Depending on results, she is either discharged or transferred to the High-Risk Unit, or labor is induced. Despite this limited use of antepartum testing, the fetal death rate in structurally normal infants is quite low in high-risk women. Indeed, most antepartum fetal deaths that we encounter are in low-risk pregnancies, and are attributable to unpreventable causes such as placental abruptions and umbilical cord accidents.

SIGNIFICANCE OF FETAL TESTING. Does antenatal fetal testing really make a difference? Platt and co-workers (1987) reviewed its impact between 1971 and 1985 at Los Angeles County Hospital. During this 15-year period, more than 200,000 pregnancies were managed, and nearly 17,000 of these women underwent antepartum testing of various types. Fetal surveillance increased from less than 1 percent of pregnancies in the early 1970s to 15 percent in the mid-1980s. These authors concluded that such testing was clearly beneficial because the fetal death rate was significantly less in the tested high-risk pregnancies compared with the rate in those not tested.

A contrasting opinion on the benefits of antenatal fetal testing was offered by Thacker and Berkelman (1986). It was their view that efficacy is best evaluated in randomized controlled trials. After reviewing 600 reports, they found only four such trials, all performed with the nonstress test and none with the contraction stress test. The numbers in these four trials were considered too small to detect important benefits. They projected that the costs of such testing exceeded \$200 million per year in 1986 and that published studies did not support the use of either test. Enkin and colleagues (2000) reviewed evidence in the Cochrane Library from controlled trials of antepartum fetal surveillance. They concluded that "despite their widespread use, most tests of fetal well-being should be considered of experimental value only rather than validated clinical tools."

Another important and unanswered question is whether antepartum fetal surveillance identifies fetal asphyxia early enough to prevent brain damage. Todd and co-workers (1992) attempted to correlate cognitive development in infants up to the age of 2 years following either abnormal Doppler velocimetry or nonstress tests. Only abnormal nonstress tests were associated with marginally poorer cognitive outcomes. They concluded that by the time fetal compromise is diagnosed with antenatal testing, fetal damage has already been sustained. Low and colleagues (2003) reached a similar conclusion in their study of 36 preterm infants delivered based on antepartum test results. Thornton (2003) randomized 548 preterm pregnancies with abnormal test results to immediate or delayed delivery with a median of 5 days. They found that immediate delivery was associated with neonatal death and delayed delivery with stillbirth.

Manning and co-authors (1998) studied the incidence of cerebral palsy in 26,290 high-risk pregnancies managed with serial biophysical profile testing. They compared these outcomes with those of 58,657 low-risk pregnancies in which antepartum testing was not performed. The rate of cerebral palsy was 1.3 per 1000 in tested pregnancies compared with that of 4.7 per 1000 in untested women. In a prior study, however, Manning and colleagues (1996) had reported that cerebral palsy was significantly associated with low biophysical profile scores, which suggested that identification of the truly compromised fetus may be too late.

Antenatal forecasts of fetal health have clearly been the focus of intense interest for more than two decades. When such testing is reviewed, several themes emerge:

1. Methods of fetal forecasting have evolved continually, a phenomenon that itself suggests dissatisfaction with the precision or efficacy of any given method.
2. The fetal biophysical performance is characterized by wide ranges of normal biological variation, resulting in difficulty determining when such performance should be considered abnormal. *How many movements, respirations, or accelerations? In what time period?* Unable to easily quantify normal fetal biophysical performance, most investigators have resorted to somewhat arbitrary answers to such questions.
3. Despite the invention of increasingly complex testing methods, abnormal results are seldom reliable, prompting many clinicians to use antenatal testing to forecast fetal *wellness* rather than *illness*.

16. Ultrasonography and Doppler

INTRODUCTION

The impact of ultrasonography on the practice of obstetrics has been profound. A carefully performed sonographic examination reveals vital information about fetal anatomy, as well as fetal environment, growth, and well-being. Technology has evolved from producing two-dimensional images of the pregnant uterus to using Doppler methods for measurement of maternal and fetal circulation and to creating three-dimensional views of maternal and fetal anatomy.

ULTRASONOGRAPHY IN OBSTETRICS

Since the first obstetrical application of ultrasound imaging by Donald and co-workers (1958), this technique has become indispensable for evaluation of the fetus. According to the National Center for Health Statistics (2002), sonography was used in 67 percent of pregnant women in the United States in 2001.

TECHNOLOGY. The picture displayed on the screen is produced by sound waves reflected back from the imaged structure. Alternating current is applied to a transducer containing piezoelectric crystals, which converts electrical energy to high-frequency sound waves. A water-soluble gel applied to the skin acts as a coupling agent. Sound waves pass through layers of tissue, encounter an interface between tissues of different densities, and are reflected back to the transducer. Converted back into electrical energy, they are displayed on the screen. Dense tissue such as bone produces high-velocity reflected waves, which are displayed as white on the screen. Fluid, however, is anechoic and generates few reflected waves, appearing black on the screen. Images are generated so quickly, more than 40 frames/sec, that the picture on the screen appears to move in real-time.

Higher-frequency transducers yield better image resolution, whereas lower frequencies penetrate tissue more effectively. For example, abdominal scanning is most commonly performed with a 3- to 5-mHz transducer. Obese patients may require a 2-mHz transducer to image the fetus, but the quality of the images (resolution) will be reduced. In early pregnancy, 7- to 10-mHz vaginal transducers may provide excellent resolution because the fetus is close to the transducer.

SAFETY. Ultrasonography should be performed only when there is a valid medical indication, using the lowest possible exposure setting to gain necessary diagnostic information—the ALARA principle or "as low as reasonably achievable" (American Institute of Ultrasound in Medicine, 2003). That said, there have been no confirmed damaging biological effects in mammalian tissue demonstrated in the frequency range of medical ultrasound (American Institute of Ultrasound in Medicine, 1991). In the low-intensity range of gray-scale imaging, no fetal harm has been demonstrated in more than 30 years of use (see Chap 9, p. 235).

CLINICAL APPLICATIONS. Obstetrical ultrasound has proven invaluable in a variety of ways, two in particular being more accurate pregnancy dating and detection of fetal anomalies. Several investigators have demonstrated that an estimated gestational age determined sonographically is more accurate than one based on last menstrual period. This alone allows reduction in the number of labor inductions for postterm pregnancy (Waldenstrom and colleagues, 1988). Tunon and colleagues (1996) performed sonography in more than 15,000 unselected women at 18 weeks and decreased the postterm delivery rate from 10 percent to 4 percent. In a randomized study of 218 low-risk women, Bennett and associates (2004) significantly reduced labor induction for postterm pregnancy from 13 to 5 percent.

Accurate dating also may alter the method of pregnancy termination. McGalliard and Gaudoin (2004) reported that there was at least a 1-week discrepancy in 38 percent of 237 women seeking pregnancy termination, and that in many of these cases, a safer method was chosen.

Several investigators have shown that routine sonography can identify at least 35 to 50 percent of major fetal malformations, with a specificity of 90 to 100 percent (Ewigman and colleagues, 1993; Goncalves and colleagues, 1994; Van Dorsten and co-workers, 1998). As technology has improved, attempts to identify fetal anatomy are applied earlier in gestation. Indeed, a complete survey of fetal anatomy can be performed before the end of the first trimester (Michailidis and colleagues, 2002; Whitlow and Economides, 1998). Even so, recently updated practice guidelines of the American Institute of Ultrasound in Medicine (2003) stress that adequate assessment of fetal anatomy is best performed after 18 weeks. Although it may be possible to document normal anatomy before this time, some structures may be difficult to visualize because of fetal size, position, or movement or maternal abdominal scars or obesity. The American College of Obstetricians and Gynecologists (1997) cautions that the sensitivity of ultrasound in detecting fetal anomalies varies in different clinical settings and according to the skill of the sonographer.

FIRST TRIMESTER. Some indications for performing sonography in the first trimester are listed in [Table 16-1](#). Early pregnancy can be evaluated using abdominal or transvaginal sonography, or both. All of the components listed in [Table 16-2](#) should be assessed. As new technical capabilities are developed, greater research emphasis is being placed on first-trimester detection of fetal disorders and even treatment (Bahado-Singh and Cheng, 2004). With transabdominal scanning, the gestational sac is reliably seen in the uterus by 6 weeks, and fetal echoes and cardiac activity by 7 weeks. With transvaginal scanning, these are seen about 1 week earlier.

Early sonography is valuable in diagnosing abnormalities such as anembryonic gestation as well as embryonic demise. With transvaginal examination, cardiac motion usually is observed when the embryo is 5 mm in length. Multifetal gestation can be identified in the first trimester, and this is the optimal time to determine chorionicity. The first trimester also may be the best time to evaluate the uterus, adnexal structures, and cul-de-sac.

Between 11 and 14 weeks, fetal *nuchal translucency* can be accurately measured. This is the maximum thickness of the subcutaneous translucent area between the skin and soft tissue that overlies the fetal spine in the sagittal plane. Measurement

of nuchal translucency was described by Nicolaides and colleagues (1992), and has gained widespread use, often in conjunction with maternal serum markers, in the detection of aneuploidy. Wapner and colleagues (2003) recently reported results of their multicenter trial of 8514 pregnancies undergoing first-trimester aneuploidy screening using nuchal translucency along with serum chorionic gonadotropin and pregnancy-associated plasma protein A. They reported detection of 85 percent of cases of Down syndrome with a false-positive rate of 9 percent. Malone and colleagues (2003) reported a multicenter trial in which 33,557 pregnancies underwent first- and second-trimester aneuploidy screening. First-trimester nuchal translucency and serum markers resulted in the detection of 85 percent of Down syndrome cases with a false-positive rate of 7.6 percent. In his review of studies that included over 200,000 pregnancies, Nicolaides (2004) found these to be 87 and 4.2 percent, respectively. When certain criteria are met, the American College of Obstetricians and Gynecologists (2004b) has concluded that first-trimester screening is an acceptable option for trisomy 18 and 21.

SECOND AND THIRD TRIMESTERS. Some of the many indications for second- and third-trimester sonography are listed in [Table 16-3](#). These examinations can be categorized as standard, limited, or specialized. Terms indicate which structures were evaluated and to what extent, and also describe which structures were not evaluated.

[Table 16-2](#) lists the components of a *standard* ⌘—also termed *basic* ⌘—obstetrical ultrasound examination. A standard examination should be performed or reviewed by an appropriately trained sonologist (American College of Obstetricians and Gynecologists, 1997). It includes a fetal anatomical survey, the components of which are listed in [Table 16-4](#). When multiple gestations are imaged, additional documentation includes the number(s) of chorions and amnions, comparison of fetal sizes, estimation of amniotic fluid volume in each sac, and description of fetal genitalia if visualized. If a complete survey of fetal anatomy cannot be obtained ⌘—for example, due to oligohydramnios, fetal position, or maternal obesity ⌘—it should be noted.

There are several types of *specialized* examinations. An example includes a detailed anatomical examination, which is performed when an anomaly is suspected on the basis of history, maternal serum screening test abnormalities, or abnormal findings from a standard or limited examination. These examinations are performed and interpreted by a sonologist with special expertise. Other types of examinations include fetal echocardiography, fetal Doppler evaluation, biophysical profile, or additional biometric studies (see [Chapter 15](#), p. 381).

A third type of procedure is the *limited* examination, performed when a specific question requires investigation. Examples include estimation of amniotic fluid volume, placental location, identification of fetal presentation, or determination of fetal viability. In most cases, limited examinations are appropriate only when a prior complete examination is on record (American Institute of Ultrasound in Medicine, 2003).

FETAL MEASUREMENTS. Various formulas and nomograms allow accurate assessment of gestational age and describe normal growth of fetal structures. Modern equipment contains software that provides an estimated gestational age from the crown-rump length measurement in the first trimester. It also estimates both gestational age and fetal weight in the second and third trimester using measurements of the biparietal diameter, head circumference, abdominal circumference, and femur length. Estimates are typically most accurate when multiple parameters are used and when nomograms have been derived from fetuses of the same ethnic or racial background living at similar altitude. Nomograms are available for other fetal structures that may help answer specific questions about organ system abnormalities or syndromes. Examples include length of the fetal ears, kidneys, cerebellum, long bones and feet, and the interocular and binocular distances.

For determining gestational age in the first trimester, the crown-rump length is most accurate. The image should be obtained in a sagittal plane and include neither the yolk sac nor a limb bud. If carefully performed, it has a variation of only 3 to 5 days. Between 14 and 26 weeks, the biparietal diameter (BPD) is usually the most accurate parameter, with a variation of 7 to 10 days. By convention, the BPD is measured from the outer edge of the proximal skull to the inner edge of the distal skull, at the level of the thalami and cavum septi pellucidi. The head circumference (HC) also is measured. If the head shape is flattened (*dolichocephaly*) or rounded (*brachycephaly*), this measurement is more reliable than the BPD. The femur length (FL) correlates well with both BPD and gestational age. The femur is measured with the beam perpendicular to the long axis of the shaft, excluding the epiphysis, and has a variation of 7 to 11 days in the second trimester. The abdominal circumference (AC) is the parameter with the widest variation of 2 to 3 weeks. This is because the AC measurement involves soft tissue rather than bone and is also the parameter most affected by fetal growth. The AC is measured at the skin line in a transverse view of the fetus at the level of the fetal stomach and umbilical vein.

The variability of gestational age estimation increases as pregnancy advances. By the third trimester, all individual measurements become less accurate. Estimates are improved by taking an average of the various parameters ⌘—the BPD, HC, AC, and FL. Also, each measurement should be assessed individually; if one measurement is significantly different from the others, it can be excluded from the calculation. The outlier measurement could result from poor visibility, or it could indicate a fetal growth abnormality. If third-trimester ultrasound measurements must be used to determine gestational age, accuracy can be improved by performing serial examinations and documenting normal interval fetal growth.

AMNIONIC FLUID. Determination of the amount of amniotic fluid is an important method of fetal assessment and is discussed in [Chapter 15](#) (see p. 382). When volume is assessed subjectively, oligohydramnios is seen as obvious crowding of the fetus and absence of any significant pockets of fluid. Conversely, hydramnios is an apparent excess of fluid.

Several objective measurement schemes have been used to evaluate amniotic fluid volume. The most widely used is the *amniotic fluid index (AFI)*, which is calculated by adding the depth in centimeters of the largest vertical pocket in each of four equal uterine quadrants (Phelan and colleagues, 1987). Reference ranges have been established from 16 weeks onward, and in the majority of normal pregnancies the AFI ranges between 8 and 24 cm (see [Table 21-1](#) and [Fig. 21-1](#), p. 526). Another method is to measure the largest vertical pocket of amniotic fluid. The normal range is 2 to 8 cm; values below 2 cm signify oligohydramnios, whereas those over 8 cm define hydramnios. This latter method is commonly used for twin pregnancies.

Figure 21-1. Normal percentiles for the amniotic fluid index (AFI) from 1400 women. For each gestational week, 50 women were studied. (Data adapted by

NORMAL AND ABNORMAL FETAL ANATOMY

One basic goal of ultrasound evaluation is to categorize fetal components as anatomically normal or abnormal. Poor visualization of a structure allows neither. Deviations from normal anatomy require that a specialized examination be performed. In the discussion that follows, only a few of literally hundreds of fetal anomalies are used as examples of distorted anatomy.

CENTRAL NERVOUS SYSTEM. Anomalies of the fetal brain are among the most common and have the potential to cause serious disability or death. Ultrasonography has proven extremely useful in detecting and characterizing these anomalies. Three transverse (axial) views of the fetal brain are imaged. The transthalamic view shown in [Figure 16-1](#) is used to measure BPD and HC and includes the thalami and cavum septi pellucidi. Moving superiorly yields the transventricular view of the atria of the lateral ventricles, which contain the echogenic choroid plexus ([Fig. 16-2](#)). The atrial measurement is normally between 5 and 10 mm from 15 weeks until term. Angling back through the posterior fossa produces the transcerebellar view ([Fig. 16-3](#)). Here the cerebellum and cisterna magna are typically measured. Between 15 and 22 weeks, the cerebellar diameter in millimeters is roughly equivalent to the gestational age in weeks (Goldstein and associates 1987).

Abnormalities detected in any of these three views alert the clinician of a possible fetal brain anomaly. Specialized evaluation may permit accurate diagnosis of relatively subtle anomalies, including neural-tube defects, ventriculomegaly, holoprosencephaly, hydranencephaly, Dandy-Walker malformation, porencephaly, or an intracranial tumor.

Neural-Tube Defects. These malformations are the second most common class of congenital anomalies—cardiac anomalies are the most common. Neural-tube defects occur in about 1.6 per 1000 live births in the United States, and their incidence is as high as 8 per 1000 in the United Kingdom. Defects result from incomplete closure of the neural tube by the sixth week, or the embryonic age of 26 to 28 days. [Chapter 13](#) (see p. 318 and p. 334) discusses diagnosis and management.

Anencephaly is a lethal defect characterized by absence of the brain and cranium above the base of the skull and orbits. It can be diagnosed as early as the first trimester. If visualization is adequate in the second trimester, anencephaly can be diagnosed in virtually all cases (see [Fig. 13-6](#), p. 321). Inability to obtain a view of the biparietal diameter should raise suspicion. Hydramnios from impaired fetal swallowing is common in the third trimester.

Cephalocele is a herniation of meninges and brain tissue through a defect in the cranium, typically an occipital midline defect. Associated hydrocephalus and microcephaly are common, and there is a high incidence of mental impairment. If the fetal head closely abuts the uterine wall, the skull defect may be difficult to image. Cephalocele is an important feature of the autosomal recessive *Meckel-Gruber syndrome*. A cephalocele that is not in the occipital midline may be caused by the *amnionic band sequence*.

Spina bifida is an opening in the vertebrae through which a meningeal sac may protrude. In 90 percent of cases, the sac contains neural elements and the anomaly is termed a *meningomyelocele*. When a meningeal sac alone protrudes through the defect, it is a *meningocele*. Spinal defects usually can be imaged in multiple planes, as shown in [Figure 16-4](#). Transverse images provide the best visualization of the extent of the defect and overlying soft tissue. Movement of the lower extremities does not predict normal function after birth. The *Arnold-Chiari II* malformation associated with spina bifida occurs when downward displacement of the spinal cord pulls a portion of the cerebellum through the foramen magnum into the upper cervical canal. Classically, fetuses with spina bifida have one or more of the following five cranial signs:

1. Small biparietal diameter.
2. Ventriculomegaly.
3. Frontal bone scalloping or the so-called lemon sign ([Fig. 16-5](#)).
4. Elongation and downward displacement of the cerebellum— the so-called banana sign ([Fig. 16-6](#)).
5. Effacement or obliteration of the cisterna magna.

When a cranial sign is present but no spinal defect is visualized, amniocentesis for amniotic fluid alpha-fetoprotein and acetylcholinesterase measurement may be diagnostic.

Ventriculomegaly. Enlargement of the cerebral ventricles has been viewed as a general marker of abnormal brain development (Callen, 2000; Wyldes and Watkinson, 2004). The lateral ventricle is commonly measured at its *atrium*, which is the confluence of the temporal and occipital horns (see [Fig. 16-2](#)). The measurement is relatively constant at 7 mm, with standard deviation of 1 mm, from 15 weeks onward (Heiserman and colleagues, 1991). Mild ventriculomegaly is diagnosed when the atrial width measures 10 to 15 mm, and overt ventriculomegaly when it exceeds 15 mm ([Fig. 16-7](#)). A *dangling choroid plexus* characteristically is found in severe cases (Cardoza and associates, 1988a, 1988b; Mahony and colleagues, 1988).

Ventriculomegaly may be caused by a wide variety of genetic and environmental insults, and prognosis is determined by both etiology and rate of progression. Generally, the larger the atrium, the greater the likelihood of abnormal outcome. Despite this generalization, Bloom and colleagues (1997) found that 36 percent of infants prenatally diagnosed with isolated and mild ventriculomegaly were developmentally delayed. Initial evaluation of ventricular enlargement includes a thorough examination of fetal anatomy and fetal karyotype and testing for congenital viral infection (Wyldes and Watkinson, 2004).

CYSTIC HYGROMA. This is a congenital malformation of the lymphatic system in which large, often multiseptated, fluid-filled sacs extend from the posterior neck ([Fig. 16-8](#)). Cystic hygromas usually develop as part of lymphatic obstruction sequence, in which lymph from the head fails to drain into the jugular vein and collects instead in jugular lymphatic sacs. The enlarged thoracic duct can impinge on the developing heart. In some cases, there are developmental flow-related anomalies such as a hypoplastic left heart or coarctation of the aorta.

In approximately 60 to 70 percent of cases, cystic hygromas are associated with fetal aneuploidy. Turner syndrome (45,X) accounts for 75 percent of these aneuploidies; trisomies 21, 18, and 13 and mosaic aneuploidies account for the remainder (Johnson and colleagues, 1993; Shulman and associates, 1992). They also may be an isolated finding or part of a genetic syndrome, such as *Noonan syndrome*.

Small hygromas may undergo spontaneous resolution, and provided that the fetal karyotype and echocardiography are normal, the prognosis may be good (Shulman and co-workers, 1992; Trauffer and associates, 1994). Conversely, large, multiseptated lesions rarely resolve, often lead to hydrops fetalis, and have a poor prognosis (Brumfield and colleagues, 1996).

Figure 16-8. Large, septated cystic hygromas in a 17-week fetus with Turner syndrome. (Courtesy of Dr. Jodi Dashe.)

THORAX. The lungs are best visualized after 20 to 25 weeks and appear as homogeneous structures surrounding the heart. In the four-chamber view of the chest, they fill approximately two thirds of the area. A variety of thoracic malformations, including cystic adenomatoid malformation, extralobar pulmonary sequestration, and bronchogenic cysts, may be visualized sonographically as cystic or solid space-occupying lesions. Prenatal diagnosis and therapy of these lesions is discussed in [Chapter 13](#) (see p. 333).

Diaphragmatic Hernia. In 90 percent of cases, these are left-sided and posterior, and the heart may be pushed to the middle or right side of the thorax by the stomach or bowel. Associated findings include absence of the stomach bubble within the abdomen, small abdominal circumference, and bowel peristalsis seen in the fetal chest. Almost half of cases are associated with other major anomalies or aneuploidy. Thus, a thorough evaluation of all fetal structures should be performed, along with amniocentesis. Diagnosis and treatment are discussed in [Chapter 13](#) (see p. 333).

HEART. As a group, cardiac malformations are the most common congenital anomalies, with an incidence of about 8 per 1000 live births (see [Chap. 12](#), p. 302). Almost 90 percent of cardiac defects are multifactorial or polygenic, another 1 to 2 percent are the result of a single-gene disorder or a gene-deletion syndrome, and about 1 to 2 percent occur after exposure to a teratogen such as isotretinoin, hydantoin, or diabetic hyperglycemia. **As many as 30 to 40 percent of cardiac defects diagnosed prenatally are associated with chromosomal abnormalities.** Fortunately, up to 50 to 70 percent of aneuploid fetuses have extracardiac anomalies that are identifiable sonographically. Thus, recognition of a cardiac malformation should prompt fetal karyotyping. The most frequently encountered aneuploidies are trisomies 21, 18, and 13, and 45, X (Turner syndrome).

A basic anatomical survey of the heart includes assessment of a four-chamber view, rate, and rhythm. The four-chamber view is a transverse plane through the fetal thorax at a level immediately above the diaphragm ([Figs. 16-9](#) and [16-10](#)). It allows evaluation of cardiac size, position in the chest and its axis, atria and ventricles, septum primum, foramen ovale, interventricular septum, and atrioventricular valves. The two atria and ventricles should be similar in size, respectively, and the apex of the heart should form a 45-degree angle with the left anterior chest wall (see [Fig. 16-9](#)). Abnormalities of cardiac axis should prompt a specialized examination. Smith and colleagues (1995) found that 75 percent of fetuses with congenital heart anomalies had a cardiac axis greater than 75 degrees to the left. Ship and co-workers (1995) found that 45 percent of those with abnormal hearts had a left axis deviation exceeding 57 degrees.

A specialized examination with fetal echocardiography is performed if any of the following are present: abnormal four-chamber view, arrhythmia, presence of extracardiac anomalies, fetus with a genetic syndrome that includes a cardiac defect, parent or sibling with a heart defect, maternal diabetes, teratogen exposure, or nonimmune hydrops. Coco and associates (2004) recommend this also if an isolated echogenic heart focus is visualized.

The American Institute of Ultrasound in Medicine (2003) further recommends that if technically feasible, each standard examination should be attempted to evaluate both left and right ventricular outflow tracts ([Fig. 16-11](#)).

Accuracy. Sonographic accuracy depends on the operator, equipment, maternal habitus, fetal gestational age and position, specific cardiac lesion, and whether a standard screening examination or specialized fetal echocardiography is being performed. The prenatal detection rate for cardiac defects ranges from about 15 percent in a low-risk population to 80 percent in a high-risk group (Benacerraf and associates, 1987; Crawford and colleagues, 1988; Ott, 1995). For example, Stoll and colleagues (2002) prospectively studied more than 80,000 pregnancies from Strasbourg, France. They reported that the overall detection of 688 cardiac anomalies in nonaneuploid fetuses was only 20 percent. When there were other malformations, however, the detection rate was 40 percent. It was considerably higher for selected cardiac lesions; for example, 62 percent of cases of hypoplastic left heart and single ventricle were detected.

Overview statistics fail to consider the importance of the type of lesion and the cardiac views imaged. Even under ideal circumstances, small septal defects are consistently missed on screening examinations. When the four-chamber view is the only image taken, anomalies such as Fallot tetralogy and transposition of the great vessels are unlikely to be detected. Incorporation of the outflow tract views shown in [Figure 16-11](#) may improve visualization of the latter anomalies. All women undergoing fetal cardiac evaluation should be counseled regarding its limitations.

Figure 16-9. Measurement of the cardiac axis from the four-chamber view of the fetal heart. (LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.) (From Comstock, 1987, with permission.)

(Courtesy of Dr. Jodi Dashe.)

GASTROINTESTINAL TRACT. The stomach is visible in 98 percent of fetuses after 14 weeks, and the liver, spleen, gallbladder, and bowel can be identified in many second- and third-trimester fetuses. Nonvisualization of the stomach within the abdomen is associated with a number of abnormalities, such as esophageal atresia, diaphragmatic hernia, abdominal wall defects, and neurological abnormalities that inhibit fetal swallowing. If the stomach is not seen on initial examination, the examination should be repeated. Millener and co-workers (1993), however, found that even with subsequent visualization of the stomach, a third of cases had an abnormal outcome.

The appearance of bowel changes with gestational age. Occasionally it may appear bright, or echogenic, particularly if a higher frequency transducer is used (Vincoff and associates, 1999). Common causes of echogenic bowel include swallowed intra-amniotic blood, malformation, infection, and aneuploidy (Kesrouani and colleagues, 2003). Cystic fibrosis and trisomy 21 also have been associated with echogenic bowel. If this is an isolated finding in a low-risk pregnancy, the risk likely may not be great enough to warrant amniocentesis.

Abdominal Wall Defects. The integrity of the abdominal wall is assessed during the standard examination (Fig. 16-12). Defects are relatively common.

GASTROSCHISIS. This is a full-thickness defect in the abdominal wall. Typically it is located to the right of the umbilical cord insertion, and the bowel herniates into the amniotic cavity (Fig. 16-13). Gastroschisis rarely is associated with aneuploidy and usually has a survival rate of at least 90 percent (Kitchanan and colleagues, 2000; Nembhard and co-workers, 2001). It is thought to result from an early vascular occlusion that leads to localized abdominal wall ischemia. Associated bowel abnormalities are found in 10 to 30 percent of cases, usually as a result of vascular damage or mechanical trauma (Hoyme and co-workers, 1983). This is the one major anomaly more common in fetuses of younger mothers.

There are two controversies in management of these pregnancies. The first is whether any ultrasound parameter predicts outcome. The second is whether early delivery will prevent bowel damage, ostensibly by limiting bowel exposure to fetal urine. Huang and colleagues (2002) reviewed a series of 57 pregnancies complicated by gastroschisis and concluded that infants delivered at term were able to undergo earlier defect closure and begin full feedings sooner than those delivered prematurely. Markers of severity that have been evaluated include fetal growth restriction, increased bowel lumen diameter or wall thickness, distention of the stomach, and hydramnios. Japaraj and co-workers (2003) found that only hydramnios was predictive of neonatal bowel complications. Aina-Mumuney and colleagues (2004), however, reported excessive neonatal morbidity if the stomach was dilated prenatally.

OMPHALOCELE. This anomaly occurs when the lateral ectomesodermal folds fail to meet in the midline of the abdomen, leaving the abdominal contents covered only by a two-layered sac of amnion and peritoneum. The umbilical cord inserts into the apex of the sac (Fig. 16-14). In over half of cases, an omphalocele is associated with other major anomalies or aneuploidy. It also may occur as part of a genetic syndrome, such as *Beckwith-Wiedemann* or *pentalogy of Cantrell* (Callen, 2000). The prognosis is determined by the size of the omphalocele and also by the accompanying genetic or structural abnormalities (Heider and colleagues, 2004). For all of these reasons, identification of an omphalocele mandates a complete fetal evaluation, including karyotype.

Gastrointestinal Atresia. Most atresias are characterized by obstruction with proximal bowel dilatation. In general, the more proximal the obstruction, the more likely it is to be associated with hydramnios. *Esophageal atresia* may be suspected when the stomach cannot be visualized and hydramnios is present. In as many as 90 percent of cases, however, there is a *tracheoesophageal fistula* and fluid is able to enter the stomach despite esophageal atresia—thus, prenatal detection is problematic (Pretorius and colleagues, 1987a). About half of fetuses with esophageal atresia have associated anomalies, including aneuploidy in 20 percent of cases and growth restriction in 40 percent. Cardiac malformations are especially common with this anomaly.

Duodenal atresia occurs in about 1 in 10,000 live births (Robertson and colleagues, 1994). The lesion may be diagnosed prenatally by the demonstration of the so-called *double-bubble sign*, which represents distention of the stomach and the first part of the duodenum (Fig. 16-15). Demonstrating continuity between these two structures will differentiate duodenal atresia from other causes of abdominal cystic structures. About 30 percent of fetuses with duodenal atresia diagnosed antenatally have trisomy 21, and more than half have other anomalies. Obstructions in the lower small bowel usually result in multiple dilated loops, which may have increased peristaltic activity.

Large bowel obstructions and *anal atresia* are less readily diagnosed by ultrasound because hydramnios is not a typical feature and the bowel may not be significantly dilated. The transverse view through the pelvis may reveal the enlarged rectum as a fluid-filled structure between the bladder and the sacrum.

KIDNEYS AND URINARY TRACT.

Fetal kidneys are seen as paraspinal masses, frequently as early as 14 weeks, and routinely by 18 weeks (Patten and co-workers, 1990). A longitudinal ultrasonic view is shown in [Figure 16-16](#). Nomograms have been developed that describe kidney dimensions throughout pregnancy (Sagi and associates, 1987). A hypoechoic adrenal gland sits atop each kidney. The placenta and membranes produce amniotic fluid early in pregnancy, but after 16 to 20 weeks, most of the fluid is produced by the kidneys. Fetal urine production increases from 5 mL/hr at 20 weeks to about 50 mL/hr at term (Rabinowitz and co-workers, 1989). Unexplained oligohydramnios suggests a urinary tract abnormality, whereas normal amniotic fluid volume in the second half of pregnancy suggests urinary tract patency with at least one functioning kidney.

Renal Agenesis. This defect has an incidence of about 1 in 4000 births. No kidneys are seen ultrasonographically at any point during gestation. The adrenal glands typically enlarge and occupy the renal fossae, which Hoffman and colleagues (1992) have aptly termed the *lying down* adrenal sign. Without kidneys, no urine is produced, and the resulting severe oligohydramnios leads to pulmonary hypoplasia, limb contractures, a distinctive compressed face, and death from cord compression or pulmonary hypoplasia. When this combination of abnormalities results from renal agenesis, it is called *Potter syndrome*, after Dr. Edith Potter who described it in 1946. When these abnormalities result from scant amniotic fluid of some other etiology, it is called *oligohydramnios sequence*.

Polycystic Kidney Disease. Of the hereditary polycystic diseases, only autosomal recessive infantile polycystic kidneys may be reliably diagnosed antenatally. As discussed in [Chapter 48](#) (see p. 1102), the autosomal dominant condition usually does not manifest until adulthood, although prenatal diagnosis has been described (Pretorius and associates, 1987b). Infantile polycystic kidney disease is characterized by abnormally large kidneys that fill the fetal abdomen and appear to have a solid, ground-glass texture. The abdominal circumference is enlarged, and there is severe oligohydramnios. The cystic changes can only be identified microscopically.

Multicystic Dysplastic Kidney Disease. These renal changes arise from complete obstruction or atresia at the level of the renal pelvis or proximal ureter prior to 10 weeks (Callen, 2000). The diagnosis usually can be made antenatally by identifying abnormally dense renal parenchyma with multiple peripheral cysts of varying size that do not communicate with each other or with the renal pelvis. This finding should be distinguished from obstructive pyelectasis, in which the fluid-filled areas can be seen to connect. The prognosis for fetuses with multicystic dysplastic kidneys is generally good if findings are unilateral and amniotic fluid volume is normal.

Ureteropelvic Junction Obstruction. This condition is the most common cause of neonatal hydronephrosis and affects males at least twice as often as females. The actual obstruction is generally functional rather than anatomical, and it is bilateral in one third of cases. Unilateral obstruction is associated with an increased risk of anomalies also in the other kidney. Sonographically, only dilatation at the level of the renal pelvis—*pyelectasis*—is visualized. Various measurements taken at all gestational ages are used to predict fetuses who will require postnatal evaluation (Corteville, 1991; Mandell, 1991; Wilson, 1997, and all their colleagues). A commonly used upper limit for the normal pelvis diameter is 4 mm before 20 weeks. If this limit is exceeded, repeat sonography is performed at 34 weeks, and if the pelvis is then greater than 7 mm, neonatal follow-up is warranted. Adra and colleagues (1995) found that two thirds of fetuses with pyelectasis greater than 8 mm had an abnormality at birth. Similarly, Ismaili and associates (2003) reported that a diameter of at least 7 mm in a fetus in the third trimester had a 70-percent positive-predictive value for a renal abnormality in the infant.

Collecting System Duplication. This defect is the most common genitourinary anomaly and affects up to 4 percent of the population. Sonographically, the characteristic obstruction of the upper pole is evident as pyelectasis, often along with a dilated ureter that may be mistaken for a loop of bowel and with an ectopic ureterocele within the bladder. Reflux of the lower pole moiety is common. Prenatal detection permits antimicrobial treatment from birth to minimize urinary infections (Callen, 2000).

Posterior Urethral Valves. This distal obstruction of the urinary tract in male fetuses may have a spectrum of sonographic findings. Characteristically, there is dilatation of the bladder and proximal urethra—with the urethra resembling a keyhole—along with thickening of the bladder wall. Oligohydramnios portends a poor prognosis because of pulmonary hypoplasia. Unfortunately, the outcome is not uniformly good even with a normal amount of fluid. As with other obstructive uropathies, prenatal diagnosis allows some affected fetuses to benefit from early intervention postnatally or even consideration of in utero therapy (see [Chap. 13](#), p. 332).

Figure 16-16. Longitudinal sonogram of fetal kidney depicting the hypoechoic medullary pyramids (M). (From Lowe and associates, 1990.)

THREE-DIMENSIONAL ULTRASONOGRAPHY. This technology offers superior views of fetal surface anatomy to be obtained, potentially allowing improved visualization of selected structures such as the face, ear, and extremities. To adequately image a fetal structure in three dimensions, the part must be surrounded by amniotic fluid because crowding by adjacent structures obscures the captured image. Even under ideal circumstances, image processing may take considerably more time than is typically devoted to two-dimensional (2-D) scanning. Further, there are limitations on image resolution, data storage, and manipulation (Michailidis and co-workers, 2001; Pretorius and colleagues, 2001). For these reasons, the American Institute of Ultrasound in Medicine (1999) recommends that 3-D scanning be used as an adjunct to 2-D sonography. There is obvious appeal of a 3-D portrait of the fetal face, however, use of this or any other ultrasound technology when not medically indicated is considered by the Institute and by the American College of Obstetricians and Gynecologists (2004) to be inappropriate and contrary to medical practice.

DOPPLER VELOCIMETRY

The Doppler shift is a phenomenon that occurs when a source of light or sound waves is moving relative to an observer; the observer detects a shift in the wave frequency. Similarly, when sound waves strike a moving target, the frequency of the sound waves reflected back is shifted proportionate to the velocity and direction of the moving target. Because the magnitude and direction of the frequency shift depend on the relative motion of the moving target, the velocity and direction of the target can be determined.

Important to obstetrics, Doppler may be used to determine the volume and rate of blood flow through maternal and fetal vessels. In this situation, the sound source is the ultrasound transducer, the moving target is the column of red blood cells flowing through the circulation, and the reflected sound waves are observed by the ultrasound transducer. Two types—continuous and pulse wave Doppler—are used in medicine.

Continuous wave Doppler equipment has separate crystals: one that transmits a high-frequency sound wave, and another that continuously receives signals. It can record high frequencies using low power output and is easy to use. Unfortunately, it is nonselective, recognizing all signals along its path, and does not allow visualization of the blood vessel(s). In m-mode echocardiography, continuous wave Doppler is used to evaluate motion through time. It defines blood flow through the heart, but because the cardiac structures are not visualized, it requires the correlation of the sequence of waveforms produced with the sequence of structures interrogated by the sound wave.

Pulse wave Doppler has equipment that uses only one crystal, which transmits the signal and then waits until the returning signal is received before transmitting another one. It is more expensive and requires higher power, but allows precise targeting and visualization of the vessel of interest. Pulse wave Doppler also can be configured to allow color-flow mapping, in which computer software displays blood flowing away from the transducer as blue and blood flowing toward the transducer as red.

Various combinations of continuous wave Doppler, pulse wave Doppler, color-flow Doppler, and real-time ultrasound are commercially available and are loosely referred to as *duplex Doppler*.

CLINICAL APPLICATIONS. The Doppler equation shown in [Figure 16-17](#) contains the variables that affect the Doppler shift. An important source of error when calculating flow or velocity is the angle between sound waves from the transducer and flow within the vessel—termed the *angle of insonation* and abbreviated as theta (θ). Because cosine θ is a component of the equation, measurement error becomes large when the angle of insonation is not close to zero. The practical solution to this problem has been the use of ratios to compare different waveform components—allowing cosine θ to cancel out of the equation. [Figure 16-18](#) is a schematic of the Doppler waveform and describes the three ratios commonly used. The simplest is the *systolic-diastolic ratio (S/D ratio)*, which compares maximum (peak) systolic flow with end-diastolic flow, thereby evaluating downstream impedance to flow.

Virtually every fetal vessel has been insonated in the research setting in an attempt to improve our knowledge of pathophysiology (Detti and colleagues, 2004). [Figure 16-19](#) illustrates several vessels and their corresponding waveforms. The following discussion is limited to selected obstetrical applications.

Umbilical Artery. This vessel normally has forward flow throughout the cardiac cycle, and the amount of flow during diastole increases as gestation advances. Thus the S/D ratio *decreases*, from about 4.0 at 20 weeks to 2.0 at term. The S/D ratio is generally less than 3.0 after 30 weeks (Fleischer and associates, 1986). Umbilical artery Doppler may be a useful adjunct in the management of pregnancies complicated by fetal growth restriction. As presented in [Chapter 15](#) (see p. 383), umbilical artery velocimetry has been subjected to more rigorous assessment than has any previous test of fetal health (Alfirevic and Neilson, 1995). It is, however, not recommended for screening of low-risk pregnancies or for complications other than growth restriction.

Umbilical artery Doppler is considered abnormal if the S/D ratio is above the 95th percentile for gestational age. In extreme cases of growth restriction, end-diastolic flow may become absent or even reversed ([Fig. 16-20](#)). These are ominous findings and should prompt a complete fetal evaluation—almost half of cases are due to fetal aneuploidy or a major anomaly (Wenstrom and associates, 1991). In the absence of a reversible maternal complication or a fetal anomaly, reversed end-diastolic flow suggests severe fetal circulatory compromise and usually prompts immediate delivery. Sezik and colleagues (2004) recently reported that fetuses of preeclamptic women who had absent or reversed end-diastolic flow were more likely to have hypoglycemia and polycythemia.

Ductus Arteriosus. Doppler evaluation of the ductus arteriosus has been used primarily to monitor fetuses exposed to indomethacin and other nonsteroidal anti-inflammatory agents. Indomethacin, which is used for tocolysis, causes constriction of the ductus in sheep and human fetuses (Huhta and colleagues (1987). The resulting increased pulmonary flow may cause reactive hypertrophy of the pulmonary arterioles, and eventually pulmonary hypertension develops (see [Chap. 36](#), p. 871). In a study of 61 indomethacin-treated pregnant women, Vermillion and colleagues (1997) reported that half of exposed fetuses developed ductal constriction. Fortunately, this complication is largely reversible if medication is discontinued before 32 weeks (Moise, 1993).

Middle Cerebral Artery. Peak systolic velocity in the middle cerebral artery is increased with fetal anemia because of increased cardiac output and decreased blood viscosity (Segata and Mari, 2004). Velocity measurements are generally problematic because a high insonating angle introduces considerable error. Middle cerebral artery measurements are an exception, however, because the path of the artery often presents a very low angle of insonation.

Mari and colleagues (1995) performed velocity studies in 135 normal fetuses and 39 with alloimmunization. They reported that all anemic fetuses had peak systolic velocity above the normal mean. This prompted a collaborative study of 376 pregnancies by Mari and colleagues (2000). Using a threshold of 1.50 multiples of the median (MoM), they correctly identified all fetuses with moderate or severe anemia with a false-positive rate of 12 percent. Other investigators have since reported similar results (Abdel-Fattah, 2002; Bahado-Singh, 2000; Cosmi, 2002; Deren and Onderoglu, 2002, and all their associates).

It also has been hypothesized that Doppler evaluation of blood flow through cerebral vessels might be used to detect altered cerebral circulation before there is hypoxemia significant enough to alter the fetal heart rate pattern. The cerebroplacental ratio has been introduced as an indicator of brain sparing in fetuses with growth restriction and as a predictor of adverse perinatal outcome (Bahado-Singh and colleagues, 1999; Gramellini and associates, 1992). Currently, the American College of Obstetricians and Gynecologists (1999) considers antepartum surveillance with cerebral artery Doppler velocimetry to be investigational.

Uterine Artery. Uterine blood flow increases from 50 mL/min early in gestation to 500 to 750 mL/min by term. The uterine artery Doppler waveform is unique and characterized by high diastolic flow velocities similar to those in systole, and by highly turbulent flow, which displays a spectrum of many different velocities ([Fig. 16-21](#)). Increased resistance to flow and development of a diastolic notch have been associated with pregnancy-induced hypertension (Arduini, 1987; Fleischer, 1986; Harrington, 1996; North, 1994, and all their colleagues). In a recent study, Zeeman and co-authors (2003) confirmed that increased impedance of uterine artery velocimetry at 16 to 20 weeks was predictive of superimposed preeclampsia developing in women with chronic hypertension. Whether it will be clinically helpful to predict preeclampsia in this manner is yet unclear.

Figure 16-17. Doppler equation: ultrasound emanating from transducer with initial frequency f_0 strikes blood moving at velocity v . Reflected frequency f_d is dependent on angle θ between beam of sound and vessel. (From Copel and associates, 1988.)

Figure 16-18. Doppler systolic-diastolic waveform indices of blood flow velocity. The mean is calculated from computer-digitized waveforms. (D = diastole; S = systole.) (From Low, 1991, with permission.)

Figure 16-19. Doppler waveforms from normal pregnancy. Shown clockwise are normal waveforms from the maternal arcuate, uterine, and external iliac arteries, and from the fetal umbilical artery and descending aorta. Reversed end-diastolic flow velocity is apparent in the external iliac artery, whereas continuous diastolic flow characterizes the uterine and arcuate vessels. Finally, note the greatly diminished end-diastolic flow in the fetal descending aorta. (From Copel and colleagues, 1988.)

M-MODE ECHOCARDIOGRAPHY

The m-mode is a linear display of the events of the cardiac cycle in real-time. It is used commonly to measure the fetal heart rate, and any deviations from the normal rate and rhythm are readily apparent. If there is an abnormality, an evaluation of cardiac anatomy is performed. M-mode echocardiography may allow precise characterization of an arrhythmia, including separate evaluation of atrial and ventricular waveforms. It can further be used to assess ventricular wall function and functional atrial and ventricular outputs, as well as the timing of these events.

Accurate diagnosis is important because some arrhythmias, for example, supraventricular tachycardia, require medications to prevent or treat heart failure. Others, such as premature atrial contractions, resolve spontaneously without intervention. Antenatal treatment is discussed in [Chapter 13](#) (see p. 332).

SECTION IV - LABOR AND DELIVERY

17. Normal Labor and Delivery

INTRODUCTION

Normal Childbirth is the period from the onset of regular uterine contractions until expulsion of the placenta. The process by which this normally occurs is called *labor*—a term that in the obstetrical context takes on several connotations from the English language. According to the *New Shorter Oxford English Dictionary* (1993), toil, trouble, suffering, bodily exertion, especially when painful, and an outcome of work are all characteristics of *labor* and thus implicated in the process of childbirth. Such connotations all seem appropriate to us and emphasize the need for all attendants to be supportive of the laboring woman's needs, particularly in regard to effective pain relief.

At Parkland Hospital in 2003, only 53 percent of 12,139 women with singleton cephalic presentations at term had a spontaneous labor and delivery. The remainder had ineffective labor requiring augmentation (29 percent) or other medical and obstetrical complications requiring induction of labor. It seems excessive to consider almost 50 percent of parturients as "abnormal" because they did not spontaneously labor and deliver. Hence, the distinction between normal and abnormal is often subjective. This high prevalence of labor abnormalities, however, can be used to underscore the importance of labor events in the successful outcome of pregnancy.

MECHANISMS OF LABOR

At the onset of labor, the position of the fetus with respect to the birth canal is critical to the route of delivery. It is thus of paramount importance to know the fetal position within the uterine cavity at the onset of labor.

LIE, PRESENTATION, ATTITUDE, AND POSITION. Fetal orientation relative to the maternal pelvis is described in terms of fetal lie, presentation, attitude, and position.

Fetal Lie. The lie is the relation of the long axis of the fetus to that of the mother, and is either *longitudinal* or *transverse*. Occasionally, the fetal and the maternal axes may cross at a 45-degree angle, forming an *oblique* lie, which is unstable and always becomes longitudinal or transverse during the course of labor. Longitudinal lies are present in over 99 percent of labors at term. Predisposing factors for transverse lies include multiparity, placenta previa, hydramnios, and uterine anomalies.

Fetal Presentation. The presenting part is that portion of the fetal body that is either foremost within the birth canal or in closest proximity to it. It can be felt through the cervix on vaginal examination. Accordingly, in longitudinal lies, the presenting part is either the fetal head or breech, creating *cephalic* and *breech* presentations, respectively. When the fetus lies with the long axis transversely, the *shoulder* is the presenting part and is felt through the cervix on vaginal examination. [Table 17-1](#) describes the incidences of the various fetal presentations.

CEPHALIC PRESENTATION. Such presentations are classified according to the relationship between the head and body of the fetus ([Fig. 17-1](#)). Ordinarily, the head is flexed sharply so that the chin is in contact with the thorax. The occipital fontanel is the presenting part, and this presentation is referred to as a *vertex* or *occiput presentation*. Much less commonly, the fetal neck may be sharply extended so that the occiput and back come in contact and the face is foremost in the birth canal—*face presentation* (see [Fig. 20-6](#), p. 507). The fetal head may assume a position between these extremes, partially flexed in some cases, with the anterior (large) fontanel, or bregma, presenting—*sinciput presentation*—or partially extended in other cases to have a *brow presentation* (see [Fig. 20-9](#), p. 508). These latter two presentations are usually transient. As labor progresses, sinciput and brow presentations almost always are converted into vertex or face presentations by neck flexion or extension, respectively. Failure to do so can lead to dystocia, as discussed in [Chapter 20](#).

The term fetus usually presents with the vertex, most logically because the uterus is pear-shaped. Although the fetal head at term is slightly larger than the breech, the entire podalic pole of the fetus—that is, the breech and its flexed extremities—is bulkier and more mobile than the cephalic pole. The cephalic pole is composed of the fetal head only. Until about 32 weeks, the amniotic cavity is large compared with the fetal mass, and there is no crowding of the fetus by the uterine walls. Subsequently, however, the ratio of amniotic fluid volume decreases relative to the increasing fetal mass. As a result, the uterine walls are apposed more closely to the fetal parts.

If presenting by the breech, the fetus often changes polarity to make use of the roomier fundus for its bulkier and more mobile podalic pole. Although the incidence of breech presentation is only a little over 3 percent at term, it is much greater earlier in pregnancy. Scheer and Nubar (1976), using ultrasonography, found the incidence of breech presentation to be 14 percent between 29 and 32 weeks' gestation. Subsequently, the breech converted spontaneously to vertex in increasingly higher percentages as term approached. The high incidence of breech presentation in hydrocephalic fetuses is in accord with this theory, because in this circumstance, the cephalic pole of the fetus is larger than the podalic pole.

BREECH PRESENTATION. When the fetus presents as a breech, the three general configurations are frank, complete, and footling presentations. These all are described in [Chapter 24](#) on management of breech presentations. Breech presentation may result from circumstances that prevent normal version from taking place, for example, a septum that protrudes into the uterine cavity (see [Chap. 40](#), p. 953). A peculiarity of fetal attitude, particularly extension of the vertebral column as seen in frank breeches, also may prevent the fetus from turning. Placentas implanted in the lower uterine segment may distort normal intrauterine anatomy and result in a higher incidence of breech presentation.

Fetal Attitude or Posture. In the later months of pregnancy the fetus assumes a characteristic posture described as attitude or habitus (see [Fig. 17-1](#)). As a rule, the fetus forms an ovoid mass that corresponds roughly to the shape of the uterine cavity. The fetus becomes folded or bent upon itself in such a manner that the back becomes markedly convex; the head is sharply flexed so that the chin is almost in contact with the chest; the thighs are flexed over the abdomen; the legs are bent at

the knees; and the arches of the feet rest upon the anterior surfaces of the legs. In all cephalic presentations, the arms are usually crossed over the thorax or become parallel to the sides, and the umbilical cord lies in the space between them and the lower extremities. This characteristic posture results from the mode of growth of the fetus and its accommodation to the uterine cavity.

Abnormal exceptions to this attitude occur as the fetal head becomes progressively more extended from the vertex to the face presentation (see Fig. 17-1D). This results in a progressive change in fetal attitude from a convex (flexed) to a concave (extended) contour of the vertebral column.

Fetal Position. Position refers to the relationship of an arbitrarily chosen portion of the fetal presenting part to the right or left side of the maternal birth canal. Accordingly, with each presentation there may be two positions, right or left. The fetal occiput, chin (mentum), and sacrum are the determining points in vertex, face, and breech presentations, respectively (Figs. 17-2, 17-3, 17-4, 17-5, and 17-6). Because the presenting part may be in either the left or right position, there are left and right occipital, left and right mental, and left and right sacral presentations, abbreviated as LO and RO, LM and RM, and LS and RS, respectively.

Varieties of Presentations and Positions. For still more accurate orientation, the relationship of a given portion of the presenting part to the anterior, transverse, or posterior portion of the maternal pelvis is considered. Because the presenting part in right or left positions may be directed anteriorly (A), transversely (T), or posteriorly (P), there are six varieties of each of the three presentations (see Figs. 17-2, 17-3, 17-4, 17-5, and 17-6). Thus, in an occiput presentation, the presentation, position, and variety may be abbreviated in clockwise fashion as:

Approximately two thirds of all vertex presentations are in the left occiput position, and one third in the right. In shoulder presentations, the acromion (scapula) is the portion of the fetus arbitrarily chosen for orientation with the maternal pelvis. One example of the terminology sometimes employed for this purpose is illustrated in Figure 17-7. The acromion or back of the fetus may be directed either posteriorly or anteriorly and superiorly or inferiorly (see Chap. 20, p. 509). Because it is impossible to differentiate exactly the several varieties of shoulder presentation by clinical examination, and because such differentiation serves no practical purpose, it is customary to refer to all transverse lies simply as *shoulder presentations*. Another term used is *transverse lie*, with back up or back down.

Figure 17-1. Longitudinal lie. Cephalic presentation. Differences in attitude of the fetal body in (A) vertex, (B) sinciput, (C) brow, and (D) face presentations. Note changes in fetal attitude in relation to fetal vertex as the fetal head becomes less flexed.

Figure 20-9. Brow posterior presentation.

DIAGNOSIS OF FETAL PRESENTATION AND POSITION. Several methods can be used to diagnose fetal presentation and position. These include abdominal palpation, vaginal examination, auscultation, and, in certain doubtful cases, imaging studies such as ultrasonography, computed tomography, or magnetic resonance imaging.

Abdominal Palpation — **Leopold Maneuvers.** Abdominal examination can be conducted systematically employing the four maneuvers described by Leopold and Sporlin in 1894 and shown in [Figure 17-8](#). The mother should be supine and comfortably positioned with her abdomen bared. These maneuvers may be difficult if not impossible to perform and interpret if the patient is obese, if there is excessive amniotic fluid, or if the placenta is anteriorly implanted.

FIRST MANEUVER. This maneuver permits identification of which fetal pole — that is, breech or head — occupies the uterine fundus. The breech gives the sensation of a large, nodular mass, whereas the head feels hard and round and is more mobile and ballotable.

SECOND MANEUVER. After determination of the fetal lie, palms are placed on either side of the maternal abdomen, and gentle but deep pressure is exerted. On one side, a hard, resistant structure is felt — the back — and on the other, numerous small, irregular, mobile parts are felt — the fetal extremities. By noting whether the back is directed anteriorly, transversely, or posteriorly, the orientation of the fetus can be determined.

THIRD MANEUVER. Using the thumb and fingers of one hand, the lower portion of the maternal abdomen is grasped just above the symphysis pubis. If the presenting part is not engaged, a movable mass will be felt, usually the head. The differentiation between head and breech is made as in the first maneuver. If the presenting part is deeply engaged, however, the findings from this maneuver are simply indicative that the lower fetal pole is in the pelvis, and details are then defined by the last (fourth) maneuver.

FOURTH MANEUVER. The examiner faces the mother's feet and, with the tips of the first three fingers of each hand, exerts deep pressure in the direction of the axis of the pelvic inlet. In many instances, when the head has descended into the pelvis, the anterior shoulder may be differentiated readily by the third maneuver.

Abdominal palpation can be performed throughout the latter months of pregnancy and during and between the contractions of labor. With experience, it is possible to estimate the size of the fetus. According to Lydon-Rochelle and colleagues (1993), experienced clinicians accurately identify fetal malpresentation using Leopold maneuvers with a high sensitivity (88 percent), specificity (94 percent), positive-predictive value (74 percent), and negative-predictive value (97 percent).

Vaginal Examination. Before labor, the diagnosis of fetal presentation and position by vaginal examination is often

inconclusive, because the presenting part must be palpated through a closed cervix and lower uterine segment. With the onset of labor and after cervical dilatation, vertex presentations and their positions are recognized by palpation of the various sutures and fontanel. Face and breech presentations are identified by palpation of the facial features and the fetal sacrum, respectively.

In attempting to determine presentation and position by vaginal examination, it is advisable to pursue a definite routine, comprising four movements:

1. Two fingers of a gloved hand are introduced into the vagina and carried up to the presenting part. The differentiation of vertex, face, and breech is then accomplished readily.
2. If the vertex is presenting, the fingers are directed into the posterior aspect of the vagina. The fingers are then swept forward over the fetal head toward the maternal symphysis ([Fig. 17-9](#)). During this movement, the fingers necessarily cross the fetal sagittal suture and its course is delineated.
3. The positions of the two fontanel then are ascertained. The fingers are passed to the most anterior extension of the sagittal suture, and the fontanel encountered there is examined and identified; then with a sweeping motion, the fingers pass along the suture to the other end of the head until the other fontanel is felt and differentiated ([Fig. 17-10](#)).
4. The station, or extent to which the presenting part has descended into the pelvis, can also be established at this time (see p. 426). Using these maneuvers, the various sutures and fontanel are located readily ([Fig. 4-8](#), p. 96).

Auscultation. Although auscultation alone with an aural fetoscope does not provide reliable information concerning fetal presentation and position, auscultatory findings sometimes reinforce results obtained by palpation. The region of the maternal abdomen in which fetal heart sounds are most clearly heard varies according to the presentation and the extent to which the presenting part has descended.

Ultrasonography and Radiography. Ultrasonographic techniques can aid identification of fetal position, especially in obese women or in women with rigid abdominal walls. In some clinical situations, the value of information obtained radiographically far exceeds the minimal risk from a single x-ray exposure (see [Chap. 41](#), p. 977).

Figure 17-10. Differentiating the fontanel by vaginal examination.

LABOR WITH OCCIPUT PRESENTATIONS. In the majority of cases, the vertex enters the pelvis with the sagittal suture lying in the transverse pelvic diameter. The fetus enters the pelvis in the *left occiput transverse (LOT)* position in 40 percent of labors and in the *right occiput transverse (ROT)* position in 20 percent (Caldwell and associates, 1934). In *occiput anterior positions (LOA or ROA)*, the head either enters the pelvis with the occiput rotated 45 degrees anteriorly from the transverse position, or subsequently does so. The mechanism of labor in all these presentations is usually similar.

In about 20 percent of labors, the fetus enters the pelvis in an *occiput posterior (OP)* position. The right occiput posterior (ROP) is slightly more common than the left (LOP) (Caldwell and associates, 1934). It appears likely from radiographic evidence that posterior positions are more often associated with a narrow forepelvis. They also are more commonly seen in association with anterior placentation (Gardberg and Tuppurainen, 1994a).

Occiput Anterior Presentation. The positional changes in the presenting part required to navigate the pelvic canal constitute the *mechanisms of labor*. The *cardinal movements of labor* are engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion ([Fig. 17-11](#)). During labor, these movements are sequential but also show great temporal overlap. For example, as part of the process of engagement, there is both flexion and descent of the head. It is impossible for the movements to be completed unless the presenting part descends simultaneously. Concomitantly, uterine contractions effect important modifications in fetal attitude, or habitus, especially after the head has descended into the pelvis. These

changes consist principally of a straightening of the fetus, with loss of dorsal convexity and closer application of the extremities to the body. As a result, the fetal ovoid is transformed into a cylinder, with the smallest possible cross section typically passing through the birth canal.

ENGAGEMENT. The mechanism by which the biparietal diameter, the greatest transverse diameter of the fetal head in occiput presentations, passes through the pelvic inlet is designated *engagement*. The fetal head may engage during the last few weeks of pregnancy or not until after the commencement of labor. In many multiparous and some nulliparous women, the fetal head is freely movable above the pelvic inlet at the onset of labor. In this circumstance, the head is sometimes referred to as "floating." A normal-sized head usually does not engage with its sagittal suture directed anteroposteriorly. Instead, the fetal head usually enters the pelvic inlet either transversely or obliquely.

ASYNCLITISM. Although the fetal head tends to accommodate to the transverse axis of the pelvic inlet, the sagittal suture, while remaining parallel to that axis, may not lie exactly midway between the symphysis and the sacral promontory. The sagittal suture frequently is deflected either posteriorly toward the promontory or anteriorly toward the symphysis ([Fig. 17-12](#)). Such lateral deflection of the head to a more anterior or posterior position in the pelvis is called *asynclitism*. If the sagittal suture approaches the sacral promontory, more of the anterior parietal bone presents itself to the examining fingers, and the condition is called *anterior asynclitism*. If, however, the sagittal suture lies close to the symphysis, more of the posterior parietal bone will present, and the condition is called *posterior asynclitism*. With extreme posterior asynclitism, the posterior ear may be easily palpated.

Moderate degrees of asynclitism are the rule in normal labor, but if severe, the condition may lead to cephalopelvic disproportion even with an otherwise normal-sized pelvis. Successive shifting from posterior to anterior asynclitism aids descent.

DESCENT. This movement is the first requisite for birth of the newborn. In nulliparas, engagement may take place before the onset of labor, and further descent may not follow until the onset of the second stage. In multiparous women, descent usually begins with engagement. Descent is brought about by one or more of four forces: (1) pressure of the amniotic fluid, (2) direct pressure of the fundus upon the breech with contractions, (3) bearing down efforts of maternal abdominal muscles, and (4) extension and straightening of the fetal body.

FLEXION. As soon as the descending head meets resistance, whether from the cervix, walls of the pelvis, or pelvic floor, flexion of the head normally results. In this movement, the chin is brought into more intimate contact with the fetal thorax, and the appreciably shorter suboccipitobregmatic diameter is substituted for the longer occipitofrontal diameter ([Figs. 17-13 and 17-14](#)).

INTERNAL ROTATION. This movement consists of a turning of the head in such a manner that the occiput gradually moves toward the symphysis pubis anteriorly from its original position or, less commonly, posteriorly toward the hollow of the sacrum ([Figs. 17-15, 17-16, and 17-17](#)). Internal rotation is essential for the completion of labor, except when the fetus is unusually small.

Calkins (1939) studied more than 5000 women in labor to the time of internal rotation. He concluded that in approximately two thirds, internal rotation is completed by the time the head reaches the pelvic floor; in about one fourth, internal rotation is completed very shortly after the head reaches the pelvic floor; and in about 5 percent, anterior rotation does not take place. When the head fails to turn until reaching the pelvic floor, it typically rotates during the next one or two contractions in multiparas. In nulliparas, rotation usually occurs during the next three to five contractions.

EXTENSION. After internal rotation, the sharply flexed head reaches the vulva and undergoes extension. If the sharply flexed head, on reaching the pelvic floor, did not extend but was driven farther downward, it would impinge on the posterior portion of the perineum and would eventually be forced through the tissues of the perineum. When the head presses upon the pelvic floor, however, two forces come into play. The first, exerted by the uterus, acts more posteriorly, and the second, supplied by the resistant pelvic floor and the symphysis, acts more anteriorly. The resultant vector is in the direction of the vulvar opening, thereby causing head extension. This brings the base of the occiput into direct contact with the inferior margin of the symphysis pubis (see [Fig. 17-16](#)).

With progressive distention of the perineum and vaginal opening, an increasingly larger portion of the occiput gradually appears. The head is born as the occiput, bregma, forehead, nose, mouth, and finally the chin pass successively over the anterior margin of the perineum (see [Fig. 17-17](#)). Immediately after its delivery, the head drops downward so that the chin lies over the maternal anal region.

EXTERNAL ROTATION. The delivered head next undergoes *restitution*. If the occiput was originally directed toward the left, it rotates toward the left ischial tuberosity; if it was originally directed toward the right, the occiput rotates to the right. Restitution of the head to the oblique position is followed by completion of external rotation to the transverse position, a movement that corresponds to rotation of the fetal body, serving to bring its bisacromial diameter into relation with the anteroposterior diameter of the pelvic outlet. Thus, one shoulder is anterior behind the symphysis and the other is posterior. This movement apparently is brought about by the same pelvic factors that produced internal rotation of the head.

EXPULSION. Almost immediately after external rotation, the anterior shoulder appears under the symphysis pubis, and the perineum soon becomes distended by the posterior shoulder. After delivery of the shoulders, the rest of the body quickly passes.

Occiput Posterior Position. In the great majority of labors in the occiput posterior positions, the mechanism of labor is identical to that observed in the transverse and anterior varieties, except that the occiput has to internally rotate to the symphysis pubis through 135 degrees, instead of 90 and 45 degrees, respectively (see [Fig. 17-17](#)).

With effective contractions, adequate flexion of the head, and a fetus of average size, the great majority of posteriorly positioned occiputs rotate promptly as soon as they reach the pelvic floor, and labor is not lengthened appreciably. In perhaps 5 to 10 percent of cases, however, rotation may be incomplete or may not take place at all, especially if the fetus is large (Gardberg and Tuppurainen, 1994b). Poor contractions, faulty flexion of the head, or epidural analgesia, which diminishes

abdominal muscular pushing and relaxes the muscles of the pelvic floor, may predispose to incomplete rotation. If rotation is incomplete, transverse arrest results. If no rotation toward the symphysis takes place, the occiput may remain in the direct occiput posterior position, a condition known as *persistent occiput posterior*. Both persistent occiput posterior and transverse arrest represent deviations from the normal mechanisms of labor and are considered further in [Chapter 20](#).

CHANGES IN SHAPE OF THE FETAL HEAD

Caput Succedaneum. In vertex presentations, the fetal head changes shape as the result of labor forces. In prolonged labors before complete cervical dilatation, the portion of the fetal scalp immediately over the cervical os becomes edematous, forming a swelling known as the *caput succedaneum* (Figs. 17-18 and 17-19). It usually attains a thickness of only a few millimeters, but in prolonged labors it may be sufficiently extensive to prevent the differentiation of the various sutures and fontanelles. More commonly the caput is formed when the head is in the lower portion of the birth canal and frequently only after the resistance of a rigid vaginal outlet is encountered. Because it develops over the most dependent area of the head, one may deduce the original fetal head position by noting the location of the caput succedaneum.

Molding. The change in fetal head shape from external compressive forces is referred to as *molding*. Possibly related to Braxton Hicks contractions, some molding develops before labor. Although taught in previous editions, most studies indicate that there is seldom overlapping of the parietal bones. A "locking" mechanism at the coronal and lambdoidal connections actually prevents such overlapping (Carlan and colleagues, 1991). Molding results in a shortened suboccipitobregmatic

diameter and a lengthened mentovertical diameter. These changes are of greatest importance in women with contracted pelves or asynclitic presentations. In these circumstances, the degree to which the head is capable of molding may make the difference between spontaneous vaginal delivery versus an operative delivery. Some older literature cited severe head molding as a cause for possible cerebral trauma. Because of the multitude of associated factors, for example, prolonged labor with fetal sepsis and acidosis, it is impossible to quantify the effects of molding with any alleged fetal or neonatal neurological sequelae.

Figure 17-19. Considerable molding of the head and caput formation in a recently delivered newborn. The arrow is directed toward the caput succedaneum caused by appreciable scalp edema that overlies the occiput.

CHARACTERISTICS OF NORMAL LABOR

The greatest impediment to understanding normal labor is recognizing its start. The strict definition of labor — *uterine contractions that bring about demonstrable effacement and dilatation of the cervix* — does not easily aid the clinician in determining when labor has actually begun, because this diagnosis is confirmed only retrospectively. Several methods may be used to define its start. One quantifies onset as the clock time when painful contractions become regular. Unfortunately, uterine activity that causes discomfort, but that does not represent true labor, may develop at any time during pregnancy. False labor often stops spontaneously, or it may proceed rapidly into effective contractions.

A second method defines the onset of labor as beginning at the time of admission to the labor unit. At the National Maternity Hospital in Dublin, efforts have been made to codify admission criteria (O'Driscoll and colleagues, 1984). These criteria at term require painful uterine contractions accompanied by any one of the following: (1) ruptured membranes, (2) bloody "show," (3) complete cervical effacement.

In the United States, admission for labor is frequently based on the extent of dilatation accompanied by painful contractions. When a woman presents with intact membranes, cervical dilatation of 3 to 4 cm or greater is presumed to be a reasonably reliable threshold for the diagnosis of labor. In this case, onset of labor commences with the time of admission. This presumptive method obviates many of the uncertainties in diagnosing labor during earlier stages of cervical dilatation.

FIRST STAGE OF LABOR. Assuming that the diagnosis has been confirmed, then what are the expectations for the progress of normal labor? A scientific approach was begun by Friedman (1954), who described a characteristic sigmoid pattern for labor by graphing cervical dilatation against time. This graphic approach, based on statistical observations, changed labor management.

Friedman developed the concept of three functional divisions of labor to describe the physiological objectives of each division (Fig. 17-20). Although the cervix dilates little during the *preparatory division*, the connective tissue components of the cervix change considerably. Sedation and conduction analgesia are capable of arresting this division of labor. The *dilatational division*, during which time dilatation proceeds at its most rapid rate, is unaffected by sedation or conduction analgesia. The *pelvic division* commences with the deceleration phase of cervical dilatation. The classical mechanisms of labor that involve the cardinal fetal movements of the cephalic presentation — engagement, flexion, descent, internal rotation, extension, and external rotation — take place principally during the pelvic division. In actual practice, however, the onset of the pelvic division is seldom clearly identifiable.

As shown in Figure 17-20, the pattern of cervical dilatation during the preparatory and dilatational divisions of normal labor is a sigmoid curve. Two phases of cervical dilatation are defined. The *latent phase* corresponds to the preparatory division and the *active phase* to the dilatational division. Friedman subdivided the active phase into the *acceleration phase*, the *phase of maximum slope*, and the *deceleration phase* (Fig. 17-21).

Latent Phase. The onset of latent labor, as defined by Friedman (1972), is the point at which the mother perceives regular contractions. The latent phase for most women ends at between 3 and 5 cm of dilatation. This threshold may be clinically useful, for it defines cervical dilatation limits beyond which active labor can be expected.

Friedman and Sachtleben (1963) defined a *prolonged latent phase* as being greater than 20 hours in the nullipara and 14 hours in the multipara. These are the 95th percentiles. Factors that affect duration of the latent phase include excessive sedation or epidural analgesia; unfavorable cervical condition, that is, thick, uneffaced, or undilated; and false labor. Following strong sedation, 85 percent of women progress to active labor. Another 10 percent cease contracting, and thus had false labor. Finally, 5 percent experience persistence of an abnormal latent phase and require oxytocin stimulation. Amniotomy was discouraged because of the 10 percent incidence of false labor. Sokol and colleagues (1977) reported a 3- to 4-percent incidence of prolonged latent phase, regardless of parity. Friedman (1972) reported that prolongation of the latent phase did not adversely influence fetal or maternal morbidity or mortality, but Chelmow and co-workers (1993) disputed the long-held belief that prolongation of the latent phase is benign.

This concept of a latent phase has great significance in understanding normal human labor because labor is considerably longer

when a latent phase is included. To better illustrate this, [Figure 17-22](#) shows eight labor curves from nulliparas in whom labor was diagnosed beginning with their admission, rather than with the onset of regular contractions. When labor is defined similarly, there is remarkable similarity of individual labor curves.

Active Labor. As shown in [Figure 17-22](#), the progress of labor in nulliparous women has particular significance because these curves all reveal a rapid change in the slope of cervical dilatation rates between 3 and 5 cm. **Thus, cervical dilatation of 3 to 5 cm or more, in the presence of uterine contractions, can be taken to reliably represent the threshold for active labor.** Similarly, these curves provide useful guideposts for labor management.

Turning again to Friedman (1955), the mean duration of active-phase labor in nulliparas was 4.9 hours. The standard deviation of 3.4 hours is quite large. Hence, the active phase was reported to have a statistical maximum of 11.7 hours. Indeed, rates of cervical dilatation ranged from a minimum of 1.2 up to 6.8 cm/hr. Friedman (1972) also found that multiparas progress somewhat faster in active-phase labor, with a minimum normal rate of 1.5 cm/hr. His analysis of active-phase labor concomitantly describes rates of fetal descent and cervical dilatation (see [Fig. 17-20](#)). Descent begins in the later stage of active dilatation, commencing at about 7 to 8 cm in nulliparas and becoming most rapid after 8 cm.

Active-labor phase abnormalities are quite common. Sokol and co-workers (1977) reported that 25 percent of nulliparous labors were complicated by active-phase abnormalities, whereas 15 percent of multigravidas developed this problem.

Friedman (1972) subdivided active-phase problems into *protraction* and *arrest* disorders. He defined protraction as a *slow rate* of cervical dilatation or descent, which for nulliparas was less than 1.2 cm dilatation per hour or less than 1 cm descent per hour. For multiparas, protraction was defined as less than 1.5 cm dilatation per hour or less than 2 cm descent per hour. He defined arrest as a *complete cessation* of dilatation or descent. *Arrest of dilatation* was defined as 2 hours with no cervical change, and *arrest of descent* as 1 hour without fetal descent.

The prognosis for protraction and arrest disorders differed considerably. Friedman found that about 30 percent of women with protraction disorders had cephalopelvic disproportion, compared with 45 percent of women in whom an arrest disorder developed. Abnormal labor patterns, diagnostic criteria, and treatment methods according to Cohen and Friedman (1983) are summarized in [Table 20-3](#) (see p. 500).

Factors contributing to both protraction and arrest disorders were excessive sedation, vaginal analgesia, and fetal malposition. In both protraction and arrest disorders, Friedman recommended fetopelvic examination to diagnose cephalopelvic disproportion. Recommended therapy for protraction disorders was expectant management, whereas oxytocin was advised for arrest disorders in the absence of cephalopelvic disproportion.

Remarkably, of the 500 women studied, only 2 percent had cesarean deliveries. Hence, the great majority of active-phase disorders did not result in cesarean delivery. This fact must be kept in mind when considering the significance of various labor abnormalities described by Friedman.

Hendricks and co-workers (1970) challenged Friedman's conclusions about the course of normal human labor. Their principal differences included (1) absence of a latent phase, (2) no deceleration phase, (3) brevity of labor, (4) dilatation at similar rates for nulliparas and multiparas after 4 cm. They disputed the concept of a latent phase because they observed that the cervix dilated and effaced slowly during the 4 weeks preceding labor. According to them, the "latent phase" actually progressed over several weeks. These investigators did observe that labor was relatively rapid; specifically, the average time from admission to complete dilatation was 4.8 hours for nulliparas and 3.2 hours for multiparas.

There have been several reports in which investigators have reassessed Friedman's labor curves. Zhang and colleagues (2002) plotted detailed labor data from 1329 nulliparous women in spontaneous labor at term. The average labor curve differed markedly from the Friedman curve. The cervix dilated more slowly in the active phase, and it took 5.5 hours to progress from 4 cm to 10 cm compared with 2.5 hours in the Friedman curve. Alexander and colleagues (2002), in a study performed at Parkland Hospital, found that epidural analgesia lengthened the active phase of the Friedman labor curve by 1 hour. This increase was the result of a slightly slower but significant rate of cervical dilatation of 1.4 cm/hr in women given epidural analgesia compared with 1.6 cm/hr in those without such analgesia. Gurewitsch and colleagues (2002, 2003) studied the labor and descent curves of women with greater and lesser parity. They concluded that poor progress from 4 to 6 cm should not be considered abnormal and that women with high parity should not be expected to progress faster than those with lower parity.

Figure 17-20. Labor course divided functionally on the basis of dilatation and descent curves into (1) a preparatory division, including latent and acceleration phases; (2) a dilatational division, occupying the phase of maximum slope of dilatation; and (3) a pelvic division, encompassing both deceleration phase and second stage concurrent with the phase of maximum slope of descent. (Illustration courtesy of Dr. L. Casey; redrawn from Friedman, 1978.)

Figure 17-21. Composite of the average dilatation curve for nulliparous labor. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts that include an acceleration phase, a linear phase of maximum slope, and a deceleration phase. (Illustration courtesy of Dr. L. Casey; redrawn from Friedman, 1978.)

Figure 17-22. Progress of labor in primigravid women from the time of admission. When the starting point on the abscissa begins with admission to the hospital, a latent phase is not observed.

SECOND STAGE OF LABOR. This stage begins when cervical dilatation is complete and ends with fetal delivery. The median duration is about 50 minutes for nulliparas and about 20 minutes for multiparas, but it can be highly variable (Kilpatrick and Laros, 1989). In a woman of higher parity with a previously dilated vagina and perineum, two or three expulsive efforts after full cervical dilatation may suffice to complete delivery. Conversely, in a woman with a contracted pelvis or a large fetus or with impaired expulsive efforts from conduction analgesia or sedation, the second stage may become abnormally long. Abnormalities of the second stage of labor are described in [Chapter 20](#) (see p. 498).

DURATION OF LABOR. Our understanding of the normal duration of human labor may be clouded by the many clinical variables that affect conduct of labor in modern obstetrical units. Kilpatrick and Laros (1989) reported that the mean length of first- and second-stage labor was approximately 9 hours in nulliparous women without regional analgesia, and that the 95th percentile upper limit was 18.5 hours. Corresponding times for multiparous women were a mean of about 6 hours with a 95th percentile maximum of 13.5 hours. These authors defined labor onset as the time when a woman recalled regular, painful contractions every 3 to 5 minutes that led to cervical change.

Spontaneous labor was analyzed in nearly 25,000 women delivered at term at Parkland Hospital in the early 1990s. Almost 80 percent of women were admitted with a cervical dilatation of 5 cm or less. Parity ¶— nulliparous versus multiparous ¶— and cervical dilatation at admission were significant determinants of the length of spontaneous labor. The median time from admission to spontaneous delivery for all parturients was 3.5 hours, and 95 percent of all women delivered within 10.1 hours. These results suggest that normal human labor is relatively short.

SUMMARY OF NORMAL LABOR. Labor is characterized by brevity and considerable biological variation. Active labor can be reliably diagnosed when cervical dilatation is 3 cm or more in the presence of uterine contractions. Once this cervical dilatation threshold is reached, normal progress to delivery can be expected, depending on parity, in the ensuing 4 to 6 hours. Anticipated progress during a 1- to 2-hour second stage is monitored to ensure fetal safety. Finally, most women in spontaneous labor, regardless of parity and if left unaided, will deliver within approximately 10 hours after admission for spontaneous labor. Insufficient uterine activity is a common and correctable cause of abnormal labor progress. **Therefore, when time breaches in normal labor boundaries are the only pregnancy complications, interventions other than cesarean delivery must be considered before resorting to this method of delivery for failure to progress.**

MANAGEMENT OF NORMAL LABOR AND DELIVERY

The ideal management of labor and delivery requires two potentially opposing viewpoints on the part of clinicians. First, birthing should be recognized as a normal physiological process that most women experience without complications. Second, intrapartum complications, often arising quickly and unexpectedly, should be anticipated. Thus, clinicians must simultaneously make every woman and her supporters feel comfortable, yet ensure safety for the mother and newborn should complications suddenly develop. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have collaborated in the development of *Guidelines for Perinatal Care*. These provide detailed information on the appropriate content of intrapartum care, including both personnel and facility requirements. Shown in [Table 17-2](#) are the recommended nurse-to-patient ratios recommended for labor and delivery. Shown in [Table 17-3](#) are the recommended room dimensions for these functions.

ADMISSION PROCEDURES. Pregnant women should be urged to report early in labor rather than to procrastinate until delivery is imminent for fear that they might be experiencing false labor. Early admittance to the labor and delivery unit is important, especially if during antepartum care the woman, her fetus, or both have been identified as being at risk.

Identification of Labor. Although the differential diagnosis between false and true labor is difficult at times, it usually can be made on the basis of the contractions, as follows:

True Labor

- ¶• Contractions occur at regular intervals.
- ¶• Intervals gradually shorten.
- ¶• Intensity gradually increases.
- ¶• Discomfort is in the back and abdomen.
- ¶• Cervix dilates.
- ¶• Discomfort is not stopped by sedation.

False Labor

- ¶• Contractions occur at irregular intervals.
- ¶• Intervals remain long.
- ¶• Intensity remains unchanged.
- ¶• Discomfort is chiefly in the lower abdomen.
- ¶• Cervix does not dilate.
- ¶• Discomfort usually is relieved by sedation.

In those instances when a diagnosis of labor cannot be established with certainty, it is often wise to observe the woman for a longer period of time. The general condition of the mother and fetus should be ascertained accurately by history and physical examination, including blood pressure, temperature, and pulse. The frequency, duration, and intensity of the uterine contractions should be documented, and the time established when they first became uncomfortable. The degree of discomfort that the mother displays is noted. The heart rate, presentation, and size of the fetus should be determined and documented on admission (see [Chap. 18](#), p. 445). Inquiries are made about the status of the fetal membranes and whether there has been any vaginal bleeding. Questions of whether fluid has leaked from the vagina and, if so, how much and when the leakage first

commenced also are addressed.

Emergency Medical Treatment and Labor Act (EMTALA). In 1986, Congress enacted EMTALA to ensure public access to emergency services regardless of the ability to pay. All Medicare-participating hospitals with emergency services must provide an appropriate screening examination for any pregnant woman experiencing contractions who comes to the emergency department for evaluation. The most recent iteration of these regulations went into effect on November 10, 2003 (Federal Register, 2003).

The definition of an emergency condition makes specific reference to a pregnant woman who is having contractions. Labor is defined as ". . . the process of childbirth beginning with the latent phase of labor continuing through delivery of the placenta. A woman experiencing contractions is in true labor unless a physician certifies that after a reasonable time of observation the woman is in false labor." A woman in true labor is considered "unstable" for interhospital transfer purposes until the newborn and placenta are delivered. An unstable woman may, however, be transferred at the direction of the patient or when a physician certifies that the benefits of treatment at another facility outweigh the risks of transfer. Physicians and hospitals violating these federal requirements are subject to civil penalties of up to \$50,000 and termination from the Medicare program.

Preadmission and Admission Electronic Fetal Heart Rate Monitoring. As discussed in [Chapter 18](#), electronic fetal heart rate monitoring is routinely used for high-risk pregnancies commencing at admission. Some investigators recommend monitoring women with low-risk pregnancies upon admission as a test of fetal well-being—the so-called *fetal admission test*. If no fetal rate abnormalities are detected, continuous electronic monitoring is replaced by intermittent assessment for the remainder of labor. We are of the view that electronic fetal heart rate monitoring is reasonable in the preadmission evaluation of women who subsequently are discharged. At Parkland Hospital, external electronic monitoring is performed for at least 1 hour before discharging women with false labor.

Home Births. A major emphasis of obstetrical care during the 20th century was the movement to birthing in hospitals rather than in homes. In 2002, 99 percent of 4,021,720 births in the United States took place in hospitals (Martin and colleagues, 2003). A total of 22,980 births were in homes, and the remainder primarily in birthing centers. The results of studies comparing neonatal and perinatal mortality associated with intended home deliveries and with that of hospital deliveries have been conflicting, with most suggesting an increased risk with home delivery. Pang and co-workers (2002) analyzed birth registry information from Washington State during 1989 through 1997 and found that newborns of planned home deliveries were at increased risk of neonatal death. Moreover, prolonged labor and postpartum bleeding were increased in women giving birth at home.

Vital Signs and Review of Pregnancy Record. The maternal blood pressure, temperature, pulse, and respiratory rate are checked for any abnormality, and these are recorded. The pregnancy record is promptly reviewed to identify complications. Any problems identified during the antepartum period and any that were anticipated should be displayed prominently in the pregnancy record.

Vaginal Examination. Most often, *unless there has been bleeding in excess of bloody show*, a vaginal examination is performed. The gloved index and second fingers are then introduced into the vagina ([Fig. 17-23](#)). It is important to avoid the anal region and not to withdraw the fingers from the vagina until the examination is completed. The number of vaginal examinations during labor does correlate with infectious morbidity, especially in cases of early membrane rupture.

Detection of Ruptured Membranes. A pregnant woman should be instructed during the antepartum period to be aware of leakage of fluid from the vagina and to report such an event promptly. Rupture of the membranes is significant for three reasons. First, if the presenting part is not fixed in the pelvis, the possibility of umbilical cord prolapse and cord compression is greatly increased. Second, labor is likely to begin soon if the pregnancy is at or near term. Third, if delivery is delayed for 24 hours or more after membrane rupture, intrauterine infection is more likely.

Using sterile speculum examination, a conclusive diagnosis of rupture of the membranes is made when amniotic fluid is seen pooling in the posterior fornix or clear fluid is passing from the cervical canal (American College of Obstetricians and Gynecologists, 2000). Although several diagnostic tests for the detection of ruptured membranes have been recommended, none is completely reliable. If the diagnosis remains uncertain, another method involves testing the pH of the vaginal fluid. The pH of vaginal secretions normally ranges between 4.5 and 5.5, whereas that of amniotic fluid is usually 7.0 to 7.5. The use of the indicator *nitrazine* for the diagnosis of ruptured membranes is a simple and fairly reliable method. Test papers are impregnated with the dye, and the color of the reaction is interpreted by comparison with a standard color chart. A pH above 6.5 is consistent with ruptured membranes. False-positive test results may occur with coexistent blood, semen, or bacterial vaginosis and false-negative test results when fluid for analysis is scant (American College of Obstetricians and Gynecologists, 2000).

Other tests have been used as markers for rupture of the membranes. Arborization or ferning of vaginal fluid suggests amniotic rather than cervical fluid. If present, amniotic fluid crystallizes to form a fernlike pattern due to the relative concentrations of sodium chloride, proteins, and carbohydrates in the fluid. Detection of alpha-fetoprotein in the vaginal vault has been used to identify amniotic fluid (Yamada and colleagues, 1998). Unequivocal identification comes from injection of various dyes, including Evans blue, methylene blue, indigo carmine, or fluorescein, into the amniotic sac via abdominal amniocentesis.

Cervical Effacement. The degree of cervical effacement usually is expressed in terms of the length of the cervical canal compared with that of an uneffaced cervix. When the length of the cervix is reduced by one half, it is 50-percent effaced. When the cervix becomes as thin as the adjacent lower uterine segment, it is completely, or 100-percent, effaced.

Cervical Dilatation. This measurement is determined by estimating the average diameter of the cervical opening by sweeping the examining finger from the margin of the cervical opening on one side to that of the opposite side. The diameter traversed is estimated in centimeters. The cervix is said to be dilated fully when the diameter measures 10 cm, because the presenting part of a term-size newborn usually can pass through a cervix this widely dilated.

Position of the Cervix. The relationship of the cervical os to the fetal head is categorized as posterior, midposition, or anterior.

Station. The level of the presenting fetal part in the birth canal is described in relationship to the ischial spines, which are halfway between the pelvic inlet and the pelvic outlet. When the lowermost portion of the presenting fetal part is at the level of the ischial spines, it is designated as being at zero (0) station. In the past, the long axis of the birth canal above the ischial spines was arbitrarily divided into thirds. In 1988, the American College of Obstetricians and Gynecologists began using a classification of station that divides the pelvis above and below the spines into fifths. These divisions represent centimeters above and below the spines. Thus, as the presenting fetal part descends from the inlet toward the ischial spines, the designation is -5, -4, -3, -2, -1, then 0 station. Below the ischial spines, the presenting fetal part passes +1, +2, +3, +4, and +5 stations to delivery. Station +5 cm corresponds to the fetal head being visible at the introitus.

If the leading part of the fetal head is at the 0 station or below, most often the fetal head has engaged; that is, the biparietal plane of the fetal head has passed through the pelvic inlet. **If the head is unusually molded, or if there is an extensive caput formation, or both, engagement might not have taken place even though the head appears to be at 0 station.**

Laboratory Studies. When the woman is admitted in labor, most often the hematocrit or hemoglobin concentration should be rechecked. The hematocrit can be measured easily and quickly. At Parkland Hospital, blood is collected in a plain tube from which a heparinized capillary tube is filled immediately. By employing a small microhematocrit centrifuge in the labor and delivery unit, the value can be obtained in 3 minutes. A labeled tube of blood is allowed to clot and is kept available for blood type and screen, if needed, and another tube is used for routine serology. We obtain a urine specimen for protein analysis only in hypertensive women. In some labor units, a voided urine specimen, as free as possible of debris, is examined in all women for protein and glucose. Patients who have had no prenatal care should be considered to be at risk for syphilis, hepatitis B, and human immunodeficiency virus (HIV) (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002). In patients with no prior prenatal care, these laboratory studies, as well as a blood type and antibody screen, should be performed. Some states, for example Texas, now require routine testing for syphilis, hepatitis B, and HIV in all women admitted to labor and delivery units.

Figure 17-23. To perform vaginal examination, the labia have been separated with one hand and the first and second fingers of the other hand are carefully inserted into the introitus.

MANAGEMENT OF THE FIRST STAGE OF LABOR. As soon as possible after admittance, the remainder of the general physical examination is completed. The physician can best reach a conclusion about the normalcy of the pregnancy when all examinations, including record and laboratory review, are completed. A rational plan for monitoring labor then can be established based on the needs of the fetus and the mother. If no abnormality is identified or suspected, the mother should be reassured. Because there are marked individual variations in lengths of labor, any precise statement as to its anticipated duration is unwise.

Monitoring Fetal Well-Being During Labor. This subject is discussed in detail in [Chapter 18](#). Briefly, the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2002) recommend that during the first stage of labor, in the absence of any abnormalities, the fetal heart rate should be checked immediately after a contraction at least every 30 minutes and then every 15 minutes during the second stage. If continuous electronic monitoring is used, the tracing is evaluated at least every 30 minutes during the first stage and at least every 15 minutes during second-stage labor. For women with pregnancies at risk, auscultation is performed at least every 15 minutes during the first stage of labor and every 5 minutes during the second stage. Continuous electronic monitoring may be used with evaluation of the tracing every 15 minutes during the first stage of labor, and every 5 minutes during the second stage.

Uterine Contractions. Although usually assessed by electronic monitoring (see [Chap. 18](#), p. 466), contractions can be both quantitatively and qualitatively evaluated manually. With the palm of the hand resting lightly on the uterus, the examiner determines the time of onset of the contraction. The intensity of the contraction is gauged from the degree of firmness the uterus achieves. At the acme of effective contractions, the finger or thumb cannot readily indent the uterus—a "firm" contraction. Next, the time that the contraction disappears is noted. This sequence is repeated in order to evaluate the frequency, duration, and intensity of uterine contractions.

Maternal Vital Signs. Maternal temperature, pulse, and blood pressure are evaluated at least every 4 hours. If fetal membranes have been ruptured for many hours before the onset of labor, or if there is a borderline temperature elevation, the temperature is checked hourly. Moreover, with prolonged membrane rupture, defined as greater than 18 hours, antimicrobial administration for prevention of group B streptococcal infections is recommended. This is discussed in [Chapter 58](#) (see p. 1285).

Subsequent Vaginal Examinations. During the first stage of labor, the need for subsequent vaginal examinations to identify the status of the cervix and the station and position of the presenting part will vary considerably. When the membranes rupture, an examination should be performed expeditiously if the fetal head was not definitely engaged at the previous vaginal examination. The fetal heart rate should be checked immediately and during the next uterine contraction to help detect occult umbilical cord compression. At Parkland Hospital, periodic pelvic examinations are typically performed at 2- to 3-hour intervals to evaluate the progress of labor (see p. 439).

Oral Intake. Food should be withheld during active labor and delivery. Gastric emptying time is remarkably prolonged once labor is established and analgesics are administered. As a consequence, ingested food and most medications remain in the stomach and are not absorbed, instead, they may be vomited and aspirated (see [Chap. 19](#), p. 490). According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002), sips of clear liquids, occasional ice

chips, and lip moisturizers are permitted.

Intravenous Fluids. Although it has become customary in many hospitals to establish an intravenous infusion system routinely early in labor, there is seldom any real need for such in the normal pregnant woman at least until analgesia is administered. An intravenous infusion system is advantageous during the immediate puerperium to administer oxytocin prophylactically and at times therapeutically when uterine atony persists. Moreover, with longer labors, the administration of glucose, sodium, and water to the otherwise fasting woman at the rate of 60 to 120 mL/hr prevents dehydration and acidosis. Garite and colleagues (2000) randomly assigned 195 women in labor to receive either 125 or 250 mL/hr of lactated Ringer or isotonic sodium chloride solution. The mean volume of total intravenous fluid was 2008 mL in the 125 mL/hr group and 2487 mL in the 250 mL/hr group. Labor lasted more than 12 hours in significantly more (26 versus 13 percent) of the women given a 125 mL/hr infusion compared with those given 250 mL/hr.

Maternal Position During Labor. The normal laboring woman need not be confined to bed early in labor. A comfortable chair may be beneficial psychologically and perhaps physiologically. In bed, the laboring woman should be allowed to assume the position she finds most comfortable, which will be lateral recumbency most of the time. She must not be restricted to lying supine. Bloom and colleagues (1998) conducted a randomized trial of walking during labor in more than 1000 women with low-risk pregnancies. They found that walking neither enhanced nor impaired active labor and that it was not harmful.

Analgesia. This topic is discussed in detail in [Chapter 19](#). In general, pain relief should depend on the needs and desires of the woman. The American College of Obstetricians and Gynecologists (2001) has specified optimal goals for anesthesia care in obstetrics.

Amniotomy. If the membranes are intact, there is a great temptation even during normal labor to perform amniotomy. The presumed benefits are more rapid labor, earlier detection of meconium-stained amniotic fluid, and the opportunity to apply an electrode to the fetus or insert a pressure catheter into the uterine cavity. The advantages and disadvantages of amniotomy are discussed in [Chapter 22](#) (see p. 542). Importantly, the fetal head must be well applied to the cervix and not be dislodged from the pelvis during the procedure to avert umbilical cord prolapse.

Urinary Bladder Function. Bladder distention should be avoided, because it can hinder descent of the fetal presenting part and lead to subsequent bladder hypotonia and infection. During each abdominal examination, the suprapubic region should be inspected and palpated to detect distention. If the bladder is readily seen or palpated above the symphysis, the woman should be encouraged to void. At times she can ambulate with assistance to a toilet and successfully void, even though she could not void on a bedpan. If the bladder is distended and she cannot void, catheterization is indicated. Carley and colleagues (2002) found that 51 of 11,332 vaginal deliveries (1 in 200) were complicated by urinary retention. Risk factors included operative vaginal delivery and regional analgesia. Most women resumed normal voiding before discharge from the hospital.

MANAGEMENT OF THE SECOND STAGE OF LABOR. With full dilatation of the cervix, which signifies the onset of the second stage of labor, a woman typically begins to bear down, and with descent of the presenting part she develops the urge to defecate. Uterine contractions and the accompanying expulsive forces may last 1 1/2 minutes and recur at an interval no longer than 1 minute. As discussed on page 423, the median duration of the second stage is 50 minutes in nulliparas and 20 minutes in multiparas, but this interval can be highly variable. Monitoring of the fetal heart rate is discussed on page 427, and interpretation of second-stage electronic fetal heart rate patterns is discussed in [Chapter 18](#) (see p. 446).

Maternal Expulsive Efforts. In most cases, bearing down is reflexive and spontaneous during second-stage labor, but occasionally a woman may not employ her expulsive forces to good advantage and coaching is desirable. Her legs should be half-flexed so that she can push with them against the mattress. Instructions should be to take a deep breath as soon as the next uterine contraction begins, and with her breath held, to exert downward pressure exactly as though she were straining at stool. She should not be encouraged to "push" beyond the time of completion of each uterine contraction. Instead, she and her fetus should be allowed to rest and recover.

During this period of active bearing down, the fetal heart rate auscultated immediately after the contraction is likely to be slow, but should recover to normal range before the next expulsive effort. Gardosi and associates (1989) have recommended a squatting or semisquatting position using a specialized pillow. They claim that this shortens second-stage labor by increasing expulsive forces and by increasing the diameter of the pelvic outlet. Eason and colleagues (2000) performed an extensive review of positions and their effect on the incidence of perineal trauma. They found that the supported upright position had no advantages over the recumbent one.

As the head descends through the pelvis, feces frequently are expelled by the woman. With further descent, the perineum begins to bulge and the overlying skin becomes stretched. Now the scalp of the fetus may be visible through the vulvar opening. At this time, the woman and her fetus are prepared for delivery.

The benefits, or lack thereof, for coached pushing during the second stage of labor are discussed in [Chapter 20](#) (see p. 500).

Preparation for Delivery. Delivery can be accomplished with the mother in a variety of positions. The most widely used and often the most satisfactory one is the dorsal lithotomy position. At Parkland Hospital the lithotomy position is not mandated for normal deliveries. In many birthing rooms delivery is accomplished with the woman lying flat on the bed.

For better exposure, leg holders or stirrups are used. In placing the legs in leg holders, care should be taken not to separate the legs too widely or place one leg higher than the other, as this will exert pulling forces on the perineum that might easily result in the extension of a spontaneous tear or an episiotomy into a fourth-degree laceration. The popliteal region should rest comfortably in the proximal portion and the heel in the distal portion of the leg holder. The legs are not strapped into the stirrups, thereby allowing quick flexion of the thighs backward onto the abdomen should shoulder dystocia develop. The legs may cramp during the second stage, in part, because of pressure by the fetal head on nerves in the pelvis. Such cramps may be relieved by changing the position of the leg or by brief massage, but leg cramps should never be ignored.

Preparation for delivery should include vulvar and perineal cleansing. If desired, sterile drapes may be placed in such a way

that only the immediate area about the vulva is exposed. In the past, the major reason for care in scrubbing, gowning, and gloving was to protect the laboring woman from the introduction of infectious agents. Although these considerations remain valid, concern today also must be extended to the health care providers, because of the exposure threat to HIV.

SPONTANEOUS DELIVERY

Delivery of the Head. With each contraction, the perineum bulges increasingly, and the vulvovaginal opening becomes more dilated by the fetal head ([Fig. 17-24](#)), gradually forming an ovoid and finally an almost circular opening ([Fig. 17-25](#)). This encirclement of the largest head diameter by the vulvar ring is known as *crowning*.

Unless an episiotomy has been made, as described later in the chapter, the perineum thins and, especially in nulliparous women, may undergo spontaneous laceration. The anus becomes greatly stretched and protuberant, and the anterior wall of the rectum may be easily seen through it. Considerable controversy exists concerning whether an episiotomy should be cut. We advocate individualization and do not routinely cut an episiotomy. It is now clear that an episiotomy will increase the risk of a tear into the external anal sphincter or the rectum, or both. Conversely, anterior tears involving the urethra and labia are much more common in women in whom an episiotomy is not cut. This issue is discussed in detail on page 435.

RITGEN MANEUVER. When the head distends the vulva and perineum enough to open the vaginal introitus to a diameter of 5 cm or more, a towel-draped, gloved hand may be used to exert forward pressure on the chin of the fetus through the perineum just in front of the coccyx. Concurrently, the other hand exerts pressure superiorly against the occiput ([Fig. 17-26](#)). Although this maneuver is simpler than that originally described by Ritgen (1855), it is customarily designated the *Ritgen maneuver*, or the *modified Ritgen maneuver*.

This maneuver allows controlled delivery of the head ([Fig. 17-27](#)). It also favors extension, so that the head is delivered with its smallest diameters passing through the introitus and over the perineum. Mayerhofer and colleagues (2002) have challenged the use of the Ritgen maneuver on the grounds that this procedure was associated with more third-degree perineal lacerations and more frequent use of episiotomy. They preferred the "hands-poised" method, in which the attendant did not touch the perineum during delivery of the head. This method had similar associated laceration rates and neonatal outcomes as the modified Ritgen maneuver, but with a lower incidence of third-degree tears.

Delivery of the Shoulders. After its delivery, the fetal head falls posteriorly, bringing the face almost into contact with the maternal anus. As described on page 417, the occiput promptly turns toward one of the maternal thighs and the head assumes a transverse position ([Fig. 17-28](#)). This movement of restitution (external rotation) indicates that the bisacromial diameter (transverse diameter of the thorax) has rotated into the anteroposterior diameter of the pelvis.

Most often, the shoulders appear at the vulva just after external rotation and are born spontaneously. If delayed, immediate extraction may appear advisable. The sides of the head are grasped with two hands, and gentle downward traction is applied until the anterior shoulder appears under the pubic arch ([Fig. 17-29](#)). Some practitioners prefer to deliver the anterior shoulder prior to suctioning the nasopharynx or checking for a nuchal cord to avoid shoulder dystocia. Next, by an upward movement, the posterior shoulder is delivered (see [Fig. 17-29](#)).

The rest of the body almost always follows the shoulders without difficulty; but with prolonged delay, its birth may be hastened by moderate traction on the head and moderate pressure on the uterine fundus. Hooking the fingers in the axillae should be avoided because this may injure the nerves of the upper extremity, producing a transient or possibly even a permanent paralysis. Traction, furthermore, should be exerted only in the direction of the long axis of the neonate, for if applied obliquely it causes bending of the neck and excessive stretching of the brachial plexus.

Immediately after delivery of the newborn, there is usually a gush of amniotic fluid, often tinged with blood but not grossly bloody.

Clearing the Nasopharynx. To minimize aspiration of amniotic fluid, particulate matter, and blood once the thorax is delivered and the newborn can inspire, the face is quickly wiped and the nares and mouth are aspirated, as demonstrated in [Figure 17-28](#).

Nuchal Cord. Following delivery of the anterior shoulder, a finger should be passed to the fetal neck to determine whether it is encircled by one or more coils of the umbilical cord ([Fig. 17-30](#)). Nuchal cords are found in about 25 percent of deliveries and ordinarily do no harm. If a coil of umbilical cord is felt, it should be slipped over the head if loose enough. If applied too tightly, the loop should be cut between two clamps and the neonate promptly delivered.

Clamping the Cord. The umbilical cord is cut between two clamps placed 4 to 5 cm from the fetal abdomen, and later an umbilical cord clamp is applied 2 to 3 cm from the fetal abdomen. A plastic clamp (Double Grip Umbilical Clamp, Hollister) that is safe, efficient, and fairly inexpensive is used at Parkland Hospital.

TIMING OF CORD CLAMPING. If after delivery, the newborn is placed at or below the level of the vaginal introitus for 3 minutes and the fetoplacental circulation is not immediately occluded by clamping the cord, an average of 80 mL of blood may be shifted from the placenta to the neonate (Yao and Lind, 1974). This provides about 50 mg of iron, which reduces the frequency of iron deficiency anemia later in infancy.

Accelerated destruction of erythrocytes, as found with maternal alloimmunization, forms additional bilirubin from the added erythrocytes and contributes further to the danger of hyperbilirubinemia (see [Chap. 29](#), p. 667). Although the theoretical risk of circulatory overloading from gross hypervolemia is formidable, especially in preterm and growth-retarded neonates, the addition of placental blood to the otherwise normal newborn's circulation ordinarily does not cause difficulty.

Our policy is to clamp the cord after first thoroughly clearing the airway, all of which usually requires about 30 seconds. The newborn is not elevated above the introitus at vaginal delivery or much above the maternal abdominal wall at the time of cesarean delivery.

Figure 17-29. A. Gentle downward traction to effect descent of the anterior shoulder. **B.** Delivery of the anterior shoulder completed; gentle upward traction to deliver the posterior shoulder.

Figure 17-30. Cord identified around the neck. It readily slipped over the head.

MANAGEMENT OF THE THIRD STAGE OF LABOR. Immediately after delivery of the newborn, the size of the uterine fundus and its consistency are examined. If the uterus remains firm and there is no unusual bleeding, watchful waiting until the placenta separates is the usual practice. Massage is not employed, but the fundus is frequently palpated to make certain that the organ does not become atonic and filled with blood from placental separation.

Signs of Placental Separation. Because attempts to express the placenta prior to its separation are futile and possibly dangerous, the clinician should be alert to the following signs of placental separation:

1. The uterus becomes globular and, as a rule, firmer. This sign is the earliest to appear.
2. There is often a sudden gush of blood.
3. The uterus rises in the abdomen because the placenta, having separated, passes down into the lower uterine segment and vagina, where its bulk pushes the uterus upward.

4. The umbilical cord protrudes farther out of the vagina, indicating that the placenta has descended.

These signs sometimes appear within about 1 minute after delivery of the newborn and usually within 5 minutes. When the placenta has separated, it should be determined that the uterus is firmly contracted. The mother may be asked to bear down, and the intra-abdominal pressure may be adequate to expel the placenta. If these efforts fail, or if spontaneous expulsion is not possible because of anesthesia, then after ensuring that the uterus is contracted firmly, pressure is exerted with the hand on the fundus to propel the detached placenta into the vagina, as depicted and described in [Figure 17-31](#). This approach has been termed *physiological management*, as later contrasted with *active management* of the third stage (Thilaganathan and colleagues, 1993).

Delivery of the Placenta. Expression should never be forced before placental separation lest the uterus be turned inside out. **Traction on the umbilical cord must not be used to pull the placenta out of the uterus.** *Inversion* of the uterus is one of the grave complications associated with delivery (see [Chap. 35](#), p. 833). As downward pressure toward the vagina is applied to the body of the uterus, the umbilical cord is kept slightly taut (see [Fig. 17-31](#)). The uterus is then lifted cephalad with the abdominal hand. This maneuver is repeated until the placenta reaches the introitus (Prendiville and associates, 1988b). As the placenta passes through the introitus, pressure on the uterus is stopped. The placenta is then gently lifted away from the introitus ([Fig. 17-32](#)). Care is taken to prevent the membranes from being torn off and left behind. If the membranes start to tear, they are grasped with a clamp and removed by gentle teasing ([Fig. 17-33](#)). The maternal surface of the placenta should be examined carefully to ensure that no placental fragments are left in the uterus.

MANUAL REMOVAL OF PLACENTA. Occasionally, the placenta will not separate promptly. This is especially common in cases of preterm delivery (Dombrowski and colleagues, 1995). If there is brisk bleeding and the placenta cannot be delivered by the above technique, manual removal of the placenta is indicated, using the safeguards described in [Chapter 35](#). It is unclear as to the length of time that should elapse in the absence of bleeding before the placenta is manually removed. Manual removal of the placenta is practiced sooner and more often than in the past. Some obstetricians practice routine manual removal of any placenta that has not separated spontaneously by the time they have completed delivery of the newborn and care of the cord in women with conduction analgesia. Proof of the benefits of this practice, however, has not been established, and most obstetricians await spontaneous placental separation unless bleeding is excessive. The American College of Obstetricians and Gynecologists (2003b) has concluded that there are no data to either support or refute the use of prophylactic antimicrobials when manual removal of the placenta is performed.

Active Management of the Third Stage. Thilaganathan and associates (1993) compared a regimen of active management with syntometrine (5 units of oxytocin with 0.5 mg of ergometrine) and controlled cord traction with one of physiological management wherein the cord was not clamped and the placenta was delivered by maternal efforts. Among 103 low-risk term deliveries, active management resulted in a reduction in the length of the third stage of labor, but no reduction in blood loss compared with that of physiological management. Mitchell and Elbourne (1993) found that syntometrine administered intramuscularly concurrent with delivery of the anterior shoulder was more effective than oxytocin (5 units intramuscularly) alone in the prevention of postpartum hemorrhage. Duration of the third stage of labor and need for manual removal of the placenta were similar. Side effects of nausea, vomiting, and blood pressure elevations with ergometrine prevented any recommendation for its routine usage.

"Fourth Stage" of Labor. The placenta, membranes, and umbilical cord should be examined for completeness and for anomalies, as described in [Chapters 31](#) and [32](#). The hour immediately following delivery is critical, and it has been designated by some as the "fourth stage of labor." Even though oxytocics are administered, postpartum hemorrhage as the result of uterine atony is more likely at this time. Consequently, the uterus and perineum should be frequently evaluated. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) recommend that maternal blood pressure and pulse be recorded immediately after delivery and every 15 minutes for the first hour.

Oxytocic Agents. After the uterus has been emptied and the placenta has been delivered, the primary mechanism by which hemostasis is achieved at the placental site is vasoconstriction produced by a well-contracted myometrium. Oxytocin, methylergonovine maleate (Methergine), and prostaglandin analogues are employed in various ways, principally to reduce blood loss by stimulating myometrial contractions.

OXYTOCICS AFTER DELIVERY. Oxytocin, ergonovine, and methylergonovine are all employed widely in the normal third stage of labor, but the timing of their administration differs in various institutions. Oxytocin, and especially ergonovine, given before delivery of the placenta will decrease blood loss (Prendiville and associates, 1988a). There is, however, a significant danger associated with this practice. The use of oxytocin, and especially ergonovine or methylergonovine, before delivery of the placenta may entrap an undiagnosed, undelivered second twin. This may prove injurious, if not fatal, to the entrapped fetus. In most cases following uncomplicated vaginal delivery, the third stage of labor can be conducted with reasonably small blood loss without using these agents before delivery of the placenta.

Several studies have evaluated the use of these agents. Jackson and colleagues (2001) randomly assigned 1486 women to infusions of 20 units of oxytocin diluted in 500 mL normal saline begun before or after delivery of the placenta. There were no benefits to beginning oxytocin before delivery of the placenta. Choy and co-authors (2002) randomly assigned 991 women to receive intravenous oxytocin or intramuscular syntometrine for prevention of third-stage blood loss. They reported oxytocin to be preferable because syntometrine induced hypertension in 3 percent of women. Munn and co-workers (2001) compared two oxytocin dosage regimens for prevention of uterine atony at cesarean delivery. Either 10 units or 80 units of oxytocin in 500 mL of lactated Ringer solution were infused during the 30 minutes following delivery of the newborn. The rate of uterine atony was significantly lower in the high-dose regimen group compared with that of the lower-dose group—19 versus 39 percent, respectively.

If an intravenous infusion is in place, our standard practice has been to add 20 units (2 mL) of oxytocin per liter of infusate. This solution is administered after delivery of the placenta at a rate of 10 mL/min (200 mU/min) for a few minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate then is reduced to 1 to 2 mL/min until the mother is ready for transfer from the recovery suite to the postpartum unit. The infusion is usually then discontinued.

OXYTOCIN. The synthetic form of the octapeptide oxytocin is commercially available in the United States as Syntocinon and

Pitocin. Each milliliter of injectable oxytocin, which is not effective by mouth, contains 10 USP units. The half-life of intravenously infused oxytocin is approximately 3 minutes.

Before delivery, the spontaneously laboring uterus is typically exquisitely sensitive to oxytocin. With an inappropriate dose of oxytocin, the pregnant uterus may contract so violently as to kill the fetus, rupture itself, or both (see [Chap. 22](#), p. 541). After delivery of the fetus, these dangers no longer exist.

Cardiovascular Effects. Secher and co-workers (1978) consistently observed that, even in healthy women, an intravenous bolus of 10 units of oxytocin caused a transient but marked fall in arterial blood pressure that was followed by an abrupt increase in cardiac output. They concluded that these hemodynamic changes could be dangerous to women already hypovolemic from hemorrhage or who had cardiac disease that limited cardiac output. The same danger is present for women with right-to-left cardiac shunts, because the decrease in systemic resistance would further increase the shunt. **Oxytocin should not be given intravenously as a large bolus**, but rather as a much more dilute solution by continuous intravenous infusion or as an intramuscular injection in a dose of 10 USP units. In cases of postpartum hemorrhage, direct injection into the uterus, either transvaginally or transabdominally, if following a vaginal birth, or directly if at cesarean delivery, has proven effective. The use of nipple stimulation in the third stage of labor also has been shown to increase uterine pressures and to decrease the duration of the third stage of labor and blood loss (Irons and associates, 1994). Indeed, results were similar to those achieved using the combination of oxytocin (5 units) and ergometrine (0.5 mg).

Water Intoxication. The considerable antidiuretic action of oxytocin can cause water intoxication. With high-dose oxytocin, it is possible to produce water intoxication if the oxytocin is administered in a large volume of electrolyte-free aqueous dextrose solution (Whalley and Pritchard, 1963). For example, Schwartz and Jones (1978) described convulsions in both the mother and her newborn following the administration of 6.5 liters of 5-percent dextrose solution and 36 units of oxytocin predelivery. The concentration of sodium in cord plasma was 114 mEq/L.

In general, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the rate of flow of a more dilute solution (see [Chap. 22](#), p. 540). Consideration also should be given to use of either normal saline or lactated Ringer solution in these circumstances.

ERGONOVINE AND METHYLERGONOVINE. Ergonovine is an alkaloid that is obtained from ergot, a fungus that grows on rye and some other grains, or is synthesized in part from lysergic acid. Methylergonovine is a similar synthetic alkaloid made from lysergic acid. There is no convincing evidence of any appreciable difference in the actions of methylergonovine compared with those of ergonovine, also called ergometrine and ergostetrine. Whether given intravenously, intramuscularly, or orally, these agents are powerful stimulants of myometrial contraction, exerting an effect that may persist for hours. In pregnant women, an intravenous dose of as little as 0.1 mg or an oral dose of only 0.25 mg results in a tetanic uterine contraction that develops almost immediately after intravenous injection of the drug and within a few minutes after intramuscular or oral administration. Moreover, the response is sustained with little tendency toward relaxation. The tetanic effect of both drugs is effective for the prevention and control of postpartum hemorrhage, but it is very dangerous for the fetus and the mother prior to delivery.

The parenteral administration of these alkaloids, especially by the intravenous route, sometimes initiates transient but severe hypertension. Such a reaction is most likely in women who are prone to develop hypertension. Browning (1974) described four instances of serious postdelivery side effects attributable to 0.5 mg of ergonovine administered intramuscularly. Two women promptly became severely hypertensive, the third became hypertensive and convulsed, and the fourth suffered a cardiac arrest. We have seen an instance of such profound vasoconstriction from these compounds when given intravenously that all peripheral pulses were lost, and sodium nitroprusside was required to restore the peripheral circulation. Unfortunately, the mother sustained cerebral hypoxic ischemic injury.

PROSTAGLANDINS. Analogues of prostaglandins are not used routinely for management of third-stage labor. Villar and colleagues (2002) reviewed prophylactic use of misoprostol to prevent postpartum hemorrhage and concluded that oxytocin or oxytocin-ergot preparations are more effective. Other prostaglandins such as 15-methyl prostaglandin $F_{2\alpha}$ are reserved for treatment of hemorrhage, which is discussed in [Chapter 35](#) (see p. 827).

Figure 17-31. Expression of placenta. Note that the hand is *not* trying to push the fundus of the uterus through the birth canal! As the placenta leaves the uterus and enters the vagina, the uterus is elevated by the hand on the abdomen (*arrow*) while the cord is held in position. The mother can aid in the delivery of the placenta by bearing down. As the placenta reaches the perineum, the cord is lifted, which in turn, lifts the placenta out of the vagina. Adherent membranes are teased free so as to prevent their being torn off and retained in the birth canal.

Figure 17-32. The placenta is removed from the vagina by lifting the cord.

Figure 17-33. Membranes that were somewhat adherent to the uterine lining are separated by gentle traction with a ring forceps.

LACERATIONS OF THE BIRTH CANAL. Lacerations of the vagina and perineum are classified as first, second, third, or fourth degree. *First-degree* lacerations involve the fourchette, perineal skin, and vaginal mucous membrane but not the underlying fascia and muscle. *Second-degree* lacerations involve, in addition to skin and mucous membrane, the fascia and muscles of the perineal body but not the anal sphincter (Fig. 17-34). These tears usually extend upward on one or both sides of the vagina, forming an irregular triangular injury. *Third-degree* lacerations extend through the skin, mucous membrane, and perineal body, and involve the anal sphincter. A *fourth-degree* laceration extends through the rectal mucosa to expose the lumen of the rectum. Tears in the region of the urethra that may bleed profusely may also accompany this type of laceration.

Because the repair of perineal tears is virtually the same as that of episiotomy incisions, albeit often less satisfactory because of irregular lines of tissue cleavage, the technique of repairing lacerations is discussed in the following section.

Figure 17-34. Deep second-degree laceration of the perineum and vagina.

EPISIOTOMY AND REPAIR. In a strict sense, episiotomy is incision of the pudenda. Perineotomy is incision of the perineum. In common parlance, however, the term *episiotomy* often is used synonymously with *perineotomy*, a practice that we follow here. The incision may be made in the midline, creating a *median* or *midline episiotomy*, or it may begin in the midline but be directed laterally and downward away from the rectum, termed a *mediolateral episiotomy*.

Purposes of Episiotomy. Although still a common obstetrical procedure, the use of episiotomy has decreased remarkably over the past 25 years. Weber and Meyn (2002) used the National Hospital Discharge Survey to analyze use of episiotomy between 1979 and 1997 in the United States. Approximately 65 percent of women who gave birth vaginally in 1979 had episiotomies compared with 39 percent by 1997. Through the 1970s, it was common practice to cut an episiotomy for almost all women having their first delivery. The reasons for its popularity included substitution of a straight surgical incision, which was easier to repair, for the ragged laceration that otherwise might result. The long-held beliefs that postoperative pain is less and healing improved with an episiotomy compared with a tear, however, appeared to be incorrect (Larsson and colleagues, 1991).

Another commonly cited but unproven benefit of routine episiotomy was that it prevented pelvic relaxation—that is, cystocele, rectocele, and urinary incontinence. A number of observational studies and randomized trials showed that routine episiotomy is associated with an increased incidence of anal sphincter and rectal tears (Angioli and co-authors, 2000; Argentine Episiotomy Trial Collaborative Group, 1993; Eason and colleagues, 2000; Nager and Helliwell, 2001).

Carroli and Belizan (2000) reviewed the Cochrane Pregnancy and Childbirth Group trials registry. There were six randomized trials of nearly 5000 deliveries in which routine (73-percent rate) versus restricted (28-percent rate) use of episiotomy was evaluated. There were lower rates of posterior perineal trauma, surgical repair, and healing complications in the restricted-use group. Alternatively, the incidence of anterior perineal trauma was lower in the routine-use group. Along with these findings came the realization that episiotomy did not protect the perineal body and contributed to anal sphincter incontinence by increasing the risk of third- and fourth-degree tears. Signorello and associates (2000) reported that fecal and flatus incontinence were increased four- to sixfold in women with an episiotomy compared with findings of a group delivered with an intact perineum. Even when compared with spontaneous lacerations, episiotomy tripled the risk of fecal incontinence and doubled it for flatus incontinence. Episiotomy without extension did not lower this risk. Finally, even with recognition and repair of a third-degree extension, 30 to 40 percent of women have long-term anal incontinence (Gjessing and co-workers, 1998; Poen and colleagues, 1998).

It seems reasonable to conclude that episiotomy should not be performed routinely (Eason and Feldman, 2000). The procedure should be applied selectively for appropriate indications, some of which include fetal indications such as shoulder dystocia and breech delivery; forceps or vacuum extractor deliveries; occiput posterior positions; and in instances where it is obvious that failure to perform an episiotomy will result in perineal rupture. **The final rule is that there is no substitute for surgical judgment and common sense.**

The important variables of episiotomy use include the timing of the incision, the type of incision, and techniques for repair.

Timing of Episiotomy. If performed unnecessarily early, bleeding from the episiotomy may be considerable during the interim between incision and delivery. If it is performed too late, lacerations will not be prevented. It is common practice to perform episiotomy when the head is visible during a contraction to a diameter of 3 to 4 cm (see Fig. 17-24). When used in conjunction with forceps delivery, most practitioners perform an episiotomy after application of the blades (see Chap. 23, p. 552).

Midline Versus Mediolateral Episiotomy. The advantages and disadvantages of the two types of episiotomies are summarized in Table 17-4. Except for the important issue of third- and fourth-degree extensions, midline episiotomy is superior. Proper selection of cases can minimize this one disadvantage. In addition to a midline episiotomy, Combs and associates (1990) reported the following factors to be associated with an increased risk of third- and fourth-degree lacerations: nulliparity, second-stage arrest of labor, persistent occiput posterior position, mid or low forceps, use of local anesthetics, and Asian race.

It is reasonable to use a mediolateral episiotomy when a third- or fourth-degree extension is likely, but to employ the midline

incision otherwise. Anthony and colleagues (1994), who presented data from the Dutch National Obstetric Database of over 43,000 deliveries, found more than a fourfold decrease in severe perineal lacerations when mediolateral episiotomy was employed compared with midline incision.

Venkatesh and colleagues (1989) reported a 5-percent incidence of third- and fourth-degree perineal tears in 20,500 vaginal deliveries. About 10 percent of these 1040 primary repairs had a postoperative wound disruption, and 67 of the 101 required surgical correction. Goldaber and associates (1993) found that 21 of 390 or 5.4 percent of women with fourth-degree lacerations experienced significant morbidity. There were 7 (1.8 percent) dehiscences, 11 (2.8 percent) infections with dehiscences, and 3 (0.8 percent) infections alone. Although administration of a perioperative 2-g intravenous dose of cefazolin reduced this morbidity, it was not totally eliminated.

Timing of the Episiotomy Repair. The most common practice is to defer episiotomy repair until the placenta has been delivered. This policy permits undivided attention to the signs of placental separation and delivery. A further advantage is that episiotomy repair is not interrupted or disrupted by the obvious necessity of delivering the placenta, especially if manual removal must be performed.

Technique. There are many ways to close an episiotomy incision, but *hemostasis and anatomical restoration without excessive suturing are essential* for success with any method. A technique that commonly is employed is shown in [Figure 17-35](#). The suture material ordinarily used is 3-0 chromic catgut, but Grant (1989) recommends suture composed of derivatives of polyglycolic acid. A decrease in postsurgical pain is cited as the major advantage of the newer materials, despite the occasional later need to remove some of the suture from the site of repair because of pain or dyspareunia. Kettle and co-authors (2002) randomly assigned 1542 women with perineal lacerations or episiotomies to undergo continuous versus interrupted repair with rapidly absorbed polyglactin 910 (Vicryl Rapids, Ethicon) or standard polyglactin 910 sutures. The former typically is absorbed by 42 days and the latter completely absorbed by about 90 days. The continuous method was associated with less perineal pain. The rapidly absorbed material was associated with lower rates of suture removal within 3 months of delivery (3 percent removal versus 13 percent removal for rapidly absorbed versus standard polyglactin). Sanders and co-workers (2002) emphasized that women without regional analgesia can experience high levels of pain during perineal suturing.

FOURTH-DEGREE LACERATION. The technique of repairing a fourth-degree laceration is shown in [Figure 17-36](#). Various techniques have been recommended, but in all instances, it is essential to approximate the torn edges of the rectal mucosa with sutures placed in the muscularis approximately 0.5 cm apart. This muscular layer then is covered with a layer of fascia. Finally, the cut ends of the anal sphincter are isolated, approximated, and sutured together with three or four interrupted stitches. The remainder of the repair is the same as for an episiotomy. The overlapping technique is an alternative method to approximate the external anal sphincter. Despite promising initial results with this technique, more recent data based on a randomized controlled trial do not support that this method yields superior anatomical or functional results over the traditional end-to-end technique (Fitzpatrick and colleagues, 2000; Sultan and co-workers, 1999). Thus, more emphasis should be placed on prevention of anal sphincter lacerations. Postrepair, stool softeners should be prescribed for a week, and enemas should be avoided. Prophylactic antimicrobials should be considered, as described by Goldaber and colleagues (1993). Unfortunately, normal function is not always assured even with correct and complete surgical repair. Some women may experience continuing fecal incontinence caused by injury to the innervation of the pelvic floor musculature (Roberts and co-workers, 1990).

Pain After Episiotomy. Application of ice packs tends to reduce swelling and allay discomfort. Minassian and colleagues (2002) randomly assigned 200 women to receive 5-percent lidocaine ointment versus placebo for relief of postpartum perineal pain. Topical application of lidocaine ointment was not effective in relieving episiotomy or perineal laceration discomfort. Analgesics such as codeine give considerable relief. **Because pain may be a signal of a large vulvar, paravaginal, or ischioanal hematoma or perineal cellulitis, it is essential to examine these sites carefully if pain is severe or persistent.** Management of these complications is discussed in [Chapter 35](#).

Signorello and co-workers (2001) surveyed 615 women 6 months postpartum to determine the impact of perineal trauma on sexual functioning. Women whose newborns were delivered over an intact perineum reported the best outcomes in this regard.

Figure 17-35. Repair of midline episiotomy. **A.** Chromic 2-0 or 3-0 suture is used as a continuous suture to close the vaginal mucosa and submucosa. **B.** After closing the vaginal incision and reapproximating the cut margins of the hymenal ring, the suture is tied and cut. Next, three or four interrupted sutures of 2-0 or 3-0 chromic are placed in the fascia and muscle of the incised perineum. **C.** A continuous suture is carried downward to unite the superficial fascia. **D.** Completion of repair. The continuous suture is carried upward as a subcuticular stitch. (An alternative method of closure of skin and subcutaneous fascia is illustrated in E.) **E.** Completion of repair of midline episiotomy. A few interrupted sutures of 3-0 chromic are placed through the skin and subcutaneous fascia and loosely tied. This closure avoids burying two layers of suture in the more superficial layers of the perineum.

Figure 17-36. Layered repair of a fourth-degree perineal laceration. **A.** Approximation of the anorectal mucosa and submucosa in a running or interrupted fashion using fine absorbable suture such as 3-0 or 4-0 chromic or Vicryl. The superior extent of the anterior anal laceration is identified and the sutures are placed through the submucosa of the anorectum approximately 0.5 cm apart down to the anal verge. **B.** A second layer is placed through the rectal muscularis using 3-0 Vicryl suture in a running or interrupted fashion. This "reinforcing layer" should incorporate the torn ends of the internal anal sphincter, which is identified as the thickening of the circular smooth muscle layer at the distal 2 to 3 cm of the anal

canal. It can be identified as the glistening white fibrous structure lying between the anal canal submucosa and the fibers of the external anal sphincter (EAS). In many cases, the internal sphincter retracts laterally and must be sought and retrieved for repair. **C.** The disrupted ends of the striated EAS muscle and capsule are then identified and grasped with Allis clamps. The torn ends of the EAS often retract laterally in an asymmetrical fashion as shown. **D.** Traditional end-to-end approximation of the EAS. Four to six simple interrupted 2-0 or 3-0 Vicryl sutures are placed at the 3, 6, 9, and 12 o'clock positions through the EAS muscle and its connective tissue capsule. The sutures through the inferior and posterior portions of the sphincter should be placed first and tied last to facilitate this part of the repair. The remainder of the repair is similar to that described for a midline episiotomy in [Figure 17-35](#).

LABOR MANAGEMENT PROTOCOLS

O'Driscoll and colleagues (1984) at the National Maternity Hospital in Dublin pioneered the concept that a disciplined, standardized labor management protocol reduced cesarean deliveries for dystocia. Their overall cesarean delivery rate was 5 percent in the 1970s and 1980s with such management. The approach is now referred to as *active management of labor*. Two of its components—amniotomy and oxytocin—have been widely used, especially in English-speaking countries outside the United States (Thornton and Lilford, 1994). Recently, Impey and Boylan (1999) observed that active management was never intended to reduce the cesarean delivery rate and that the rate had in fact been low (about 5 percent) at the National Maternity Hospital prior to implementation of active management. In their view, active management did serve, however, to prevent the escalating rate of cesarean deliveries in Dublin that developed in the United States and elsewhere. More recently, however, the cesarean delivery rate for nulliparous women who gave birth at the National Maternity Hospital in 1997 has more than doubled to 11.6 percent. This increase was attributed to induction of labor, cesarean delivery for breech presentation, and changing maternal attitudes.

ACTIVE MANAGEMENT OF LABOR. This phrase describes a codified approach to labor diagnosis and management only in nulliparous women. Labor is diagnosed when painful contractions are accompanied by complete cervical effacement, bloody "show," or ruptured membranes. Women with such findings are committed to delivery within 12 hours. Pelvic examination is performed each hour for the next 3 hours, and thereafter at 2-hour intervals. When dilatation has not increased by at least 1 cm/hr, amniotomy is performed. Progress is again assessed at 2 hours and high-dose oxytocin infusion, described in [Chapter 22](#) (see p. 540), is started unless dilatation of at least 1 cm/hr is documented. Women are constantly attended by midwives.

If membranes rupture prior to admission, oxytocin is begun for no progress at the 1-hour mark. No special equipment is used, either to dispense oxytocin or to monitor its effects, and electronic uterine contraction monitoring is not used. Oxytocin is dispensed by gravity regulated by a personal nurse. The solution contains 10 units of oxytocin in 1 L of dextrose and water. The total dose may not exceed 10 units and the infusion rate may not exceed 60 drops/min or 30 to 40 mU/min (15 to 20 drops = 1 mL). In the Irish protocol, scalp blood sampling is used as the definitive test for fetal distress.

Lopez-Zeno and colleagues (1992) prospectively compared active management with the "traditional" approach to labor management practiced at Northwestern Memorial Hospital in Chicago. They randomly assigned 705 nulliparas with uncomplicated pregnancies in spontaneous labor at term. The cesarean delivery rate was statistically different: 10.5 percent with active management and 14.1 percent with the "traditional" approach. Frigoletto and co-workers (1995) also reported a randomized trial of active management in 1934 nulliparous women delivered at Brigham and Women's Hospital in Boston. Although they found that such management somewhat shortened labor, it did not affect the cesarean delivery rate. Similar results were reported by Rogers and colleagues (1997), Sadler and co-authors (2000), and Impey and co-workers (2000). The American College of Obstetricians and Gynecologists (2003a) has concluded that active management of labor may shorten labor, although it has not consistently been shown to reduce rates of cesarean delivery.

World Health Organization Partogram. A *partogram* was designed by the World Health Organization for use in developing countries (Dujardin and co-workers, 1992). Labor is divided into a latent phase, which should last no longer than 8 hours, and an active phase, starting at 3 cm dilatation and during which the rate of dilatation should be no slower than 1 cm/hr. A 4-hour wait is recommended before intervention when the active phase is slow. Labor is graphed, and analysis includes use of alert and action lines.

Parkland Hospital Labor Management Protocol. During the 1980s, the obstetrical volume at Parkland Hospital doubled to approximately 15,000 births per year. In response, a second delivery unit designed for women with uncomplicated term pregnancies was developed. This provided a unique opportunity to implement and evaluate a standardized protocol for labor management. Its design was based on the labor management approach that had evolved at our hospital up to that time, which emphasized the implementation of specific, sequential interventions when abnormal labor was suspected. This approach currently is used in both complicated and uncomplicated pregnancies.

Women are admitted when active labor—defined as cervical dilatation of 3 to 4 cm or more in the presence of uterine contractions—is diagnosed or ruptured membranes are confirmed. Management guidelines summarized in [Figure 17-37](#) stipulate that pelvic examinations be performed approximately every 2 hours. Ineffective labor is suspected when the cervix does not dilate within about 2 hours of admission. Amniotomy is then performed and labor progress determined at the next 2-hour evaluation. In women whose labors do not progress, an intrauterine pressure catheter is placed to assess uterine function. Hypotonic contractions and no cervical dilatation after an additional 2 to 3 hours result in stimulation of labor using the high-dose oxytocin regimen described in [Chapter 22](#) (see p. 540). Uterine activity of 200 to 250 Montevideo units is expected for 2 to 4 hours before dystocia is diagnosed.

Dilatation rates of 1 to 2 cm/hr are accepted as evidence of progress after satisfactory uterine activity has been established with oxytocin. As shown in [Figure 17-37](#), this can require up to 8 hours or more before cesarean delivery is performed for dystocia. The cumulative time required to effect this stepwise management approach permits many women to establish effective labor. This management protocol has been evaluated in more than 20,000 women with uncomplicated pregnancies. Cesarean delivery rates in nulliparous and parous women were 8.7 and 1.5 percent, respectively. Importantly, these labor interventions and the relatively infrequent use of cesarean delivery did not jeopardize the fetus-newborn.

Figure 17-37. Summary of labor management protocol in use at Parkland Hospital. The total admission-to-delivery times are shorter than the potential sum of the intervention intervals because not every woman requires every intervention.

18. Intrapartum Assessment

INTRODUCTION

During the late 1960s, continuous electronic fetal monitoring was introduced into obstetrical practice. No longer were intrapartum fetal surveillance and the suspicion of fetal distress based upon periodic auscultation with a fetoscope. Instead, the continuous graph paper portrayal of the fetal heart rate was potentially diagnostic in assessing pathophysiological events affecting the fetus. Indeed, there were great expectations that:

1. Electronic fetal heart rate monitoring provided accurate information.
2. The information was of value in diagnosing fetal distress.
3. It would be possible to intervene to prevent fetal death or morbidity.
4. Continuous electronic fetal heart rate monitoring was superior to intermittent methods.

When first introduced, electronic fetal heart rate monitoring was used primarily in complicated pregnancies, but gradually it came to be used in most pregnancies. By 1978 it was estimated that nearly two thirds of American women were being monitored electronically during labor (Banta and Thacker, 1979). In 2002, approximately 3.4 million American women, comprising 85 percent of all live births, underwent electronic fetal monitoring (Martin and colleagues, 2003). Indeed, fetal monitoring has become the most prevalent obstetrical procedure in the United States.

ELECTRONIC FETAL MONITORING

INTERNAL ELECTRONIC FETAL HEART RATE MONITORING. The fetal heart rate may be measured by attaching a bipolar spiral electrode directly to the fetus (Fig. 18-1). The wire electrode penetrates the fetal scalp, and the second pole is a metal wing on the electrode. Vaginal body fluids create a saline electrical bridge that completes the circuit and permits measurement of the voltage differences between the two poles. The electrical fetal cardiac signal — P wave, QRS complex, and T wave — is amplified and fed into a cardiometer for heart rate calculation. The peak R-wave voltage is the portion of the fetal electrocardiogram most reliably detected. The two wires of the bipolar electrode are attached to a reference electrode on the maternal thigh to eliminate electrical interference.

Shown in Figure 18-2 is an example of the method of fetal heart rate processing employed when a scalp electrode is used. Time (t) in milliseconds between fetal R waves is fed into a cardiometer, where a new fetal heart rate is set with the arrival of each new R wave. As also shown in Figure 18-2, a premature atrial contraction is computed as a heart rate acceleration because the interval (t₂) is shorter than the preceding one (t₁). The phenomenon of continuous R-to-R wave fetal heart rate computation is known as *beat-to-beat variability*. The physiological event being counted, however, is not a mechanical event corresponding to a heartbeat but rather an electrical event.

Electrical cardiac complexes detected by the electrode include those generated by the mother. Although the maternal electrocardiogram (ECG) signal is approximately five times stronger than the fetal ECG, its amplitude is diminished when it is recorded through the fetal scalp electrode. In a live fetus, this low maternal ECG signal is detected but masked by the fetal ECG. If the fetus is dead, the weaker maternal signal will be amplified and displayed as the "fetal" heart rate (Freeman and co-authors, 2003). Shown in Figure 18-3 are simultaneous recordings of maternal chest wall ECG signals and fetal scalp electrode ECG signals. This fetus is experiencing premature atrial contractions, which cause the cardiometer to rapidly and erratically seek new heart rates, resulting in the "spiking" shown in the standard fetal monitor tracing. Importantly, when the fetus is dead, the maternal R waves are still detected by the scalp electrode as the next best signal and are counted by the cardiometer (Fig. 18-4).

Figure 18-1. Schematic representation of a bipolar electrode attached to fetal scalp for detection of fetal QRS complexes (F). Also shown is the maternal heart and corresponding electrical complexes (M) that are detected.

Figure 18-2. Schematic representation of fetal electrocardiographic signals used to compute continuing beat-to-beat heart rate with scalp electrodes. Time intervals (t₁, t₂, t₃) in milliseconds between successive fetal R waves are used by cardiometer to compute instantaneous fetal heart rate. (PAC = premature atrial contraction.)

Figure 18-3. Standard fetal monitor tracing of heart rate using fetal scalp electrode shown at top. Bottom two tracings represent cardiac electrical complexes detected from fetal scalp and maternal chest wall electrodes. Spiking of the fetal rate in the monitor tracing is due to the premature atrial contractions. (F = fetus; M = mother; PAC = fetal premature atrial contraction.)

Figure 18-4. Placental abruption: The fetal scalp electrode detected the heart rate first of the dying fetus. After fetal death, the maternal electrocardiogram complex is detected and recorded.

EXTERNAL (INDIRECT) ELECTRONIC FETAL HEART RATE MONITORING.

The necessity for membrane rupture and uterine invasion may be avoided by use of external detectors to monitor fetal heart action and uterine activity. External monitoring does not provide the precision of fetal heart rate measurement or the quantification of uterine pressure afforded by internal monitoring.

The fetal heart rate is detected through the maternal abdominal wall using the *ultrasound Doppler principle* (Fig. 18-5). Ultrasonic waves undergo a shift in frequency as they are reflected from moving fetal heart valves and from pulsatile blood ejected during systole. The unit consists of a transducer that emits ultrasound and a sensor to detect a shift in frequency of the reflected sound. The transducer is placed on the maternal abdomen at a site where fetal heart action is best detected. A coupling gel must be applied because air conducts ultrasound poorly. The device is held in position by a belt. Care should be taken that maternal aortic pulsations are not confused with fetal cardiac motion.

Ultrasound Doppler signals are edited electronically before fetal heart rate data are printed onto the bedside monitor tracing paper. Reflected ultrasound signals from moving fetal heart valves are analyzed through a microprocessor that compares incoming signals with the most recent previous signal. This process, called *autocorrelation*, is based on the premise that the fetal heart rate has regularity whereas "noise" is random and without regularity. Several fetal heart motions must be deemed electronically acceptable by the microprocessor before the fetal heart rate is printed. Such electronic editing has greatly improved the tracing quality of the externally recorded fetal heart rate.

Figure 18-5. Ultrasound Doppler principle used externally to measure fetal heart motions. Pulsations of the maternal aorta also may be detected and counted. (Adapted from Klavan and co-authors, 1977, with permission.)

FETAL HEART RATE PATTERNS. It is now generally accepted that interpretation of fetal heart rate patterns can be problematic because of the lack of agreement on definitions and nomenclature (Freeman, 2002). The National Institute of Child Health and Human Development Research Planning Workshop (1997) brought together investigators with expertise in the field to propose standardized, unambiguous definitions for interpretation of fetal heart rate patterns during labor. The definitions proposed as a result of this workshop will be used in this chapter. It is important to recognize that interpretation of electronic fetal heart rate data is based on the visual pattern of the heart rate as portrayed on chart recorder graph paper. Thus, the choice of vertical and horizontal scaling greatly affects the appearance of the fetal heart rate. Scaling factors recommended by the workshop are 30 beats per minute (beats/min or bpm) per vertical cm (range, 30 to 240 beats/min) and 3 cm/min chart recorder paper speed. Fetal heart rate variation is falsely displayed at the slower 1 cm/min paper speed when compared with that of the smoother baseline recorded at 3 cm/min (Fig. 18-6). Thus, pattern recognition can be considerably distorted depending on the scaling factors used.

Baseline Fetal Heart Activity. Baseline fetal heart activity refers to the modal characteristics that prevail apart from periodic accelerations or decelerations associated with uterine contractions. Descriptive characteristics of baseline fetal heart activity include *rate*, *beat-to-beat variability*, *fetal arrhythmia*, and distinct patterns such as *sinusoidal* or *saltatory* fetal heart rates.

RATE. With increasing fetal maturation, the heart rate decreases. This continues postnatally such that the average rate is 90 beats/min by age 8 (Behrman, 1992). Pillai and James (1990) longitudinally studied fetal heart rate characteristics in 43 normal pregnancies. The baseline fetal heart rate decreased an average of 24 beats/min between 16 weeks and term, or approximately 1 beat/min per week. It is postulated that this normal gradual slowing of the fetal heart rate corresponds to maturation of parasympathetic (vagal) heart control (Renou and co-workers, 1969).

The baseline fetal heart rate is the approximate mean rate rounded to increments of 5 beats/min during a 10-minute tracing segment. In any 10-minute window, the minimum interpretable baseline duration must be at least 2 minutes. If the baseline fetal heart rate is less than 110 beats/min, it is termed *bradycardia*; if the baseline rate is greater than 160 beats/min, it is termed *tachycardia*. The average fetal heart rate is considered to be the result of tonic balance between *accelerator* and *decelerator* influences on pacemaker cells. In this concept, the sympathetic system is the accelerator influence, and the parasympathetic system is the decelerator factor mediated via vagal slowing of heart rate (Dawes, 1985). Heart rate also is under the control of arterial chemoreceptors such that both hypoxia and hypercapnia can modulate rate. More severe and prolonged hypoxia, with a rising blood lactate level and severe metabolic acidemia, induces a prolonged fall of heart rate due to direct effects on the myocardium.

BRADYCARDIA. During the third trimester, the normal mean baseline fetal heart rate has generally been accepted to be between 120 and 160 beats/min. The lower normal limit is disputed internationally with some investigators recommending 110 beats/min (Manassiev, 1996). Pragmatically, a rate between 100 and 119 beats/min, in the absence of other changes, usually is not considered to represent fetal compromise. Such low but potentially normal baseline heart rates also have been attributed to head compression from occiput posterior or transverse positions, particularly during second-stage labor (Young and Weinstein, 1976). Such mild bradycardias were observed in 2 percent of monitored pregnancies and averaged about 50 minutes in duration. Freeman and colleagues (2003) have concluded that bradycardia within the range of 80 to 120 beats/min with good variability is reassuring. Interpretation of rates less than 80 beats/min is problematic, and such rates generally are considered nonreassuring.

Some causes of fetal bradycardia include congenital heart block and serious fetal compromise. [Figure 18-7](#) shows bradycardia in a fetus dying from placental abruption. Maternal hypothermia under general anesthesia for repair of a cerebral aneurysm or during maternal cardiopulmonary bypass for open-heart surgery also can cause fetal bradycardia (see [Chap. 44](#), p. 1023). Sustained fetal bradycardia in the setting of severe pyelonephritis and maternal hypothermia also has been reported (Hankins and co-workers, 1997). These infants apparently are not harmed by several hours of such bradycardia.

TACHYCARDIA. Fetal tachycardia is defined as a baseline heart rate in excess of 160 beats/min. The most common explanation for fetal tachycardia is maternal fever from amnionitis, although fever from any source can increase baseline fetal heart rate. Such infections also have been observed to induce fetal tachycardia before overt maternal fever is diagnosed (Gilstrap and associates, 1987). Fetal tachycardia caused by maternal infection typically is not associated with fetal compromise unless there are associated periodic heart rate changes or fetal sepsis.

Other causes of fetal tachycardia include fetal compromise, cardiac arrhythmias, and maternal administration of parasympathetic (atropine) or sympathomimetic (terbutaline) drugs. The key feature to distinguish fetal compromise in association with tachycardia seems to be concomitant heart rate decelerations. Prompt relief of the compromising event, such as correction of maternal hypotension caused by epidural analgesia, can result in fetal recovery.

WANDERING BASELINE. This baseline rate is unsteady and "wanders" between 120 and 160 beats/min (Freeman and colleagues, 2003). This rare finding is suggestive of a neurologically abnormal fetus and may occur as a preterminal event.

BEAT-TO-BEAT VARIABILITY. Baseline variability is an important index of cardiovascular function and appears to be regulated largely by the autonomic nervous system (Kozuma and colleagues, 1997). That is, sympathetic and parasympathetic "push-pull," mediated via the sinoatrial node, produces moment-to-moment or beat-to-beat oscillation of the baseline heart rate. Such irregularity of the heart rate is defined as baseline variability. Variability is further divided into short term and long term.

Short-term variability reflects the instantaneous change in fetal heart rate from one beat P— or R wave P— to the next. This variability is a measure of the time interval between cardiac systoles ([Fig. 18-8](#)). Short-term variability can most reliably be determined to be normally present only when electrocardiac cycles are measured directly with a scalp electrode. *Long-term variability* is used to describe the oscillatory changes that occur during the course of 1 minute and result in the waviness of the baseline ([Fig. 18-9](#)). The normal frequency of such waves is three to five cycles per minute (Freeman and co-authors, 2003).

It should be recognized that precise quantitative analysis of both short- and long-term variability presents a number of frustrating problems due to technical and scaling factors. For example, Parer and co-workers (1985) evaluated 22 mathematical formulas designed to quantify heart rate variability and most were unsatisfactory. Consequently, most clinical interpretation is based on visual analysis with subjective judgment of the smoothness or flatness of the baseline. According to Freeman and colleagues (2003), there is no current evidence that the distinction between short- and long-term variability has any clinical relevance. Similarly, the NICHD Workshop (1997) did not recommend differentiating short- and long-term variability because in actual practice they are visually determined as a unit. The workshop panel defined baseline variability as those baseline fluctuations of two cycles per minute or greater. They recommended the criteria shown in [Figure 18-10](#) for quantification of variability. Normal beat-to-beat variability was accepted to be 6 to 25 beats/min.

Several physiological and pathological processes can affect or interfere with beat-to-beat variability. Dawes and co-workers (1981) described increased variability during *fetal breathing*. In healthy infants, short-term variability is attributable to respiratory sinus arrhythmia (Divon and co-workers, 1986). *Fetal body movements* also affect variability (Van Geijn and co-workers, 1980). Pillai and James (1990) reported increased baseline variability with *advancing gestation*. Up to 30 weeks, baseline characteristics were similar during both fetal rest and activity. After 30 weeks, fetal inactivity was associated with diminished baseline variability and conversely, variability was increased during fetal activity. Fetal gender does not affect heart rate variability (Ogueh and Steer, 1998).

It is important to recognize that the baseline fetal heart rate becomes more physiologically fixed (less variable) as the rate increases. Conversely, there is more instability or variability of the baseline at lower heart rates. This phenomenon presumably reflects less cardiovascular physiological wandering as beat-to-beat intervals shorten due to increasing heart rate.

Diminished beat-to-beat variability can be an ominous sign indicating a seriously compromised fetus. Paul and co-workers (1975) reported that loss of variability in combination with decelerations was associated with fetal acidemia. They analyzed variability in the 20 minutes preceding delivery in 194 pregnancies. Decreased variability was defined as 5 or fewer beats/min excursion of the baseline (see [Fig. 18-10](#)), whereas acceptable variability exceeded this range. Fetal scalp pH was measured 1119 times in these pregnancies, and mean values were found to be increasingly more acidemic when decreased variability was added to progressively intense heart rate decelerations. For example, mean fetal scalp pH of about 7.10 was found when severe decelerations were combined with 5 beats/min or less variability compared with a pH about 7.20 when greater variability was associated with similarly severe decelerations.

Severe *maternal acidemia* also can cause decreased fetal beat-to-beat variability, as shown in [Figure 18-11](#) in a mother with diabetic ketoacidosis. The precise pathological mechanisms by which fetal hypoxemia results in diminished beat-to-beat variability are not totally understood.

Interestingly, mild degrees of fetal hypoxemia have been reported actually to *increase* variability, at least at the outset of the hypoxic episode (Murotsuki and co-authors, 1997). According to Dawes (1985), it seems probable that the loss of variability is a result of metabolic acidemia that causes depression of the fetal brainstem or the heart itself. Thus, diminished beat-to-beat variability, when a reflection of compromised fetal condition, likely reflects acidemia rather than hypoxia.

A common cause of diminished beat-to-beat variability is *analgesic drugs* given during labor (see [Chap. 19](#), p. 476). A large variety of central nervous system depressant drugs can cause transient diminished beat-to-beat variability. Included are narcotics, barbiturates, phenothiazines, tranquilizers, and general anesthetics. Diminished variability occurs regularly within 5 to 10 minutes following intravenous meperidine administration, and the effects may last up to 60 minutes or longer depending on the dosage given (Petrie, 1993). Butorphanol given intravenously diminishes fetal heart rate reactivity (Schucker and

colleagues, 1996). Hill and colleagues (2003), in a study performed at Parkland Hospital, found that 5 beats/min or less variability occurred in 30 percent of women given continuous intravenous meperidine compared with 7 percent in those given continuous labor epidural analgesia using 0.0625-percent bupivacaine and 2 µg/mL of fentanyl.

It Magnesium sulfate, widely used in the United States for tocolysis as well as management of hypertensive women, has been arguably associated with diminished beat-to-beat variability. Hallak and colleagues (1999) randomly assigned 34 normal, nonlaboring women to standard magnesium sulfate infusion versus isotonic saline. Magnesium sulfate was associated with statistically decreased variability only in the third hour of the infusion. However, the average decrease in variability was deemed clinically insignificant because the mean variability was 2.7 beats/min in the third hour of magnesium infusion compared with 2.8 beats/min at baseline. Magnesium sulfate also blunted the frequency of accelerations.

It is generally believed that reduced baseline heart rate variability is the single most reliable sign of fetal compromise. For example, Smith and co-workers (1988) performed a computerized analysis of beat-to-beat variability in growth-restricted fetuses *before* labor. They observed that diminished variability (4.2 beats/min or less) that was maintained for 1 hour was diagnostic of developing acidemia and imminent fetal death. By contrast, Samueloff and associates (1994) evaluated variability as a predictor of fetal outcome during labor in 2200 consecutive deliveries. They concluded that variability by itself cannot be used as the only indicator of fetal well-being. Conversely, they also concluded that good variability should not be interpreted as necessarily reassuring.

In summary, beat-to-beat variability is affected by a variety of pathological and physiological mechanisms. Variability has considerably different meaning depending on the clinical setting. The development of decreased variability in the absence of decelerations is unlikely to be due to fetal hypoxia (Davidson and co-workers, 1992). A persistently flat fetal heart rate baseline—absent variability—within the normal baseline rate range and without decelerations may reflect a previous insult to the fetus that has resulted in neurological damage (Freeman and colleagues, 2003).

CARDIAC ARRHYTHMIA. When fetal cardiac arrhythmias are first suspected using electronic monitoring, findings can include baseline bradycardia, tachycardia, or most commonly in our experience, *abrupt baseline spiking* (Fig. 18-12). Intermittent baseline bradycardia is frequently due to congenital heart block. As discussed in Chapter 54 (p. 1215), conduction defects, most commonly complete atrioventricular (AV) block, usually are found in association with maternal connective-tissue diseases. Documentation of an arrhythmia can only be accomplished, practically speaking, when scalp electrodes are used. Some fetal monitors can be adapted to output the scalp electrode signals into an electrocardiographic recorder. Because only a single lead is obtained, analysis and interpretation of rhythm and rate disturbances are severely limited.

Southall and co-authors (1980) studied antepartum fetal cardiac rate and rhythm disturbances in 934 normal pregnancies between 30 and 40 weeks. Arrhythmias and episodes of bradycardia less than 100 beats/min, or tachycardia greater than 180 beats/min, were encountered in 3 percent. Most supraventricular arrhythmias are of little significance during labor unless there is coexistent heart failure as evidenced by fetal hydrops. Many supraventricular arrhythmias disappear in the immediate neonatal period, although some are associated with structural cardiac defects. Copel and co-authors (2000) used echocardiography to evaluate 614 fetuses referred for auscultated irregular heart rate without hydrops. Only 10 fetuses (2 percent) were found to have significant arrhythmias, and all but one infant survived.

Boldt and colleagues (2003) followed 292 consecutive fetuses diagnosed with a cardiac arrhythmia through birth and into childhood. Atrial extrasystoles comprised the most common arrhythmia (68 percent), followed by atrial tachycardias (12 percent), atrioventricular block (12 percent), sinus bradycardia (5 percent), and ventricular extrasystoles (2.5 percent). Chromosomal anomalies were found in 1.7 percent of the fetuses. Fetal hydrops developed in 11 percent, and 2 percent had intrauterine deaths. Fetal hydrops was a bad prognostic finding. Overall, 93 percent of the study population was alive at a median follow-up period of 5 years, and 3 percent (7 infants) had neurological handicaps. Almost all (97 percent) of the infants with atrial extrasystoles lived, and none suffered neurological injury. Only 6 percent required postnatal cardiac medications.

Although most fetal arrhythmias are of little consequence during labor when there is no evidence of fetal hydrops, such arrhythmias impair interpretation of intrapartum heart rate tracings. Ultrasonic survey of fetal anatomy as well as echocardiography may be useful. Some clinicians use fetal scalp sampling as an adjunct. Generally, in the absence of fetal hydrops, neonatal outcome is not measurably improved by pregnancy intervention. At Parkland Hospital, intrapartum fetal cardiac arrhythmias, especially in the presence of clear amniotic fluid, are managed conservatively. Freeman and colleagues (2003) have extensively reviewed interpretation of the fetal electrocardiogram during labor.

SINUSOIDAL HEART RATE. A true sinusoidal pattern such as that shown in panel 5 of Figure 18-10 may be observed with serious fetal anemia, whether from D-isoimmunization, ruptured vasa previa, fetomaternal hemorrhage, or twin-to-twin transfusion. Insignificant sinusoidal patterns have been reported following administration of meperidine, morphine, alphaprodine, and butorphanol (Angel, 1984; Egley, 1991; Epstein, 1982, and all their associates). Shown in Figure 18-13 is a sinusoidal pattern seen with maternal meperidine administration. An important characteristic of this pattern when due to narcotics is the sine frequency of 6 cycles per minute. A sinusoidal pattern also has been described with amnionitis, fetal distress, and umbilical cord occlusion (Murphy and associates, 1991). Young and co-workers (1980a) and Johnson and colleagues (1981) concluded that intrapartum sinusoidal fetal heart patterns were not generally associated with fetal compromise.

Modanlou and Freeman (1982), based on their extensive review, proposed adoption of a strict definition:

1. Stable baseline heart rate of 120 to 160 beats/min with regular oscillations.
2. Amplitude of 5 to 15 beats/min (rarely greater).
3. Long-term variability frequency of 2 to 5 cycles per minute.
4. Fixed or flat short-term variability.
5. Oscillation of the sinusoidal waveform above or below a baseline.

6. Absence of accelerations.

Although these criteria were selected to define a sinusoidal pattern that is most likely ominous, they observed that the pattern associated with alphaprodine is indistinguishable. Other investigators have proposed a classification of sinusoidal heart rate patterns into mild (amplitude 5 to 15 beats/min), intermediate (16 to 24 beats/min), and major (25 or more beats/min) to quantify fetal risk (Murphy and colleagues, 1991; Neesham and co-workers, 1993).

Some investigators have defined intrapartum sine wave-like baseline variation with periods of acceleration as *pseudosinusoidal*. Murphy and co-workers (1991) reported that pseudosinusoidal patterns were seen in 15 percent of monitored labors. Mild pseudosinusoidal patterns were associated with use of meperidine and epidural analgesia. Intermediate pseudosinusoidal patterns were linked to fetal sucking or transient episodes of fetal hypoxia caused by umbilical cord compression. Egly and colleagues (1991) reported that 4 percent of fetuses demonstrated sinusoidal patterns transiently during normal labor. These authors observed patterns for up to 90 minutes in some cases and also in association with oxytocin or alphaprodine usage, or both.

The pathophysiology of sinusoidal patterns is unclear, in part due to various definitions. There seems to be general agreement that *antepartum* sine wave baseline undulation portends severe fetal anemia, however, few D-isoimmunized fetuses develop this pattern (Nicolaidis and associates, 1989). The sinusoidal pattern has been reported to develop or disappear after fetal transfusion (Del Valle and associates, 1992; Lowe and co-workers, 1984). Ikeda and colleagues (1999) have proposed, based on studies in fetal lambs, that the sinusoidal fetal heart rate pattern is related to waves of arterial blood pressure, reflecting oscillations in the baroreceptor-chemoreceptor feedback mechanism for control of the circulation.

Periodic Fetal Heart Rate Changes. The periodic fetal heart rate refers to deviations from baseline that are related to uterine contractions. *Acceleration* refers to an increase in fetal heart rate above baseline and *deceleration* to a decrease below baseline rate. The nomenclature most commonly used in the United States is based upon the *timing* of the deceleration in relation to contractions—thus, *early*, *late*, or *variable* in onset related to the corresponding uterine contraction. The waveform of these decelerations is also significant for pattern recognition. In early and late decelerations, the slope of fetal heart rate change is gradual, resulting in a curvilinear and uniform or symmetrical waveform. With variable decelerations, the slope of fetal heart rate change is abrupt and erratic, giving the waveform a jagged appearance. It has been proposed that decelerations be defined as *recurrent* if they occur with 50 percent or more of contractions in any 20-minute period (NICHD Research Planning Workshop, 1997).

Another system now used less often for description of decelerations is based on the pathophysiological events considered most likely to cause the pattern. In this system, early decelerations are termed *head compression*, late decelerations are termed *uteroplacental insufficiency*, and variable decelerations become *cord compression patterns*. The nomenclature of type I (early), type II (late), and type III (variable) "dips" proposed by Caldeyro-Barcia and co-workers (1973) is not used in the United States.

ACCELERATIONS. An acceleration is a visually apparent abrupt increase—defined as onset of acceleration to a peak in less than 30 seconds—in the fetal heart rate baseline (NICHD Research Planning Workshop, 1997). According to Freeman and co-authors (2003), accelerations most often occur antepartum, in early labor, and in association with variable decelerations. Proposed mechanisms for intrapartum accelerations include fetal movement, stimulation by uterine contractions, umbilical cord occlusion, and fetal stimulation during pelvic examination. Fetal scalp blood sampling and acoustic stimulation also incite fetal heart rate acceleration (Clark and co-workers, 1982). Finally, acceleration can occur during labor without any apparent stimulus. Indeed, accelerations are common in labor and nearly always associated with fetal movement. These accelerations are virtually always reassuring and almost always confirm that the fetus is not acidemic at that time.

Accelerations seem to have the same physiological explanations as beat-to-beat variability in that they represent intact neurohormonal cardiovascular control mechanisms linked to fetal behavioral states. Krebs and co-workers (1982) analyzed electronic heart rate tracings in nearly 2000 fetuses and found sporadic accelerations during labor in 99.8 percent. The presence of fetal heart accelerations during the first or last 30 minutes, or both, was a favorable sign for fetal well-being. The absence of such accelerations during labor, however, is not necessarily an unfavorable sign unless coincidental with other nonreassuring changes. There is about a 50-percent chance of acidemia in the fetus who fails to respond to stimulation in the presence of an otherwise nonreassuring pattern (Clark and colleagues, 1984; Smith and colleagues, 1986).

EARLY DECELERATION. Early deceleration of the fetal heart rate consists of a gradual decrease and return to baseline associated with a contraction (Fig. 18-14). Such early deceleration was first described by Hon (1958). He observed that there was a drop in heart rate with uterine contractions and that this was related to cervical dilatation. He considered these findings to be physiological.

Freeman and co-authors (2003) defined early decelerations as those generally seen in active labor between 4 and 7 cm dilatation. In their definition, the degree of deceleration is generally proportional to the contraction strength and rarely falls below 100 to 110 beats/min or 20 to 30 beats/min below baseline. Such decelerations are uncommon during active labor and are not associated with tachycardia, loss of variability, or other fetal heart rate changes. Importantly, early decelerations are not associated with fetal hypoxia, acidemia, or low Apgar scores.

Head compression probably causes vagal nerve activation as a result of dural stimulation and that mediates the heart rate deceleration (Paul and co-workers, 1964). Ball and Parer (1992) concluded that fetal head compression is a likely cause not only of the deceleration shown in Figure 18-14 but also of those shown in Figure 18-15, which typically occur during second-stage labor. Indeed, they observed that head compression is the likely cause of many variable decelerations classically attributed to cord compression.

LATE DECELERATION. The fetal heart rate response to uterine contractions can be an index of either uterine perfusion or placental function. A late deceleration is a smooth, gradual, symmetrical decrease in fetal heart rate beginning at or after the peak of the contraction and returning to baseline only after the contraction has ended (American College of Obstetricians and Gynecologists, 1995b). In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively (Fig. 18-16). The magnitude of late decelerations is rarely more than 30 to 40 beats/min below baseline and typically not more than 10 to 20 beats/min. Late decelerations usually are not accompanied by

accelerations.

Myers and associates (1973) studied monkeys in which they compromised uteroplacental perfusion by lowering maternal aortic blood pressure. The time interval, or lag period, from the onset of a contraction to the onset of a late deceleration was directly related to basal fetal oxygenation. They demonstrated that the length of the lag phase was predictive of the fetal Po_2 but not fetal pH. The lower the fetal Po_2 prior to contractions, the shorter the lag phase to onset of late decelerations. This lag period reflected the time necessary for the fetal Po_2 to fall below a critical level necessary to stimulate arterial chemoreceptors, which mediated decelerations.

Murata and co-workers (1982) also showed that a late deceleration was the first fetal heart rate consequence of uteroplacental-induced hypoxia. During the course of progressive hypoxia that led to death over 2 to 13 days, the monkey fetuses invariably exhibited late decelerations before the development of acidemia. Variability of the baseline heart rate disappeared as acidemia developed.

A large number of clinical circumstances can result in late decelerations. Generally, any process that causes maternal hypotension, excessive uterine activity, or placental dysfunction can induce late decelerations. The two most common causes are hypotension from epidural analgesia and uterine hyperactivity caused by oxytocin stimulation. Maternal diseases such as hypertension, diabetes, and collagen-vascular disorders can cause chronic placental dysfunction. A rare cause is severe chronic maternal anemia without hypovolemia. Placental abruption can cause acute late decelerations ([Fig. 18-17](#)).

VARIABLE DECELERATIONS. The most common deceleration patterns encountered during labor are variable decelerations attributed to umbilical cord occlusion. Melchior and Bernard (1985) identified variable decelerations in 40 percent of over 7000 monitor tracings when labor had progressed to 5 cm dilatation and in 83 percent by the end of the first stage. Variable deceleration of the fetal heart rate is defined as a visually apparent *abrupt* decrease in rate. The onset of deceleration commonly varies with successive contractions ([Fig. 18-18](#)). The duration is less than 2 minutes.

Very early in the development of electronic monitoring, Hon (1959) tested the effects of umbilical cord compression on fetal heart rate ([Fig. 18-19](#)). Similar complete occlusion of the umbilical cord in experimental animals produces abrupt, jagged-appearing deceleration of the fetal heart rate ([Fig. 18-20](#)). Concomitantly, fetal aortic pressure increases. Itskovitz and co-workers (1983) observed that variable decelerations in fetal lambs occurred only after umbilical blood flow was reduced by at least 50 percent.

Two types of variable decelerations are shown in [Figure 18-21](#). The deceleration denoted by A is very much like that seen with complete umbilical cord occlusion in experimental animals (see [Fig. 18-20](#)). Deceleration B, however, has a different configuration because of the "shoulders" of acceleration before and after the deceleration component. Lee and co-workers (1975) proposed that this variation of variable decelerations was caused by differing degrees of partial cord occlusion. In this physiological scheme, occlusion of only the vein reduces fetal blood return, thereby triggering a baroreceptor-mediated acceleration. Subsequent complete occlusion results in fetal systemic hypertension due to obstruction of umbilical artery flow. This stimulates a baroreceptor-mediated deceleration. Presumably, the aftercoming shoulder of acceleration represents the same events occurring in reverse ([Fig. 18-22](#)).

Ball and Parer (1992) concluded that variable decelerations are mediated vagally and that the vagal response may be due to chemoreceptor or baroreceptor activity, or both. Partial or complete cord occlusion produces an increase in afterload (baroreceptor) and a decrease in fetal arterial oxygen content (chemoreceptor). These both result in vagal activity leading to deceleration. In fetal monkeys the baroreceptor reflexes appear to be operative during the first 15 to 20 seconds of umbilical cord occlusion followed by decline in Po_2 at approximately 30 seconds, which then serves as a chemoreceptor stimulus (Mueller-Heubach and Battelli, 1982).

Thus, variable decelerations represent fetal heart rate reflexes that reflect either blood pressure changes due to interruption of umbilical flow or changes in oxygenation. It is likely that most fetuses have experienced brief but recurrent periods of hypoxia due to umbilical cord compression during gestation. The frequency and inevitability of cord occlusion undoubtedly has provided the fetus with these physiological mechanisms as a means of coping. The great dilemma for the obstetrician in managing variable fetal heart rate decelerations is determining when variable decelerations are pathological. The American College of Obstetricians and Gynecologists (1995b) has defined *significant* variable decelerations as those decreasing to less than 70 beats/min and lasting more than 60 seconds.

Other fetal heart rate patterns have been associated with umbilical cord compression. *Saltatory* baseline heart rate ([Fig. 18-23](#)) was first described by Hammacher and co-workers (1968) and linked to umbilical cord complications during labor. *Saltatory* derives from the Latin and French words meaning "to leap." The pattern consists of rapidly recurring couplets of acceleration and deceleration causing relatively large oscillations of the baseline fetal heart rate. We also observed a relationship between cord occlusion and the saltatory pattern (Leveno and associates, 1984). In the absence of other fetal heart rate findings, these do not signal fetal compromise. *Lambda* is a pattern involving an acceleration followed by a variable deceleration with no acceleration at the end of the deceleration. This pattern typically is seen in early labor and is not ominous (Freeman and colleagues, 2003). This lambda pattern may result from mild cord compression or stretch. *Overshoot* is a variable deceleration followed by acceleration. The clinical significance of this pattern is controversial (Westgate and colleagues, 2001).

PROLONGED DECELERATION. Shown in [Figure 18-24](#), this pattern is defined as an isolated deceleration lasting 2 minutes or longer but less than 10 minutes from onset to return to baseline (NICHD Research Planning Workshop, 1997). Prolonged decelerations are difficult to interpret because they are seen in many different clinical situations. Some of the more common causes include cervical examination, uterine hyperactivity, cord entanglement, and maternal supine hypotension.

Epidural, spinal, or paracervical analgesia may induce prolonged deceleration of the fetal heart rate. For example, Eberle and colleagues (1998) reported that prolonged decelerations occurred in 4 percent of normal parturients given either epidural or intrathecal labor analgesia. Hill and colleagues (2003) observed prolonged deceleration in 1 percent of women given epidural analgesia during labor at Parkland Hospital. Other causes of prolonged deceleration include maternal hypoperfusion or hypoxia from any cause, placental abruption, umbilical cord knots or prolapse, maternal seizures including eclampsia and epilepsy,

application of a fetal scalp electrode, impending birth, or even maternal Valsalva maneuver.

The placenta is very effective in resuscitating the fetus if the original insult does not recur immediately. Occasionally, such self-limited prolonged decelerations are followed by loss of beat-to-beat variability, baseline tachycardia, and even a period of late decelerations, all of which resolve as the fetus recovers. Freeman and co-authors (2003) emphasize rightfully that the fetus may die during prolonged decelerations. Thus, management of prolonged decelerations can be extremely tenuous. Management of isolated prolonged decelerations is based upon bedside clinical judgment, which inevitably will sometimes be imperfect given the unpredictability of these decelerations.

Fetal Heart Rate Patterns During Second-Stage Labor. Decelerations are virtually ubiquitous. Melchior and Bernard (1985) reported that only 1.4 percent of more than 7000 deliveries did not have fetal heart rate decelerations during second-stage labor. Both cord compression and fetal head compression have been implicated as causes of decelerations and baseline bradycardia during second-stage labor. The high incidence of such patterns minimized their potential significance during the early development and interpretation of electronic monitoring. For example, Boehm (1975) described profound, prolonged fetal heart rate deceleration in the 10 minutes preceding vaginal delivery of 18 healthy infants. Subsequently, Herbert and Boehm (1981) reported another 18 pregnancies with similar prolonged decelerations during second-stage labor, but now associated with one stillbirth and one neonatal death. These experiences attest to the unpredictability of the fetal heart rate during second-stage labor. Spong and colleagues (1998) analyzed the characteristics of second-stage variable fetal heart rate decelerations in 250 deliveries and found that as the total number of decelerations to less than 70 beats/min increased, the 5-minute Apgar score decreased. Put another way, the longer a fetus was exposed to variable decelerations, the lower the Apgar score at 5 minutes.

Picquard and co-workers (1988) analyzed heart rate patterns during second-stage labor in 234 women in an attempt to identify specific patterns to diagnose fetal compromise. Loss of beat-to-beat variability and baseline fetal heart rate less than 90 beats/min were predictive of fetal acidemia. Krebs and co-workers (1981) also found that persistent or progressive baseline bradycardia and baseline tachycardia were associated with low Apgar scores. Gull and colleagues (1996) observed that abrupt fetal heart rate deceleration to less than 100 beats/min, and associated with loss of beat-to-beat variability for 4 minutes or longer, was predictive of fetal acidemia. Thus, abnormal baseline heart rate \mathfrak{R} — either bradycardia or tachycardia, absent beat-to-beat variability, or both \mathfrak{R} — in the presence of second-stage decelerations is associated with increased but not inevitable fetal compromise ([Fig. 18-25](#)).

Figure 18-6. Fetal heart rate obtained by scalp electrode and recorded at 1 cm/min compared with that of 3 cm/min chart recorder paper speed.

Figure 18-7. Fetal bradycardia measured with a scalp electrode in a pregnancy complicated by placental abruption and subsequent fetal death.

Figure 18-8. Schematic representation of short-term beat-to-beat variability measured by a fetal scalp electrode. (t =time interval between successive fetal R waves.) (From Klavan and co-authors, 1977.)

Figure 18-9. Schematic representation of long-term beat-to-beat variability of the fetal heart rate ranging between 125 and 135 beats/min. (From Klavan and co-authors, 1977.)

Figure 18-10. Grades of baseline fetal heart rate variability (irregular fluctuations in the baseline of 2 cycles per minute or greater) together with a sinusoidal pattern. The sinusoidal pattern differs from variability in that it has a smooth, sinelike pattern of regular fluctuation and is excluded in the definition of fetal heart rate variability. (1) Undetectable, absent variability; (2) minimal $\mathfrak{R} \leq 5$ beats/min variability; (3) moderate (normal), 6 to 25 beats/min variability; (4) marked, > 25 beats/min variability; (5) sinusoidal pattern. (From National Institute of Child Health and Human Development Research Planning Workshop, 1997.)

Figure 18-12. Internal fetal monitoring at term demonstrated occasional abrupt beat-to-beat fetal heart rate spiking due to erratic extrasystoles shown in the superimposed fetal electrocardiogram. The normal infant was delivered spontaneously and had a normal cardiac rhythm in the nursery.

Figure 18-13. Sinusoidal fetal heart rate pattern associated with maternal intravenous meperidine administration. Sine waves are occurring at a rate of 6 cycles per minute.

Figure 18-14. Features of early fetal heart rate deceleration. Characteristics include gradual decrease in the heart rate with both onset and recovery coincident with the onset and recovery of the contraction. The nadir of the deceleration is 30 seconds or more after the onset of the deceleration.

Figure 18-15. Two different fetal heart rate patterns during second-stage labor that are likely both due to head compression. Maternal bearing-down efforts correspond to the spikes with uterine contractions. Fetal heart rate deceleration C is consistent with the pattern of head compression shown in [Figure 18-12](#). Deceleration B, however, is "variable" in appearance because of its jagged configuration and may also represent cord occlusion.

Figure 18-16. Features of late fetal heart rate deceleration. Characteristics include gradual decrease in the heart rate with the nadir and recovery occurring after the end of the contraction. The nadir of the deceleration occurs 30 seconds or more after the onset of the deceleration.

Figure 18-17. Late decelerations due to uteroplacental insufficiency resulting from placental abruption. Immediate cesarean delivery was performed. Umbilical artery pH was 7.05 and the P_{O_2} was 11 mm Hg.

Figure 18-18. Features of variable fetal heart rate decelerations. Characteristics include abrupt decrease in the heart rate with onset commonly varying with successive contractions. The decelerations measure ≥ 15 beats/min for 15 seconds or longer with an onset to nadir phase of less than 30 seconds. Total duration is less than 2 minutes.

Figure 18-19. Fetal heart rate effects of compression of a prolapsed umbilical cord in a 25-week footling breech. Panel **A** shows the effects of 25-second compression compared with those of 40 seconds in panel **B**. (Redrawn from Hon, 1959, with permission.)

Figure 18-20. Total umbilical cord occlusion (*arrow*) in the sheep fetus is accompanied by increase in fetal aortic blood pressure. Blood pressure changes in the umbilical vessels are also shown. (From Kunzel, 1985, with permission.)

Figure 18-21. Varying (variable) fetal heart rate decelerations. Deceleration B exhibits "shoulders" of acceleration compared with deceleration A.

Figure 18-22. Schematic representation of the fetal heart rate (FHR) effects of partial occlusion (PO) and complete occlusion (CO) of the umbilical cord. (FSBP = fetal systemic blood pressure; UA = umbilical artery; UC = uterine contraction; UV = umbilical vein.) (From Lee and co-authors, 1975, with permission.)

Figure 18-23. Saltatory baseline fetal heart rate showing rapidly recurring couplets of acceleration combined with deceleration.

Figure 18-24. Prolonged fetal heart rate deceleration due to uterine hyperactivity. Approximately 3 minutes of the tracing are shown, but the fetal heart rate returned to normal after uterine hypertonus resolved. Vaginal delivery later ensued.

Figure 18-25. Cord compression fetal heart rate decelerations in second-stage labor associated with tachycardia and loss of variability. The umbilical cord arterial pH was 6.9.

ADMISSION FETAL MONITORING IN LOW-RISK PREGNANCIES. In this application of electronic fetal monitoring, women with low-risk pregnancies are monitored for a short period on admission for labor and continuous monitoring is used only if abnormalities of the fetal heart rate are subsequently identified. Mires and colleagues (2001) randomly assigned 3752 low-risk women in spontaneous labor at the time of admission to either auscultation of the fetal heart rate using Doppler during and immediately after at least one contraction or to 20 minutes of electronic fetal monitoring. Use of admission electronic fetal monitoring did not improve infant outcome. Moreover, its use resulted in increased interventions, including operative delivery. Impey and colleagues (2003) performed a similar study in 8588 low-risk women and also found no improvement in infant outcome. More than half of the women enrolled in these studies, whether they received admission electronic monitoring or auscultation, eventually required continuous monitoring for diagnosed abnormalities in the fetal heart rate.

COMPLICATIONS OF ELECTRONIC FETAL MONITORING. Injury to the fetal scalp or breech by the electrode is rarely a major problem, although application at some other site—such as the eye in case of a face presentation—can prove serious. Rarely, a fetal vessel in the placenta may be ruptured by catheter placement (Trudinger and Pryse-Davies, 1978). Severe cord compression has been described from entanglement with the catheter. Penetration of the placenta, causing hemorrhage and possibly uterine perforation during catheter insertion, has led to serious morbidity, as well as spurious recordings that resulted in inappropriate management.

Both the fetus and the mother may be at increased risk of *infection* as the consequence of internal monitoring. Scalp wounds from the electrode may become infected, and subsequent cranial osteomyelitis has been reported (Eggink and co-investigators, 2004; McGregor and McFarren, 1989). Puerperal infection increased from 12 to 18 percent in externally monitored women compared with those in whom an internal apparatus was used (Faro and associates, 1990). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have recommended that certain maternal infections, including human immunodeficiency virus (HIV), herpes simplex virus, hepatitis B virus, and hepatitis C virus, are relative contraindications to internal fetal heart rate monitoring.

OTHER INTRAPARTUM ASSESSMENT TECHNIQUES

FETAL SCALP BLOOD SAMPLING. According to the American College of Obstetricians and Gynecologists (1995b), measurements of the pH in capillary scalp blood may help to identify the fetus in serious distress. The College also notes that the procedure is now used uncommonly. An illuminated endoscope is inserted through the dilated cervix after ruptured membranes so as to press firmly against the fetal scalp (Fig. 18-26). The skin is wiped clean with a

cotton swab and coated with a silicone gel to cause the blood to accumulate as discrete globules. An incision is made through the skin to a depth of 2 mm with a special blade on a long handle. As a drop of blood forms on the surface, it is immediately collected into a heparinized glass capillary tube, and the pH of the blood is measured promptly.

The pH of fetal capillary scalp blood is usually lower than that of umbilical venous blood and approaches that of umbilical arterial blood. Zalar and Quilligan (1979) recommended the following protocol to try to confirm fetal distress: If the pH is greater than 7.25, labor is observed. If the pH is between 7.20 and 7.25, the pH measurement is repeated within 30 minutes. If the pH is less than 7.20, another scalp blood sample is collected immediately and the mother is taken to an operating room and prepared for surgery. Delivery is performed promptly if the low pH is confirmed. Otherwise, labor is allowed to continue and scalp blood samples are repeated periodically. The only benefits reported for scalp pH testing were estimates of fewer cesarean deliveries for fetal distress (Young and co-workers, 1980b). Goodwin and associates (1994), however, in a study of 112,000 deliveries, showed a decrease in the scalp pH sampling rate from approximately 1.8 percent in the mid-1980s to 0.03 percent by 1992 with no increased delivery rate for fetal distress. They concluded that scalp pH sampling was unnecessary. Kruger and colleagues (1999) have advocated use of fetal scalp blood lactate concentration as an adjunct to pH.

Figure 18-26. The technique of fetal scalp sampling using an amnioscope. The end of the endoscope is displaced from the fetal vertex approximately 2 cm to show the disposable blade against the fetal scalp before incision. (Modified from Hamilton and McKeown, 1974, with permission.)

SCALP STIMULATION. Clark and associates (1984) have suggested that scalp stimulation is an alternative to scalp blood sampling. This proposal was based on the observation that acceleration of the heart rate in response to pinching of the scalp with an Allis clamp just prior to obtaining blood was invariably associated with a normal pH. Conversely, failure to provoke acceleration was not uniformly predictive of fetal acidemia. Later, Elimian and associates (1997) reported that of 58 cases in which the fetal heart rate accelerated 10 beats/min or more after 15 seconds of gentle digital stroking of the scalp, 100 percent had a scalp pH of 7.20 or greater. Without an acceleration, however, only 30 percent had a scalp pH less than 7.20.

VIBROACOUSTIC STIMULATION. Fetal heart rate acceleration in response to vibroacoustic stimulation has been recommended as a substitute for scalp sampling (Edersheim and colleagues, 1987). The technique involves use of an electronic artificial larynx placed a centimeter or so from, or directly onto, the maternal abdomen (see [Chap. 15](#), p. 380). Response to vibroacoustic stimulation is considered normal if a fetal heart rate acceleration of at least 15 beats/min for at least 15 seconds occurs within 15 seconds after the stimulation and with prolonged fetal movements (Sherer, 1994). Lin and colleagues (2001) prospectively studied vibroacoustic stimulation in 113 women in labor with either moderate to severe variable or late fetal heart rate decelerations. They concluded that this technique is an effective predictor of fetal acidosis in the setting of variable decelerations. However, the predictability for fetal acidosis in the setting of late decelerations is limited. Other investigators have reported that although vibroacoustic stimulation in second-stage labor is associated with fetal heart rate reactivity, the quality of the response did not predict neonatal outcome or enhance labor management (Anyagbunam and associates, 1994).

Skupski and colleagues (2002) performed a meta-analysis of reports on intrapartum fetal stimulation tests published between 1966 and 2000. Four types of fetal stimulation were analyzed, including scalp puncture for pH testing, use of an Allis clamp to pinch the fetal scalp, vibroacoustic stimulation, and digital stroking of the scalp. Results were similar for all four methods. These investigators concluded that intrapartum stimulation tests were useful to rule out fetal acidemia. However, they cautioned that these tests are "less than perfect."

FETAL PULSE OXIMETRY. Using technology similar to that of adult pulse oximetry, instrumentation has been developed that may allow assessment of fetal oxyhemoglobin saturation once the membranes are ruptured. A unique padlike sensor ([Fig. 18-27](#)) is inserted through the cervix and positioned against the fetal face, where it is held in place by the uterine wall. As reviewed by Yam and co-authors (2000), this device has been used extensively by many investigators and has been reported to reliably register fetal oxygen saturation in 70 to 95 percent of women throughout 50 to 88 percent of their labors. The lower limit for normal fetal oxygen saturation is generally considered to be 30 percent by most investigators (Gorenberg and colleagues, 2003; Stiller and colleagues, 2002). However, as shown in [Figure 18-28](#), fetal oxygen saturation normally varies greatly when measured in umbilical artery blood (Arikan and colleagues, 2000). Bloom and colleagues (1999) reported that brief, transient fetal oxygen saturations below 30 percent were common during labor because such values were observed in 53 percent of fetuses with normal outcomes. Saturation values below 30 percent, however, when persistent for 2 minutes or longer, were associated with an increased risk of potential fetal compromise.

Garite and colleagues (2000) randomly assigned 1010 women with term pregnancies, and who developed predefined abnormal fetal heart rate patterns, to either conventional fetal monitoring alone or fetal monitoring plus continuous fetal pulse oximetry. Cesarean delivery for fetal distress was performed when pulse oximetry values remained less than 30 percent for the entire interval between two contractions or when the fetal heart rate patterns met predefined guidelines. The use of fetal pulse oximetry significantly reduced the rate of cesarean delivery for nonreassuring fetal status from 10.2 to 4.5 percent. Alternatively, the cesarean delivery rate for dystocia increased significantly from 9 to 19 percent when pulse oximetry was used. There were no neonatal benefits or adverse effects associated with fetal pulse oximetry. In January 2000, the Obstetrics and Gynecology Devices Panel of the Medical Devices Advisory Committee of the Food and Drug Administration, based on this randomized study, recommended marketing of the Nellcor N-400 Fetal Oxygen Monitoring System. The American College of Obstetricians and Gynecologists (2001) has recommended that additional randomized trials be conducted to evaluate fetal pulse oximetry before adoption of this device into clinical practice. The technique currently is being evaluated by the NICHD Maternal-Fetal Medicine Units Network.

FETAL ELECTROCARDIOGRAPHY. Concerns about the validity of continuous electronic fetal monitoring during labor have prompted searches for better methods of monitoring. Because as fetal hypoxia worsens, there are changes in the ST segment and PR interval of the fetal ECG, several investigators have assessed the value of analyzing these parameters as an adjunct to conventional fetal monitoring. The technique requires internal monitoring of the fetal heart rate and special equipment to process the fetal ECG. Westgate and co-workers (1993) studied the benefits of monitoring ST-segment changes in a randomized trial of 2400 pregnancies. Infant outcomes were not improved compared with those with use of conventional fetal monitoring alone, although there was a reduction in the cesarean delivery rate for fetal distress.

In another randomized trial of 4966 Swedish women, Amer-Wahlin and colleagues (2001) found that the addition of ST analysis to conventional fetal monitoring significantly reduced cesarean delivery rates for fetal distress as well as metabolic acidemia in umbilical artery blood. ST data were collected from all the fetuses in this study. A total of 29 infants had adverse outcomes defined to include death (3), neonatal encephalopathy (7), or metabolic acidemia (19), and 22 of these had abnormal ST waveforms (Noren and colleagues, 2003). A serious confounding factor in interpretation of this study is the long intervals of abnormal fetal heart rate patterns before intervention. For example, the median interval before delivery, and during which time the fetal heart rate pattern was significantly abnormal, was almost 3 hours in the infants with encephalopathy. This may explain why U.S. clinicians shown these very same fetal monitoring tracings more often intervened compared with their European counterparts (Ross and colleagues, 2004). It must be considered that ST abnormalities may occur late in the course of fetal jeopardy, manifest as abnormal heart rate patterns.

INTRAPARTUM DOPPLER VELOCIMETRY. Doppler analysis of the umbilical artery has been studied as another potential adjunct to conventional fetal monitoring. Abnormal Doppler waveforms (see [Chap. 16](#), p. 401), when present, may signify pathological umbilical-placental vessel resistance. Farrell and co-authors (1999) reviewed the literature on the use of intrapartum Doppler velocimetry and concluded that this technique was a poor predictor of adverse perinatal outcomes. They concluded that Doppler velocimetry had little, if any, role in the surveillance of fetal well-being during labor.

"FETAL DISTRESS"

DEFINITION. The term *fetal distress* is too broad and vague to be applied with any precision to clinical situations. Uncertainty about the diagnosis of fetal distress based on interpretation of fetal heart rate patterns has given rise to use of descriptions such as *reassuring* or *nonreassuring*. "Reassuring" suggests a restoration of confidence by a particular pattern, whereas "nonreassuring" suggests inability to remove doubt. These patterns during labor are dynamic, such that they can rapidly change from reassuring to nonreassuring and vice versa. In this situation, obstetricians experience surges of both confidence and doubt. Put another way, most diagnoses of fetal distress using heart rate patterns occur when obstetricians lose confidence or cannot assuage doubts about fetal condition. **These fetal assessments are entirely subjective clinical judgments inevitably subject to imperfection and must be recognized as such.**

Why is diagnosis of fetal distress based on heart rate patterns so tenuous? One explanation is that these patterns are more a reflection of fetal physiology than of pathology. Physiological control of heart rate includes a variety of interconnected mechanisms that depend on blood flow as well as oxygenation. Moreover, the activity of these control mechanisms is influenced by the preexisting state of fetal oxygenation as seen, for example, with chronic placental insufficiency. Importantly, the fetus is tethered by an umbilical cord whereby blood flow is constantly in jeopardy, which demands that the fetus have a strategy for survival. Moreover, normal labor is a process of increasing acidemia (Rogers and colleagues, 1998). Thus, normal labor is a process of repeated fetal hypoxic events resulting inevitably in acidemia. Put another way, and assuming that "asphyxia" can be defined as hypoxia leading to acidemia, normal parturition is an asphyxiating event for the fetus.

DIAGNOSIS. It follows that identification of "fetal distress" based upon fetal heart rate patterns is imprecise and controversial. Experts in interpretation of these patterns so often disagree with each other that one organizer of the NICHD fetal monitoring workshop (1997) lightheartedly compared the experts in attendance with marine iguanas of the Galapagos Islands ☹— "all on the same beach but facing different directions and spitting at one another constantly" (Parer, 1997).

Ayres-de-Campos and colleagues (1999) investigated interobserver agreement on interpretation of fetal heart rate patterns and found that agreement ☹— or conversely, disagreement ☹— was related to whether the pattern was normal, suspicious, or pathological. Specifically, experts agreed on 62 percent of normal patterns, 42 percent of suspicious patterns, and only 25 percent of pathological patterns. Keith and co-workers (1995) asked each of 17 experts to review 50 tracings on two occasions, at least 1 month apart. About 20 percent changed their own interpretations, and approximately 25 percent did not agree with the interpretations of their colleagues. Similarly, Murphy and colleagues (2003) concluded that at least part of the

interpretation problem is due to a lack of formalized education in U.S. training programs.

Several research efforts have been aimed at testing the utility of well-defined fetal heart rate classification systems. Berkus and colleagues (1999) retrospectively analyzed fetal heart rate patterns during the last 30 minutes of labor in 1859 term pregnancies. The study was designed to determine if specific patterns, or combinations of patterns, predicted neonatal outcome. Indisputably normal fetal heart rate patterns were recorded within 30 minutes of delivery in only 26 percent of cases. Prolonged bradycardia or tachycardia or fetal heart rate patterns that combined the absence of accelerations with severe variable or late decelerations were associated with an increased incidence of adverse infant outcome. Low and colleagues (1999) analyzed fetal heart rate patterns of term infants born with significant metabolic acidemia, defined as an umbilical artery base deficit greater than 16 mmol/L. Such acidemia was rare, occurring in only 71 of 23,000 births. Patterns with absent baseline variability were the most specific, but identified only 17 percent of the acidemic fetuses.

Dellinger and colleagues (2000) analyzed intrapartum fetal heart rate patterns in 898 pregnancies using a classification system of their design. Fetal heart rate patterns during the hour before delivery were classified as "normal," "stress," or "distress." Fetal "distress" was diagnosed in eight (1 percent) tracings, and 70 percent were classified as "normal." Almost one third were intermediate patterns. Fetal "distress" was classified as patterns with zero variability *plus* late or moderate-to-severe variable decelerations or with baseline rates less than 110 beats/min for 5 minutes or longer. Outcomes such as cesarean delivery, fetal acidemia, and admission to the neonatal intensive care nursery were significantly related to the fetal heart rate pattern. The authors concluded that their classification system accurately predicted normal outcomes for fetuses as well as discriminating true fetal distress. Others have used computers in an effort to improve interpretation of fetal heart rate patterns, with variable results (Agrawal, 2003; Bellver, 2004; Devoe, 2000, and all their co-authors).

In summary, after more than 30 years of experience with interpretation of fetal heart rate patterns, there is finally emerging evidence that some combinations of fetal heart rate characteristics can be meaningfully used to identify normal and severely abnormal fetuses. As shown in [Table 18-1](#), true fetal distress patterns appear to be those in which beat-to-beat variability is zero in conjunction with severe decelerations or persistent baseline rate changes, or both. Fortunately, such fetal distress is rare. One explanation for the persistent failure to scientifically establish the benefits of fetal heart rate monitoring is the rarity of such fetal distress, effectively precluding statistically significant results from clinical trials (Hornbuckle and colleagues, 2000).

MECONIUM IN THE AMNIONIC FLUID. Obstetrical teaching throughout the past century has included the concept that meconium passage is a potential warning of fetal asphyxia. In 1903, J. Whitridge Williams observed and attributed meconium passage to "relaxation of the sphincter ani muscle induced by faulty aeration of the (fetal) blood." Obstetricians, however, have also long realized that the detection of meconium during labor is problematic in the prediction of fetal distress or asphyxia. In their review, Katz and Bowes (1992) emphasized the prognostic uncertainty of meconium by referring to the topic as a "murky subject." Indeed, although 12 to 22 percent of human labors are complicated by meconium, few such labors are linked to infant mortality. In an investigation from Parkland Hospital, meconium was found to be a "low-risk" obstetrical hazard because the perinatal mortality attributable to meconium was 1 death per 1000 live births (Nathan and co-workers, 1994).

Three theories have been suggested to explain fetal passage of meconium and may, in part, explain the tenuous connection between the detection of meconium and infant mortality. The pathological explanation proposes that fetuses pass meconium in response to hypoxia, and that meconium therefore signals fetal compromise (Walker, 1953). Alternatively, in utero passage of meconium may represent normal gastrointestinal tract maturation under neural control (Mathews and Warshaw, 1979). Third, meconium passage could follow vagal stimulation from common but transient umbilical cord entrapment and resultant increased peristalsis (Hon and colleagues, 1961). Thus, fetal release of meconium also could represent physiological processes.

Ramin and co-authors (1996) studied almost 8000 pregnancies with meconium-stained amniotic fluid delivered at Parkland Hospital. Meconium aspiration syndrome was significantly associated with fetal acidemia at birth. Other significant correlates of aspiration included cesarean delivery, forceps to expedite delivery, intrapartum heart rate abnormalities, depressed Apgar scores, and need for assisted ventilation at delivery. Analysis of the type of fetal acidemia based on umbilical blood gases suggested that the fetal compromise associated with meconium aspiration syndrome was an acute event, because most acidemic fetuses had abnormally increased P_{CO_2} rather than a pure metabolic acidemia.

Interestingly, hypercarbia in fetal lambs has been shown to induce fetal gasping and resultant increased amniotic fluid inhalation (Dawes and co-workers, 1972). Jovanovic and Nguyen (1989) observed that meconium gasped into the fetal lungs caused aspiration syndrome only in asphyxiated animals. Ramin and co-authors (1996) hypothesized that the pathophysiology of meconium aspiration syndrome includes, but is not limited to, fetal hypercarbia, which stimulates fetal respiration leading to aspiration of meconium into the alveoli, and lung parenchymal injury secondary to acidemia-induced alveolar cell damage. In this pathophysiological scenario, meconium in amniotic fluid is a fetal environmental hazard rather than a marker of preexistent compromise. This proposed pathophysiological sequence is not all-inclusive, because it does not account for approximately half of the cases of meconium aspiration syndrome in which the fetus was not acidemic at birth.

Thus, it was concluded that the high incidence of meconium observed in the amniotic fluid during labor often represents fetal passage of gastrointestinal contents in conjunction with normal physiological processes. Although normal, such meconium becomes an environmental hazard when fetal acidemia supervenes. Importantly, such acidemia occurs acutely, and therefore meconium aspiration is unpredictable and likely unpreventable. Moreover, Greenwood and colleagues (2003), in a prospective study of 8394 women with clear amniotic fluid, emphasize that clear fluid is an unreliable sign of fetal well-being.

There is accumulating evidence that many infants with meconium aspiration syndrome have suffered chronic hypoxia before birth (Ghidini and Spong, 2001). For example, Blackwell and colleagues (2001) found that 60 percent of infants diagnosed as having meconium aspiration syndrome had umbilical artery blood pH 7.20 or greater, suggesting that this syndrome was unrelated to the neonatal condition at delivery. Similarly, markers of chronic hypoxia, such as fetal erythropoietin levels and nucleated red blood cells counts in newborn infants, suggest that chronic hypoxia is involved in many cases of meconium aspiration syndrome (Dollberg and colleagues, 2001; Jazayeri and colleagues, 2000).

MANAGEMENT OPTIONS WITH "FETAL DISTRESS." Management for significantly variant fetal heart rate patterns consists of correcting any fetal insult, if possible. Measures suggested by the American College of Obstetricians and Gynecologists (1998) are listed in [Table 18-2](#). Moving the mother to the lateral position, correcting maternal hypotension caused by regional analgesia, and discontinuing oxytocin serve to improve uteroplacental perfusion. Examination is done to rule out prolapsed cord or impending delivery.

Tocolysis. A single intravenous or subcutaneous injection of 0.25 mg of terbutaline sulfate given to relax the uterus has been described as a temporizing maneuver in the management of nonreassuring fetal heart rate patterns during labor. The rationale for this action is that inhibition of uterine contractions might improve fetal oxygenation, thus achieving in utero resuscitation. Cook and Spinnato (1994) described their experience with terbutaline tocolysis for fetal resuscitation in 368 pregnancies over a 10-year period. Such resuscitation improved fetal scalp blood pH values, although all of these women were delivered by cesarean. These investigators concluded that although the studies were small and rarely randomized, most reported favorable results with terbutaline tocolysis for nonreassuring patterns. Small intravenous doses of nitroglycerin (60 to 180 µg) also have been reported to be beneficial (Mercier and colleagues, 1997).

Amnioinfusion. Gabbe and co-workers (1976) showed in monkeys that removal of amniotic fluid produced variable decelerations and that replenishment of fluid with saline relieved the decelerations. Miyazaki and Taylor (1983) infused saline through the intrauterine pressure catheter in laboring women who had either variable decelerations or prolonged decelerations attributed to cord entrapment. Such therapy improved the heart rate pattern in half of the women studied. Later, Miyazaki and Nevarez (1985) randomly assigned 96 nulliparous women in labor with cord compression patterns and found that those who were treated with amnioinfusion less often required cesarean delivery for fetal distress.

On the basis of many of these early reports, transvaginal amnioinfusion has been extended into three clinical areas:

1. Treatment of variable or prolonged decelerations.
2. Prophylaxis for cases of known oligohydramnios, as with prolonged rupture of membranes.
3. In an attempt to dilute or wash out thick meconium (see [Chap. 29](#), p. 675).

Many different amnioinfusion protocols have been reported, but most include a 500 to 800 mL bolus of warmed normal saline followed by a continuous infusion of approximately 3 mL per minute (Owen and co-workers, 1990; Pressman and Blakemore, 1996). In another study, Rinehart and colleagues (2000) randomly gave either 500 mL boluses of normal saline at room temperature alone, or 500 mL boluses plus continuous infusion of 3 mL per minute. Their study included 65 women with variable decelerations, and the investigators found neither method to be superior. Wenstrom and co-authors (1995) surveyed use of amnioinfusion in U.S. teaching hospitals. The procedure was used in 96 percent of the 186 centers surveyed, and it was estimated that 3 to 4 percent of all women delivered at these centers received such infusion. Potential complications of amnioinfusion are summarized in [Table 18-3](#).

PROPHYLACTIC AMNIOINFUSION FOR OLIGOHYDRAMNIOS. Amnioinfusion for oligohydramnios has been used prophylactically in an effort to avoid intrapartum fetal heart rate patterns from umbilical cord occlusion. Nageotte and co-workers (1991) found that such amnioinfusion resulted in significantly decreased frequency and severity of variable decelerations in labor. There was no improvement, however, in the cesarean delivery rate or condition of term infants. In a randomized investigation, Macri and co-workers (1992) studied prophylactic amnioinfusion in 170 term and postterm pregnancies complicated by both thick meconium and oligohydramnios. Amnioinfusion significantly reduced cesarean delivery rates for fetal distress as well as meconium aspiration syndrome. In contrast, Ogundipe and associates (1994) randomly assigned 116 term pregnancies with an amniotic fluid index of less than 5 cm to receive prophylactic amnioinfusion or standard obstetrical care. There were no significant differences in overall cesarean delivery rates, delivery rates for fetal distress, or umbilical gas studies.

AMNIOINFUSION FOR MECONIUM-STAINED AMNIONIC FLUID. Pierce and associates (2000) summarized the results of 13 prospective trials of intrapartum amnioinfusion in 1924 women with moderate to thick meconium-stained fluid. Infants born to women treated by amnioinfusion were significantly less likely to have meconium below the vocal cords and were less likely to develop meconium aspiration syndrome than infants not given amnioinfusion. The cesarean delivery rate was also lower in the amnioinfusion group. Similar results were reported by Rathore and colleagues (2002). In contrast, at the University of Tennessee, amnioinfusion was found not feasible in half of women with moderate or thick meconium who were randomized to this treatment (Usta and colleagues, 1995). These investigators were unable to demonstrate any improvement in neonatal outcomes. Spong and associates (1994) also concluded that, although prophylactic amnioinfusion did dilute meconium, it did not improve perinatal outcome.

FETAL HEART RATE PATTERNS AND BRAIN DAMAGE. Attempts to correlate fetal heart rate patterns with brain damage have been based primarily on studies of infants identified as a result of medicolegal actions. For example, Rosen and Dickinson (1992) analyzed intrapartum fetal heart rate patterns in 55 such cases and found no specific pattern that was correlated with neurological injury. Phelan and Ahn (1994) reported that among 48 fetuses later found to be neurologically impaired, a persistent nonreactive fetal heart rate tracing was already present at the time of admission in 70 percent. They concluded that fetal neurological injury occurred predominately prior to arrival to the hospital. When they looked retrospectively at heart rate patterns in 209 brain-damaged infants, they concluded that there was not a single unique pattern associated with fetal neurological injury (Ahn and co-workers, 1996). Identical results were reported by Williams and Galerneau (2004), who also found that neonatal seizures due to hypoxic ischemic encephalopathy were related to nonspecific abnormal fetal heart rate pattern only when the patterns had been present an average of 72 minutes.

Experimental Evidence. Fetal heart rate patterns necessary for perinatal brain damage have been studied in experimental animals. Myers (1972) described the effects of complete and partial asphyxia in rhesus monkeys in studies of brain damage due to perinatal asphyxia. Complete asphyxia was produced by total occlusion of umbilical blood flow that led to prolonged deceleration ([Fig. 18-29](#)). Fetal arterial pH did not reach 7.0 until about 8 minutes after complete cessation of oxygenation and umbilical flow. At least 10 minutes of such prolonged deceleration was required before there was evidence of brain damage in surviving fetuses.

Myers (1972) also produced partial asphyxia in rhesus monkeys by impeding maternal aortic blood flow. This resulted in late decelerations due to uterine and placental hypoperfusion. He observed that several hours of these late decelerations did not damage the fetal brain unless the pH fell below 7.0. Indeed, Adamsons and Myers (1977) reported subsequently that late decelerations were a marker of partial asphyxia long before brain damage occurred.

The most common fetal heart rate pattern during labor, due to umbilical cord occlusion, requires considerable time to significantly affect the fetus in experimental animals. Clapp and colleagues (1988) partially occluded the umbilical cord for 1 minute every 3 minutes in fetal sheep and observed brain damage only after 2 hours. In another experiment in fetal sheep, Westgate and colleagues (2001) totally occluded the umbilical cord for 1 minute every 5 minutes for 4 hours without causing significant acidemia. Total occlusions for 2 minutes every 5 minutes resulted in the rapid onset of progressive fetal metabolic acidemia. The results from experiments such as these suggest that the effects of umbilical cord entrapment depend on the degree of occlusion (partial versus total), the duration of individual occlusions, and the frequency of such occlusions.

Human Evidence. The contribution of intrapartum events to subsequent neurological handicaps has been greatly overestimated (see [Chap. 29](#), p. 654). Nelson and Grether (1998) performed a population-based study of children with disabling spastic cerebral palsy in which the intrapartum records of these children were compared with matched controls. Intrapartum fetal heart rate abnormalities did not distinguish between children with cerebral palsy and normal controls. Badawi and colleagues (1998) performed a case-control population-based study of infants with cerebral palsy in Western Australia. Only 5 percent of the brain-damaged infants had intrapartum factors, which led them to conclude that most cerebral palsy is unrelated to labor events.

Low and co-workers (1989) divided perinatal brain damage found following an asphyxial event into three categories based on microscopic findings:

1. From 18 to 48 hours ☞ neuronal necrosis with pyknosis or lysis of the nucleus in shriveled eosinophilic cells.
2. From 48 to 72 hours ☞ more intense neuronal necrosis with macrophage response.
3. More than 3 days ☞ all the preceding plus astrocytic response with gliosis and in some, early cavitation.

Abnormal brain histopathology was not observed with acute, lethal asphyxia. Moreover, 43 percent of brain damage episodes occurred prior to labor and 25 percent were in the neonatal period. In another investigation, Low and co-workers (1984) estimated that more than 1 hour of fetal hypoxia associated with profound metabolic acidemia ☞ pH less than 7.0 ☞ was required before neurological abnormalities could be diagnosed at 6 to 12 months of age. Low and co-workers (1988) identified 37 term infants with profound metabolic acidemia at birth, followed them for 1 year, and found major neurological deficits in 13 percent. Minor deficits were diagnosed in 10 infants, and the remaining 60 percent were normal. These investigators further observed that intrapartum fetal asphyxia with metabolic acidemia at delivery in both the term and preterm fetus was marked by severe complications not only of the central nervous system, but also of the respiratory and renal systems (Low and colleagues, 1994, 1995).

Clearly, for brain damage to occur, the fetus must be exposed to much more than a brief period of hypoxia. Moreover, the hypoxia must cause profound, just barely sublethal metabolic acidemia. Fetal heart rate patterns consistent with these sublethal conditions are fortunately rare. These observations strengthen the position of the American College of Obstetricians and Gynecologists (2003) on the criteria necessary to consider birth asphyxia as a cause of cerebral palsy ([Table 18-4](#)). Importantly, spastic quadriplegia and, less commonly, dyskinetic cerebral palsy are the only types of cerebral palsy associated with acute hypoxic intrapartum events. Unilateral brain lesions ☞ hemiplegia or diplegia ☞ are not a result of intrapartum hypoxia.

BENEFITS OF ELECTRONIC FETAL HEART RATE MONITORING. There are several fallacious assumptions behind expectations of improved perinatal outcome with electronic monitoring. One assumption is that fetal distress is a slowly developing phenomenon and that electronic monitoring makes possible early detection of the compromised fetus. This assumption is illogical, viz., how can all fetuses die slowly? Another presumption is that all fetal damage develops in the hospital. Only recently has attention focused on the reality that most damaged fetuses suffered insults before arrival at labor units. The very term *fetal monitor* implies that this inanimate technology in some fashion "monitors." The assumption is made that if a dead or damaged infant is delivered, the tracing strip must provide some clue, because this device was monitoring fetal condition. All of these assumptions led to great expectations and fostered the belief that all dead or damaged neonates were preventable. Parer and King (2000) reviewed reasons why fetal heart rate monitoring did not live up to its expectations. These unwarranted expectations have greatly fueled litigation in obstetrics. Indeed, Symonds (1994) reported that 70 percent of all liability claims related to fetal brain damage are based on reputed abnormalities seen in the electronic fetal monitor tracing.

By the end of the 1970s, questions about the efficacy, safety, and costs of electronic monitoring were being voiced from the Office of Technology Assessment, the United States Congress, and the Centers for Disease Control and Prevention. Banta and Thacker (2002) have reviewed the last 25 years of controversy on the benefits, or lack thereof, of electronic fetal monitoring. Parer (2003) points out that the controversy continues and that "... to justify our continued use of EFM [electronic fetal monitoring], we need to clean up our house. We must come to some agreement on a national level about interpretation and management."

Parkland Hospital Experience: Selective Versus Universal Monitoring. In July 1982, an investigation began at Parkland

Hospital to ascertain whether all women in labor should undergo electronic monitoring (Leveno and co-workers, 1986). In alternating months, universal electronic monitoring was rotated with selective heart rate monitoring, which was the prevailing practice. During the 3-year investigation, 17,410 labors were managed using universal electronic monitoring. No significant differences were found in any perinatal outcomes. There was a significantly small increase in the cesarean delivery rate for fetal distress associated with universal monitoring. Thus, increased application of electronic monitoring at Parkland Hospital did not improve perinatal results, but it increased the frequency of cesarean delivery for fetal distress.

Summary of Randomized Studies. Thacker and co-authors (1995) identified 12 published randomized clinical trials of electronic fetal monitoring from 1966 to 1994. There were 58,624 total pregnancies included in these studies. These investigators concluded that the benefits once claimed for electronic monitoring are clearly more modest than were believed and appear to be primarily in the prevention of neonatal seizures. Long-term implications of this outcome, however, appear less serious than once believed. Abnormal neurological consequences were not consistently higher among children monitored by auscultation compared with electronic methods. The authors concurred with the position of the American College of Obstetricians and Gynecologists (1995b) on intrapartum fetal surveillance ([Table 18-5](#)).

CURRENT RECOMMENDATIONS. The methods most commonly used for intrapartum fetal heart rate monitoring include auscultation with a fetal stethoscope or a Doppler ultrasound device, or continuous electronic monitoring of the heart rate and uterine contractions. No scientific evidence has identified the most effective method, including the frequency or duration of fetal surveillance that ensures optimum results. Summarized in [Table 18-5](#) are the current recommendations of the American College of Obstetricians and Gynecologists (1995b). These recommendations have been reaffirmed by both the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002). Intermittent auscultation or continuous electronic monitoring is considered an acceptable method of intrapartum surveillance in both low- and high-risk pregnancies. The recommended interval between checking the heart rate, however, is longer in the uncomplicated pregnancy. When auscultation is used, it is recommended that it be performed after a contraction and for 60 seconds. It also is recommended that a 1-to-1 nurse-patient ratio be used if auscultation is employed.

INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY

Analysis of electronically measured uterine activity permits some generalities concerning the relationship of certain contraction patterns to labor outcome. There is considerable normal variation, however, and caution must be exercised before judging true labor or its absence solely from study of a monitor tracing. Uterine muscle efficiency to effect delivery varies greatly. To use an analogy, 100-meter sprinters all have the same muscle groups yet cross the finish line at different times.

INTERNAL UTERINE PRESSURE MONITORING. Amniotic fluid pressure is measured between and during contractions by a fluid-filled plastic catheter with its distal tip located above the presenting part. The catheter is connected to a strain-gauge pressure sensor adjusted to the same level as the catheter tip in the uterus. The amplified electrical signal produced in the strain gauge by variation in pressure within the fluid system is recorded on a calibrated moving paper strip simultaneously with the fetal heart rate recording. Intrauterine pressure catheters are now available that have the pressure sensor in the catheter tip, which obviates the need for the fluid column.

EXTERNAL MONITORING. Uterine contractions can be measured by a displacement transducer in which the transducer button, or "plunger," is held against the abdominal wall. As the uterus contracts, the button moves in proportion to the strength of the contraction. This movement is converted into a measurable electrical signal that indicates the *relative* intensity of the contraction \mathfrak{R} — it does not give an accurate measure of intensity. External monitoring can give a good indication of the onset, peak, and end of the contraction.

PATTERNS OF UTERINE ACTIVITY. Caldeyro-Barcia and Poseiro (1960) from Montevideo, Uruguay, were pioneers who have done much to elucidate the patterns of spontaneous uterine activity throughout pregnancy. Contractile waves of uterine activity were usually measured using intra-amniotic pressure catheters, but early in their studies as many as four simultaneous intramyometrial microballoons also were used to record uterine pressure. They also introduced the concept of *Montevideo units* to define uterine activity (see [Chap. 20](#), p. 498). By this definition, uterine performance is the product of the intensity \mathfrak{R} — increased uterine pressure above baseline tone \mathfrak{R} — of a contraction in millimeters of mercury multiplied by contraction frequency per 10 minutes. For example, three contractions in 10 minutes, each of 50 mm Hg intensity, would equal 150 Montevideo units.

During the first 30 weeks, uterine activity is comparatively quiescent. Contractions are seldom greater than 20 mm Hg, and these have been equated with those first described in 1872 by John Braxton Hicks. Uterine activity increases gradually after 30 weeks, and it is noteworthy that these *Braxton Hicks contractions* also increase in intensity and frequency. Further increases in uterine activity are typical of the last weeks of pregnancy, termed *prelabor*. During this phase, the cervix ripens, presumably as a consequence of increasing uterine contractions (see [Chap. 6](#), p. 153).

According to Caldeyro-Barcia and Poseiro (1960), clinical labor usually commences when uterine activity reaches values between 80 and 120 Montevideo units. This translates into approximately three contractions of 40 mm Hg every 10 minutes. Importantly, there is no clear-cut division between prelabor and labor, but rather a gradual and progressive transition.

During first-stage labor, uterine contractions increase progressively in intensity from about 25 mm Hg at commencement of labor to 50 mm Hg at the end. At the same time, frequency increases from three to five contractions per 10 minutes, and uterine baseline tone from 8 to 12 mm Hg. Uterine activity further increases during second-stage labor, aided by maternal bearing down. Indeed, contractions of 80 to 100 mm Hg are typical and occur as frequently as five to six per 10 minutes. Interestingly, the duration of uterine contractions \mathfrak{R} — 60 to 80 seconds \mathfrak{R} — does not increase appreciably from early active labor extending through the second-stage (Pontonnier and colleagues, 1975). Presumably, this constancy of duration serves a fetal respiratory gas-exchange function. That is, functional fetal "breath holding" during a uterine contraction, which results in isolation of the intervillous space where respiratory gas exchange occurs, has a 60- to 80-second limit that remains relatively constant.

Caldeyro-Barcia and Poseiro (1960) also observed empirically that uterine contractions are clinically palpable only after their intensity exceeds 10 mm Hg. Moreover, until the intensity of contractions reaches 40 mm Hg, the uterine wall can readily be depressed by the finger. At greater intensity, the uterine wall then becomes so hard that it resists easy depression. Uterine contractions usually are not associated with pain until their intensity exceeds 15 mm Hg, presumably because this is the minimum pressure required for distending the lower uterine segment and cervix. It follows that Braxton Hicks contractions exceeding 15 mm Hg may be perceived as uncomfortable because distention of the uterus, cervix, and birth canal is generally thought to elicit discomfort.

Hendricks (1968) observed that "the clinician makes great demands upon the uterus." The uterus is expected to remain well relaxed during pregnancy, to contract effectively but intermittently during labor, and then to remain in a state of almost constant contraction for several hours postpartum. [Figure 18-30](#) demonstrates an example of normal uterine activity during labor. As also described by Caldeyro-Barcia and Poseiro (1960), uterine activity progressively and gradually increases from prelabor through late labor. Interestingly, as shown in [Figure 18-30](#), uterine contractions after birth are identical to those resulting in delivery of the infant. Indeed, the pattern of uterine activity is one of gradual subsidence or reverse of that leading up to delivery. It is therefore not surprising that the uterus that performs poorly before delivery is also prone to atony and puerperal hemorrhage.

Origin and Propagation of Contractions. The uterus has not been studied extensively in terms of its nonhormonal physiological mechanisms of function. The normal contractile wave of labor originates near the uterine end of one of the fallopian tubes; thus, these areas act as "pacemakers" ([Fig. 18-31](#)). The right pacemaker usually predominates over the left and starts the great majority of contractile waves. Contractions spread from the pacemaker area throughout the uterus at 2 cm/sec, depolarizing the whole organ within 15 seconds. This depolarization wave propagates downward toward the cervix. Intensity is greatest in the fundus, and it diminishes in the lower uterus. This phenomenon is thought to reflect reductions of myometrial thickness from the fundus to the cervix. Presumably, this descending gradient of pressure serves to direct fetal descent toward the cervix as well as to efface the cervix. Importantly, all parts of the uterus are synchronized and reach their peak pressure almost simultaneously, giving rise to the curvilinear waveform shown in [Figure 18-31](#).

The pacemaker theory also serves to explain the varying intensity of adjacent coupled contractions shown in panels A and B of [Figure 18-30](#). Such coupling was termed *incoordination* by Caldeyro-Barcia and Poseiro (1960). A contractile wave begins in one cornual-region pacemaker, but does not synchronously depolarize the entire uterus. As a result, another contraction begins in the contralateral pacemaker and produces the second contractile wave of the couplet. These small contractions alternating with larger ones appear to be typical of early labor, and indeed, labor may progress with such uterine activity, albeit at a slower pace. These authors also observed that labor would progress slowly if regular contractions were hypotonic—that is, contractions with intensity less than 25 mm Hg or frequency less than two per 10 minutes. Similar observations were made by Seitchik (1981) in a computer-aided analysis comparing women in active labor with those in arrested labor. Normal labor was characterized by a minimum of three contractions that averaged greater than 25 mm Hg and less than 4-minute intervals between contractions. A lesser amount of uterine activity was associated with arrest of active labor. Prospective diagnosis of hypotonic labor cannot be reliably based simply on a few uterine pressures.

Hauth and co-workers (1986) quantified uterine contraction pressures in 109 women at term who received oxytocin for labor induction or augmentation. Most of these women achieved 200 to 225 Montevideo units, and 40 percent had up to 300 units to effect delivery. The authors suggested that these levels of uterine activity should be sought before consideration of cesarean delivery for presumed dystocia. This recommendation later was endorsed by the American College of Obstetricians and Gynecologists (1995a).

Figure 18-30. Intrauterine pressure recorded through a single catheter. **A.** Prelabor. **B.** Early labor. **C.** Active labor. **D.** Late labor. **E.** Spontaneous activity 1/2 hour postpartum. **F.** Spontaneous activity 2 1/2 hours postpartum. (From Hendricks, 1968.)

Figure 18-31. Schematic representation of the normal contractile wave of labor. Large uterus on the left shows the four points at which intramyometrial pressure was recorded with microballoons. Four corresponding pressure tracings are shown in relation to each other by shading on the small uteri at top. (From Caldeyro-Barcia and Poseiro, 1960.)

19. Obstetrical Anesthesia

INTRODUCTION

Pain relief in labor presents unique problems. Labor begins without warning, and obstetrical anesthesia may be required within minutes of a full meal. Vomiting with aspiration of gastric contents is a constant threat that poses serious maternal morbidity and mortality. Moreover, a host of disorders unique to pregnancy, such as preeclampsia, placental abruption, and chorioamnionitis, all superimposed on unique physiological adaptations of pregnancy, are directly affected by the choice of analgesia and anesthesia selected.

Anesthesia complications caused 1.6 percent of pregnancy-related maternal deaths in the United States from 1991 through 1997 (Berg and co-workers, 2003). Data from the Pregnancy Mortality Surveillance Program of the Centers for Disease Control and Prevention indicate that anesthesia-related maternal mortality has declined significantly over the past two decades, from 4.3 per million live births during 1979 to 1981 to less than 2 per million between 1991 and 1999 (Chang and colleagues, 2003; Hawkins and associates, 1997b). The proportion of maternal deaths caused by anesthesia-related complications also has declined from 2.5 percent between 1979 and 1990 to 1.6 percent between 1991 and 1999 (Koonin and associates, 1997).

Several factors likely have contributed to improved safety of obstetrical anesthesia. Eltzschig and associates (2003) and Hawkins and colleagues (1997b) have suggested that the recent trend toward increased use of regional analgesia, rather than general anesthesia, may be the most significant factor. The increased availability of in-house anesthesia coverage almost certainly is another important reason (Hawkins and associates, 1997a). Indeed, inadequate anesthesia services have been identified as a leading and potentially preventable cause of maternal deaths in Japan (Nagaya and associates, 2000).

GENERAL PRINCIPLES

OBSTETRICAL ANESTHESIA SERVICES. The American College of Obstetricians and Gynecologists (2002b) recently reaffirmed its position published jointly with the American Society of Anesthesiologists that a request for pain relief by the woman is sufficient medical indication for its use. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have specified that it is the responsibility of the obstetrician or certified nurse-midwife, in consultation with an anesthesiologist, if appropriate, to develop the most suitable response to accomplish the request for pain relief. Identification of any of the risk factors shown in [Table 19-1](#) should prompt consultation with anesthesia personnel to permit a joint management plan. This plan should include strategies to minimize the need for emergency anesthesia in women for whom such anesthesia would be especially hazardous.

Goals for optimizing obstetrical anesthesia services have been jointly established by the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2001). These goals should be sought by any hospital providing obstetrical care:

1. Availability of a licensed practitioner who is credentialed to administer an appropriate anesthetic whenever necessary and to maintain support of vital functions in an obstetrical emergency.
2. Availability of anesthesia personnel to permit the start of a cesarean delivery within 30 minutes of the decision to perform the procedure.
3. Anesthesia personnel immediately available to perform an emergency cesarean delivery during the active labor of a woman attempting vaginal birth after cesarean (see [Chap. 26](#), p. 610).
4. Appointment of a qualified anesthesiologist to be responsible for all anesthetics administered.
5. Availability of a qualified physician with obstetrical privileges to perform operative vaginal or cesarean delivery during administration of anesthesia.
6. Availability of equipment, facilities, and support personnel equal to that provided in the surgical suite.
7. Immediate availability of personnel, other than the surgical team, to assume responsibility for resuscitation of the depressed newborn (see [Chap. 28](#), p. 634).

To meet these goals, 24-hour in-house anesthesia coverage is usually necessary. Providing such services in smaller facilities is more challenging — a problem underscored by the fact that approximately half of all hospitals providing obstetrical care have fewer than 500 deliveries per year (American College of Obstetricians and Gynecologists, 2001).

Bell and colleagues (2000) calculated the financial burden that may be incurred when trying to provide "24/7" obstetrical anesthesia coverage. Given the average indemnity and Medicaid reimbursement for labor epidural analgesia, they concluded that such coverage could not operate profitably at their tertiary referral institution. Compounding this burden, some third-party payers have denied reimbursement for epidural analgesia in the absence of a specific medical indication. In response, the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2004) issued a joint statement that reimbursement for regional analgesia should not be denied if given *only* for pain relief.

Role of Obstetrician. Every obstetrician should be proficient in local and pudendal analgesia. Regional analgesia may be administered by the properly trained obstetrician in appropriately selected circumstances. In general, however, it is preferable for an anesthesiologist or anesthetist to provide this care so that the obstetrician can focus attention on the concerns for the laboring woman and her fetus. **General anesthesia should be administered only by those with special training.**

PRINCIPLES OF PAIN RELIEF. In a scholarly review, Lowe (2002) emphasized that the experience of

labor pain is a highly individual reflection of variable stimuli that are uniquely received and interpreted by each woman individually. These stimuli are modified by emotional, motivational, cognitive, social, and cultural circumstances. The complexity and individuality of the experience suggest that a woman and her caregivers may have a limited ability to anticipate her pain experience prior to labor. Thus, choice among a variety of methods and individualization of pain relief is desirable.

NONPHARMACOLOGICAL METHODS OF PAIN CONTROL. Fear and the unknown potentiate pain. A woman who is free from fear, and who has confidence in the obstetrical staff that cares for her, usually requires smaller amounts of analgesia. Read (1944) emphasized that the intensity of pain during labor is related in large measure to emotional tension. He urged that women be well informed about the physiology of parturition and the various hospital procedures to which they will be subjected during labor and delivery. Lamaze (1970) subsequently described his psychoprophylactic method, which emphasized childbirth as a natural physiological process. Pain often can be lessened by teaching pregnant women relaxed breathing and their labor partners psychological support techniques. These concepts have considerably reduced the use of potent analgesic, sedative, and amnestic drugs during labor and delivery.

When motivated women have been prepared for childbirth, pain and anxiety during labor have been found to be diminished significantly and labors are even shorter (Melzack, 1984; Saisto and associates, 2001). In addition, the presence of a supportive spouse or other family member, of conscientious labor attendants, and of a considerate obstetrician who instills confidence, have all been found to be of considerable benefit. In one study, Kennell and associates (1991) randomly assigned 412 nulliparous women in labor to either continuous emotional support from an experienced companion or to monitoring by an inconspicuous observer who did not interact with the laboring woman. The cesarean delivery rate was significantly lower in the continuous support group compared with that of the hands-off monitored group (8 versus 13 percent), as was the frequency of epidural analgesia for vaginal delivery (8 versus 23 percent).

ANALGESIA AND SEDATION DURING LABOR

When uterine contractions and cervical dilatation cause discomfort, pain relief with a narcotic such as meperidine, plus one of the tranquilizer drugs such as promethazine, is usually appropriate. With a successful program of analgesia and sedation, the mother should rest quietly between contractions. In this circumstance, discomfort usually is felt at the acme of an effective uterine contraction, but the pain is generally not unbearable. Appropriate drug selection and administration of the medications shown in [Table 19-2](#) should safely accomplish these objectives for the great majority of women in labor.

PARENTERAL AGENTS

Meperidine and Promethazine. Meperidine, 50 to 100 mg, with promethazine, 25 mg, may be administered intramuscularly at intervals of 2 to 4 hours. A more rapid effect is achieved by giving meperidine intravenously in doses of 25 to 50 mg every 1 to 2 hours. Whereas analgesia is maximal about 30 to 45 minutes after an intramuscular injection, it develops almost immediately following intravenous administration. Meperidine readily crosses the placenta, and the half-life is approximately 13 hours or longer in the newborn (American College of Obstetricians and Gynecologists, 2002b). Its depressant effect in the fetus follows closely behind the peak maternal analgesic effect.

In a randomized investigation of epidural analgesia conducted at Parkland Hospital, patient-controlled intravenous analgesia with meperidine was found to be an inexpensive and effective method for labor analgesia (Sharma and colleagues, 1997). Women randomized to self-administered analgesia were given 50-mg meperidine with 25-mg promethazine intravenously as an initial bolus. Thereafter, an infusion pump was set to deliver 15 mg of meperidine every 10 minutes as needed until delivery. The mean and maximum total meperidine doses until delivery were 140 and 500 mg, respectively. One fourth of the women received more than 200 mg of meperidine during their labors. Neonatal sedation, as measured by need for naloxone treatment in the delivery room, was identified in 3 percent of newborns.

Butorphanol (Stadol). This synthetic narcotic, given in 1- to 2-mg doses, compares favorably with 40 to 60 mg of meperidine (Quilligan and colleagues, 1980). The major side effects are somnolence, dizziness, and dysphoria. Neonatal respiratory depression is reported to be less than with meperidine, but care must be taken that the two drugs are not given contiguously because butorphanol antagonizes the narcotic effects of meperidine. Angel and colleagues (1984) and Hatjis and Meis (1986) described a sinusoidal fetal heart rate pattern following butorphanol administration (see [Chap. 18](#), p. 451).

Fentanyl. This short-acting and very potent synthetic opioid may be given in doses of 50 to 100 μ g intravenously every hour. Its main disadvantage is a short duration of action, which requires frequent dosing or the use of a patient-controlled intravenous pump. Atkinson and associates (1994) reported that butorphanol provided better initial analgesia than fentanyl and was associated with fewer requests for more medication or for epidural analgesia.

Efficacy and Safety of Parenteral Agents. Bricker and Lavender (2002) have reviewed the effectiveness and safety of parenteral opioids for labor analgesia. Based on their systematic review of 85 investigations, they concluded the following:

1. Meperidine is the most common opioid used worldwide for pain relief in labor.
2. There is no convincing evidence demonstrating that alternative opioids are better.
3. There is no evidence that parenteral opioids influence the length of labor or need for obstetrical intervention.
4. Epidural analgesia provides superior pain relief.

Intravenous and intramuscular sedation are not without risks. Hawkins and colleagues (1997b) reported that 4 of 129 maternal anesthetic-related deaths were from such sedation— one from aspiration, two from inadequate ventilation, and one from overdosage. Moreover, meperidine or other narcotics used during labor may cause newborn respiratory depression.

Narcotic Antagonists. Naloxone is a narcotic antagonist capable of reversing respiratory depression induced by opioid

narcotics. It acts by displacing the narcotic from specific receptors in the central nervous system. Withdrawal symptoms may be precipitated in recipients who are physically dependent on narcotics. For this reason, naloxone is contraindicated in a newborn of a narcotic-addicted mother (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002). Naloxone, along with proper ventilation, may be given to reverse respiratory depression in a newborn infant whose mother received narcotics (see [Chap. 28](#), p. 637).

NITROUS OXIDE. A self-administered mixture of 50-percent nitrous oxide (N_2O) and oxygen provides satisfactory analgesia during labor for many women (Rosen, 2002a). Some preparations are premixed in a single cylinder (Entonox), and in others, a blender mixes the two gases from separate tanks (Nitronox). The gases are connected to a breathing circuit through a valve that opens only when the patient inspires. The use of intermittent nitrous oxide for labor pain has been reviewed by Rosen (2002a) and the following technique suggested:

1. Instruct the woman to take slow deep breaths and to begin inhaling 30 seconds before the next anticipated contraction and to cease when the contraction starts to recede.
2. Remove the mask between contractions and encourage her to breathe normally. No one but the patient or knowledgeable personnel should hold the mask.
3. Instruct a caregiver to remain in verbal contact with the patient.
4. Provide the expectation that the pain will likely not be eliminated, but that the gas should provide some relief.
5. Ensure intravenous access, pulse oximetry, and adequate scavenging of exhaled gases.
6. Use with additional caution after previous opioid administration because the combination can more easily render a woman unconscious and unable to protect her airway.

REGIONAL ANALGESIA

Various nerve blocks have been developed over the years to provide pain relief during labor and delivery. They are correctly referred to as *regional analgesics*.

SENSORY INNERVATION OF THE GENITAL TRACT

Uterine Innervation. Pain during the first stage of labor is generated largely from the uterus. Visceral sensory fibers from the uterus, cervix, and upper vagina traverse through the Frankenhauser ganglion, which lies just lateral to the cervix, into the pelvic plexus, and then to the middle and superior internal iliac plexuses ([Fig. 19-1](#)). From there, the fibers travel in the lumbar and lower thoracic sympathetic chains to enter the spinal cord through the white rami communicantes associated with the T10 through T12 and L1 nerves. Early in labor, the pain of uterine contractions is transmitted predominantly through the T11 and T12 nerves.

The motor pathways to the uterus leave the spinal cord at the level of the T7 and T8 vertebrae. Theoretically, any method of sensory block that does not also block the motor pathways to the uterus can be used for analgesia during labor.

Lower Genital Tract Innervation. Pain with vaginal delivery arises from stimuli from the lower genital tract. These are transmitted primarily through the pudendal nerve, the peripheral branches of which provide sensory innervation to the perineum, anus, and the more medial and inferior parts of the vulva and clitoris. The pudendal nerve passes beneath the posterior surface of the sacrospinous ligament just as the ligament attaches to the ischial spine. As discussed in [Chapter 2](#) (see p. 26), the sensory nerve fibers of the pudendal nerve are derived from the ventral branches of the S2 through S4 nerves (see [Fig. 19-1](#)).

Figure 19-1. Pathways of labor pain. (From Eltzhig and associates, 2003, with permission.)

ANESTHETIC AGENTS. Some of the more commonly used local anesthetics, along with their usual concentrations, doses, and durations of action, are summarized in [Table 19-3](#). Some preparations that contain dilute epinephrine to prolong the action of the anesthetic will also cause symptoms when a test dose is inadvertently given intravenously. The dose of each agent varies widely and is dependent on the particular nerve block and physical status of the woman. The onset, duration, and quality of analgesia can be enhanced by increasing the dose. This can be done safely by only incrementally administering small-volume boluses of the agent and by carefully monitoring for early warning signs of toxicity. Administration of these agents must be followed by appropriate monitoring for adverse reactions, and equipment and personnel to manage these reactions must be immediately available.

Most often, serious toxicity follows inadvertent intravenous injection, but it also may be induced by administration of excessive amounts. Because many of these agents are manufactured in more than one concentration and ampule size, a thorough knowledge of this information is essential for safety. Systemic toxicity from local anesthetics typically manifests in the central nervous and cardiovascular systems.

Central Nervous System Toxicity. Early symptoms are those of stimulation but, as serum levels increase, depression

follows. Symptoms may include light-headedness, dizziness, tinnitus, metallic taste, and numbness of the tongue and mouth. Patients may show bizarre behavior, slurred speech, muscle fasciculation and excitation, and ultimately, generalized convulsions, followed by loss of consciousness. The convulsions should be controlled, an airway established, and oxygen delivered. Succinylcholine abolishes the peripheral manifestations of the convulsions and allows tracheal intubation. Thiopental or diazepam act centrally to inhibit convulsions. Magnesium sulfate, administered according to the regimen for eclampsia, also controls convulsions (see [Chap. 34](#), p. 788). Abnormal fetal heart rate patterns, such as late decelerations or persistent bradycardia, may develop from maternal hypoxia and lactic acidosis induced by convulsions. With arrest of the convulsions, administration of oxygen, and application of other supportive measures, the fetus usually recovers more quickly in utero than following immediate cesarean delivery. Moreover, maternal well-being is usually better served by waiting until the intensity of the hypoxia and the metabolic acidosis have diminished.

Cardiovascular Toxicity. These manifestations generally develop later than those from cerebral toxicity. They do not always follow central nervous system involvement, because they are induced by higher drug levels. The notable exception is bupivacaine, which is associated with the development of neurotoxicity and cardiotoxicity at virtually identical serum drug levels (Mulroy, 2002). Because of this risk of systemic toxicity, use of 0.75-percent solution of bupivacaine for epidural injection was proscribed by the Food and Drug Administration in 1984. Similar to neurotoxicity, cardiovascular toxicity is characterized first by stimulation and then by depression. Accordingly, there is hypertension and tachycardia, which soon is followed by hypotension and cardiac arrhythmias. The latter contribute appreciably to impaired uteroplacental perfusion and fetal distress.

Hypotension is managed initially by turning the woman onto either side to avoid aortocaval compression. A crystalloid solution is infused rapidly along with intravenously administered ephedrine. Emergency cesarean delivery should be considered if maternal vital signs have not been restored within 5 minutes of cardiac arrest (see [Chap. 42](#), p. 1002). As with convulsions, however, the fetus is likely to recover more quickly in utero once maternal cardiac output is reestablished.

PUDENDAL BLOCK. This block is a relatively safe and simple method of providing analgesia for spontaneous delivery. As shown in [Figure 19-2](#), a tubular introducer that allows 1.0 to 1.5 cm of a 15-cm 22-gauge needle to protrude beyond its tip is used to guide the needle into position over the pudendal nerve. The end of the introducer is placed against the vaginal mucosa just beneath the tip of the ischial spine. The needle is pushed beyond the tip of the director into the mucosa and a mucosal wheal is made with 1 mL of 1-percent lidocaine solution or an equivalent dose of another local anesthetic (see [Table 19-3](#)). To guard against intravascular infusion, aspiration is attempted before this and all subsequent injections. The needle is then advanced until it touches the sacrospinous ligament, which is infiltrated with 3 mL of lidocaine. The needle is advanced farther through the ligament, and as it pierces the loose areolar tissue behind the ligament, the resistance of the plunger decreases. Another 3 mL of the anesthetic solution is injected into this region. Next, the needle is withdrawn into the introducer, which is moved to just above the ischial spine. The needle is inserted through the mucosa and the rest of 10 mL of solution is deposited. The procedure is then repeated on the other side.

Within 3 to 4 minutes of the time of injection, the successful pudendal block will allow pinching of the lower vagina and posterior vulva bilaterally without pain. It is often of benefit before pudendal block to infiltrate the fourchette, perineum, and adjacent vagina with 5 to 10 mL of 1-percent lidocaine solution directly at the site where the episiotomy is to be made. Then, if delivery occurs before pudendal block becomes effective, an episiotomy can be made without pain. By the time of the repair, the pudendal block usually has become effective.

Pudendal block usually does not provide adequate analgesia when delivery requires extensive obstetrical manipulation. Moreover, such analgesia is usually inadequate for women in whom complete visualization of the cervix and upper vagina, or manual exploration of the uterine cavity, are indicated.

Complications. As previously described (see p. 478), intravascular injection of a local anesthetic agent may cause serious systemic toxicity. Hematoma formation from perforation of a blood vessel also may develop. This complication is most likely when there is a coagulopathy (Lee and colleagues, 2004). One example is defective coagulation seen with placental abruption (see [Chap. 35](#), p. 843). Rarely, severe infection may originate at the injection site. The infection may spread posterior to the hip joint, into the gluteal musculature, or into the retrosoas space (Svancarek and associates, 1977).

Figure 19-2. Local infiltration of the pudendal nerve. Transvaginal technique showing the needle extended beyond the needle guard and passing through the sacrospinous ligament (S) to reach the pudendal nerve (N).

PARACERVICAL BLOCK. This block usually provides satisfactory pain relief during the first stage of labor. Because the pudendal nerves are not blocked, however, additional analgesia is required for delivery. Usually lidocaine or chlorprocaine, 5 to 10 mL of a 1-percent solution, is injected into the cervix laterally at 3 and 9 o'clock. Bupivacaine is contraindicated because of an increased risk of cardiotoxicity (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002; Rosen, 2002b). Because these anesthetics are relatively short acting, paracervical block may have to be repeated during labor.

Complications. Fetal bradycardia is a worrisome complication that occurs in approximately 15 percent of paracervical blocks (Rosen, 2002b). Bradycardia usually develops within 10 minutes and may last up to 30 minutes. Several investigators stress that bradycardia is not a sign of fetal asphyxia, because it usually is transient and the newborns are in most instances vigorous at birth. There are reports, however, in which fetal scalp blood pH and Apgar scores were sometimes low, and a few fetuses have died. The effect may be the consequence of transplacental transfer of the anesthetic agent or its metabolites and in turn, a depressant effect on the fetal heart. Based on studies in pregnant ewes, Greiss (1976) and Fishburne (1979) and their associates believe that fetal bradycardia results from decreased placental perfusion as the consequence of drug-induced

uterine artery vasoconstriction and myometrial hypertonus. Doppler studies have shown an increase in the pulsatility index of the uterine arteries following paracervical block (see [Chap. 16](#), p. 403). These observations further support the hypothesis of drug-induced vasospasm (Manninen and co-workers, 2000). For these reasons, paracervical block should not be used in situations of potential fetal compromise.

SPINAL (SUBARACHNOID) BLOCK. Introduction of a local anesthetic into the subarachnoid space to effect analgesia has long been used for delivery. Advantages include a short procedure time, rapid onset of the block, and high success rate. Because of the smaller subarachnoid space during pregnancy, likely the consequence of engorgement of the internal vertebral venous plexus, the same amount of anesthetic agent in the same volume of solution produces a much higher blockade in parturients than in nonpregnant women.

Vaginal Delivery. Low spinal block is a popular form of analgesia for forceps or vacuum delivery. The level of analgesia should extend to the T10 dermatome, which corresponds to the level of the umbilicus ([Fig. 19-3](#)). Blockade to this level provides excellent relief from the pain of uterine contractions (see [Fig. 19-1](#)).

Several local anesthetic agents have been used for spinal analgesia. Lidocaine given in a hyperbaric solution produces excellent analgesia and has the advantage of a rapid onset and relatively short duration. Bupivacaine in a dose of 10 to 12 mg in an 8.5-percent dextrose solution provides satisfactory anesthesia to the lower vagina and the perineum for more than 1 hour. Neither is administered until the cervix is fully dilated and all other criteria for safe forceps delivery have been fulfilled (see [Chap. 23](#), p. 550). Preanalgesic intravenous hydration with 1 L of crystalloid solution will prevent or minimize hypotension in many cases.

Cesarean Delivery. A level of sensory blockade extending to the T4 dermatome is desired for cesarean delivery (see [Fig. 19-3](#)). Depending on maternal size, 10 to 12 mg of hyperbaric bupivacaine or 50 to 75 mg of hyperbaric lidocaine are administered. The addition of 20 to 25 μ g of fentanyl increases the rapidity of the onset of the block and reduces shivering. The addition of 0.2 mg of morphine improves pain control during delivery and postoperatively.

Complications. Shown in [Table 19-4](#) are some of the more common complications associated with regional analgesia. The estimated incidences were derived from 19 studies published between 1987 and 2000, as well as data from the Maternal-Fetal Medicine Units Network, which included more than 50,000 women undergoing cesarean delivery (Bloom and colleagues, 2004). Not listed is that obese women have significantly impaired ventilation (von Ungern-Sternberg and associates, 2004). Clearly, close clinical monitoring is imperative.

HYPOTENSION. This common complication may develop soon after injection of the local anesthetic agent and is the consequence of vasodilatation from sympathetic blockade compounded by obstructed venous return from uterine compression of the vena cava and adjacent large veins. **In the supine position, even in the absence of maternal hypotension measured in the brachial artery, placental blood flow may still be significantly reduced.** Treatment of spinal block hypotension includes uterine displacement, intravenous hydration, and intravenous bolus injections of ephedrine or phenylephrine. The predominant action of ephedrine is to raise blood pressure by increasing cardiac output rather than vasoconstriction. Phenylephrine is a pure α -agonist which, at least until recently, we have generally avoided because of concerns about potential adverse effects on uterine blood flow. A meta-analysis of seven randomized trials by Lee and colleagues (2002b), however, suggests that the safety profiles of ephedrine and phenylephrine are comparable.

In a randomized trial at Parkland Hospital, Morgan and colleagues (2000) found that infusion of 1000 mL of Ringer lactate during the 20 minutes before spinal injection and 5-mg boluses of ephedrine as needed to maintain normal blood pressure resulted in a mean umbilical artery blood pH of 7.26. In contrast, prophylactic infusions containing diluted ephedrine were associated with significant fetal acidemia—the mean pH was about 7.12. Following a systematic review of 14 reports of elective cesarean deliveries, Lee and colleagues (2002a) question whether routine prophylactic ephedrine is needed. Ngan Kee and associates (2004) have used prophylactic phenylephrine infusion with good results.

HIGH SPINAL BLOCKADE. Most often, complete spinal blockade is the consequence of administration of an excessive dose of local anesthetic agent. This is certainly not always the case, because accidental total spinal block has even occurred following an epidural test dose (Palkar and associates, 1992). In complete spinal block, hypotension and apnea promptly develop and must be immediately treated to prevent cardiac arrest. In the undelivered woman, (1) the uterus is immediately displaced laterally to minimize aortocaval compression; (2) effective ventilation is established, preferably with tracheal intubation; and (3) intravenous fluids and ephedrine are given to correct hypotension.

SPINAL (POSTDURAL PUNCTURE) HEADACHE. Leakage of cerebrospinal fluid from the site of puncture of the meninges is thought to be the major factor in the genesis of spinal headache. Presumably, when the woman sits or stands, the diminished volume of cerebrospinal fluid allows traction on pain-sensitive central nervous system structures. This complication can be reduced by using a small-gauge spinal needle and avoiding multiple punctures. In a prospective, randomized study of five different spinal needles, Vallejo and colleagues (2000) concluded that Sprotte and Whitacre needles had the lowest risks of postdural puncture headaches.

There is no good evidence that placing the woman absolutely flat on her back for several hours is effective in preventing headache. Vigorous hydration may be of value, but also without compelling evidence to support its use. The administration of *caffeine*, a cerebral vasoconstrictor, has been shown in randomized studies to afford temporary relief (Sechzer and Abel, 1978; Camann and colleagues, 1990). With severe headache, an *epidural blood patch* is effective. A few milliliters of autologous blood are obtained aseptically by venipuncture without anticoagulant. This is injected into the epidural space at the site of the dural puncture. Relief is immediate and complications uncommon. If the headache does not have the pathognomonic postural characteristics or persists despite treatment with a blood patch, other diagnoses should be considered and appropriate testing performed. For example, Chisholm and Campbell (2001) described a case of superior sagittal sinus thrombosis that manifested as a postural headache. Chan and Paech (2004) have described persistent cerebrospinal fluid leak in three women.

CONVULSIONS. In rare instances, postdural puncture cephalgia is associated with blindness and convulsions. Shearer and colleagues (1995) described eight such cases associated with 19,000 regional analgesic procedures. It is presumed that these too are caused by cerebrospinal fluid hypotension.

BLADDER DYSFUNCTION. With spinal analgesia, bladder sensation is likely to be obtunded and bladder emptying impaired for the first few hours after delivery. As a consequence, bladder distention is a frequent postpartum complication, especially if appreciable volumes of intravenous fluid are given.

OXYTOCICS AND HYPERTENSION. Paradoxically, hypertension from ergonovine or methylergonovine injected following delivery is more common in women who have received a spinal or epidural block.

ARACHNOIDITIS AND MENINGITIS. Local anesthetics are no longer preserved in alcohol, formalin, or other toxic solutes, and disposable equipment is used by most. These practices, coupled with aseptic technique, have made meningitis and arachnoiditis rarities (see [Table 19-4](#)). Still, these complications are occasionally documented (Harding and colleagues, 1994; Newton and associates, 1994).

Contraindications to Spinal Analgesia. Shown in [Table 19-5](#) are the absolute contraindications to regional analgesia according to the American College of Obstetricians and Gynecologists (2002b). Obstetrical complications that are associated with maternal hypovolemia and hypotension—such as severe hemorrhage—are contraindications to the use of spinal block. The cardiovascular effects of spinal block in the presence of acute blood loss, but in the absence of the hemodynamic effects of pregnancy, have been investigated by Kennedy and co-workers (1968). In 15 nonpregnant volunteers, spinal analgesia to the T5 sensory level was induced twice, the second time after a phlebotomy of 10 mL/kg. In the case of block without hemorrhage, the mean arterial blood pressure fell 10 percent while cardiac output rose slightly. In the case of hemorrhage without block, the mean blood pressure fell to the same degree and again the cardiac output rose slightly. With subarachnoid block administered after the modest hemorrhage, however, the mean arterial pressure fell nearly 30 percent and cardiac output fell 15 percent.

In addition to refractory maternal hypotension, disorders of coagulation and defective hemostasis also preclude the use of spinal analgesia. Similarly, subarachnoid puncture is contraindicated when the skin or underlying tissue at the site of needle entry is infected. Neurological disorders are considered by many to be a contraindication, if for no other reason than that exacerbation of the neurological disease might be attributed without cause to the anesthetic agent. Other maternal conditions, such as significant aortic stenosis or pulmonary hypertension, are also relative contraindications to the use of spinal analgesia (see [Chap. 44](#), pp. 1026 and 1029).

Preeclampsia. As with significant hemorrhage, severe preeclampsia is another complication in which markedly decreased blood pressure can be predicted when subarachnoid analgesia is used. Gambling and Writer (1999) have reviewed the use of spinal analgesia in women with severe preeclampsia. Although they acknowledge it to be quite controversial, they concluded that with severe preeclampsia, epidural analgesia is preferable to a subarachnoid block and especially preferable to a general anesthetic. The latter has inherent risks of difficult intubation due to airway edema and cerebrovascular accidents due to increased blood pressure. As subsequently discussed, hypotension is also a risk with epidural analgesia. Wallace and colleagues (1995) randomly assigned 80 women with severe preeclampsia undergoing cesarean delivery to receive general anesthesia or either epidural or spinal-epidural analgesia. There were no differences in maternal or neonatal outcomes, but 30 percent of those given epidural analgesia and 22 percent of those given spinal-epidural blockage developed hypotension, with an average reduction in mean arterial pressure between 15 and 25 percent.

Figure 19-3. Dermatome distribution. (Redrawn from Keegan and Garrett, 1948, with permission.)

EPIDURAL ANALGESIA. Relief from the pain of labor and childbirth, including cesarean delivery, can be accomplished by injection of a local anesthetic agent into the epidural or peridural space ([Fig. 19-4](#)). This potential space contains areolar tissue, fat, lymphatics, and the internal venous plexus. These latter vessels become engorged during pregnancy such that the volume of the epidural space is appreciably reduced. Entry for obstetrical analgesia is usually through a lumbar intervertebral space, and less often through the sacral hiatus and sacral canal for caudal epidural analgesia. Although one injection may be used, these usually are repeated through an indwelling catheter, or they are given by continuous infusion using a volumetric pump.

Continuous Lumbar Epidural Block. Complete analgesia for the pain of labor and vaginal delivery necessitates a block from the T10 to the S5 dermatomes ([Figs. 19-1](#) and [19-3](#)). For cesarean delivery, a block extending from the T4 to the S1 dermatomes is desired. The spread of the anesthetic depends upon the location of the catheter tip; the dose, concentration, and volume of anesthetic agent used, as shown in [Table 19-3](#); and whether the mother is head-down, horizontal, or head-up (Setayesh and colleagues, 2001). Individual variations in the epidural space anatomy also will affect the block, and in some cases, synechiae may preclude a completely satisfactory block. It also should be recognized that the catheter tip might move from its original location during the course of labor.

Technique. One example of the sequential steps and techniques for performance of epidural analgesia is detailed in [Table 19-6](#). Before any injection of the local anesthetic agent, a test dose is given and the woman is observed for features of toxicity from intravascular injection and for signs of spinal blockade from subarachnoid injection. Only then is a full dose given. Analgesia is maintained by intermittent boluses of similar volume, or small volumes of the drug are delivered continuously by infusion pump. The addition of small doses of a short-acting narcotic, either fentanyl or sufentanil, has been shown to improve analgesic efficacy for labor or cesarean delivery (Chestnut and colleagues, 1988). The rationale for opiate use during labor is to avoid motor block by allowing reduction in the dose of local anesthetic. **Appropriate resuscitation equipment and drugs must be available during administration of epidural analgesia.**

Complications. For most women, epidural analgesia provides unparalleled relief from the pain of labor and delivery. That said, as shown in [Table 19-4](#), there are certain problems inherent in its use and as with spinal blockade, it is imperative that

close monitoring, including the level of analgesia, be performed by trained personnel.

TOTAL SPINAL BLOCKADE. Dural puncture with inadvertent subarachnoid injection may cause total spinal block. Personnel and facilities must be immediately available to manage this complication, as described under complications of spinal analgesia (see p. 481).

INEFFECTIVE ANALGESIA. Establishment of effective pain relief with maximum safety takes time. Using currently popular continuous epidural infusion regimens such as 0.125-percent bupivacaine with 2- μ g/mL fentanyl, 90 percent of women rate their pain relief as good to excellent, and 95 percent express a desire for the same type of analgesia during a future delivery (Sharma and colleagues, 1997). Alternatively, a few women find epidural analgesia to be inadequate. In a study of 1963 parturients who received epidural analgesia, Hess and associates (2001) found that approximately 12 percent complained of three or more episodes of pain or pressure. Risk factors for such breakthrough pain included nulliparity, heavier fetal weights, and epidural catheter placement at an earlier cervical dilatation. If the epidural analgesia is allowed to dissipate before another injection of anesthetic drug, subsequent pain relief may be delayed, incomplete, or both. In the Maternal-Fetal Medicine Units Network study cited earlier, 4 percent of women initially given epidural analgesia required a general anesthetic for cesarean delivery (Bloom and colleagues, 2004).

At times, perineal analgesia for delivery is difficult to obtain, especially with the lumbar epidural technique. When this condition is encountered, a low spinal or pudendal block or systemic analgesia is added.

HYPOTENSION. By blocking sympathetic tracts, epidurally injected analgesic agents may cause hypotension and decreased cardiac output. In normal pregnant women, hypotension induced by epidural analgesia usually can be prevented by rapid infusion of 500 to 1000 mL of crystalloid solution, or treated successfully as described for spinal analgesia. Danilenko-Dixon and associates (1996) showed that maintaining a lateral position minimized hypotension compared with the supine position. Despite these precautions, hypotension is the most common side effect and is severe enough to require treatment in one third of women (Sharma and colleagues, 1997).

CENTRAL NERVOUS STIMULATION. Convulsions are an uncommon but serious complication, the immediate management of which was described previously.

MATERNAL PYREXIA. Fusi and associates (1989) observed that the mean temperature in laboring women given epidural analgesia was significantly higher than in those given meperidine. Subsequently, a number of randomized and retrospective cohort studies have confirmed an increase in intrapartum fever. Unfortunately, most investigations are limited by inability to control for other important risk factors, such as length of labor, duration of ruptured membranes, and number of vaginal examinations (Yancey and co-workers, 2001a). With this in mind, the frequency of intrapartum fever was found to be 10 to 15 percent by Lieberman and O'Donoghue (2002).

The precise etiology of maternal hyperthermia with epidural use is unclear. There are two general theories: (1) that fever results from *maternal-fetal infection* or (2) that it is caused by *dysregulation of body temperature*. Infection seems a reasonable explanation, and Dashe and co-workers (1999) studied placental histopathology in these women. After labor with epidural analgesia, they identified intrapartum fever only with placental inflammation. This suggests that fever is due to infection rather than to the analgesia itself. Conversely, other proposed mechanisms include alteration in the hypothalamic thermoregulatory set point, impairment of peripheral thermoreceptor input to the central nervous system with selective blockage of warm stimuli, or imbalance between heat production and heat loss (Yancey and co-workers, 2001a). With the current incomplete understanding of the underlying cause, the clinical significance of the association between epidural use and fever is an undoubtedly higher rate of intrapartum antimicrobial use and perhaps a higher rate of operative delivery.

BACK PAIN. Although an association between epidural analgesia and back pain has been reported by some clinicians, others have not found such a relationship (Breen, 1994; Howell, 2001; MacArthur, 1997, and all their colleagues). In a prospective cohort study, Butler and Fuller (1998) reported that postpartum back pain was common after epidural analgesia, however, persistent or chronic back pain was uncommon. Based on their systematic review of the literature, Lieberman and O'Donoghue (2002) concluded that available data do not support an association between the use of epidural analgesia and development of new, long-term backache.

Effect on Labor. Most studies, including the combined five randomized trials from Parkland Hospital shown in [Table 19-7](#), report that epidural analgesia prolongs labor and increases the need for oxytocin stimulation. Alexander and associates (2002) examined the effects of epidural analgesia on the Friedman (1955) active labor curve, which is described in [Chapter 17](#) (see p. 422). The study included 459 nulliparas randomly assigned to patient-controlled epidural analgesia or patient-controlled intravenous meperidine. Compared with Friedman's original criteria, epidural analgesia prolonged the active phase of labor by 1 hour. As shown in [Table 19-7](#), epidural analgesia also has been found to increase the need for instrumental delivery due to prolonged second-stage labor, however, there were no adverse neonatal effects (Chestnut, 1999; Thorp and Breedlove, 1996). More contemporaneous is the concern for perineal trauma associated with instrumental delivery. This relationship is discussed in detail in [Chapters 17](#) (see p. 435) and [23](#) (see p. 556).

FETAL HEART RATE. Hill and colleagues (2003) examined the effects of initiation of epidural analgesia using 0.25-percent bupivacaine on fetal heart rate patterns. Compared with intravenous meperidine, no deleterious effects were identified. In fact, reduced beat-to-beat variability and fewer accelerations were more common in fetuses whose mothers received meperidine (see [Chap. 18](#), p. 449). Based on their systematic review of eight studies, Reynolds and co-workers (2002) found that epidural analgesia was associated with improved neonatal acid-base status compared with that with meperidine.

CESAREAN DELIVERY. A more contentious issue is whether epidural analgesia increases the risk for cesarean delivery. From their review, Sharma and Leveno (2000) found that several retrospective studies and a few randomized trials concluded that labor epidural analgesia is associated with increased cesarean deliveries. Conversely, others have concluded that the available evidence is insufficient to establish such an association (Eltzschig and associates, 2003; Lieberman and O'Donoghue, 2002; Sharma and colleagues, 2004).

Several studies conducted at Parkland Hospital were designed to answer some of these questions. In the 8-year period from 1995 to 2002, a total of 2703 nulliparous women with term pregnancies in spontaneous labor were studied. There were five

trials of various labor epidural analgesia techniques using dilute solutions of local anesthetic as well as methods for administration of meperidine intravenously (Fig. 19-5). Epidural analgesia did not significantly increase cesarean deliveries in any individual trial or in their aggregate. These results are consistent with the belief of many investigators that the epidural administration of dilute solutions of local anesthetic is less likely to increase cesarean delivery rates than concentrated solutions (Chestnut, 1997; Thompson and colleagues, 1998).

Yancey and co-workers (1999) described the effects of introduction of an on-demand labor epidural analgesia service at Tripler Army Hospital in Hawaii. In late 1993, a policy change within the Department of Defense required the availability of on-demand labor epidural analgesia in military medical centers. As a result, the incidence of epidural analgesia during labor increased from 1 percent before the policy to 60 percent 2 years after the policy had been implemented. The primary cesarean rate was 13.4 percent before and 13.2 percent after this dramatic change in epidural usage. In a follow-up study, Yancey and co-workers (2001b) reported that fetal malpresentations at the time of vaginal delivery were not more common after epidural usage became prevalent. The only significant difference they found was an increased duration of second-stage labor by approximately 25 minutes (Zhang and co-workers, 2001).

Based on their randomized studies and review of the literature, Sharma and Leveno (2003) and Sharma and colleagues (2004) concluded that epidural analgesia is not associated with an excessive rate of cesarean births. Other investigators have drawn the same conclusion. Leighton and Halpern (2002) performed a meta-analysis of 14 randomized studies involving 2161 women who received epidural analgesia and 2136 who received opioids for labor pain. They found no increase in the cesarean rate attributable to epidural analgesia. The American College of Obstetricians and Gynecologists (2002a) has recently reaffirmed the following statement published jointly with the American Society of Anesthesiologists: "There is no other circumstance where it is considered acceptable for a person to experience severe pain, amenable to safe intervention, while under a physician's care." This statement implies that all women should have access to effective pain relief during labor. We are of the view that the fear of increasing the risk of cesarean delivery should not preclude women from choosing epidural analgesia during labor.

TIMING OF EPIDURAL PLACEMENT. Several retrospective studies have found an association between early epidural placement and a higher rate of cesarean delivery (Lieberman, 1996; Rogers, 1999; Seyb, 1999, and all their co-workers). Conversely, randomized trials comparing early versus late epidural placement in nulliparous women have found no difference in the rates of cesarean birth, forceps delivery, or fetal malposition (Chestnut and associates, 1994a, 1994b; Luxman and colleagues, 1998). The inconsistent findings between retrospective and randomized studies may be caused by confounding variables inherently associated with retrospective study designs (Sharma and Leveno, 2003). Based on their review, Eltzschig and colleagues (2003) recently concluded that there is currently insufficient evidence to justify waiting until a certain degree of cervical dilatation or fetal station is reached before instituting epidural analgesia. Finally, the American College of Obstetricians and Gynecologists (2002b) has concluded that "women in labor should not be required to reach 4 to 5 cm of cervical dilatation before receiving epidural analgesia."

Safety. The relative safety of epidural analgesia is attested to by the extraordinary experiences reported by Crawford (1985) from the Birmingham Maternity Hospital in England. From 1968 through 1985, over 26,000 women were given epidural analgesia for labor, and there were no maternal deaths. The nine potentially life-threatening complications followed either inadvertent intravenous or intrathecal injection of lidocaine, bupivacaine, or both. Similarly, according to the Confidential Enquiries into Maternal Deaths in the United Kingdom between 1997 and 1999, only one anesthesia-related death was associated with epidural use (Thomas and Cooper, 2002). More recently, no anesthesia-related maternal deaths were recorded among nearly 19,000 women who received epidural analgesia in the Network Study cited earlier (Bloom and colleagues, 2004). Finally, in their Cochrane Library review, Ng and associates (2004) cited a very low incidence of complications.

Contraindications. As with spinal analgesia, contraindications to epidural analgesia include actual or anticipated serious maternal hemorrhage, infection at or near the sites for puncture, and suspicion of neurological disease (see Table 19-5). Rolbin and colleagues (1988) advise against epidural analgesia if the platelet count is below 100,000/ μ L. Conversely, Rasmus and associates (1989) found no cases in which bleeding was caused by regional analgesia in thrombocytopenic women. They recommended consideration of this method if the patient might be difficult to intubate or ventilate. The American College of Obstetricians and Gynecologists (2002b) has concluded that women with platelet counts of 50,000 to 100,000/ μ L may be considered potential candidates for regional analgesia.

ANTICOAGULATION. Women receiving anticoagulation therapy who are given regional analgesia are at increased risk for spinal cord hematoma and compression (see Chap. 47, p. 1083). The American College of Obstetricians and Gynecologists (2002b) has recommended the following for women taking anticoagulants:

1. Women receiving unfractionated heparin therapy should be able to receive regional analgesia if they have a normal activated partial thromboplastin time (aPTT).
2. Women receiving prophylactic doses of unfractionated heparin or low-dose aspirin are not at increased risk and can be offered regional analgesia.
3. For women receiving once-daily low-dose low-molecular-weight heparin, regional analgesia should not be placed until 12 hours after the last injection.
4. Low-molecular-weight heparin should be withheld for at least 2 hours after the removal of an epidural catheter.
5. The safety of regional analgesia in women receiving twice-daily low-molecular-weight heparin has not been studied sufficiently, and it is not known whether delaying regional analgesia for 24 hours after the last injection is adequate.

Severe Preeclampsia-Eclampsia. As previously discussed, ideal labor analgesia for women with severe preeclampsia is controversial. Obstetrical concerns include hypotension induced by sympathetic blockade, dangers from pressor agents given to correct hypotension, and potential for pulmonary edema following infusion of large volumes of crystalloid. Conversely, general anesthesia with tracheal intubation may result in severe, sudden hypertension further complicated by pulmonary or cerebral edema or intracranial hemorrhage.

Over the past two to three decades, most obstetrical anesthesiologists have come to favor epidural blockade for labor and delivery in women with severe preeclampsia (Cheek and Samuels, 1991; Gambling and Writer, 1999; Gutsche, 1986). There seems to be no argument that epidural analgesia for women with severe preeclampsia-eclampsia can be safely used when specially trained anesthesiologists and obstetricians are responsible for the woman and her fetus (American College of Obstetricians and Gynecologists, 2002b; Cunningham and Leveno, 1995; Hogg and colleagues, 1999). In a study from Parkland Hospital, Lucas and colleagues (2001) randomly assigned 738 women with hypertension to epidural analgesia or patient-controlled intravenous analgesia during labor. A standardized protocol for prehydration, incremental epidural administration, and ephedrine use was employed. They concluded that labor epidural analgesia was to be considered in women with hypertensive disorders, but that it was not to be considered as *therapy*. In a similar study from the University of Alabama at Birmingham, Head and colleagues (2002) randomly assigned 116 women with severe preeclampsia to receive either intrapartum epidural or patient-controlled intravenous opioid analgesia. Epidural analgesia provided superior pain relief without a significant increase in maternal or neonatal complications.

INTRAVENOUS FLUID PRELOAD. Women with severe preeclampsia have remarkably diminished intravascular volume compared with normal pregnancy (Zeeman and colleagues, 2002). Conversely, total body water is increased because of the capillary leak caused by endothelial cell activation (see [Chap. 34](#), p. 769). This imbalance is manifested as pathological peripheral edema, proteinuria, ascites, and total lung water. For all of these reasons, aggressive volume replacement increases the risk for pulmonary edema, especially in the first 72 hours postpartum (Clark and colleagues, 1985; Cotton and associates, 1986). In one study, Hogg and associates (1999) reported that 3.5 percent of women with severe preeclampsia developed pulmonary edema when preloaded without a protocol limitation to volume. Importantly, this risk can be reduced or obviated with judicious prehydration—usually with 500 to 1000 mL of crystalloid solution. Specifically, in the study by Lucas and colleagues (2001) cited earlier, there were no instances of pulmonary edema among the 738 women in whom crystalloid preload was limited to 500 mL. Moreover, vasodilation produced by epidural blockade is less abrupt if the analgesia level is achieved slowly with dilute solutions of local anesthetic agents. This allows maintenance of blood pressure while simultaneously avoiding infusion of large volumes of crystalloid.

With vigorous intravenous crystalloid therapy, there is also concern about development of cerebral edema (see [Chap. 34](#), p. 778). Moreover, Heller and co-workers (1983) demonstrated that the majority of cases of *pharyngolaryngeal edema* were related to aggressive volume therapy.

Epidural Opiate Analgesia. Injection of opiates into the epidural space to relieve pain from labor has become popular. Their mechanism of action derives from interaction with specific receptors in the dorsal horn and dorsal roots. Apparently both cerebral and spinal opioid receptors are stimulated by these narcotics (Ackerman and colleagues, 1992).

Opiates alone usually will not provide adequate analgesia, and they most often are given with a local anesthetic agent such as bupivacaine. The major advantages of using such a combination are the rapid onset of pain relief, a decrease in shivering, and less dense motor blockade. Meister and colleagues (2000), in a randomized study of 50 laboring women, compared epidural analgesia with 0.125-percent ropivacaine and fentanyl to 0.125-percent bupivacaine and fentanyl. Both groups had similar labor analgesia, but the ropivacaine group had significantly less motor block.

Side effects are common and include pruritus and urinary retention. Immediate or delayed respiratory depression is worrisome (Ackerman and colleagues, 1992). Naloxone, given intravenously, will abolish these symptoms without affecting the analgesic action. Horta and colleagues (2000) reported a reduction in the incidence of pruritus with droperidol given epidurally in doses of up to 5 mg.

Figure 19-4. Introduction of a catheter into the epidural space through a Tuohy needle. (Redrawn from Sharma and Leveno, 2003, with permission.)

Figure 19-5. Results of five studies comparing the incidence of cesarean delivery in women given either epidural analgesia or intravenous meperidine. The individual odds ratios (ORs) with 95-percent confidence intervals (CIs) for each randomized study, as well as overall crude and adjusted ORs with 95-percent CIs, are shown. An OR of less than 1.0 favored epidural over meperidine analgesia. (From Sharma and associates, 2004, with permission.)

COMBINED SPINAL-EPIDURAL TECHNIQUES. The combination of spinal and epidural techniques has increased in popularity and may provide rapid and effective analgesia for labor as well as for cesarean delivery. As shown in [Figure 19-6](#), an introducer needle is first placed in the epidural space. A small-gauge spinal needle is then introduced through the epidural needle into the subarachnoid space—this is called the *needle-through-needle technique*. A single bolus of an opioid, sometimes in combination with a local anesthetic, is injected into the subarachnoid space, the spinal needle is withdrawn, and an epidural catheter is then placed. The use of a subarachnoid opioid bolus results in the rapid onset of profound pain relief with virtually no motor blockade. The epidural catheter permits repeated dosing of analgesia.

In a randomized trial of 110 laboring women, Van de Velde and associates (1999) compared epidural with combined spinal-epidural analgesia and reported that the combined method produced excellent immediate pain relief. Side effects were similar between the two groups. The largest study of the combined technique for laboring women was conducted at Parkland Hospital by Gambling and co-workers (1998). These investigators randomized 1223 women with an uncomplicated term pregnancy to receive either continuous spinal-epidural analgesia or boluses of intravenous meperidine. Rather unexpectedly, emergency cesarean delivery was performed for profound fetal bradycardia in 9 of 616 women (1.4 percent) who had combined spinal-epidural analgesia compared with none of 607 in the meperidine groups ($P < .005$). Fetal bradycardia typically occurred within 30 minutes of the 10- μ g dose of sufentanil, injected intrathecally. None of these women responded to conservative measures such as changing maternal position, oxygen administration, or intravenous ephedrine. Interestingly, none of these cases were

associated with maternal hypotension, and none of the infants suffered ill effects. Subsequently, we and others have observed that the risk of fetal bradycardia is minimized with fentanyl, or with a 2.5- μ g dose of sufentanil (Mardirosoff and Dumont, 1999).

Figure 19-6. Combined spinal-epidural block, needle-through-needle technique. An extra-long spinal needle is introduced through a regular Tuohy needle into the subarachnoid space. (Redrawn from Sharma and Leveno, 2003, with permission.)

LOCAL INFILTRATION FOR CESAREAN DELIVERY. Local block is occasionally useful to augment an inadequate or "patchy" regional block that was given in an emergency. On more rare occasions, local infiltration may be used to perform an emergency cesarean to save the life of the fetus in the absence of any anesthesia support.

Technique. In one technique, the skin is infiltrated in the line of the proposed incision, and the subcutaneous, muscle, and posterior rectus sheath layers are injected as the abdomen is opened. A dilute solution of lidocaine 1%—30 mL of 2-percent with 1:200,000 epinephrine diluted with 60 mL of normal saline 1%—is prepared, and a total of 100 to 120 mL is infiltrated. Injection of large volumes into the fatty layers, which are relatively devoid of nerve supply, is avoided to limit the total dose of local anesthetic needed. To minimize pain, nausea, and hypotension that may accompany intraperitoneal manipulations, each step is accomplished without haste.

A second technique involves a field block of the major branches supplying the abdominal wall, to include the 10th, 11th, and 12th intercostal nerves and the ilioinguinal and genitofemoral nerves (Busby, 1963). As shown in [Figure 19-7](#), the former group of nerves is located at a point midway between the costal margin and iliac crest in the midaxillary line. The latter group is found at the level of the external inguinal ring. Only one skin puncture is made at each of the four sites (right and left sides). At the intercostal block site, the needle is directed horizontally and injection is carried down to the transversalis fascia, avoiding injection of the subcutaneous fat. Approximately 5 to 8 mL of 0.5-percent lidocaine is injected. The procedure is repeated at a 45-degree angle cephalad and caudad at this site. The other side is then injected. At the ilioinguinal and genitofemoral sites, the injection is started at a site 2 to 3 cm from the pubic tubercle at a 45-degree angle. Finally, the skin overlying the planned incision is injected.

Figure 19-7. Local anesthetic block for cesarean delivery. The first injection site is halfway between the costal margin and iliac crest in midaxillary line to block the 10th, 11th, and 12th intercostal nerves. The second site is along the line of proposed skin incision. The third injection at the external inguinal blocks the genitofemoral and ilioinguinal nerves.

GENERAL ANESTHESIA

The increased safety of regional analgesia has increased the relative risk of general anesthesia. The case-fatality rate of general anesthesia for cesarean delivery is estimated to be approximately 32 per million live births compared with 1.9 per million for regional anesthesia (Hawkins and associates, 1997b). Failed intubation occurs in approximately 1 of every 250 general anesthetics administered to pregnant women, a 10-fold higher rate than the nonpregnant population (Barnardo and Jenkins, 2000). The American College of Obstetricians and Gynecologists (2002b) has concluded that this relative increased morbidity and mortality suggest that regional analgesia is the preferred method of pain control and should be used unless contraindicated (see [Table 19-5](#)). Indeed, in the Network study that has been cited, 95 percent of more than 50,000 cesarean deliveries were attempted with regional analgesia (Bloom and colleagues, 2004). Trained personnel and specialized equipment 1%—including fiberoptic intubation 1%—are mandatory for the safe use of general anesthesia.

PATIENT PREPARATION. Prior to anesthesia induction, several steps should be taken to help minimize the risk of complications for the mother and fetus. These include the use of antacids, lateral uterine displacement, and preoxygenation.

Antacids. The practice of administering antacids shortly before induction of anesthesia has probably done more to decrease mortality from general anesthesia than any other single practice. Gibbs and Banner (1984) reported that 30 mL of sodium citrate with citric acid (Bicitra), given about 45 minutes before surgery, neutralized gastric contents in nearly 90 percent of women undergoing cesarean delivery. For many years we have recommended administration of 30 mL of Bicitra within a few minutes of the anticipated time of anesthesia induction, either by general or major regional block. If more than 1 hour has passed between when the first dose was given and when anesthesia is induced, then a second dose is given.

Uterine Displacement. As discussed in [Chapter 5](#) (see p. 135), the uterus may compress the inferior vena cava and aorta when the mother is in the supine position. With lateral uterine displacement, the duration of general anesthesia has less effect on neonatal condition than when the woman remains supine (Crawford and colleagues, 1972).

Preoxygenation. Because functional reserve capacity is reduced, pregnant women become hypoxemic more rapidly during periods of apnea than do nonpregnant patients. In order to minimize hypoxia between the time of muscle relaxant injection and intubation, it is important first to replace nitrogen in the lungs with oxygen. This is accomplished by administering 100-percent oxygen via face mask for 2 to 3 minutes prior to anesthesia induction. In an emergency, four vital capacity breaths of 100-percent oxygen via a tight breathing circuit will provide similar benefit (Norris and Dewan, 1985).

INDUCTION OF ANESTHESIA

Thiopental. This thiobarbiturate given intravenously is widely used and offers the advantages of ease and extreme rapidity of induction as well as prompt recovery with minimal risk of vomiting. Thiopental and similar compounds are poor analgesic agents, and the administration of sufficient drug given alone to maintain anesthesia may cause appreciable newborn depression. Thus, thiopental is not used as the sole anesthetic agent, but rather is administered in a dose that induces sleep.

Ketamine. This agent also may be used to render the patient unconscious. Given intravenously in low doses of 0.2 to 0.3 mg/kg, ketamine may be used to produce analgesia and sedation just prior to vaginal delivery. Doses of 1 mg/kg induce general anesthesia. Ketamine may prove useful in women with acute hemorrhage because, unlike thiopental, it is not associated with hypotension. Conversely, it usually causes a rise in blood pressure, and thus it generally should be avoided in women who are already hypertensive. Unpleasant delirium and hallucinations are commonly induced by this agent.

INTUBATION. Immediately after the patient is rendered unconscious, a muscle relaxant is given to facilitate intubation. *Succinylcholine*, a rapid-onset and short-acting agent, commonly is used. Cricoid pressure \mathfrak{R} — the *Sellick maneuver* \mathfrak{R} — is used to occlude the esophagus from induction until intubation is completed by a trained assistant. Before the operation begins, proper placement of the endotracheal tube must be confirmed. Such confirmation includes auscultation of bilateral breath sounds and end-tidal carbon dioxide analysis.

Failed Intubation. Although uncommon, failed intubation is a major cause of anesthesia-related maternal mortality (Wallace and Sidawi, 1997). In their review of 67 maternal deaths associated with general anesthesia, Hawkins and colleagues (1997b) reported that 22 percent were secondary to induction or intubation problems. A history of previous difficulties with intubation as well as a careful assessment of anatomical features of the neck, maxillofacial, pharyngeal, and laryngeal structures may help predict a difficult intubation. Even in cases where the initial assessment of the airway was uneventful, edema may develop intrapartum and present considerable difficulties (Farcon and associates, 1994). Morbid obesity is also a major risk factor for failed or difficult intubation. Of paramount importance is appropriate preoperative preparation to include the immediate availability of specialized equipment, including a variety of different shaped laryngoscopes, laryngeal mask airways, a fiberoptic bronchoscope, a transtracheal ventilation set, as well as liberal use of awake oral intubation techniques (Ezri and associates, 2001; Stamer and co-workers, 2000).

MANAGEMENT. An important principle is to start the operative procedure only after it has been ascertained that tracheal intubation has been successful and that adequate ventilation can be accomplished. Even with an abnormal fetal heart rate pattern, initiation of cesarean delivery will only serve to complicate matters if there is difficult or failed intubation. Frequently, the woman must be allowed to awaken and a different technique used, such as an awake intubation or regional analgesia.

Following failed intubation, the woman is ventilated by mask and cricoid pressure is applied to reduce the chance of aspiration (Cooper and colleagues, 1994). Surgery may proceed with mask ventilation or the woman may be allowed to awaken. In those cases where the woman has been paralyzed, and where ventilation cannot be reestablished by insertion of an oral airway, laryngeal mask airway, or use of a fiberoptic laryngoscope to intubate the trachea, a life-threatening emergency exists. To restore ventilation, percutaneous or even open cricothyrotomy is performed, and jet ventilation begun (Reisner and colleagues, 1999).

GAS ANESTHETICS. Once the endotracheal tube is secured, a 50:50 mixture of nitrous oxide and oxygen is administered to provide analgesia. Usually, a volatile halogenated agent is added to provide amnesia and additional analgesia. The mechanisms of actions of inhaled anesthetics have been reviewed recently by Campagna and colleagues (2003).

Volatile Anesthetics. The most commonly used volatile anesthetic in the United States is *isoflurane*. Both it and *halothane* are potent, nonexplosive agents that produce remarkable uterine relaxation when given in high, inhaled concentrations. Their use in high concentrations is restricted to those uncommon situations in which uterine relaxation is a requisite rather than a hazard. They are used for internal podalic version of the second twin (see [Chap. 39](#), p. 940), breech decomposition (see [Chap. 24](#), p. 579), and replacement of the acutely inverted uterus (see [Chap. 35](#), p. 833). As soon as the maneuver has been completed, anesthetic administration should be stopped and immediate efforts begun to promote myometrial contraction to minimize hemorrhage. Because of cardiodepressant and hypotensive effects, these agents may intensify the adverse effects of maternal hypovolemia. Halothane and isoflurane occasionally have been associated with hepatitis and massive hepatic necrosis (Gunaratnam and associates, 1995).

Anesthesia Gas Exposure and Pregnancy Outcome. Without exception, all anesthetic agents that depress the maternal central nervous system cross the placenta and depress the fetal central nervous system. As a result, personnel responsible for the care of the newborn immediately following delivery with a general anesthetic should be prepared to provide respiratory support (see [Chap. 28](#), p. 634). Ideally, induction-to-delivery time should be minimized when general anesthesia is used (American College of Obstetricians and Gynecologists, 2002b). In one study, Datta and colleagues (1981) concluded that fetal exposure of more than 8 minutes was associated with increased neonatal depression. Kavak and co-workers (2001) randomly assigned 84 women scheduled for elective cesarean delivery to either spinal analgesia or general anesthesia. There were no significant differences in short-term measures of neonatal outcome, including Apgar scores, umbilical artery blood gas determinations, or length of stay. The risks of anesthetic gas exposure associated with nonobstetrical surgery are discussed in [Chapter 41](#) (see p. 974) and the risks of occupational exposure in [Chapter 14](#) (see p. 356).

EXTUBATION. The tracheal tube may be safely removed only if the woman is conscious to a degree that enables her to follow commands and is capable of maintaining oxygen saturation with spontaneous respiration. Typically, the stomach is emptied via a nasogastric tube prior to extubation.

ASPIRATION. Massive gastric acidic inhalation causing pulmonary insufficiency from aspiration pneumonitis was first described by the obstetrician Mendelson, and the syndrome bears his name (Marik, 2001). Such pneumonitis has in the past been the most common cause of anesthetic deaths in obstetrics and therefore deserves special attention. In a survey of maternal deaths between 1979 and 1990, the Centers for Disease Control and Prevention identified that inhalation of gastric contents was associated with 23 percent of the 129 anesthesia-related deaths (Hawkins and colleagues, 1997b). Procedures

mentioned previously that are important to effective prophylaxis include use of antacids, skillful intubation accompanied by cricoid pressure, emptying of the stomach with a nasogastric tube, and use of regional analgesia when possible.

Fasting. According to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (1999), there are insufficient data regarding fasting times for clear liquids and the risk of pulmonary aspiration during labor. Clear liquids such as water, clear tea, black coffee, carbonated beverages, and fruit juices without pulp may be allowed in uncomplicated laboring women. Obvious solid foods should be avoided. The Task Force also recommended that "a fasting period of 8 hours or more is preferable for uncomplicated parturients undergoing elective cesarean delivery." Despite these precautions, it should be assumed that any woman in labor has both gastric particulate matter as well as acidic contents.

Pathophysiology. In 1952, Teabeaut demonstrated experimentally that if the pH of aspirated fluid was below 2.5, severe chemical pneumonitis developed. It was later demonstrated that the pH of gastric juice of nearly half of women tested intrapartum was below 2.5 (Taylor and Pryse-Davies, 1966). The right mainstem bronchus usually offers the simplest pathway for aspirated material to reach the lung parenchyma, and therefore the right lower lobe is most often involved. In severe cases, there is bilateral widespread involvement.

The woman who aspirates may develop evidence of respiratory distress immediately or as long as several hours after aspiration, depending in part on the material aspirated and the severity of the process. Aspiration of a large amount of solid material causes obvious signs of airway obstruction. Smaller particles without acidic liquid may lead to patchy atelectasis and later to bronchopneumonia.

When highly acidic liquid is inspired, decreased oxygen saturation along with tachypnea, bronchospasm, rhonchi, rales, atelectasis, cyanosis, tachycardia, and hypotension are likely to develop. At the sites of injury, pulmonary capillary leakage results in protein-rich fluid containing numerous erythrocytes exuding from capillaries into the lung interstitium and alveoli to cause decreased pulmonary compliance, shunting of blood, and severe hypoxemia. Radiographic changes may not appear immediately and they may be quite variable, although the right lobe most often is affected. Therefore, chest radiographs alone should not be used to exclude aspiration.

Treatment. The methods recommended for treatment of aspiration have changed appreciably in recent years, indicating that previous therapy was not very successful. Suspicion of aspiration of gastric contents demands very close monitoring for evidence of any pulmonary damage. Respiratory rate and oxygen saturation as measured by pulse oximetry are the most sensitive and earliest indicators of injury.

As much of the inhaled fluid as possible should be immediately wiped out of the mouth and removed from the pharynx and trachea by suction. Saline lavage may further disseminate the acid throughout the lung and is not recommended. If large particulate matter is inspired, bronchoscopy may be indicated to relieve airway obstruction. There is no convincing clinical or experimental evidence that corticosteroid therapy or prophylactic antimicrobial administration is beneficial (Marik, 2001). If clinical evidence of infection develops, however, then vigorous treatment is given. When acute respiratory distress syndrome develops, mechanical ventilation with positive end-expiratory pressure may prove lifesaving (see [Chap. 42](#), p. 991).

20. Dystocia: Abnormal Labor

INTRODUCTION

In 2002, the cesarean delivery rate was 26.1 percent—the highest level ever reported for the United States (Martin and co-workers, 2003). According to the American College of Obstetricians and Gynecologists (2003), about 60 percent of cesarean deliveries in the United States are attributable to the diagnosis of dystocia, and thus, its diagnosis has assumed major importance in contemporary obstetrical practice. Dystocia literally means *difficult labor* and is characterized by abnormally slow progress of labor. Generally, abnormal labor is common whenever there is disproportion between the presenting part of the fetus and the birth canal.

Roy (2003) has proposed that the high frequency of dystocia diagnosed contemporaneously results from environmental changes that are developing more rapidly than Darwinian natural selection. Humans are poorly adapted to the affluence of our modern diet, and the result is dystocia. There is some evidence to support this hypothesis. For example, Joseph and colleagues (2003) analyzed changes in maternal characteristics related to the recent increase in primary cesarean deliveries in Nova Scotia. They concluded that the recent increase could be attributed to changes in maternal age, parity, prepregnancy weight, and weight gain during pregnancy. Others also have observed that maternal weight is associated with dystocia (Nuthalapaty and co-workers, 2004; Wilkes and co-workers, 2003).

DYSTOCIA

Dystocia is the consequence of four distinct abnormalities that may exist singly or in combination:

1. Abnormalities of the expulsive forces, either uterine forces insufficiently strong or inappropriately coordinated to efface and dilate the cervix—uterine dysfunction—or inadequate voluntary muscle effort during the second stage of labor.
2. Abnormalities of presentation, position, or development of the fetus.
3. Abnormalities of the maternal bony pelvis—that is, pelvic contraction.
4. Abnormalities of soft tissues of the reproductive tract that form an obstacle to fetal descent (see [Chap. 40](#)).

More simply, these abnormalities can be mechanistically simplified into three categories:

1. Abnormalities of the *powers*—uterine contractility and maternal expulsive effort.
2. Abnormalities involving the *passenger*—the fetus.
3. Abnormalities of the *passage*—the pelvis.

Common clinical findings in women with these labor abnormalities are summarized in [Table 20-1](#).

OVERDIAGNOSIS OF DYSTOCIA. Combinations of the abnormalities shown in [Table 20-1](#) often interact to produce dysfunctional labor. Today, expressions such as *cephalopelvic disproportion* and *failure to progress* often are used to describe ineffective labors.

The expression *cephalopelvic disproportion* came into use prior to the 20th century to describe obstructed labor resulting from disparity between the dimensions of the fetal head and maternal pelvis such as to preclude vaginal delivery. This term, however, originated at a time when the main indication for cesarean delivery was overt pelvic contracture due to rickets (Olah and Neilson, 1994). Such true disproportion is now rare, and most disproportions are the result of malposition of the fetal head within the pelvis (asynclitism) or of ineffective uterine contractions. True cephalopelvic disproportion is a tenuous diagnosis because two thirds or more of women diagnosed as having this disorder and delivered by cesarean subsequently deliver even larger newborns vaginally (see [Chap. 26](#), p. 612).

Failure to progress in either spontaneous or stimulated labor has become an increasingly popular description of ineffectual labor. This term is used to include lack of progressive cervical dilatation or lack of fetal descent.

As previously stated, dystocia is the most common current indication for primary cesarean delivery. Gifford and colleagues (2000) reported that lack of progress in labor was the reason for 68 percent of unplanned cesarean deliveries for cephalic-presenting fetuses. Notzon and associates (1994) found that 12 percent of American women without prior cesarean delivery were diagnosed as having dystocia requiring abdominal delivery in 1990, and the rate had increased from 7 percent in 1980. A similar change also was reported in the United Kingdom (Leitch and Walker, 1998). Because many women with a primary cesarean delivery for dystocia undergo repeat cesarean delivery in subsequent pregnancies, an estimated 50 to 60 percent of all cesarean deliveries in the United States may be attributable to this diagnosis.

It is generally agreed that dystocia leading to cesarean delivery is overdiagnosed in the United States and elsewhere. Factors leading to increased use of cesarean delivery for dystocia, however, are controversial. Those implicated have included incorrect diagnosis of dystocia, epidural analgesia, fear of litigation, and even clinician convenience (Lieberman and co-workers, 1996; Savage and Francome, 1994; Thorp and colleagues, 1993a).

Variability in the criteria for diagnosis is a major determinant of this increase. For example, Gifford and colleagues (2000) found that almost 25 percent of the cesarean deliveries performed annually in the United States for lack of progress were in women with cervical dilatation of only 0 to 3 cm ([Fig. 20-1](#)). According to Stephenson (2000), this practice is contrary to recommendations of the American College of Obstetricians and Gynecologists (1995a) that the cervix be dilated to 4 cm or more before a diagnosis is made. Thus, the diagnosis often is made before the active phase of labor and therefore, before an

adequate trial of labor. Another factor implicated is insufficient oxytocin stimulation of labor in women with slow labor (Rouse and colleagues, 1999). King (1993) found that cesarean deliveries for dystocia in private patients in the United Kingdom were related to office hours and surgery schedules, whereas the timing of procedures for fetal distress were evenly distributed throughout the day.

Figure 20-1. Distribution of cervical dilatation at the time of cesarean delivery for dystocia. (From Gifford and colleagues, 2000, with permission.)

MECHANISMS OF DYSTOCIA. The discussion concerning dystocia by Williams (1903) in the first edition of this text is still true today. [Figure 20-2](#) is from the first edition, and demonstrates the mechanical process of labor and the potential obstacles. The cervix and lower uterus are shown at the end of pregnancy and at the end of labor. At the end of pregnancy, the fetal head, to traverse the birth canal, must encounter a relatively thicker lower uterine segment and undilated cervix. The uterine fundus muscle is less developed and presumably less powerful. Uterine contractions, cervical resistance, and the forward pressure exerted by the leading fetal head are the factors influencing the progress of the first stage of labor (see [Chap. 17](#), p. 421).

After complete cervical dilatation (see [Fig. 20-2](#)), however, the mechanical relationship between the fetal head size and position and the pelvic capacity, namely fetopelvic proportion, becomes clearer as the fetus descends. The uterine musculature is much thicker and thus more powerful. Accordingly, abnormalities in fetopelvic proportions become more apparent once the second stage is reached.

Uterine muscle malfunction can result from uterine overdistention or obstructed labor, or both. Thus, ineffective labor is generally accepted as a possible warning sign of fetopelvic disproportion. Simply dividing labor abnormalities into pure *uterine dysfunction* and *fetopelvic disproportion* is incorrect because these two abnormalities are so closely interlinked. Indeed, according to the American College of Obstetricians and Gynecologists (1995a), the bony pelvis is not the factor, with rare exceptions, that limits vaginal delivery. In the absence of objective means of precisely distinguishing these two causes of labor failure, clinicians must rely on a *trial of labor* to determine if labor can be successful in effecting vaginal delivery. Defining the adequacy of a trial of labor is a priority, in our opinion, in moderating the primary cesarean delivery rate for dystocia in the United States.

Figure 20-2. Diagrams of the birth canal **(A)** at the end of pregnancy and **(B)** during the second stage of labor, showing formation of the birth canal. (C.R. = contraction ring; o.i. = internal cervical os; o.e. = external cervical os.) (From Williams, 1903.)

ABNORMALITIES OF THE EXPULSIVE FORCES

Cervical dilatation and propulsion and expulsion of the fetus is brought about by contractions of the uterus, reinforced during the second stage by voluntary or involuntary muscular action of the abdominal wall— "pushing." Either of these factors may lack intensity and result in delayed or interrupted labor. The diagnosis of uterine dysfunction in the latent phase is difficult and sometimes can be made only in retrospect (see [Chap. 17](#), p. 422). One of the most common errors is to treat women for uterine dysfunction who are not yet in active labor.

There have been three significant advances in the treatment of uterine dysfunction:

1. Realization that undue prolongation of labor may contribute to perinatal morbidity and mortality.
2. Use of dilute intravenous infusion of oxytocin in the treatment of certain types of uterine dysfunction.
3. More frequent use of cesarean delivery rather than difficult midforceps delivery when oxytocin fails or its use is inappropriate.

TYPES OF UTERINE DYSFUNCTION. Reynolds and co-workers (1948) emphasized that uterine contractions of normal labor are characterized by a gradient of myometrial activity, being greatest and lasting longest at the fundus (fundal dominance) and diminishing toward the cervix. Caldeyro-Barcia and colleagues (1950) from Montevideo, Uruguay, inserted small balloons into the myometrium at various levels (see [Chap. 18](#), p. 466). They reported that in addition to a gradient of activity, there was a time differential in the onset of the contractions in the fundus, midzone, and lower uterine segments. Larks (1960) described the stimulus as starting in one cornu and then several milliseconds later in the other, the excitation waves then joining and sweeping over the fundus and down the uterus.

The Montevideo group also ascertained that the lower limit of contraction pressure required to dilate the cervix is 15 mm Hg. This figure is in agreement with the findings of Hendricks and co-workers (1959), who reported that normal spontaneous contractions often exert pressures of about 60 mm Hg. From these observations, it is possible to define two types of uterine dysfunction. In the more common *hypotonic uterine dysfunction*, there is no basal hypertonus and uterine contractions have a normal gradient pattern (synchronous), but the slight rise in pressure during a contraction is insufficient to dilate the cervix. In the other, *hypertonic uterine dysfunction* or *incoordinate uterine dysfunction*, either basal tone is elevated appreciably or the

pressure gradient is distorted. Gradient distortion may result from contraction of the midsegment of the uterus with more force than the fundus or from complete asynchronism of the impulses originating in each cornu, or a combination of these two.

Active-Phase Disorders. Labor abnormalities are clinically divided into either slower-than-normal progress \mathfrak{R} — protraction disorder \mathfrak{R} — or complete cessation of progress \mathfrak{R} — arrest disorder. A woman must be in the active phase of labor with cervical dilatation to at least 3 to 4 cm to be diagnosed with either of these. Handa and Laros (1993) diagnosed active-phase arrest, defined as no dilatation for 2 hours or more, in 5 percent of term nulliparas. This incidence has not changed since the 1950s (Friedman, 1978). Inadequate uterine contractions, defined as less than 180 Montevideo units ([Fig. 20-3](#)), were diagnosed in 80 percent of women with active-phase arrest.

Protraction disorders are less well described, probably because the time interval necessary before diagnosing slow progress is undefined. The World Health Organization (1994) has proposed a labor management *partograph* in which protraction is defined as less than 1 cm/hr cervical dilatation for a minimum of 4 hours.

The criteria recommended by the American College of Obstetricians and Gynecologists (1995a) for diagnosis of protraction and arrest disorders are shown in [Table 20-2](#). These criteria were adapted from those of Cohen and Friedman (1983), shown in [Table 20-3](#).

Hauth and co-workers (1986, 1991) reported that when labor is effectively induced or augmented with oxytocin, 90 percent of women achieve 200 to 225 Montevideo units, and 40 percent achieve at least 300 Montevideo units. These results suggest that there are certain minimums of uterine activity that should be achieved before performing cesarean delivery for dystocia. Accordingly, the American College of Obstetricians and Gynecologists (1989) has suggested that, before the diagnosis of arrest during first-stage labor is made, both of these criteria should be met:

1. The latent phase has been completed, with the cervix dilated 4 cm or more.
2. A uterine contraction pattern of 200 Montevideo units or more in a 10-minute period has been present for 2 hours without cervical change.

Rouse and colleagues (1999) have recently challenged the "2-hour rule" on the grounds that a longer time, that is, at least 4 hours, is necessary before concluding that the active phase of labor has failed. We agree.

Second-Stage Disorders. As previously noted in [Chapter 17](#) (see p. 416 and [Fig. 17-20](#)), fetal descent largely follows complete dilatation. Moreover, the second stage incorporates many of the cardinal movements necessary for the fetus to negotiate the birth canal. Accordingly, disproportion of the fetus and pelvis frequently becomes apparent during the second stage.

Until recently, there have been unquestioned second-stage rules that limited its duration. The second stage in nulliparas was limited to 2 hours and extended to 3 hours when regional analgesia was used. For multiparas, 1 hour was the limit, extended to 2 hours with regional analgesia. At Parkland Hospital during 1999, only 6 percent of second-stage labors in nulliparas at term exceeded 2 hours. The second-stage rule of 2 hours was established in American obstetrics by the beginning of the 20th century. It stemmed from concerns about maternal and fetal health, likely regarding infection, and led to difficult forceps operations.

Cohen (1977) investigated the fetal effects of second-stage labor length at Beth Israel Hospital. He included 4403 term nulliparas in whom electronic fetal heart rate monitoring was performed. Neonatal mortality was not increased in women whose second-stage labor exceeded 2 hours. Epidural analgesia was used commonly, and this likely accounted for the large number of pregnancies with a prolonged second stage. These data influenced decisions to permit an additional hour for the second stage when regional analgesia was used.

Menticoglou and colleagues (1995b) challenged the prevailing dictums on the duration of the second stage based on their experiences in Winnipeg. These dictums came under scrutiny at their hospitals because of grave neonatal injuries associated with forceps rotations to shorten second-stage labor (Menticoglou and colleagues, 1995a). As a result, they allowed longer second stages in the hope that fewer vaginal operative deliveries would be necessary. Between 1988 and 1992, the second stage of labor exceeded 2 hours in one fourth of 6041 nulliparas at term. Labor epidural analgesia was used in 55 percent. The length of the second stage, even in those lasting up to 6 hours or more, was not related to neonatal outcome. These good results were attributed to careful use of electronic monitoring and scalp pH measurements. They concluded that there is no compelling reason to intervene with a possibly difficult forceps or vacuum extraction because a certain number of hours has elapsed. They offered, however, an important caveat. After 3 hours in the second stage, delivery by cesarean or other operative method increases progressively such that by 5 hours the prospects for spontaneous delivery in the subsequent hour are only 10 to 15 percent.

Myles and Santolaya (2003) analyzed both the maternal and neonatal consequences of prolonged second stage of labor in 7818 women who gave birth in Chicago between 1996 and 1999. Excluding nonvertex and multiple gestations, 87 percent of the women reached the second stage of labor. Neonatal mortality and morbidity was not related to the length of the second stage. Shown in [Table 20-4](#) are maternal outcomes in relation to the duration of the second stage of labor.

With achievement of full cervical dilatation, the great majority of women cannot resist the urge to "bear down" or "push" each time the uterus contracts. Typically, a laboring woman contracts her abdominal musculature repetitively with vigor to generate increased intra-abdominal pressure throughout the contractions. The combined force created by contractions of the uterus and abdominal musculature propels the fetus downward.

At times, the magnitude of the force created by contractions of abdominal musculature is compromised sufficiently to prevent spontaneous vaginal delivery. Heavy sedation or regional analgesia \mathfrak{R} — lumbar epidural or spinal \mathfrak{R} — is likely to reduce the reflex urge to push, and at the same time may impair the ability to contract the abdominal muscles sufficiently. In other instances, the inherent urge to push is overridden by the intense pain created by bearing down.

Two approaches to maternal pushing during the second stage of labor with epidural analgesia have yielded contradictory

results. One approach advocates pushing forcefully once the cervix has completely dilated, regardless of the urge to push. The second favors the delay of pushing until a woman regains the sensory urge to bear down. Fraser and colleagues (2000) found that delayed pushing reduced difficult operative deliveries, whereas Manyonda and colleagues (1990) found the opposite effect. Hansen and colleagues (2002) randomly assigned 252 women with epidural analgesia to one of the two approaches. There were no adverse maternal or neonatal outcomes linked to delayed pushing despite significantly prolonging second-stage labor. Plunkett and colleagues (2003), in a similar study, confirmed these findings.

Figure 17-20. Labor course divided functionally on the basis of dilatation and descent curves into (1) a preparatory division, including latent and acceleration phases; (2) a dilatational division, occupying the phase of maximum slope of dilatation; and (3) a pelvic division, encompassing both deceleration phase and second stage concurrent with the phase of maximum slope of descent. (Illustration courtesy of Dr. L. Casey; redrawn from Friedman, 1978.)

Figure 20-3. Montevideo units are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window and adding the pressures generated by each contraction. In the example shown, there were five contractions, producing pressure changes of 52, 50, 47, 44, and 49 mm Hg, respectively. The sum of these five contractions is 242 Montevideo units.

FETAL STATION AT ONSET OF ACTIVE LABOR. Descent of the fetal biparietal diameter to the level of the maternal pelvic ischial spines (0 station) is defined as engagement ([Fig. 2-27](#), p. 37). Friedman and Sachtleben (1965) reported that there was a significant association between higher station at the onset of labor and subsequent dystocia. They described both protraction and arrested labor disorders in women with fetal head stations above +1 cm and noted that the higher the station at the onset of labor in nulliparas, the more prolonged the labor (Friedman and Sachtleben, 1976). Handa and Laros (1993) found that fetal station at the time of arrested labor was also a risk factor for dystocia. Roshanfekar and associates (1999) analyzed fetal station in 803 nulliparas women with term pregnancies in whom active labor had been diagnosed. About 30 percent of these women presented to the hospital with the fetal head at or below 0 station, and their cesarean delivery rate was 5 percent compared with that of 14 percent for those with higher fetal stations. The prognosis for dystocia, however, was not related to incrementally higher fetal head stations above the pelvic midplane (0 station). Importantly, 86 percent of nulliparous women without fetal head engagement at diagnosis of active labor delivered vaginally. Thus, lack of engagement at the onset of labor, although a statistical risk factor for dystocia, should not be assumed to necessarily predict fetopelvic disproportion. This caveat is especially true for parous women because the head typically descends later in labor.

Figure 2-27. When the lowermost portion of the fetal head is at or below the ischial spines, it is usually engaged. Exceptions occur when there is considerable molding, caput formation, or both. (P = sacral promontory; S = ischial spine; Sym = symphysis pubis.)

REPORTED CAUSES OF UTERINE DYSFUNCTION. Various labor factors have been implicated as causes of uterine dysfunction.

Epidural Analgesia. It is important to emphasize that epidural analgesia can slow labor (Sharma and Leveno, 2000). As shown in [Table 20-5](#), epidural analgesia has been associated with lengthening of both first- and second-stage labor as well as slowing of the rate of fetal descent.

Chorioamnionitis. Because of the association of prolonged labor with maternal intrapartum infection, some clinicians have suggested that infection itself plays a role in the development of abnormal uterine activity. Satin and co-workers (1992) studied the effects of chorioamnionitis on labor stimulation with oxytocin in 266 pregnancies. Chorioamnionitis diagnosed late in labor was found to be a marker of cesarean delivery for dystocia, whereas this was not observed in women diagnosed as having chorioamnionitis early in labor. Specifically, 40 percent of women developing chorioamnionitis after requiring oxytocin for dysfunctional labor later required cesarean delivery for dystocia. It is likely that uterine infection in this clinical setting is a consequence of dysfunctional, prolonged labor rather than a cause of dystocia.

Maternal Position During Labor. Advocacy for recumbency or ambulation during labor has swung back and forth over time. Proponents of walking during labor report it to shorten labor, decrease rates of oxytocin augmentation, decrease the need for analgesia, and lower the frequency of operative vaginal delivery (Flynn and co-authors, 1978; Read and colleagues, 1981).

According to Miller (1983), the uterus contracts more frequently but with less intensity with the mother in the supine position compared with that of lying on her side. Conversely, contraction frequency and intensity have been reported to increase with sitting or standing. Lupe and Gross (1986) concluded, however, that there is no conclusive evidence that upright maternal posture or ambulation improves labor. They reported that women preferred to lie on their side or sit in bed. Few chose to walk, fewer to squat, and none wanted the knee-chest position. They tended to assume fetal positions in later labor. Most women enthusiastic about ambulation returned to bed when active labor began (Carlson and associates, 1986; Williams and co-workers, 1980).

Bloom and colleagues (1998) conducted a randomized trial to study the effects of walking during first-stage labor. In 1067 women with uncomplicated term pregnancies delivered at Parkland Hospital, these investigators reported that ambulation neither improved nor delayed labor in nulliparous or parous women. Walking during labor did not reduce the need for analgesia, nor was it harmful to the fetus-neonate. Because these results provided no evidence for or against walking during labor, we now give women without complications the option of electing either recumbency or supervised ambulation during labor. The American College of Obstetricians and Gynecologists (2003) has concluded that ambulation in labor is not harmful, and mobility may result in greater comfort.

Birthing Position in Second-Stage Labor. Considerable interest has been shown in alternative second-stage labor birth positions and their effect on labor. Johnson and co-workers (1991) reported that several randomized controlled trials with and without the use of specific birthing aids—for example, birthing chairs—have produced conflicting results and are confounded by observer bias. One reported advantage from avoiding the traditional lithotomy position is an increase in the dimensions of the pelvic outlet. Specifically, Russell (1969) described a 20- to 30-percent increase in the area of the pelvic outlet with squatting compared with that of the supine position. Gupta and co-workers (1991) compared the usual delivery position in the western world—recumbent with the head and shoulders elevated 30 degrees—with the squatting position and found no significant change in the dimensions of either the pelvic inlet or outlet. Crowley and associates (1991) randomly assigned 634 women to deliver in an obstetrical birthing chair and 596 women to deliver in bed. There were no advantages with use of the chair, but hemorrhage was increased in this group. De Jong and co-workers (1997), in a randomized trial of 517 women, found no increase in hemorrhage with the sitting position. Obstetrical outcomes were not improved by enforcing the upright position for second-stage labor. The main benefits reported were less maternal pain and enhanced maternal satisfaction with the birthing experience. Babayer and coauthors (1998) cautioned that prolonged sitting or squatting during the second stage may cause peroneal neuropathy.

Immersion in Water. This approach has been advocated as a means of relaxation that may contribute to more efficient labor (Odent, 1983). Schorn and colleagues (1993) randomly assigned 96 women at term to immersion in a hot tub with air jets or to prevailing labor management at their hospital. The women were permitted to stay in the tub as long as they desired, and most stayed 30 to 45 minutes. Water immersion did not alter the rate of cervical dilation, length of labor, route of delivery, or analgesia use. Robertson and associates (1998) reported that immersion was not associated with chorioamnionitis or endometritis. Kwee and co-workers (2000) studied the effects of immersion in 20 women and reported that maternal blood pressure decreased, whereas fetal heart rate was unaffected.

RUPTURED MEMBRANES WITHOUT LABOR. Membrane rupture without spontaneous uterine contractions occurs in about 8 percent of term pregnancies. Until recently, management generally included stimulation of contractions when labor did not begin after 6 to 12 hours. This intervention evolved about 40 years ago because of maternal and fetal complications due to amnionitis (Calkins, 1952). Such routine intervention was the accepted practice until challenged by Kappy and co-workers (1979), who reported excessive cesarean delivery in term pregnancies with ruptured membranes managed with labor stimulation compared with that of those managed by expectant observation.

Hannah and co-workers (1996) and Peleg and associates (1999) performed an international randomized investigation of 5042 pregnancies with ruptured membranes at term. They measured the effects of induction versus expectant management and also compared induction with intravenous oxytocin to prostaglandin E₂ gel. There were approximately 1200 pregnancies in each of the four study arms. They concluded that labor induction with intravenous oxytocin was the preferred management. This determination was based on significantly fewer intrapartum and postpartum infections in women whose labor was induced. There were no significant differences in cesarean delivery rates. Subsequent analysis by Hannah and colleagues (2000) indicated increased adverse outcomes when expectant management at home was compared with in-hospital observation. Similar conclusions were reached by Mozurkewich and Wolf (1997) after meta-analysis of reported trials of management of ruptured membrane at term. At Parkland Hospital, labor is induced when ruptured membranes are diagnosed at term.

PRECIPITOUS LABOR AND DELIVERY. Not only can labor be too slow, but it also can be abnormally rapid. Precipitous—that is, extremely rapid—labor and delivery may result from an abnormally low resistance of the soft parts of the birth canal, from abnormally strong uterine and abdominal contractions, or rarely from the absence of painful sensations and thus a lack of awareness of vigorous labor.

Definition. According to Hughes (1972), precipitous labor terminates in expulsion of the fetus in less than 3 hours. Using this definition, 79,933 live births (2 percent) were complicated by precipitous labor in the United States during 1998 (Ventura and co-workers, 2000). There is little published information, however, on its maternal and fetal effects. Mahon and colleagues (1994) described 99 pregnancies delivered within 3 hours of labor onset. Short labors, defined as a rate of cervical dilatation of 5 cm/hr or faster for nulliparas and 10 cm/hr for multiparas, were associated with abruption (20 percent), meconium, postpartum hemorrhage, cocaine abuse, and low Apgar scores. Most (93 percent) of the women were multiparas and typically had uterine contractions at intervals less than 2 minutes.

Maternal Effects. Precipitous labor and delivery seldom are accompanied by serious maternal complications if the cervix is effaced appreciably and compliant, the vagina has been stretched previously, and the perineum is relaxed. Conversely, vigorous uterine contractions combined with a long, firm cervix and a noncompliant birth canal may lead to uterine rupture or extensive lacerations of the cervix, vagina, vulva, or perineum. It is in these latter circumstances that the rare condition of *amniotic fluid embolism* most likely develops (see [Chap. 35](#), p. 845). **The uterus that contracts with unusual vigor before delivery is likely to be hypotonic after delivery, with hemorrhage from the placental implantation site as the consequence.** Postpartum hemorrhage from uterine atony is discussed in [Chapter 35](#) (see p. 826).

Effects on Fetus and Neonate. Perinatal mortality and morbidity from precipitous labor may be increased considerably for several reasons. The tumultuous uterine contractions, often with negligible intervals of relaxation, prevent appropriate uterine blood flow and fetal oxygenation. Additionally, resistance of the birth canal may cause intracranial trauma, although this is rare. Acker and colleagues (1988) reported that Erb or Duchenne brachial palsy was associated with such labors in one third of cases. Finally, during an unattended birth, the newborn may fall to the floor and be injured or may need resuscitation that is

not immediately available.

Treatment. Unusually forceful spontaneous uterine contractions are not likely to be modified to a significant degree by analgesia. The use of tocolytic agents such as magnesium sulfate is unproven in these circumstances. Use of general anesthesia with agents that impair uterine contractibility, such as halothane and isoflurane, is often excessively heroic. Certainly, any oxytocin agents being administered should be stopped immediately.

FETOPELVIC DISPROPORTION

Fetopelvic disproportion arises from diminished pelvic capacity, excessive fetal size, or more usually, a combination of both.

PELVIC CAPACITY. Any contraction of the pelvic diameters that diminishes the capacity of the pelvis can create dystocia during labor. There may be contractions of the pelvic inlet, the midpelvis, the pelvic outlet, or a generally contracted pelvis caused by combinations of these.

Contracted Pelvic Inlet. The pelvic inlet usually is considered to be contracted if its shortest anteroposterior diameter is less than 10 cm or if the greatest transverse diameter is less than 12 cm. The anteroposterior diameter of the pelvic inlet is commonly approximated by manually measuring the diagonal conjugate, which is about 1.5 cm greater (see [Chap. 2](#), p. 36). Therefore, inlet contraction usually is defined as a diagonal conjugate of less than 11.5 cm.

Using clinical and, at times, imaging pelvimetry, it is important to identify the shortest anteroposterior diameter through which the fetal head must pass. Occasionally, the body of the first sacral vertebra is displaced forward so that the shortest distance may actually be between this abnormal sacral promontory and the symphysis pubis.

Prior to labor, the fetal biparietal diameter has been shown to *average* from 9.5 to as much as 9.8 cm. Therefore, it might prove difficult or even impossible for some fetuses to pass through an inlet that has an anteroposterior diameter of less than 10 cm. Mengert (1948) and Kaltreider (1952), employing x-ray pelvimetry, demonstrated that the incidence of difficult deliveries is increased to a similar degree when either the anteroposterior diameter of the inlet is less than 10 cm or the transverse diameter is less than 12 cm. As expected, when both diameters are contracted, dystocia is much greater than when only one is contracted.

A small woman is likely to have a small pelvis, but she is also likely to have a small neonate. Thoms (1937) studied 362 nulliparas and found the mean birthweight of their offspring was significantly lower (280 g) in women with small pelvises than in those with medium or large pelvises. In veterinary obstetrics, it frequently has been observed that in most species maternal size rather than paternal size is the important determinant of fetal size.

Normally, cervical dilatation is facilitated by hydrostatic action of the unruptured membranes or, after their rupture, by direct application of the presenting part against the cervix. In contracted pelvises, however, when the head is arrested in the pelvic inlet, the entire force exerted by the uterus acts directly on the portion of membranes that overlie the dilating cervix. Consequently, early spontaneous rupture of the membranes is more likely.

After membrane rupture, the absence of pressure by the head against the cervix and lower uterine segment predisposes to less effective contractions. Hence, further dilatation may proceed very slowly or not at all. Cibils and Hendricks (1965) reported that the mechanical adaptation of the fetal passenger to the bony passage plays an important part in determining the efficiency of contractions. The better the adaptation, the more efficient are the contractions. Thus, cervical response to labor provides a prognostic view of the labor outcome in women with inlet contraction.

A contracted inlet plays an important part in the production of abnormal presentations. In normal nulliparas, the presenting part at term commonly descends into the pelvic cavity before the onset of labor. When the inlet is contracted considerably, however, descent usually does not take place until after the onset of labor, if at all. Cephalic presentations still predominate, but because the head floats freely over the pelvic inlet or rests more laterally in one of the iliac fossae, very slight influences may cause the fetus to assume other presentations. **In women with contracted pelvises, face and shoulder presentations are encountered three times more frequently**, and cord prolapse occurs four to six times more frequently. Critchlow and colleagues (1994) have quantified the magnitude of risk for cord prolapse in women with cephalopelvic disproportion.

Contracted Midpelvis. This finding is more common than inlet contraction. It frequently causes transverse arrest of the fetal head, which potentially can lead to a difficult midforceps operation or to cesarean delivery.

The obstetrical plane of the midpelvis extends from the inferior margin of the symphysis pubis through the ischial spines and touches the sacrum near the junction of the fourth and fifth vertebrae (see [Chap. 2](#), p. 34). A transverse line theoretically connecting the ischial spines divides the midpelvis into anterior and posterior portions. The former is bounded anteriorly by the lower border of the symphysis pubis and laterally by the ischiopubic rami. The posterior portion is bounded dorsally by the sacrum and laterally by the sacrospinous ligaments, forming the lower limits of the sacrosacral notch.

Average midpelvis measurements are as follows: *transverse*, or interspinous, 10.5 cm; *anteroposterior*, from the lower border of the symphysis pubis to the junction of S4-S5, 11.5 cm; and *posterior sagittal*, from the midpoint of the interspinous line to the same point on the sacrum, 5 cm. The definition of midpelvic contractions has not been established with the same precision possible for inlet contractions. Even so, the midpelvis is likely contracted when the sum of the interischial spinous and posterior sagittal diameters of the midpelvis is—normal, 10.5 plus 5 cm, or 15.5 cm—falls to 13.5 cm or below. This concept was emphasized by Chen and Huang (1982) in evaluating possible midpelvic contraction. There is reason to suspect midpelvic contraction whenever the interischial spinous diameter is less than 10 cm. When it measures less than 8 cm, the midpelvis is contracted.

Although there is no precise manual method of measuring midpelvic dimensions, a suggestion of contraction sometimes can be inferred if the spines are prominent, the pelvic sidewalls converge, or the sacrosacral notch is narrow. Moreover, Eller and Mengert (1947) pointed out that the relationship between the intertuberous and interspinous diameters of the ischium is sufficiently constant that narrowing of the interspinous diameter can be anticipated when the intertuberous diameter is narrow.

A normal intertuberous diameter, however, does not always exclude a narrow interspinous diameter.

Contracted Pelvic Outlet. This finding usually is defined as an interischial tuberos diameter of 8 cm or less. The pelvic outlet may be roughly likened to two triangles, with the interischial tuberos diameter constituting the base of both. The sides of the anterior triangle are the pubic rami, and its apex is the inferior posterior surface of the symphysis pubis. The posterior triangle has no bony sides but is limited at its apex by the tip of the last sacral vertebra (not the tip of the coccyx). Diminution of the intertuberous diameter with consequent narrowing of the anterior triangle must inevitably force the fetal head posteriorly. Floberg and associates (1987) reported that outlet contractions were found in almost 1 percent of more than 1400 unselected nulliparas with term pregnancies. A contracted outlet may cause dystocia not so much by itself as through the often-associated midpelvic contraction. *Outlet contraction without concomitant midplane contraction is rare.*

Even when the disproportion between the fetal head and the pelvic outlet is not sufficiently great to give rise to severe dystocia, it may play an important part in the production of perineal tears. With increasing narrowing of the pubic arch, the occiput cannot emerge directly beneath the symphysis pubis but is forced increasingly farther down upon the ischiopubic rami. The perineum, consequently, becomes increasingly distended and thus exposed to greater danger of laceration.

Pelvic Fractures and Rare Contractures. Speer and Peltier (1972) reviewed experiences with pelvic fractures and pregnancy. Trauma from automobile collisions was the most common cause of pelvic fractures. With bilateral fractures of the pubic rami, compromise of the birth canal capacity by callus formation or malunion was common. A history of pelvic fracture warrants careful review of previous radiographs and possibly computed tomographic pelvimetry later in pregnancy. Descriptions and illustrations of rare pelvic contractions are provided in the 10th through 17th editions of *Williams Obstetrics*.

Estimation of Pelvic Capacity. The techniques for clinical evaluation using digital examination of the bony pelvis during labor are described in detail in [Chapter 2](#) (p. 36). Briefly, the examiner attempts to judge the anteroposterior diameter of the inlet (the diagonal conjugate), the interspinous diameter of the midpelvis, and the intertuberous distances of the pelvic outlet. A narrow pelvic arch, less than 90 degrees, can signify a narrow pelvis. An unengaged fetal head can indicate either excessive fetal head size or reduced pelvic inlet capacity.

X-RAY PELVIMETRY. The prognosis for successful vaginal delivery in any given pregnancy cannot be established on the basis of x-ray pelvimetry alone, because the pelvic capacity is but one of several factors that determine the outcome (Mengert, 1948). Thus, x-ray pelvimetry is considered to be of limited value in the management of labor with cephalic presentations (American College of Obstetricians and Gynecologists, 1995b).

COMPUTED TOMOGRAPHIC (CT) SCANNING. Advantages of CT pelvimetry, such as that shown in [Figure 20-4](#), compared with those of conventional x-ray pelvimetry include reduced radiation exposure, greater accuracy, and easier performance. With either method, costs are comparable and x-ray exposure is minuscule (see [Chap. 41](#), p. 977). With conventional x-ray pelvimetry, the mean gonadal exposure is estimated to be 885 mrad by the Committee on Radiological Hazards to Patients (Osborn, 1963). Depending on the machine and technique employed, fetal doses with computed tomography may range from 250 to 1500 mrad (Moore and Shearer, 1989).

MAGNETIC RESONANCE IMAGING (MRI). The advantages of MRI pelvimetry include lack of ionizing radiation, accurate measurements, complete fetal imaging, and the potential for evaluating soft tissue dystocia (McCarthy, 1986; Stark and co-workers, 1985). Currently its use is limited because of expense, time involved for adequate imaging studies, and equipment availability.

Sporri and co-workers (1997) used MRI postpartum to measure capacity at each level of the pelvis and ultrasonography intrapartum to measure fetal head dimensions. In this study, "cephalic pelvic disproportion" was defined as arrested labor for more than 4 hours in the presence of normal uterine contractions. "Failure to progress" was diagnosed when there was no labor progress and uterine activity was hypotonic. A fetal head volume exceeding measured pelvic capacity was a frequent finding in women with cephalopelvic disproportion, but not those with failure to progress. Clearly, use of MRI to measure pelvic capacity is investigational.

Figure 20-4. A. Anteroposterior view of a digital radiograph. Illustrated is the measurement of the transverse diameter of the pelvic inlet using an electronic cursor. The fetal body is clearly outlined. **B.** Lateral view of a digital radiograph. Illustrated are measurements of the anteroposterior diameters of the inlet and midpelvis measurements using the electronic cursor. **C.** An axial computed tomographic section through the midpelvis. The level of the fovea of the femoral heads was ascertained from the anteroposterior digital radiograph because it corresponds to the level of the ischial spines. The interspinous diameter is measured using the electronic cursor. The total fetal radiation dose using the three exposures shown in parts **A** to **C** is approximately 250 mrad.

FETAL DIMENSIONS IN FETOPELVIC DISPROPORTION. In earlier editions of *Williams Obstetrics*, excessive fetal size as a cause of dystocia in a normally formed pelvis was considered to be 5000 g in the 1st edition (1903) and 4500 g in the 7th and 13th editions (1956, 1966). Despite these variations, the common theme was that fetal size alone is seldom a suitable explanation for failed labor. Now, even with the evolution of remarkable technology, selection of a fetal size threshold to predict fetopelvic disproportion is still elusive. This is because most cases of disproportion occur in fetuses whose weight is well within the range of the general obstetrical population. As shown in [Figure 20-5](#), two thirds of neonates who required cesarean delivery at Parkland Hospital after an attempt at forceps delivery had failed, weighed less than 3700 g (8 lb 2 oz). Thus, fetopelvic disproportion usually is not associated simply with excessive fetal size. Other factors, such as malpositions of the fetal head—for example, occiput position, face and brow presentations—obstruct passage of the fetus through the birth canal.

Estimation of Fetal Head Size. Efforts to clinically and radiographically predict fetopelvic disproportion based on fetal head size have proved disappointing. Muller (1880) and Hillis (1930) both described a clinical maneuver to predict disproportion. In an occiput presentation, the fetal brow and the suboccipital region are grasped through the abdominal wall with the fingers and firm pressure is directed downward in the axis of the inlet. Fundal pressure by an assistant usually is helpful. The effect of the forces on the descent of the head can be evaluated by concomitant vaginal examination. If no disproportion exists, the head readily enters the pelvis, and vaginal delivery can be predicted. Inability to push the head into the pelvis, however, does not necessarily indicate that vaginal delivery is impossible. A clear demonstration of a flexed fetal head that overrides the symphysis pubis, however, is presumptive evidence of disproportion. Thorp and colleagues (1993b) performed a prospective evaluation of the *Mueller-Hillis maneuver* and concluded that there was no relation between dystocia and failure of descent of the head.

Measurements of fetal head diameters using plain radiographic techniques are not used because of parallax distortions. The biparietal diameter and head circumference can be measured ultrasonographically, and there have been attempts to use this information in the management of dystocia. Thurnau and colleagues (1991) used the fetal-pelvic index to identify labor complications. Unfortunately, the sensitivity of such measurements to predict cephalopelvic disproportion is poor (Ferguson and associates, 1998). We are of the view that there is no currently satisfactory method for accurate prediction of fetopelvic disproportion based on fetal head size.

Face Presentation. With a face presentation, the head is hyperextended so that the occiput is in contact with the fetal back and the chin (mentum) is presenting. The fetal face may present with the chin (mentum) anteriorly or posteriorly, relative to the maternal symphysis pubis. In term-size fetuses, labor progression usually is impeded with mentum posterior face presentations because the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion of the fetal head necessary to negotiate the birth canal (Fig. 20-6). In contrast, flexion of the head and vaginal delivery are typical with mentum anterior presentations. Many mentum posterior presentations convert spontaneously to anterior even in late labor (Duff, 1981).

Cruikshank and White (1973) reported an incidence of 1 in 600, or 0.17 percent. Among more than 70,000 singleton newborns delivered at Parkland Hospital from 1995 through 1999, 36 ♂—or about 1 in 2000 ♂—were face presentations at delivery (see Table 17-1, p. 410).

DIAGNOSIS. Face presentation is diagnosed by vaginal examination and palpation of the distinctive facial features of the mouth and nose, the malar bones, and particularly the orbital ridges. As discussed in Chapter 24 (see p. 567), it is possible to mistake a breech for a face presentation, because the anus may be mistaken for the mouth and the ischial tuberosities for the malar prominences. The radiographic demonstration of the hyperextended head with the facial bones at or below the pelvic inlet is characteristic (Fig. 20-7).

ETIOLOGY. Causes of face presentations are numerous, generally stemming from any factor that favors extension or prevents head flexion. In exceptional instances, marked enlargement of the neck or coils of cord about the neck may cause extension. Anencephalic fetuses naturally present by the face. Extended positions develop more frequently when the pelvis is contracted or the fetus is very large. In a series of 141 face presentations studied by Hellman and co-workers (1950), the incidence of inlet contraction was 40 percent. This high incidence of pelvic contraction must be kept in mind when considering management.

In multiparous women, a pendulous abdomen may predispose to face presentation. It permits the back of the fetus to sag forward or laterally, often in the same direction in which the occiput points, thus promoting extension of the cervical and thoracic spine. High parity itself is a predisposing factor (Fuchs and colleagues, 1985).

MECHANISM OF LABOR. Face presentations rarely are observed above the pelvic inlet. The brow generally presents, and it is usually converted into a face presentation after further extension of the head during descent. The mechanism of labor in these cases consists of the cardinal movements of descent, internal rotation, and flexion, and the accessory movements of extension and external rotation (Fig. 20-8). Descent is brought about by the same factors as in cephalic presentations. Extension results from the relation of the fetal body to the deflected head, which is converted into a two-armed lever, the longer arm of which extends from the occipital condyles to the occiput. When resistance is encountered, the occiput must be pushed toward the back of the fetus while the chin descends (see Fig. 20-6).

The objective of internal rotation of the face is to bring the chin under the symphysis pubis. Only in this way can the neck traverse the posterior surface of the symphysis pubis. If the chin rotates directly posteriorly, the relatively short neck cannot span the anterior surface of the sacrum, which measures about 12 cm in length (see Fig. 20-6). Hence, the birth of the head is impossible unless the shoulders enter the pelvis at the same time, an event that is impossible except when the fetus is extremely small or macerated. Internal rotation results from the same factors as in vertex presentations.

After anterior rotation and descent, the chin and mouth appear at the vulva, the undersurface of the chin presses against the symphysis, and the head is delivered by flexion (see Fig. 20-8). The nose, eyes, brow (bregma), and occiput then appear in succession over the anterior margin of the perineum. After birth of the head, the occiput sags backward toward the anus. Next, the chin rotates externally to the side toward which it was originally directed, and the shoulders are born as in cephalic presentations.

Edema may sometimes significantly distort the face. At the same time, the skull undergoes considerable molding, manifested by an increase in length of the occipitontal diameter of the head (see Fig. 20-6).

MANAGEMENT. In the absence of a contracted pelvis, and with effective labor, successful vaginal delivery usually will follow. Fetal heart rate monitoring is probably better done with external devices to avoid damage to the face and eyes. Because face presentations among term-size fetuses are more common when there is some degree of pelvic inlet contraction, cesarean delivery frequently is indicated.

Attempts to convert a face presentation manually into a vertex presentation, manual or forceps rotation of a persistently posterior chin to a mentum anterior position, and internal podalic version and extraction are dangerous and not attempted.

Neuman and colleagues (1994) have described intrapartum bimanual conversion of mentoposterior to occipitoanterior presentations in 11 women who refused cesarean delivery.

Brow Presentation. This presentation is the rarest (see [Table 17-1](#), p. 410) and is diagnosed when that portion of the fetal head between the orbital ridge and the anterior fontanel presents at the pelvic inlet. As shown in [Figure 20-9](#), the fetal head thus occupies a position midway between full flexion (occiput) and extension (mentum or face). Except when the fetal head is small or the pelvis is unusually large, engagement of the fetal head and subsequent delivery cannot take place as long as the brow presentation persists.

DIAGNOSIS. The presentation may be recognized by abdominal palpation when both the occiput and chin can be palpated easily, but vaginal examination is usually necessary. The frontal sutures, large anterior fontanel, orbital ridges, eyes, and root of the nose can be felt on vaginal examination. However, neither mouth nor chin is within reach (see [Fig. 20-9](#)).

ETIOLOGY. The causes of persistent brow presentation are the same as those for face presentation. A brow presentation is commonly unstable and often converts to a face or an occiput presentation (Cruikshank and White, 1973).

MECHANISM OF LABOR. With a very small fetus and a large pelvis, labor is generally easy. With a larger fetus, however, it is usually difficult, because engagement is impossible until there is marked molding that shortens the occipitomenal diameter or, more commonly, until there is either flexion to an occiput presentation or extension to a face presentation. The considerable molding essential for vaginal delivery of a persistent brow characteristically deforms the head. The caput succedaneum is over the forehead, and it may be so extensive that identification of the brow by palpation is impossible. In these instances, the forehead is prominent and squared, and the occipitomenal diameter is diminished.

In transient brow presentations, the prognosis depends on the ultimate presentation. If the brow persists, prognosis is poor for vaginal delivery unless the fetus is small or the birth canal is huge. Principles of management are much the same as those for a face presentation.

Transverse Lie. This position occurs when the long axis of the fetus is approximately perpendicular to that of the mother. When the long axis forms an acute angle, an oblique lie results. The latter is usually only transitory, because either a longitudinal or transverse lie commonly results when labor supervenes. For this reason, the oblique lie is called an unstable lie in Great Britain.

In transverse lies, the shoulder is usually over the pelvic inlet, with the head lying in one iliac fossa and the breech in the other. In such a *shoulder presentation*, the side of the mother on which the acromion rests determines the designation of the lie as right or left acromial. Moreover, because in either position the back may be directed anteriorly or posteriorly, superiorly or inferiorly, it is customary to distinguish varieties as dorsoanterior and dorsoposterior ([Fig. 20-10](#)).

Transverse lie occurred once in 322 singleton deliveries (0.3 percent) at both the Mayo Clinic and the University of Iowa Hospital (Cruikshank and White, 1973; Johnson 1964). At Parkland Hospital, transverse lie was encountered in about 1 in 335 singleton fetuses delivered during a 4-year period (see [Table 17-1](#), p. 410).

DIAGNOSIS. The diagnosis usually is made easily, often by inspection alone. The abdomen is unusually wide, whereas the uterine fundus extends to only slightly above the umbilicus. No fetal pole is detected in the fundus, and the ballotable head is found in one iliac fossa and the breech in the other. The position of the back is readily identifiable. When the back is anterior (see [Fig. 20-10](#)), a hard resistance plane extends across the front of the abdomen. When it is posterior, irregular nodulations representing the small parts are felt through the abdominal wall.

On vaginal examination, in the early stages of labor, the side of the thorax, if it can be reached, may be recognized by the "gridiron" feel of the ribs. When dilatation is further advanced, the scapula and the clavicle are distinguished on opposite sides of the thorax. The position of the axilla indicates the side of the mother toward which the shoulder is directed. Later in labor, the shoulder will become tightly wedged in the pelvic canal, and a hand and arm frequently prolapse into the vagina and through the vulva ([Fig. 20-11](#)).

ETIOLOGY. The common causes of transverse lie are:

1. Abdominal wall relaxation from high parity.
2. Preterm fetus.
3. Placenta previa.
4. Abnormal uterine anatomy.
5. Excessive amniotic fluid.
6. Contracted pelvis.

Women with four or more deliveries have a 10-fold incidence of transverse lie compared with that of nulliparous women. Relaxation of the abdominal wall with a pendulous abdomen allows the uterus to fall forward, deflecting the long axis of the fetus away from the axis of the birth canal into an oblique or transverse position. Placenta previa and pelvic contraction act similarly. A transverse or oblique lie occasionally develops in labor from an initial longitudinal position.

MECHANISM OF LABOR. Spontaneous delivery of a fully developed newborn is impossible with a persistent transverse lie. After rupture of the membranes, if labor continues, the fetal shoulder is forced into the pelvis, and the corresponding arm frequently prolapses ([Fig. 20-11](#)). After some descent, the shoulder is arrested by the margins of the pelvic inlet, with the head in one iliac fossa and the breech in the other. As labor continues, the shoulder is impacted firmly in the upper part of the pelvis. The uterus then contracts vigorously in an unsuccessful attempt to overcome the obstacle. With time, a retraction ring rises increasingly higher and becomes more marked. The situation is referred to as a *neglected transverse lie*. If not promptly

managed, the uterus eventually ruptures, placing the mother and fetus at grave risk. Even with the best of care, morbidity is increased because of the frequent association with placenta previa, the increased likelihood of cord prolapse, and the necessity for major operative efforts.

If the fetus is small ☞— usually less than 800 g ☞— and the pelvis is large, spontaneous delivery is possible despite persistence of the abnormal lie. The fetus is compressed with the head forced against the abdomen. A portion of the thoracic wall below the shoulder thus becomes the most dependent part, appearing at the vulva. The head and thorax then pass through the pelvic cavity at the same time, and the fetus, which is doubled upon itself, sometimes referred to as *conduplicato corpore*, is expelled.

MANAGEMENT. In general, the onset of active labor in a woman with a transverse lie is an indication for cesarean delivery. Once labor is well established, attempts at conversion to a longitudinal lie by abdominal manipulation will likely not be successful. Before labor or early in labor, with the membranes intact, attempts at external version are worthy of a trial in the absence of other complications that indicate cesarean delivery. Phelan and co-workers (1986) recommend such an attempt only after 39 weeks because of the high (83 percent) spontaneous conversion to a longitudinal lie. If during early labor, the fetal head can be maneuvered by abdominal manipulation into the pelvis, it should be held there during the next several contractions in an attempt to fix the head in the pelvis. If these measures fail, cesarean delivery is performed.

Because neither the feet nor the head of the fetus occupies the lower uterine segment, a low transverse incision into the uterus may lead to difficulty in extraction of a fetus entrapped in the body of the uterus above the level of incision. Therefore, a vertical incision is likely to be indicated (see [Chap. 25](#), p. 598).

Compound Presentation. In a compound presentation, an extremity prolapses alongside the presenting part, with both presenting in the pelvis simultaneously ([Fig. 20-12](#)).

INCIDENCE AND ETIOLOGY. Goplerud and Eastman (1953) identified a hand or arm prolapsed alongside the head once in every 700 deliveries. Much less common was prolapse of one or both lower extremities alongside a cephalic presentation or a hand alongside a breech. We identified compound presentations in only 68 of more than 70,000 singleton fetuses delivered from 1995 through 1999, for an incidence of about 1 in 1000 (see [Table 17-1](#), p. 410). Causes of compound presentations are conditions that prevent complete occlusion of the pelvic inlet by the fetal head, including preterm birth (Goplerud and Eastman, 1953).

PROGNOSIS AND MANAGEMENT. Perinatal loss is increased as a result of concomitant preterm delivery, prolapsed cord, and traumatic obstetrical procedures. In most cases, the prolapsed part should be left alone, because most often it will not interfere with labor. Goplerud and Eastman (1953) described 50 cases not associated with a prolapsed cord. In almost half, normal delivery ensued, but there was one fetal death. If the arm is prolapsed alongside the head, the condition should be observed closely to ascertain whether the arm retracts out of the way with descent of the presenting part. If it fails to retract and if it appears to prevent descent of the head, the prolapsed arm should be pushed gently upward and the head simultaneously downward by fundal pressure. Tebes and co-authors (1999) described a tragic outcome in a newborn delivered spontaneously with the hand alongside the head. The infant developed ischemic necrosis of the presenting forearm, which required amputation.

Persistent Occiput Posterior Position. Most often, occiput posterior positions undergo spontaneous anterior rotation followed by uncomplicated delivery. Although the precise reasons for failure of spontaneous rotation are not known, transverse narrowing of the midpelvis is undoubtedly a contributing factor. Gardberg and associates (1998) used ultrasonography to record the position of the fetal head in 408 term pregnancies at entry into labor ([Fig. 20-13](#)). Early in labor, about 15 percent of the fetuses were occiput posterior, and 5 percent were in this position at delivery. Importantly, two thirds of occiput posterior deliveries occurred with fetuses who were occiput anterior at the beginning of labor. Thus, most occiput posterior presentations at delivery are the result of malrotation of occiput anterior position during labor, and most (87 percent) of occiput posterior presentations at the outset of labor spontaneously rotate anteriorly. Induction of labor and epidural analgesia are not factors linked to occiput posterior presentations (Gardberg and associates, 1998).

Labor and delivery need not differ remarkably from that with the occiput anterior. Progress may be determined by assessing cervical dilatation and descent of the head. In most instances, delivery usually can be accomplished without great difficulty once the head reaches the perineum. The possibilities for vaginal delivery are:

1. Spontaneous delivery.
2. Forceps delivery with the occiput directly posterior.
3. Manual rotation to the anterior position followed by spontaneous or forceps delivery.
4. Forceps rotation of the occiput to the anterior position and delivery.

SPONTANEOUS DELIVERY. If the pelvic outlet is roomy and the vaginal outlet and perineum are somewhat relaxed from previous vaginal deliveries, rapid spontaneous delivery often will take place. If the vaginal outlet is resistant to stretch and the perineum is firm, the late first stage or the second stage of labor, or both, may be appreciably prolonged. During each expulsive effort, the head is driven against the perineum to a much greater degree than when anterior. Therefore, forceps delivery often is indicated. A generous episiotomy usually is needed.

FORCEPS DELIVERY AS AN OCCIPUT POSTERIOR. The need for more traction compared with forceps deliveries from the occiput anterior position can be minimized when perineal resistance is lowered by making a larger episiotomy. The use of forceps and a large episiotomy warrant more complete analgesia than may be achieved with pudendal block and local perineal infiltration. The forceps are applied bilaterally along the occipitomenal diameter, as described in [Chapter 23](#) (see p. 554).

Infrequently, protrusion of fetal scalp through the introitus is the consequence of marked elongation of the fetal head from molding combined with formation of a large caput succedaneum. The head may not even be engaged ☞— that is, the biparietal diameter may not have passed through the pelvic inlet. In such cases labor is characteristically long and descent of the head is

slow. Careful palpation above the symphysis may disclose the fetal head to be above the pelvic inlet. Prompt cesarean delivery is appropriate.

MANUAL ROTATION. The requirements for forceps rotation must be met before performing a manual rotation. When the hand is introduced to locate the posterior ear and thus confirm the posterior position, the occiput often spontaneously rotates toward the anterior position. If not, the head may be grasped with the fingers over one ear and the thumb over the other and rotation of the occiput to the anterior position attempted (see [Chap. 23](#), p. 554).

FORCEPS ROTATION. If the head is engaged, the cervix fully dilated, and the pelvis adequate, forceps rotation may be attempted. These circumstances most likely prevail when expulsive efforts of the mother during the second stage are ineffective. Rotation with forceps is described in [Chapter 23](#) (see p. 555).

Menticoglou and co-workers (1995b) reviewed the obstetrical features of 15 newborns with birth-related high cervical spinal cord injuries in 13 Canadian hospitals between 1982 and 1994. All of these neonates underwent cephalic delivery with forceps rotation of 90 degrees or more from occipitoposterior or occipitotransverse positions. Investigators could not determine whether these serious, albeit rare, fetal injuries resulted from mismanagement or from an intrinsic risk of properly performed forceps rotation. They estimated that this complication developed in less than 1 per 1000 forceps rotations.

OUTCOME. There are notable differences when persistent occiput posterior position is compared with the occiput anterior. Fitzpatrick and colleagues (2001) compared outcomes of 246 women with persistent occiput posterior presentations with those of 13,543 women with occiput anterior positions. Virtually every possible delivery complication was found more frequently in women with persisting occiput posterior presentations. Only 40 percent of these women delivered spontaneously, and cesarean delivery for occiput posterior presentations accounted for 12 percent of all cesarean deliveries performed for dystocia. Similar results were reported by Ponkey and colleagues (2003).

At Parkland Hospital, either manual rotation to the anterior position followed by forceps delivery, or forceps delivery from the occiput posterior position, is used to effect delivery. When neither can be carried out with relative ease, cesarean delivery is performed.

Persistent Occiput Transverse Position. In the absence of a pelvic architecture abnormality, the occiput transverse position is most likely a transitory one because the occiput tends toward the anterior position. Unless hypotonic uterine contractions result, either spontaneously or as the consequence of regional analgesia, spontaneous anterior rotation usually is completed rapidly, thus allowing the choice of spontaneous delivery or delivery with outlet forceps.

DELIVERY. If rotation ceases because of poor expulsive forces and pelvic contractures are absent, vaginal delivery usually can be accomplished readily in a number of ways. The occiput may be manually rotated anteriorly or posteriorly and forceps delivery performed from either the anterior or posterior position. Alternatively, clinicians may apply Kielland forceps to the fetal head in the occiput transverse position (see [Chap. 23](#), p. 555), rotate the occiput to the anterior position, and then deliver the head either with the same forceps or with Simpson or Tucker-McLane forceps. If failure of spontaneous rotation is caused by hypotonic uterine contractions *without cephalopelvic disproportion*, oxytocin may be infused and closely monitored.

The genesis of the occiput transverse position is not always so simple, or the treatment so benign. With the platypelloid (anteroposteriorly flattened) and the android (heart-shaped) pelvises, there may not be adequate room for rotation of the occiput to either the anterior or the posterior position. With the android pelvis, the head may not even be engaged, yet the scalp may be visible through the vaginal introitus as the consequence of considerable molding and caput formation. Consequently, if forceps delivery is attempted, undue force should be avoided.

Shoulder Dystocia. The incidence of shoulder dystocia varies greatly depending on the criteria used for diagnosis. For example, Gross and co-authors (1987) identified that 0.9 percent of almost 11,000 vaginal deliveries were coded for shoulder dystocia at the Toronto General Hospital. True shoulder dystocia, however, diagnosed as such when maneuvers were required to deliver the shoulders in addition to downward traction and episiotomy, was identified in only 24 births (0.2 percent). Significant neonatal trauma was observed only in true shoulder dystocias. Current reports cite an incidence of shoulder dystocia that varies between 0.6 percent and 1.4 percent (American College of Obstetricians and Gynecologists, 2002).

There is some evidence that the incidence of shoulder dystocia increased from 1960 to 1980 (Hopwood, 1982). This is likely due to increasing birthweight. Modanlou and co-workers (1982) showed that neonates experiencing shoulder dystocia had significantly greater shoulder-to-head and chest-to-head disproportions compared with those of equally macrosomic newborns delivered without dystocia. The increased incidence of shoulder dystocia also likely results from increased attention to its appropriate documentation (Nocon and co-workers, 1993).

Use of maneuvers to define shoulder dystocia has been criticized (Beall and associates, 1998; Spong and colleagues, 1995). In deliveries in which shoulder dystocia is anticipated, one or more maneuvers may be used prophylactically, and the diagnosis of shoulder dystocia is therefore not reported. In other cases, one or two maneuvers may be used with rapid resolution of shoulder dystocia and excellent outcome, and the diagnosis may not be recorded. Spong and colleagues (1995) attempted to more objectively define shoulder dystocia by witnessing 250 unselected deliveries and timing the intervals from delivery of the head, to delivery of the shoulders, and to completion of the birth. The incidence defined by the use of obstetrical maneuvers was higher than previously reported (11 percent), and only about half of these were recorded as such by the clinicians. The mean head-to-body delivery time in normal births was 24 seconds compared with 79 seconds in those with shoulder dystocia. They proposed that a head-to-body delivery time exceeding 60 seconds be used to define shoulder dystocia. Gonik and colleagues (2003) have developed computer models to measure the forces necessary to release shoulder dystocia.

MATERNAL CONSEQUENCES. Postpartum hemorrhage, usually from uterine atony, but also from vaginal and cervical lacerations, is the major maternal risk (Benedetti and Gabbe, 1978; Parks and Ziel, 1978).

FETAL CONSEQUENCES. Shoulder dystocia may be associated with significant fetal morbidity and even mortality. Gherman and co-workers (1998) reviewed 285 cases of shoulder dystocia and found 25 percent were associated with fetal injuries. Transient Erb or Duchenne brachial plexus palsies were the most common injury, accounting for two thirds; 38 percent had clavicular fractures; and 17 percent sustained humeral fractures. There was one neonatal death, and four newborns had

persistent brachial plexus injuries. In this series, almost half of the cases of shoulder dystocia required a direct fetal manipulation such as the Woods maneuver, in addition to the McRoberts procedure, to effect release of the impacted shoulders. Direct fetal manipulation, however, when compared with use of the McRoberts procedure alone, was not associated with an increased rate of fetal injury.

Brachial Plexus Injury. Injury to the brachial plexus may be localized to the upper or lower part of the plexus (see [Chap. 29](#), p. 683). It usually results from downward traction on the brachial plexus during delivery of the anterior shoulder. Erb palsy results from injury to the spinal nerves C5-6 and sometimes C7. The resultant paralysis of the shoulder and arm muscles causes a hanging upper arm that may be extended at the elbow. Involvement of the lower spinal nerves, C7-T1, always includes injury of the upper nerves and results in a palsy including the hand, which can cause a clawhand deformity. Hardy (1981) studied the prognosis of 36 infants with brachial plexus injuries. Interestingly, shoulder dystocia had been reported in only 10 of these, and two had been delivered abdominally. Nearly 80 percent of these children had complete recovery by 13 months, and none with residual defects had severe sensory or motor deficits in the hand. Jennett and associates (2001, 2002) have presented evidence that brachial plexus injuries may precede delivery itself and may occur even prior to labor. Gherman and colleagues (2003) and Donnelly and co-authors (2002) concluded that these injuries were not predictable before birth.

Clavicular Fracture. Fractured clavicles are relatively common and have been diagnosed in 0.4 percent of newborns delivered vaginally at Parkland Hospital (Roberts and co-workers, 1995). Although at times associated with shoulder dystocia, the clavicle often fractures without any suspect clinical events. Investigators have concluded that isolated fractured clavicles are unavoidable, unpredictable, and of no clinical consequence (Lam and colleagues, 2002).

PREDICTION AND PREVENTION OF SHOULDER DYSTOCIA. There has been considerable evolution in obstetrical thinking about the preventability of shoulder dystocia in the past two decades. Although there are clearly several risk factors associated with shoulder dystocia, identification of individual instances before the fact has proven to be impossible.

Risk Factors. Various maternal, intrapartum, and fetal characteristics have been implicated in the development of shoulder dystocia (Baskett and Allen, 1995; Nesbitt and associates, 1998; Nocon and coauthors, 1993; Robinson and colleagues, 2003). Several maternal risk factors, including obesity, multiparity, and diabetes, all exert their effects because of associated increased birthweight. For example, Keller and co-workers (1991) identified shoulder dystocia in 7 percent of pregnancies complicated by gestational diabetes. Similarly, the association of postterm pregnancy with shoulder dystocia is likely because many fetuses continue to grow after 42 weeks (see [Chap. 37](#), p. 889). [Table 20-6](#) gives the incidence of shoulder dystocia related to birthweight groupings at Parkland Hospital during 1994. Clearly, shoulder dystocia increases with greater birthweight, however, almost half of the newborns with shoulder dystocia weighed less than 4000 g. Indeed, Nocon and co-workers (1993) described shoulder dystocia with birth of a 2260-g neonate.

Despite this, some authors advocate identification of macrosomia with ultrasonography and liberal use of cesarean delivery to avoid shoulder dystocia (O'Leary, 1992). Others have disputed the concept that cesarean delivery is indicated for identified large fetuses, even those estimated to weigh in excess of 4500 g. Rouse and Owen (1999) concluded that a prophylactic cesarean delivery policy for macrosomic newborns would require more than 1000 cesarean deliveries and millions of dollars to avert a single permanent brachial plexus injury. The American College of Obstetricians and Gynecologists (2002) has concluded that performing cesarean deliveries for all women suspected of carrying a macrosomic fetus is not appropriate, except possibly for estimated fetal weights over 5000 g in nondiabetic women and over 4500 g in those with diabetes.

Intrapartum complications associated with shoulder dystocia include midforceps delivery and prolonged first- and second-stage labor (Baskett and Allen, 1995; Nocon and co-authors, 1993). Conversely, McFarland and co-workers (1995) found that abnormalities of first- and second-stage labor were not useful clinical predictors of shoulder dystocia. Beall and co-authors (2003) randomly assigned 128 women carrying fetuses estimated to weigh over 3800 g to delivery with or without prophylactic McRoberts maneuvers and found that such use of this maneuver was not beneficial.

Prior Shoulder Dystocia. Ginsberg and Moisidis (2001) identified recurrent shoulder dystocia in 17 percent of women with prior deliveries complicated by shoulder dystocia. In contrast, Baskett and Allen (1995) found the risk to be only 1 to 2 percent for recurrent dystocia. The American College of Obstetricians and Gynecologists (2002) recommends that estimated fetal weight, gestational age, maternal glucose intolerance, and severity of prior neonatal injury should be evaluated and risks and benefits of cesarean delivery discussed with any woman with a history of shoulder dystocia.

Summary. The American College of Obstetricians and Gynecologists (2002) reviewed studies classified according to the evidence-based methods outlined by the United States Preventive Services Task Force. It concluded that the preponderance of current evidence is consistent with the view that:

1. Most cases of shoulder dystocia cannot be accurately predicted or prevented.
2. Elective induction of labor or elective cesarean delivery for all women suspected of carrying a macrosomic fetus is not appropriate.
3. Planned cesarean delivery may be considered for the nondiabetic woman carrying a fetus with an estimated fetal weight exceeding 5000 g or the diabetic woman whose fetus is estimated to weigh more than 4500 g.

MANAGEMENT. Because shoulder dystocia cannot be predicted, the clinician must be well versed in the management principles of this occasionally devastating complication. Reduction in the interval of time from delivery of the head to delivery of the body is of great importance to survival. An initial gentle attempt at traction, assisted by maternal expulsive efforts, is recommended. Some clinicians have advocated performing a large episiotomy, and adequate analgesia is certainly ideal. After clearing the neonate's mouth and nose, a variety of techniques can be used to free the anterior shoulder from its impacted position beneath the symphysis pubis:

1. Moderate *suprapubic pressure* can be applied by an assistant while downward traction is applied to the fetal head.
2. The *McRoberts maneuver* was described by Gonik and associates (1983) and named for William A. McRoberts, Jr., who popularized its use at the University of Texas at Houston. The maneuver consists of removing the legs from the stirrups and

sharply flexing them up onto the abdomen ([Fig. 20-14](#)). Gherman and colleagues (2000) analyzed the McRoberts maneuver using x-ray pelvimetry. They found that the procedure caused straightening of the sacrum relative to the lumbar vertebrae, rotation of the symphysis pubis toward the maternal head, and a decrease in the angle of pelvic inclination. Although this does not increase pelvic dimensions, pelvic rotation cephalad tends to free the impacted anterior shoulder. Gonik and co-workers (1989) tested the McRoberts position objectively with laboratory models and found that the maneuver reduced the forces needed to free the fetal shoulder.

3. Woods (1943) reported that, by progressively rotating the posterior shoulder 180 degrees in a corkscrew fashion, the impacted anterior shoulder could be released. This is frequently referred to as the *Woods corkscrew maneuver* ([Fig. 20-15](#)).

4. *Delivery of the posterior shoulder* consists of carefully sweeping the posterior arm of the fetus across the chest, followed by delivery of the arm. The shoulder girdle is then rotated into one of the oblique diameters of the pelvis with subsequent delivery of the anterior shoulder ([Fig. 20-16](#)).

5. Rubin (1964) recommended two maneuvers. First, the fetal shoulders are rocked from side to side by applying force to the maternal abdomen. If this is not successful, the pelvic hand reaches the most easily accessible fetal shoulder, which is then pushed toward the anterior surface of the chest. This maneuver most often results in abduction of both shoulders, which in turn produces a smaller shoulder-to-shoulder diameter and displacement of the anterior shoulder from behind the symphysis pubis ([Fig. 20-17](#)).

6. Deliberate *fracture of the clavicle* by pressing the anterior clavicle against the ramus of the pubis can be performed to free the shoulder impaction. In practice, however, it is difficult to deliberately fracture the clavicle of a large neonate. The fracture will heal rapidly and is not nearly as serious as a brachial nerve injury, asphyxia, or death.

7. Hibbard (1982) recommended that pressure be applied to the fetal jaw and neck in the direction of the maternal rectum, with strong fundal pressure applied by an assistant as the anterior shoulder is freed. Strong fundal pressure, however, applied at the wrong time may result in even further impaction of the anterior shoulder. Gross and associates (1987) reported that fundal pressure in the absence of other maneuvers "resulted in a 77 percent complication rate and was strongly associated with (fetal) orthopedic and neurologic damage."

8. Sandberg (1985) reported the *Zavanelli maneuver* for cephalic replacement into the pelvis and then cesarean delivery. The first part of the maneuver consists of returning the head to the occiput anterior or occiput posterior position if the head had rotated from either position. The operator flexes the head and slowly pushes it back into the vagina, following which cesarean delivery is performed. Terbutaline (250 µg subcutaneously) is given to produce uterine relaxation. Sandberg (1999) has subsequently reviewed 103 reported cases in which the Zavanelli maneuver was used. This maneuver was successful in 91 percent of cephalic cases and in all cases of breech head entrapments. Fetal injuries were common in the desperate circumstances under which the Zavanelli maneuver was used. There were eight neonatal deaths, six stillbirths, and ten neonates suffered brain damage. Uterine rupture also was reported.

9. *Cleidotomy* consists of cutting the clavicle with scissors or other sharp instruments and is usually used for a dead fetus (Schramm, 1983).

10. *Symphysiotomy* also has been applied successfully, as described by Hartfield (1986). Goodwin and colleagues (1997) reported three cases in which symphysiotomy was performed after the Zavanelli maneuver had failed— all three neonates died and maternal morbidity was significant due to urinary tract injury.

Hernandez and Wendel (1990) suggested use of a *shoulder dystocia drill* to better organize emergency management of an impacted shoulder. The drill is a set of maneuvers performed sequentially as needed to complete vaginal delivery:

1. Call for help— mobilize assistants, an anesthesiologist, and a pediatrician. Initially, a gentle attempt at traction is made. Drain the bladder if it is distended.
2. A generous episiotomy (mediolateral or episiotomy) may afford room posteriorly.
3. Suprapubic pressure is used initially by most practitioners because it has the advantage of simplicity. Only one assistant is needed to provide suprapubic pressure while normal downward traction is applied to the fetal head.
4. The McRoberts maneuver requires two assistants. Each assistant grasps a leg and sharply flexes the maternal thigh against the abdomen.

These maneuvers will resolve most cases of shoulder dystocia. If they fail, however, the following steps may be attempted:

1. The Woods screw maneuver.
2. Delivery of the posterior arm is attempted, but if fully extended, this is usually difficult to accomplish.
3. Other techniques generally should be reserved for cases in which all other maneuvers have failed. These include intentional fracture of the anterior clavicle or humerus and the Zavanelli maneuver.

The American College of Obstetricians and Gynecologists (2002) has concluded that there is no evidence that any one maneuver is superior to another in releasing an impacted shoulder or reducing the chance of injury. Performance of the McRoberts maneuver, however, was deemed a reasonable initial approach.

Hydrocephalus as a Cause of Dystocia. Hydrocephalus is an excessive accumulation of cerebrospinal fluid with consequent cranial enlargement. For a number of reasons, discussed in [Chapter 13](#) (see p. 323), it is uncommon with births at term. Associated defects are common, especially neural-tube defects. Normal fetal head circumference at term ranges between 32 and 38 cm. With hydrocephalus, the circumference often exceeds 50 cm and may reach 80 cm. Fluid volume is usually between 500 and 1500 mL, but as much as 5 L may accumulate. Breech presentation is found in at least one third of cases.

Whatever the presentation, gross cephalopelvic disproportion is the rule, with dystocia the usual consequence (Figs. 20-18 and 20-19).

Hydrocephalus is somewhat more difficult to diagnose radiographically with a breech presentation, because the outline of a normal fetal head often appears enlarged to a degree suggestive of hydrocephalus. The difficulties inherent in radiological diagnosis are obviated by the use of ultrasonography to measure the diameter of the lateral ventricles and the thickness of the cerebral cortex and to compare the size of the head with that of the thorax and abdomen (Clark and associates, 1985).

MANAGEMENT. Most often, the size of the hydrocephalic head must be reduced if the head is to pass through the birth canal. Even with cesarean delivery, it may be desirable to remove cerebrospinal fluid just before incising the uterus to circumvent extensions of a low transverse or vertical incision or to avoid deliberately creating a long vertical uterine incision. Removal of fluid by *cephalocentesis* was a mainstay in the historical management of fetal hydrocephalus with macrocephaly but has come under considerable scrutiny in recent years. Chervenak and colleagues (1985) described results of cephalocentesis in 11 fetuses for whom the procedure was used to permit vaginal or cesarean delivery. Ten of these fetuses died either in utero or within 3 hours of delivery, and seven had intracranial bleeding found at autopsy. Chervenak and McCullough (1986) and Chasen and colleagues (2001) advocate that use of cephalocentesis be limited to fetuses with severe associated abnormalities. They recommended that all others be delivered abdominally. Such management requires precise knowledge of the extent of fetal malformations, which is not always possible.

Technique of Cephalocentesis. The technique varies depending on fetal presentation. With cephalic presentation, as soon as the cervix is dilated 3 to 4 cm, the ventricles may be tapped transvaginally with a needle. An 8-inch, 17-gauge needle is satisfactory for prompt removal of appreciable volumes of cerebrospinal fluid. With a breech presentation, labor can be allowed to progress and the breech and trunk delivered. With the head over the inlet and the face toward the maternal back, the needle is inserted transvaginally just below the anterior vaginal wall and into the aftercoming head through the widened suture line. To protect the birth canal from the needle as it is passed toward the head, the more distal part of the needle, including the point, may be covered with a segment of sterile plastic tubing about 6 inches long cut from an intravenous infusion set. Alternatively, fluid may be withdrawn through a needle inserted via the maternal abdomen into the fetal head. After the bladder is emptied and the skin is cleansed, the needle is inserted in the midline somewhat below the maternal umbilicus and inferior to the top of the fetal skull. The transabdominal approach to remove cerebrospinal fluid also can be used in the event of a cephalic presentation before stimulating labor with oxytocin. The transabdominal approach has also been successfully applied in the breech fetus using ultrasonography to guide the needle (Osathanondh and associates, 1980).

FETAL ABDOMEN AS A CAUSE OF DYSTOCIA. Enlargement of the fetal abdomen sufficient to cause dystocia is usually the result of a *greatly distended bladder* (Fig. 20-20), *ascites*, or *enlargement of the kidneys or liver*. Occasionally, the edematous fetal abdomen may attain such proportions that spontaneous delivery is impossible. Enlargement of the fetal abdomen may escape detection until fruitless attempts at delivery have demonstrated an obstruction. An enlarged abdomen and intra-abdominal accumulation of fluid usually can be diagnosed by ultrasonography. If the diagnosis is made before delivery, the decision must be made whether or not to perform a cesarean delivery (Clark and associates, 1985). In general, fetal prognosis is poor, regardless of the method of delivery.

In nearly 97 percent of such pregnancies, at delivery, the fetus enters the pelvis as a cephalic presentation. In about 3 percent a breech presents, and this is discussed in Chapter 24. In the remaining 0.5 percent, the fetus presents with the long axis either transversely or obliquely, or the head may be extended to present the fetal face or brow.

Figure 20-5. Birthweight distribution of 362 newborns delivered by cesarean at Parkland Hospital (1989-1999) after a failed attempt to effect vaginal delivery with forceps. Only 12 percent ($n = 44$) of the newborns weighed ≥ 4000 g (shaded bars).

Figure 20-6. Face presentation. The occiput is the longer end of the head lever. The chin is directly posterior. Vaginal delivery is impossible unless the chin rotates anteriorly.

Figure 20-7. Radiograph showing face presentation. Note the marked hyperextension of the head and spine of fetus.

Figure 20-8. Mechanism of labor for right mentoposterior position with subsequent rotation of the mentum anteriorly and delivery.

Figure 20-9. Brow posterior presentation.

Figure 20-10. Palpation in transverse lie, right acromiodorsoanterior position. **A.** First maneuver. **B.** Second maneuver. **C.** Third maneuver. **D.** Fourth maneuver.

Figure 20-11. Neglected shoulder presentation. A thick muscular band forming a pathological retraction ring has developed just above the thin lower uterine segment. The force generated during a uterine contraction is directed centripetally at and above the level of the pathological retraction ring. This serves to stretch further and possibly to rupture the thin lower segment below the retraction ring. (P.R.R. = pathological retraction ring.)

Figure 20-12. Compound presentation. The left hand is lying in front of the vertex. With further labor, the hand and arm may retract from the birth canal and the head may then descend normally.

Figure 20-13. Occiput posterior presentation in early labor compared with presentation at delivery. Ultrasonography was used to determine position of the fetal head in early labor. (From Gardberg and associates, 1998.)

Figure 20-14. The McRoberts maneuver. The maneuver consists of removing the legs from the stirrups and sharply flexing the thighs up onto the abdomen, as shown by the horizontal arrow. The assistant is also providing suprapubic pressure simultaneously (*vertical arrow*).

Figure 20-15. Woods maneuver. The hand is placed behind the posterior shoulder of the fetus. The shoulder is then rotated progressively 180 degrees in a corkscrew manner so that the impacted anterior is released.

Figure 20-16. Shoulder dystocia with impacted anterior shoulder of the fetus. **A.** The operator's hand is introduced into the vagina along the fetal posterior humerus, which is splinted as the arm is swept across the chest, keeping the arm flexed at the elbow. **B.** The fetal hand is grasped and the arm extended along the side of the face. **C.** The posterior arm is delivered from the vagina.

Figure 20-17. The second Rubin maneuver. **A.** The shoulder-to-shoulder diameter is shown as the distance between the two small arrows. **B.** The more easily accessible fetal shoulder (the anterior is shown here) is pushed toward the anterior chest wall of the fetus. Most often, this results in abduction of both shoulders, reducing the shoulder-to-shoulder diameter and freeing the impacted anterior

shoulder.

Figure 20-18. Severe dystocia from hydrocephalus, cephalic presentation. Note the disparity between the small size of the face and the rest of the cranium.

Figure 20-19. Severe dystocia from hydrocephalus, breech presentation. Note the distention of the lower uterine segment.

Figure 20-20. Fetal abdominal dystocia at 28 weeks caused by an immensely distended bladder. Delivery was made possible by expression of fluid through a bladder perforation at the level of the fetal umbilicus. Section shows the interior of the bladder and compression of organs of abdominal and thoracic cavities. A black thread has been laid in the urethra. (From Savage, 1935.)

MATERNAL-FETAL EFFECTS OF DYSTOCIA

Although maternal and fetal effects resulting from dystocia are divided arbitrarily in the following discussion, dystocia may result in serious consequences to either or both simultaneously.

MATERNAL EFFECTS

Intrapartum Infection. Infection may complicate prolonged labor and pose a serious danger to mother and fetus. After membrane rupture, bacteria enter the amniotic fluid, traverse the amnion, and invade decidua and chorionic vessels, thus causing maternal and fetal bacteremia and sepsis. Fetal pneumonia, caused by aspiration of infected amniotic fluid, is another serious consequence. Digital cervical examinations following membrane rupture introduce vaginal bacteria into the uterus (Imseis and co-authors, 1999). These examinations should be limited during labor, especially when dystocia is suspected. Maternal and fetal infections are discussed in [Chapter 31](#) and [Chapters 58](#) and [59](#), respectively.

Uterine Rupture. Abnormal thinning of the lower uterine segment creates a serious danger during prolonged labor, particularly in women of high parity and in those with prior cesarean deliveries (see [Chap. 35](#), p. 837). When the disproportion between the fetal head and pelvis is so pronounced that there is no engagement or descent, the lower uterine segment becomes increasingly stretched, and rupture may follow. In such cases, a *pathological retraction ring* may develop (see below) and should prompt immediate abdominal delivery.

Pathological Retraction Ring. Rarely, localized rings or constrictions of the uterus develop in association with prolonged labors. The most common type is the *pathological retraction ring of Bandl*, an exaggeration of the normal retraction ring described in [Chapter 6](#) (see p. 156). It is often the result of obstructed labor, with marked stretching and thinning of the lower uterine segment. The ring may be seen clearly as a uterine indentation and signifies impending rupture of the lower uterine segment (see [Fig. 6-3](#), p. 155). Localized uterine constrictions rarely are seen today because prolonged, obstructed labor is unacceptable. These may still develop occasionally as hourglass constrictions of the uterus following birth of a first twin. The ring can sometimes be relaxed and delivery effected with appropriate general anesthesia, but occasionally prompt cesarean delivery offers a better prognosis for the second twin (see [Chap. 39](#), p. 940).

Fistula Formation. When the presenting part is firmly wedged into the pelvic inlet but does not advance for a considerable time, tissues of the birth canal lying between it and the pelvic wall may be subjected to excessive pressure. Because of impaired circulation, necrosis may result and become evident several days after delivery with the appearance of vesicovaginal, vesicocervical, or rectovaginal fistulas. Most often, pressure necrosis follows a very prolonged second stage of labor. Formerly, when operative delivery was deferred as long as possible, such complications were frequent, but today they are rarely seen except in undeveloped countries.

Pelvic Floor Injury. A long-held belief is that injury to the pelvic floor muscles or to their nerve supply or to the interconnecting fascia is an inevitable consequence of vaginal delivery, particularly if the delivery is difficult. During childbirth the pelvic floor is exposed to direct compression from the fetal head as well as to downward pressure from maternal expulsive efforts. These forces stretch and distend the pelvic floor, resulting in functional and anatomical alterations in the muscles, nerves, and connective tissues. There is accumulating concern that such effects on the pelvic floor during childbirth lead to urinary and anal incontinence and to pelvic organ prolapse (Leitch and Walker, 1998; Sultan and Stanton, 1996). The anal sphincter is torn in 3 to 6 percent of deliveries, and approximately half of these women report subsequent fecal or gas incontinence (Zetterstrom and co-workers, 1999). In continuing studies underway at Parkland Hospital, Casey and colleagues (2004) found that the incidence of symptoms of pelvic floor dysfunction reported within a few months of delivery were

increased in women whose newborn was delivered using forceps, in those whose newborn weighed more than 4000 g, and in those who had an episiotomy performed. In a recent poll of English female obstetricians, 30 percent expressed preference for an elective cesarean delivery rather than vaginal delivery and cited avoidance of pelvic floor injury as the explanation for their choice (Wagner, 2000).

Although childbirth undoubtedly plays a significant role in pelvic floor injury, the incidence and types of injuries reported vary widely between studies. Handa and colleagues (2003) found that abnormal pelvic bony architecture was associated with pelvic floor disorders later in life. Currently, there is uncertainty regarding the incidence of childbirth-associated pelvic floor injury, and there is insufficient information as to the relative roles of specific obstetrical antecedents (Samuelsson and associates, 1999).

Postpartum Lower Extremity Nerve Injury. Wong and colleagues (2003) have reviewed neurological injury involving the lower extremities in association with labor and delivery. Such injuries may manifest as footdrop, which can be secondary to injury at the level of the lumbosacral root, lumbosacral plexus, sciatic nerve, or common peroneal nerve. Components of the lumbosacral plexus cross the pelvic brim and can be compressed by the fetal head or by forceps. Fetal macrosomia and malpresentations such as occiput posterior have been reported to predispose women to footdrop. The most common mechanism of injury, however, is external compression of the peroneal nerves usually caused by inappropriate leg positioning in stirrups especially during a prolonged second stage of labor. Fortunately, symptoms resolve within 6 months of delivery in most women.

Figure 6-3. Sequence of development of the segments and rings in the uterus in pregnant women at term and in labor. Note comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower segment of the uterine body is derived from the isthmus; the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. (Anat. Int. Os = anatomical internal os; E.O. = external os; Hist. Int. Os = histological internal os; Ph.R.R. = physiological retraction ring.)

FETAL EFFECTS

Caput Succedaneum. If the pelvis is contracted, during labor a large *caput succedaneum* frequently develops on the most dependent part of the fetal head. As shown in [Figure 17-19](#) (see p. 421), this may assume considerable size and lead to serious diagnostic errors. **The caput may reach almost to the pelvic floor while the head is still not engaged. An inexperienced physician may make premature and unwise attempts at forceps delivery.** Typically, even a large caput disappears within a few days after birth.

Fetal Head Molding. Under the pressure of strong uterine contractions, the fetal head changes shape in a process referred to as *molding* (see [Fig. 17-19](#)). Factors associated with molding included nulliparity, oxytocin labor stimulation, and delivery with a vacuum extractor. Previously considered an overlapping of the parietal bones, ultrasonographic evidence shows molding to be an unbending or straightening of the parietal bones in combination with an inward movement of the occipital and frontal bone apices (Carlan and colleagues, 1991). These investigators further described a locking mechanism by which the free edges of the cranial bones are forced into one another, preventing further molding and providing protection for the fetal brain. They also observed that severe fetal head molding could develop before labor.

These changes frequently are accomplished without obvious detriment. Alternatively, when the distortion is marked, molding may lead to tentorial tears, laceration of fetal blood vessels, and intracranial hemorrhage. Whitby and colleagues (2004) analyzed nine neonates born with asymptomatic subdural hemorrhages and found that three followed normal vaginal deliveries, suggesting that such hemorrhages are not necessarily evidence of birth trauma. In all nine newborns, hemorrhages resolved spontaneously within 4 weeks. Holland (1922) observed that severe molding could lead to fatal subdural hemorrhage as a result of tears involving the dura mater septa, especially the tentorium cerebelli. Such tears were observed in both normal and complicated deliveries.

Fetal skull bones mold more readily when they are imperfectly ossified. This important feature may explain the differences observed in the course of labor when two apparently similar cases initially present with identical measurements of the pelvis and the fetal head. In one case, the head is softer and more readily molded, and spontaneous delivery results. In the other, the more ossified head retains its original shape, and dystocia develops.

Characteristic pressure marks may form on the scalp, covering the portion of the head that passes over the promontory of the sacrum. From their location, it is frequently possible to ascertain the movements that the head has undergone in passing through the inlet. Rarely, similar marks appear on the portion of the head that has been in contact with the symphysis pubis. Such marks usually disappear within a few days.

Skull fractures occasionally are encountered, usually following forcible attempts at delivery. As discussed in [Chapter 29](#) (see p. 684), the skull also may fracture with spontaneous delivery or even with cesarean delivery (Skajaa and associates, 1987). The fractures are either a shallow groove or a spoon-shaped depression just posterior to the coronal suture. The former is relatively common, but because it involves only the external bone plate, it is not very dangerous. The latter, however, if not surgically corrected, may lead to neonatal death, because it extends through the entire thickness of the skull and may create inner surface projections that exert injurious pressure on the brain. In these cases, it usually is advisable to elevate or remove the depressed portion of the skull.

Figure 17-19. Considerable molding of the head and caput formation in a recently delivered newborn. The arrow is directed toward the caput succedaneum caused by

appreciable scalp edema that overlies the occiput.

21. Disorders of Amnionic Fluid Volume

INTRODUCTION

Fetal membranes include the amnion and chorion. Their development, physiology, and histology are detailed in [Chapter 3](#) (see p. 66). Both physiological and pathological events may result in anatomical changes such as meconium staining and chorioamnionitis, which are discussed in [Chapter 27](#) (see p. 624). The most common intrinsic abnormalities that are encountered clinically are too much or too little amnionic fluid — (poly)hydramnios and oligohydramnios, respectively.

NORMAL AMNIONIC FLUID VOLUME

Normally, amnionic fluid volume increases to about 1 L by 36 weeks and decreases thereafter to only 100 to 200 mL or less postterm ([Table 21-1](#)). Diminished fluid volume is termed *oligohydramnios*. Somewhat arbitrarily, more than 2 L of amnionic fluid is considered excessive and is termed *hydramnios*. This is sometimes called *polyhydramnios*. In rare instances, the uterus may contain an enormous quantity of fluid, with reports of as much as 15 L. In most instances, chronic hydramnios develops, which is the gradual increase of excessive fluid. In acute hydramnios, the uterus may become markedly distended within a few days.

MEASUREMENT OF AMNIONIC FLUID. Over the past decades, a number of ultrasound methods have been used to measure the amount of amnionic fluid. Phelan and colleagues (1987) described the clinical utility of quantification using the *amnionic fluid index*. This is calculated by adding the vertical depths of the largest pocket in each of four equal uterine quadrants. According to their calculations, significant hydramnios is defined by an index greater than 24 cm. Magann and colleagues (2000) performed a cross-sectional study of longitudinal changes in the amnionic fluid index in normal pregnancies ([Fig. 21-1](#)). Porter and associates (1996) and Hill and co-workers (2000) have provided normal values for twin pregnancies (see [Chap. 39](#), p. 936).

The group from the University of Mississippi has performed several investigations to correlate ultrasonic accuracy of predicting abnormal amnionic fluid volume with measurement by dye dilution. Magann and associates (1992) used the dye-dilution technique to measure amnionic fluid in 40 women undergoing amniocentesis in late pregnancy. They found that the amnionic fluid index was reasonably reliable in determining normal or increased amnionic fluid but was inaccurate in diagnosing oligohydramnios. In later studies by Chauhan (1997) and Magann (2003a, 2004) and their associates, poor correlation of fluid volume was found with the amnionic fluid index, the two-diameter fluid pocket, and the single deepest pocket methods. Magann and colleagues (2001) evaluated the addition of color Doppler imaging and found that its concurrent use with amnionic fluid index measurements leads to overdiagnosis of oligohydramnios. Peedicayil and colleagues (1994) emphasized that borderline values should be repeated before interventions are undertaken. Morris and colleagues (2003) studied 1584 women at term and found that the amnionic fluid index was superior to the single deepest pocket but had a poor sensitivity for adverse pregnancy outcome. Magann and colleagues (2003b, 2004) also found that amnionic fluid volumes are not predictive of intrapartum or neonatal outcomes.

Several factors may modulate the amnionic fluid index. For example, Yancey and Richards (1994) reported that high altitude (6000 ft) was associated with an increased index. Magann and colleagues (2003c), Deka and Malhotra (2001), Bush and associates (1996), and Kilpatrick and Safford (1993), but not Kerr and associates (1996), showed that maternal hydration increased the index. This effect dissipates by 24 hours (Malhotra and Deka, 2004). Conversely, fluid restriction or dehydration may lower the index. Ross and colleagues (1996) administered 1-deamino-[8-d-arginine] vasopressin (DDAVP) to women with oligohydramnios. This resulted in maternal serum hypoosmolality (285 to 265 mOsm/kg) associated with an increase in the amnionic fluid index from 4 to 8 cm within 8 hours.

Figure 21-1. Normal percentiles for the amnionic fluid index (AFI) from 1400 women. For each gestational week, 50 women were studied. (Data adapted by Schrimmer and Moore, 2002, with permission.)

HYDRAMNIOS

INCIDENCE. Hydramnios is identified in about 1 percent of pregnancies. The diagnosis usually is suspected clinically and confirmed by sonographic examination. An extreme example is shown in [Figure 21-2](#). Most investigators define hydramnios as an amnionic fluid index of greater than 24 to 25 cm — corresponding to greater than the 95th or 97.5th percentiles. Using an index of 25 cm or greater, Biggio and colleagues (1999) reported a 1-percent incidence in more than 36,000 women examined at the University of Alabama.

In an earlier study by Hill and associates (1987) from the Mayo Clinic, more than 9000 prenatal patients underwent routine ultrasonic evaluation near the beginning of the third trimester. The incidence of hydramnios was 0.9 percent. Mild hydramnios — defined as pockets measuring 8 to 11 cm in vertical dimension — was present in 80 percent of cases with excessive fluid. Moderate hydramnios — defined as a pocket containing only small parts and measuring 12 to 15 cm deep — was found in 15 percent. Only 5 percent had severe hydramnios, defined by a free-floating fetus found in pockets of fluid of 16 cm or greater. Although two thirds of all cases were idiopathic, the others were associated with fetal anomalies, maternal diabetes, or multifetal gestation. Golan and co-workers (1993) reported remarkably similar findings in nearly 14,000 women.

Figure 21-2. Advanced degree of hydramnios — 5500 mL of amnionic fluid was

measured at delivery.

CAUSES OF HYDRAMNIOS. The degree of hydramnios, as well as its prognosis, is often related to the cause. Many reports are biased because they consist of observations from women referred for targeted ultrasonic evaluation. Others are population based but still may not reflect an accurate incidence unless universal ultrasound screening is performed. In either case, obvious pathological hydramnios frequently is associated with fetal malformations, especially of the central nervous system or gastrointestinal tract. For example, hydramnios accompanies about half of cases of anencephaly and esophageal atresia. In the study by Hill and associates (1987), the cause of mild hydramnios was identified in only 15 percent of cases. Conversely, with moderate or severe hydramnios, the cause was identified in more than 90 percent and fetal anomalies were present in half of these cases. The opposite is not true, however, and in the Spanish Collaborative Study of Congenital Malformations with more than 27,000 anomalous fetuses, only 3.7 percent had hydramnios whereas another 3 percent had oligohydramnios (Martinez-Frias and colleagues, 1999).

The population-based study from Birmingham included more than 40,000 women (Biggio and co-workers, 1999). These investigators compared 370 women identified as having hydramnios with more than 36,000 control women having a normal index. As shown in [Table 21-2](#), hydramnios was found to portend a significantly increased risk for adverse outcomes. Most of these were in nondiabetic women with hydramnios.

Damato and colleagues (1993) reported findings from 105 women referred for evaluation of excessive fluid, of whom almost 65 percent had confirmed hydramnios ([Table 21-3](#)). There were 47 singletons with one or more abnormalities, viz., gastrointestinal anomalies (15), nonimmune hydrops (12), and central nervous system (12), thoracic (9), skeletal (8), chromosomal (7), and cardiac malformations (4). Among 19 twin pregnancies, 12 involved twin-to-twin transfusion and only two were normal.

Other less common causes of polyhydramnios include fetal pseudohypoaldosteronism, fetal Bartter or hyperprostaglandin E syndrome, nephrogenic diabetes insipidus, placental chorioangioma, sacrococcygeal teratoma, and maternal substance abuse (Narchi and colleagues, 2000; Panting-Kemp and colleagues, 2002).

Using an amniotic fluid index of greater than 24 or 25 cm to define hydramnios, most studies report substantive increases in perinatal mortality. In a report by Carlson and associates (1990) of 49 women, there were 14 perinatal deaths, 22 fetal malformations, and six cases of aneuploidy. Brady and colleagues (1992) identified 125 cases of unexplained or idiopathic hydramnios in 5000 population-based pregnancies. Of these, two fetuses had trisomy 18 and two had trisomy 21. Conversely, Panting-Kemp and co-workers (1999) found that idiopathic hydramnios was not associated with increased adverse outcomes except for cesarean delivery.

PATHOGENESIS. Early in pregnancy, the amniotic cavity is filled with fluid very similar in composition to extracellular fluid. During the first half of pregnancy, transfer of water and other small molecules takes place not only across the amnion but also through fetal skin. During the second trimester, the fetus begins to urinate, swallow, and inspire amniotic fluid (Abramovich and colleagues, 1979; Duenhoelter and Pritchard, 1976). These processes have a modulating role in the control of fluid volume. Although the major source of amniotic fluid in hydramnios has most often been assumed to be the amniotic epithelium, no histological changes in amnion or chemical changes in amniotic fluid have been found.

Because the fetus normally swallows amniotic fluid, it has been assumed that this mechanism is one of the ways by which the volume is controlled. The theory gains validity by the nearly constant presence of hydramnios when swallowing is inhibited, as in cases of esophageal atresia. But swallowing is not the only mechanism for preventing hydramnios. Specifically, Pritchard (1966) and Abramovich (1970) found in some instances of gross hydramnios that appreciable volumes of fluid were swallowed.

In cases of anencephaly and spina bifida, increased transudation of fluid from the exposed meninges into the amniotic cavity may result in hydramnios. Another possible explanation in anencephaly, when swallowing is not impaired, is excessive urination caused either by stimulation of cerebrospinal centers deprived of their protective coverings or by lack of antidiuretic effect because of impaired arginine vasopressin secretion. In hydramnios associated with monozygotic twin pregnancy, the hypothesis has been advanced that one fetus usurps the greater part of the circulation common to both twins and develops cardiac hypertrophy, which in turn results in increased urine output (see [Chap. 39](#), p. 929). Naeye and Blanc (1972) identified dilated renal tubules, enlarged bladder, and an increased urinary output in the early neonatal period, suggesting that increased fetal urine production is responsible for hydramnios. Conversely, donor members of twin-to-twin transfusion pairs had dystrophic renal tubules with oligohydramnios.

The hydramnios that commonly develops with maternal diabetes during the third trimester remains unexplained. One explanation is that maternal hyperglycemia causes fetal hyperglycemia, resulting in osmotic diuresis. Bar-Hava and associates (1994) reported that increases in third-trimester amniotic fluid volume in women with gestational diabetes correlated with hyperglycemia the day prior to fluid measurement.

SYMPTOMS. Major maternal symptoms accompanying hydramnios arise from purely mechanical causes and result principally from pressure exerted within the overdistended uterus and upon adjacent organs. When distention is excessive, the mother may suffer from severe dyspnea and, in extreme cases, she may be able to breathe only when upright (see [Fig. 21-2](#)). Edema, the consequence of compression of major venous systems by the enlarged uterus, is common, especially in the lower extremities, the vulva, and the abdominal wall. Rarely, oliguria may result from ureteral obstruction by the enlarged uterus (see [Chap. 48](#), p. 1107). Hydramnios associated with fetal hydrops may cause the *mirror syndrome*, whereby the maternal condition mimics the fetus in that she develops edema and mild proteinuria (Carbillon and colleagues, 1997). This was originally described by Ballantyne in 1892, and it is discussed further in [Chapter 29](#) (see p. 674).

With chronic hydramnios, the accumulation of fluid takes place gradually, and the woman may tolerate the excessive abdominal distention with relatively little discomfort. In acute hydramnios, however, distention may lead to disturbances sufficiently serious to be threatening. Acute hydramnios tends to develop earlier in pregnancy than does the chronic form—often as early as 16 to 20 weeks—and it may rapidly expand the hypertonic uterus to enormous size. As a rule, acute hydramnios leads to labor before 28 weeks, or the symptoms become so severe that intervention is mandatory.

DIAGNOSIS. The primary clinical finding with hydramnios is uterine enlargement in association with difficulty in palpating fetal small parts and in hearing fetal heart tones. In severe cases, the uterine wall may be so tense that it is impossible to palpate any fetal parts (see [Fig. 21-2](#)). The differentiation between hydramnios, ascites, or a large ovarian cyst usually can be made by ultrasonic evaluation.

PREGNANCY OUTCOME. In general, the more severe the degree of hydramnios, the higher the perinatal mortality rate. Even when sonography and radiography show an apparently normal fetus, the prognosis is still guarded, because fetal malformations and chromosomal abnormalities are common. Furman and co-workers (2000) described substantively increased adverse perinatal outcomes if fetal growth restriction accompanies hydramnios. Perinatal mortality is increased further by preterm delivery, which was more common in women with an anomalous fetus (40 percent). Other conditions adding to bad outcomes are erythroblastosis, maternal diabetes, umbilical cord prolapse, and placental abruption.

The most frequent maternal complications associated with hydramnios are placental abruption, uterine dysfunction, and postpartum hemorrhage. Extensive premature separation of the placenta caused by the decrease in the area of the emptying uterus beneath the placenta sometimes follows escape of massive quantities of amniotic fluid (see [Chap. 35](#), p. 811). Uterine dysfunction and postpartum hemorrhage result from uterine atony consequent to overdistention. Abnormal fetal presentations and operative intervention are also common.

MIDTRIMESTER HYDRAMNIOS. The prognosis of midtrimester hydramnios depends on the severity. Mild hydramnios has a reasonably good outcome. Glantz and co-workers (1994) studied 47 consecutive singleton pregnancies with a single deepest pocket of 6 to 10 cm that was identified at 14 to 27 weeks. Excessive fluid resolved spontaneously in three fourths of these pregnancies, and perinatal outcomes were similar to matched controls without hydramnios. In the group in which hydramnios persisted, 2 of 10 had fetal aneuploidy.

MANAGEMENT. Minor degrees of hydramnios rarely require treatment. Even moderate degrees with some discomfort usually can be managed without intervention until labor ensues or until the membranes rupture spontaneously. If dyspnea or abdominal pain is present, or if ambulation is difficult, hospitalization becomes necessary. Bed rest, diuretics, and water and salt restriction are ineffective. Recently, indomethacin therapy has been used for symptomatic hydramnios.

Amniocentesis. The principal purpose of amniocentesis is to relieve maternal distress, and to that end it is transiently successful. Amniotic fluid also can be tested to predict fetal lung maturity as described in [Chapter 29](#) (see p. 651). Elliott and associates (1994) reported results from 200 therapeutic amniocenteses in 94 women with hydramnios. Common causes included twin-to-twin transfusion (38 percent), idiopathic (26 percent), fetal or chromosomal anomalies (17 percent), and diabetes (12 percent). These authors removed a mean of 1650 mL of fluid at each procedure and gained an average duration to delivery of 7 weeks. Only three procedures were complicated: one woman had ruptured membranes, one developed chorioamnionitis, and another suffered placental abruption after 10 L of fluid was removed. Leung and co-workers (2004) cited a 3.1-percent incidence of complications in 134 rapid aminodrainage procedures.

TECHNIQUE. To remove amniotic fluid, a commercially available plastic catheter that tightly covers an 18-gauge needle is inserted through the locally anesthetized abdominal wall into the amniotic sac, the needle is withdrawn, and an intravenous infusion set is connected to the catheter hub. The opposite end of the tubing is dropped into a graduated cylinder placed at floor level, and the rate of flow of amniotic fluid is controlled with the tubing screw clamp so that about 500 mL/hr is withdrawn. After about 1500 to 2000 mL have been collected, the uterus usually has decreased in size sufficiently that the catheter may be withdrawn from the amniotic sac. At the same time, maternal relief is dramatic and the danger of placental separation from decompression is slight. Using strict aseptic technique, this procedure can be repeated as necessary to make the woman comfortable. Elliott and colleagues (1994) used wall suction and removed 1000 mL over 20 minutes (50 mL/min), however, we prefer more gradual removal.

Amniotomy. The disadvantage inherent in amniotomy during labor is the possibility of cord prolapse and especially of placental abruption. Slow removal of the fluid by amniocentesis helps to obviate these dangers.

Indomethacin Therapy. In their review of several studies, Kramer and colleagues (1994) concluded that indomethacin impairs lung liquid production or enhances absorption, decreases fetal urine production, and increases fluid movement across fetal membranes. Doses employed by most investigators range from 1.5 to 3 mg/kg per day.

Cabrol and associates (1987) used indomethacin therapy for 2 to 11 weeks in eight women with idiopathic hydramnios from 24 to 35 weeks. Hydramnios, defined by at least one 8-cm fluid pocket, improved in all cases. There were no serious adverse effects and the outcomes were good. Mamopoulos and colleagues (1990) treated 15 women—11 were diabetic—who had hydramnios at 25 to 32 weeks. Amniotic fluid volume decreased in all women after indomethacin was begun. The fluid in the maximum pocket decreased from a mean of 10.7 cm at 27 weeks to 5.9 cm after therapy. The outcome was good in all 15 newborns. Kriplani and colleagues (2001) successfully treated with indomethacin a patient who had polyhydramnios from a placental chorioangioma.

A major concern for the use of indomethacin is the potential for closure of the fetal ductus arteriosus (see [Chap. 14](#), p. 356). Moise and colleagues (1988) reported that 50 percent of 14 fetuses whose mothers received indomethacin had ductal constriction detected by Doppler ultrasound. Persistent constriction was not demonstrated in the studies described earlier in this section, nor has it been described in studies in which indomethacin was given for tocolysis (Kramer and colleagues, 1994).

OLIGOHYDRAMNIOS

In rare instances, the volume of amniotic fluid may fall far below the normal limits and occasionally be reduced to only a few milliliters. In general, oligohydramnios developing early in pregnancy is less common and frequently has a bad prognosis. By contrast, diminished fluid volume may be found often with pregnancies that continue beyond term. Marks and Divon (1992) found oligohydramnios—defined as an amniotic fluid index of 5 cm or less—in 12 percent of 511 pregnancies of 41 weeks or greater. In 121 women studied longitudinally, there was a mean decrease of 25 percent per week in the amniotic fluid index beyond 41 weeks. Gagnon and colleagues (2002) found that chronic severe placental insufficiency caused a reduction in amniotic fluid volume not attributable to reduced fetal urine production. The risk of cord compression, and in turn fetal distress, is increased with diminished fluid in all labors, but especially in postterm pregnancy (Grubb and Paul, 1992; Leveno and colleagues, 1984).

EARLY-ONSET OLIGOHYDRAMNIOS. Several conditions have been associated with diminished amniotic fluid (Table 21-4). Oligohydramnios almost always is evident when there is either obstruction of the fetal urinary tract or renal agenesis. Therefore, anuria almost certainly has an etiological role in such cases. A chronic leak from a defect in the fetal membranes may reduce the volume of fluid appreciably, but most often labor soon ensues. Exposure to angiotensin-converting enzyme inhibitors has been associated with oligohydramnios (see Chap. 14, p. 349). Anywhere from 15 to 25 percent of cases are associated with the fetal anomalies shown in Table 21-5. Pryde and co-workers (2000) were able to visualize fetal structures in only half of women referred for ultrasonic evaluation of midtrimester oligohydramnios. They performed amnioinfusion and were then able to visualize 77 percent of routinely imaged structures. Identification of associated anomalies increased from 12 to 31 percent of fetuses.

Prognosis. Fetal outcome is poor with early-onset oligohydramnios. Shenker and colleagues (1991) described 80 pregnancies and only half of these fetuses survived. Mercer and Brown (1986) described 34 midtrimester pregnancies complicated by oligohydramnios diagnosed ultrasonically by the absence of amniotic fluid pockets greater than 1 cm. Nine fetuses (one fourth) had anomalies, and 10 of the 25 who were phenotypically normal either aborted spontaneously or were stillborn because of severe maternal hypertension, restricted fetal growth, or placental abruption. Of the 14 liveborn infants, eight were preterm and seven died. The six infants who were delivered at term did well. Garmel and co-workers (1997) observed that appropriately grown fetuses associated with oligohydramnios prior to 37 weeks had a threefold increase in preterm birth but not of later growth restriction or fetal death.

Newbould and colleagues (1994) described autopsy findings in 89 infants with the oligohydramnios sequence or Potter syndrome. Only 3 percent had a normal renal tract; 34 percent had bilateral renal agenesis; 34 percent, bilateral cystic dysplasia; 9 percent, unilateral agenesis with dysplasia; and 10 percent, minor urinary abnormalities.

Otherwise normal infants may suffer the consequences of early-onset severely diminished amniotic fluid. Adhesions between the amnion may entrap fetal parts and cause serious deformities, including amputation. Moreover, subjected to pressure from all sides, musculoskeletal deformities such as clubfoot are observed frequently.

Pulmonary Hypoplasia. The incidence of pulmonary hypoplasia at birth ranges from 1.1 to 1.4 per 1000 infants (Moessinger and colleagues, 1989). When amniotic fluid is scant, pulmonary hypoplasia, such as that shown in Figure 21-3, is common. Winn and associates (2000) performed a prospective cohort study in 163 cases of oligohydramnios that followed prematurely ruptured membranes at 15 to 28 weeks. Almost 13 percent of fetuses developed pulmonary hypoplasia. This complication was more common as the gestational age at the time of rupture decreased. Kilbride and co-workers (1996) studied 115 women with prematurely ruptured membranes before 29 weeks. There ultimately were seven stillbirths and 40 neonatal deaths for a perinatal mortality of 409 per 1000. The risk of lethal pulmonary hypoplasia was 20 percent. Adverse outcomes were more likely with earlier rupture as well as duration exceeding 14 days.

According to Fox and Badalian (1994) and Lauria and colleagues (1995), there are three possibilities that account for pulmonary hypoplasia. First, thoracic compression may prevent chest wall excursion and lung expansion. Second, lack of fetal breathing movements decreases lung inflow. The third and the most widely accepted model involves a failure to retain intrapulmonary amniotic fluid or an increased outflow with impaired lung growth and development. Albuquerque and colleagues (2002) found a relationship between oligohydramnios and spinal flexion in the human fetus that also may contribute to fetal pulmonary hypoplasia.

The appreciable volume of amniotic fluid demonstrated by Duenhoelter and Pritchard (1976) to be inhaled by the normal fetus suggests a role for the inspired fluid in expansion, and in turn growth, of the lung. Fisk and colleagues (1992), however, concluded that fetal breathing impairment does not cause pulmonary hypoplasia with oligohydramnios. In a unique experiment, McNamara and associates (1995) described findings from two sets of monoamniotic twins with discordant renal anomalies. They provided evidence that normal amniotic fluid volume in the presence of fetal renal obstruction allows normal lung development.

Figure 21-3. Normal-sized lungs (top) are shown in comparison with hypoplastic lungs (bottom) of fetuses at the same gestational age. (From Newbould and colleagues, 1994, with permission.)

OLIGOHYDRAMNIOS IN LATE PREGNANCY. As shown in Table 21-1 and Figure 21-1, amniotic fluid volume diminishes normally after 35 weeks. Management of oligohydramnios in late pregnancy depends on the clinical situation. An evaluation for fetal anomalies and growth is critical. In a pregnancy complicated by oligohydramnios and fetal growth restriction, close fetal surveillance is important because of associated morbidity, and delivery is recommended for fetal or maternal indications. Although gestational age is considered in this decision, evidence for fetal or maternal compromise

usually overrides potential complications from preterm delivery. Oligohydramnios detected before 36 weeks in the presence of normal fetal anatomy and growth may be managed expectantly in conjunction with antepartum fetal testing discussed in [Chapter 15](#).

Oz and colleagues (2002) investigated the etiology of oligohydramnios in postterm pregnancy. They found a reduction in renal artery end-diastolic velocity, suggesting that increased arterial impedance is an important factor. Using an amniotic fluid index of less than 5 cm, Casey and co-workers (2000) found an incidence of oligohydramnios of 2.3 percent in more than 6400 pregnancies undergoing sonography after 34 weeks at Parkland Hospital. They confirmed previous observations that this finding is associated with an increased risk of adverse perinatal outcomes ([Table 21-6](#)). Conversely, using the RADIUS trial database, Zhang and colleagues (2004) reported that oligohydramnios of this degree was not associated with adverse perinatal outcomes. Similarly, Magann and co-workers (1999) did not find that associated oligohydramnios increased risks for intrapartum complications.

Chauhan and associates (1999) performed meta-analysis of 18 studies comprising more than 10,500 pregnancies in which the intrapartum amniotic fluid index was less than 5 cm. Compared with controls whose index was over 5 cm, women with oligohydramnios had a significantly increased, 2.2-fold, risk for cesarean delivery for fetal distress and a 5.2-fold increased risk for a 5-minute Apgar score of less than 7.

Cord compression during labor is common with oligohydramnios. Sarno and co-workers (1989, 1990) reported that an index of 5 cm or less was associated with a fivefold increased cesarean delivery rate. Baron and colleagues (1995) reported a 50-percent increase in variable decelerations during labor and a sevenfold increased cesarean delivery rate in these women. By contrast, Casey and co-workers (2000) showed a 25-percent increase in nonreassuring fetal heart rate patterns when women with oligohydramnios were compared with normal controls. Moreover, the cesarean rate for pregnancies with this finding increased only from 3 to 5 percent (see [Table 21-6](#)).

Divon and associates (1995) studied 638 women with a postterm pregnancy in labor and observed that only those whose amniotic fluid index was 5 cm or less had fetal heart rate decelerations and meconium. Interestingly, Chauhan and collaborators (1995) showed that diminished amniotic fluid index increased the cesarean delivery rate only in women whose labor attendants were made aware of the findings!

Amnioinfusion. Results with intrapartum amnioinfusion to prevent fetal morbidity from meconium-stained fluid are often associated with oligohydramnios are mixed. Pierce and colleagues (2000) performed meta-analysis of 13 studies with 1924 such women randomized to amnioinfusion or no treatment. They found that amnioinfusion resulted in significantly decreased adverse outcomes: meconium beneath the cords (OR 0.18), meconium aspiration syndrome (OR 0.30), neonatal acidemia (OR 0.42), and cesarean delivery rate (0.74). Conversely, Spong and associates (1994) found no benefits when they compared therapeutic with prophylactic amnioinfusion for meconium. Indeed, meconium aspiration syndrome occurred only in the group undergoing therapeutic amnioinfusion. Surprisingly, only 16 percent of the group randomized to expectant therapy ultimately required amnioinfusion for variable fetal heart rate decelerations. These findings are in agreement with reviews of outcomes before and after amnioinfusion protocols were implemented (DeMeeus and colleagues, 1998; Rogers and colleagues, 1996; Usta and colleagues 1995). Taken together these results suggest that routine prophylactic amnioinfusion for meconium is not warranted.

The American College of Obstetricians and Gynecologists (1995), however, states that either prophylactic or therapeutic amnioinfusion for meconium is reasonable. Wenstrom and associates (1995) surveyed academic obstetrical departments and reported that amnioinfusion is widely performed with relatively few complications. The procedure is discussed in greater detail in [Chapter 29](#) (see p. 676), and the technique is described in [Chapter 18](#) (see p. 462).

22. Induction of Labor

INTRODUCTION

According to the National Center for Health Statistics, the annual incidence of labor induction or augmentation in the United States almost doubled from 20 percent in 1989 to 38 percent in 2002 (Martin and associates, 2003). The incidence is variable between practices. For example, at Parkland Hospital, approximately 35 percent of labors are induced or augmented. And at the University of Alabama at Birmingham Hospital, from 1996 through 1999, 20 percent of women were given oxytocin for induction and 35 percent for augmentation. This chapter includes a description of various techniques to effect cervical ripening as well as schemata for the induction or augmentation of labor.

GENERAL CONCEPTS

ELECTIVE INDUCTION OF LABOR. There can be no doubt that elective induction for convenience of the practitioner or the patient is becoming more prevalent. Despite this, the American College of Obstetricians and Gynecologists (1999a) does not support this practice, except for logistical reasons such as risk of rapid labor, the woman lives a long distance from the hospital, or for psychosocial indications. One reason is that induced labor is associated with an increased cesarean delivery rate, especially in nulliparas (Luthy and colleagues, 2002; Yeast and associates, 1999). A number of investigators have reported that elective induction consistently results in a two- to threefold risk for cesarean delivery (Hoffman and Sciscione, 2003; Maslow and Sweeny, 2000; Smith and colleagues, 2003).

In the Flanders region of Belgium, 30 percent of women delivering in 1996 and 1997 had induction of labor, and two thirds of these were elective (Cammu and colleagues, 2002). The investigators matched 3683 women who had elective inductions with a similar number of women whose labor was spontaneous. Induction resulted in significantly more cesarean deliveries ¶— 9.9 versus 6.5 percent ¶— in part due to an increased incidence of dystocia and "fetal distress." This increase appears to be unchanged even when the cervix is more "favorable." Specifically, in a retrospective cohort study, Hamar and associates (2001) found that the rate of cesarean delivery following elective induction was significantly increased in low-risk women with a Bishop score of 7 or greater compared with women with spontaneous labor. Using a decision-tree model, Kaufman and associates (2001) reported that elective induction resulted in more cesarean deliveries at term and increased costs.

For all of these reasons, we agree that routine elective induction at term cannot be justified. Cesarean delivery imposes increased risk for severe, albeit infrequent, adverse maternal outcomes including death (see [Chap. 25](#), p. 592). If elective induction is considered at term, these risks must be discussed with and consented to by each patient. The American College of Obstetricians and Gynecologists (1999a) defines term as 38 completed weeks.

INDICATED LABOR INDUCTION. Induction is indicated when the benefits to either the mother or the fetus outweigh those of continuing the pregnancy. Indications include emergent conditions such as ruptured membranes with chorioamnionitis or severe preeclampsia. More common indications include membrane rupture without labor, hypertension, nonreassuring fetal status, and postterm gestation.

Induction for *postterm* or *prolonged pregnancy* is discussed in [Chapter 37](#) (see p. 887). Many clinicians consider this diagnosis, especially at 41 weeks, to be within the normal range of term gestation and that induction of such women is considered elective. This belief is due in part to definitions and methods used to support this diagnosis. For example, in a randomized trial, Bennett and associates (2004) reported that *combined* first- and second-trimester ultrasound examination pregnancy dating, compared with a single second-trimester screening examination, reduced the number of women attaining 41 weeks to 6.7 from 16.3 percent. Savitz and colleagues (2002) described a systematic tendency to overstate gestational age from the last menstrual period compared with that from early ultrasound examination ¶— 12.1 percent versus 3.4 percent, respectively. This overstatement most likely reflected delayed ovulation. Menticoglou and Hall (2002) present an elegant and compelling analysis to refute routine induction at 41 weeks as a "nonsensus consensus" and as a "rescue from normalcy."

Although induction is widely practiced for suspected *fetal macrosomia*, there is little evidence that it is of benefit. Sanchez-Ramos and colleagues (2002) conducted a meta-analysis of observational studies in which women with suspected fetal macrosomia were managed expectantly or underwent labor induction. Perinatal outcomes were similar, however, the cesarean delivery rate was significantly lower with expectant management compared with that of induction ¶— 8.4 versus 16.6 percent.

Women whose labor is induced have an increased incidence of chorioamnionitis and cesarean delivery compared with those in spontaneous labor. In many cases, it seems that the uterus is simply poorly prepared for labor. One example is an "unripe cervix." It is also likely that the increase in cesarean deliveries associated with induction is influenced by the duration of the induction attempt, especially in the circumstance of an unfavorable cervix (Rouse and colleagues, 2000). The duration for either labor induction or augmentation and successful delivery has received too little attention. More precise data are needed to understand the wide range of individual management. For example, Garcia and associates (2001), after adjustment for case mix, reported that cesarean births were significantly lower at academic medical centers (odds ratio 0.66) compared with those at community hospitals. Doyle and colleagues (2002) reported that cesarean deliveries in a community hospital were twice that of a county hospital. There are other factors too. For example, Bland and co-workers (2001) observed a significant decrease in elective induction with a change from individual practitioner billing to revenue sharing.

Cesarean birth is associated with markedly increased common and uncommon maternal infectious morbidities (Goepfert and colleagues, 2001). These morbidities are further increased in women with overt chorioamnionitis. The need for emergent hysterectomy also is increased. Shellhaas and associates (2001), from the Maternal-Fetal Units Network, reported 146 emergent cesarean hysterectomies amongst 136,948 deliveries ¶— about 1 per 1000 vaginal deliveries versus 1 per 200 cesarean deliveries. Importantly, 41 percent of hysterectomies followed primary cesarean delivery. Uterine atony was the indication for one third of all cesarean hysterectomies, and this indication was more prevalent in women with induced or augmented labor, or in those with chorioamnionitis. Kastner and colleagues (2002) reported similar findings.

CONTRAINDICATIONS. Contraindications to labor induction are similar to those that preclude spontaneous labor or delivery. The most common example is a prior uterine disruption such as a classical incision or some type of uterine surgery that involved the myometrium. Most types of placenta previa preclude labor. Labor prohibition due to fetal factors includes appreciable macrosomia, severe hydrocephalus, malpresentations, or nonreassuring fetal status. The few maternal contraindications are related to small maternal size, distorted pelvic anatomy, and conditions such as active genital herpes infection or cervical cancer.

PREINDUCTION CERVICAL RIPENING

The condition of the cervix or "favorability" is important to the success of labor induction. One quantifiable method predictive of an outcome of labor induction is that described by Bishop (1964). Elements of the *Bishop score* are presented in [Table 22-1](#). A score of 9 conveys a high likelihood for a successful induction. Most practitioners would consider that a woman whose cervix is 2 cm dilated, 80 percent effaced, soft, and midposition, and with the fetal occiput at -1 station would have a successful labor induction.

Unfortunately, women too frequently have an indication for induction but with an unfavorable cervix. As favorability or Bishop score decreases, there is an increasingly unsuccessful induction rate. Thus, considerable research has been directed toward various techniques to "ripen" the cervix prior to stimulation of uterine contractions. For research purposes, a Bishop score of 4 or less identifies an unfavorable cervix, and may be an indication for cervical ripening.

PHARMACOLOGICAL TECHNIQUES

Prostaglandin E₂. Local application of prostaglandin E₂ (dinoprostone) is commonly used for cervical ripening (American College of Obstetricians and Gynecologists, 1999a, 1999b). Prostaglandin E₂ gel (Prepidil) is available in a 2.5-mL syringe for an intracervical application of 0.5 mg of dinoprostone. Owen and colleagues (1991) did a meta-analysis of 18 studies that included 1811 women. They found that prostaglandin E₂ improved Bishop scores and induction-to-delivery times when compared with those of untreated controls. Unfortunately, they found no benefit in lowering the cesarean delivery rate. This finding may be the result of other factors. For example, Ramsey and colleagues (2002) reported that dinoprostone gel was more effective when the vaginal pH was greater than 4.5 compared with that of 4.5 or less.

A 10-mg dinoprostone vaginal insert (Cervidil) also is approved for cervical ripening. The insert provides slower release of medication (0.3 mg/hr) than the gel. As with dinoprostone gel, these inserts will shorten the induction-to-delivery interval (Bolnick and associates, 2004; Rayburn and colleagues, 1992). An advantage of the insert is that it can be removed should hyperstimulation occur.

ADMINISTRATION. Prostaglandin preparations should only be administered in or near the delivery suite and where uterine activity and fetal heart rate monitoring can be performed (American College of Obstetricians and Gynecologists, 1995b). When contractions occur, they are usually apparent in the first hour and show peak activity in the first 4 hours (Bernstein, 1991; Miller and colleagues, 1991). Perry and Leapart (2004) compared intracervical with intravaginal administration of the insert and found the latter to result in quicker delivery—11.7 versus 16.2 hours. When more than two sequential doses were used, Chan and associates (2004) reported that 59 percent of women required emergency cesarean delivery. Finally, according to manufacturer guidelines, oxytocin induction that follows prostaglandin use for cervical ripening should be delayed for 6 to 12 hours following prostaglandin E₂ administration.

SIDE EFFECTS. Uterine tachysystole has been reported to follow vaginally administered prostaglandin E₂ in 1 to 5 percent of women (Brindley and Sokol, 1988; Rayburn, 1989). Because hyperstimulation that can cause fetal compromise may occur when prostaglandins are used with preexisting spontaneous labor, such use is not recommended. When hyperstimulation occurs with the 10-mg insert, its removal by pulling on the tail of the surrounding net will usually reverse this effect. Irrigation to remove the gel preparation has not been helpful.

Prostaglandin E₁. Misoprostol (Cytotec) is a synthetic prostaglandin E₁, available as a 100- or 200- μ g tablet for prevention of peptic ulcers. It has been used "off label" for preinduction cervical ripening and may be administered orally or vaginally. The tablets are stable at room temperature. Misoprostol costs less than \$1 per 100- μ g tablet compared with \$75 for the 0.5-mg dose of dinoprostone gel.

In October 2000, G. D. Searle & Company notified physicians that misoprostol is not approved for labor induction or abortion. Despite this, in December 2000, the American College of Obstetricians and Gynecologists reaffirmed its recommendation for use of the drug because of proven safety and efficacy.

VAGINAL ADMINISTRATION. Several investigators have reported that misoprostol tablets placed into the vagina were either superior to or equivalent in efficacy when compared with intracervical prostaglandin E₂ gel (Gemund and associates, 2004; Wing and co-workers, 1995a, 1995b). The Committee on Obstetrics of the American College of Obstetricians and Gynecologists (1999b) reviewed 19 randomized trials in which more than 1900 women were given intravaginal misoprostol in doses ranging from 25 to 200 μ g. The Committee on Obstetrics recommended the use of a 25- μ g intravaginal dose, which is one fourth of a 100- μ g tablet. The drug is evenly distributed among these quartered tablets. Although Williams and colleagues (2002) showed that accurate dosing with 25 μ g is possible if the quartered tablets are individually weighed, this seems unnecessary. Also, although it may lower pH, moistening of misoprostol tablets with 3-percent acetic acid solution does not improve efficacy (Sanchez-Ramos and associates, 2002).

Misoprostol use may decrease the need for oxytocin, achieve higher rates of vaginal delivery within 24 hours of induction, and reduce induction-to-delivery intervals (Sanchez-Ramos and colleagues, 1997). Data from the United Kingdom Cochrane Centre support these recommendations, but the investigators cautioned that increased uterine hyperstimulation with adverse fetal heart rate changes was of concern (Hofmeyr and associates, 1999). A 50- μ g misoprostol intravaginal dose was associated with

significantly increased tachysystole, meconium passage, and meconium aspiration when compared with prostaglandin E₂ gel (Wing and co-workers, 1995a, 1995b). A 25- μ g dose was found comparable to dinoprostone (van Gemund and associates, 2004). There is also an increased cesarean delivery rate due to uterine hyperstimulation when compared with that from dinoprostone (Buser and collaborators, 1997). Uterine rupture has been reported with prostaglandin E₁ use in women with a prior cesarean delivery (Wing and colleagues, 1998). Plaut and associates (1999) described uterine rupture in 5 of 89 (6 percent) women with a prior cesarean incision who were induced with misoprostol. This finding is compared with only 1 of 423 such women not given misoprostol. Most now agree that prior uterine surgery, including cesarean delivery, precludes the use of misoprostol (American College of Obstetricians and Gynecologists, 2004).

ORAL ADMINISTRATION. Prostaglandin E₁ tablets are also effective when given orally. Windrim and associates (1997) reported oral misoprostol to be of similar efficacy for cervical ripening as intravaginal administration. Wing and collaborators (1999) reported that 50 μ g of oral misoprostol was less effective than 25 μ g administered vaginally for cervical ripening. Subsequently, Wing and colleagues (2003) and Hall and associates (2002) reported that a 100- μ g oral dose was as effective as the 25- μ g intravaginal dose. In women with premature rupture of membranes at term, Mozurkewich and colleagues (2003) and Pearson and associates (2002) have reported similar success with labor initiation with either oral misoprostol or standard oxytocin regimens. Lo and co-workers (2003), in a similar group of women at term with prematurely ruptured membranes, found that oral misoprostol predictably induced at least 200 Montevideo units within 30 to 60 minutes, and results were comparable to their standard intravenous oxytocin infusion.

MECHANICAL TECHNIQUES

Transcervical Catheter. Sherman and colleagues (1996) summarized the results of 13 trials with balloon-tipped catheters to effect cervical dilatation and concluded that, with or without saline infusion, the method resulted in rapid improvement in Bishop scores and shorter labors. Several comparative trials have been done. Huang and colleagues (2002) randomized 135 women to labor induction with vaginal misoprostol, an intrauterine extra-amnionic Foley catheter with bulb inflation to 30 mL, or both therapies. Outcomes were similar in all three groups, and there was no apparent benefit of combining these two techniques. Bujold and co-workers (2004) retrospectively compared women with a prior cesarean incision undergoing a trial of labor. They reported a lower incidence of success when induction by Foley catheter was compared with that by oxytocin \mathfrak{R} — 56 versus 78 percent. Culver and colleagues (2004) compared oxytocin plus an intracervical Foley catheter to 25 μ g of misoprostol administered vaginally every 4 hours in women with a Bishop score less than 6. The mean induction-to-delivery time was significantly shorter in the catheter-plus-oxytocin group \mathfrak{R} — 16 versus 22 hours.

The addition of *extra-amnionic saline infusion (EASI)*, shown in [Figure 22-1](#), has been reported to significantly improve the Bishop score and decrease induction-to-delivery times when compared with that by (1) 50- μ g intravaginal misoprostol tablets (Vengalil and colleagues, 1998), (2) 0.5 mg of intracervical prostaglandin E₂ (Goldman and Wigton, 1999; Hemlin and Moller, 1998; Sciscione and associates, 1999), or (3) 50- μ g oral misoprostol. Abramovici and co-workers (1999) studied nulliparas with a Bishop score of 5 or less, and reported that 85 percent of those induced by catheter infusion delivered within 24 hours compared with 55 percent of those given misoprostol.

Guinn and colleagues (2000) randomized women to intracervical prostaglandin E₂, laminaria plus intravenous oxytocin, or EASI plus oxytocin. Normal saline was infused through the catheter port at 30 mL/hr. Oxytocin infusion was begun immediately after placement of the catheter. The cesarean delivery rate was similar with all three interventions. The induction-to-delivery mean time of 18 hours with catheter infusion was significantly less than that with laminaria plus oxytocin (21.5 hours) or with prostaglandin E₂ gel (24.8 hours). Mullin and associates (2002) randomized 200 women with no cervical dilatation or effacement to receive 25 μ g of misoprostol vaginally every 4 hours compared with EASI plus intravenous oxytocin. The mean induction-to-delivery time was shorter in the catheter-plus-oxytocin group (16.2 versus 22.1 hours). Women given misoprostol had a higher incidence of uterine hyperstimulation.

Hygroscopic Cervical Dilators. Cervical dilatation has been achieved with hygroscopic osmotic cervical dilators (see [Chap. 9](#), p. 243). These dilators have long been accepted as efficacious when inserted prior to pregnancy termination (Hale and Pion, 1972). More recently, they have also been used for cervical ripening before labor induction in pregnancies with a healthy fetus. Gilson and associates (1996) reported a rapid improvement of cervical favorability in women randomized to hygroscopic dilators prior to oxytocin induction. There was, however, no beneficial effect on the vaginal delivery rate or induction-to-delivery times compared with those of women given oxytocin only. In the randomized study cited earlier, Guinn and co-workers (2000) reported a longer induction-to-delivery time with cervical dilators plus oxytocin compared with that of EASI plus oxytocin. The use of hygroscopic dilators appears to be safe, although anaphylaxis has followed laminaria insertion (Cole and Bruck, 2000; Nguyen and Hoffman, 1995). The attraction of dilators is their low cost and ease of placement and removal.

Membrane Stripping. Induction of labor by membrane "stripping" is a common practice. McColgin and colleagues (1990) reported that stripping was safe and decreased the incidence of postterm gestation. They documented significantly increased serum levels of endogenous prostaglandins with stripping (McColgin and coauthors, 1993). Allott and Palmer (1993) randomized 195 women with normal pregnancies beyond 40 weeks to digital cervical examination either with or without membrane stripping. The women were examined as outpatients. Two thirds of those who underwent stripping entered spontaneous labor within 72 hours compared with one third of the other group. The incidence of ruptured membranes, infection, and bleeding was not increased. Importantly, subsequent induction for postterm pregnancy at 42 weeks was significantly decreased with stripping.

Boulvain and colleagues (1999) reviewed 13 reports that included almost 2000 women who underwent membrane stripping to prevent postterm pregnancy. The risks for maternal and neonatal infection and membrane rupture were similar in intervention versus control groups as were the cesarean delivery rates. Stripping was considered beneficial because women in this group were significantly more likely to deliver within 48 hours, within 1 week, and before 41 weeks, thus, fewer women in the stripping group required labor induction.

Figure 22-1. Extra-amnionic saline infusion (EASI) through 26F Foley catheter

placed through the cervix. The 30-mL balloon is inflated with saline and pulled snugly against the internal os and the catheter taped to the thigh.

SUMMARY OF PREINDUCTION CERVICAL RIPENING. Labor induction frequently is indicated when there is an "unripe" cervix. The preceding preinduction techniques may have some benefit when compared with no attempt at cervical ripening before oxytocin induction. That said, there are few data to support the premise that any of these techniques results in a reduction in cesarean delivery rates or in lower maternal or neonatal morbidity compared with women in whom such techniques are not used.

LABOR INDUCTION AND AUGMENTATION WITH OXYTOCIN

Synthetic oxytocin is one of the most commonly used medications in the United States. It was the first polypeptide hormone synthesized, and the 1955 Nobel Prize in chemistry was awarded for this (DuVigneaud and co-workers, 1953). Regarding labor, it has two uses. *Induction* implies stimulation of contractions before the spontaneous onset of labor, with or without ruptured membranes. *Augmentation* refers to stimulation of spontaneous contractions that are considered inadequate because of failure of progressive cervical dilatation and fetal descent. With oxytocin use, the American College of Obstetricians and Gynecologists (1999a) recommends fetal heart rate and contraction monitoring similar to that for any high-risk pregnancy. Contractions can be monitored either by palpation or by electronic means of recording uterine activity (see [Chap. 18](#), p. 466). Uterine contraction pressures cannot be accurately quantified by palpation (Arrabal and Nagey, 1996).

INTRAVENOUS OXYTOCIN ADMINISTRATION. The goal of induction or augmentation is to effect uterine activity sufficiently to produce cervical change and fetal descent while avoiding development of a nonreassuring fetal status. Oxytocin should be discontinued if the number of contractions persists with a frequency greater than five in a 10-minute period or seven in a 15-minute period or with a persistent nonreassuring fetal heart rate pattern. Discontinuation of oxytocin nearly always rapidly decreases the frequency of contractions. When oxytocin is stopped, its concentration in plasma rapidly falls because the mean half-life is approximately 5 minutes. Seitchik and co-workers (1984) found that a uterine response occurs within 3 to 5 minutes of beginning an oxytocin infusion and that a plasma steady state is reached in 40 minutes. Response depends on preexisting uterine activity, cervical status, pregnancy duration, and individual biological differences. Caldeyro-Barcia and Poseiro (1960) reported that the uterine response to oxytocin increases from 20 to 30 weeks and increases rapidly at term (see [Chap. 18](#), p. 466).

Oxytocin Dosage. Oxytocin usually is diluted into 1000 mL of a balanced salt solution and administered by infusion pump. A typical oxytocin infusate consists of 10 or 20 units ¶— or 10,000 to 20,000 mU ¶— mixed into 1000 mL of lactated Ringer solution. This mixture results in an oxytocin concentration of 10 or 20 mU/mL, respectively. To avoid bolus administration, the infusion should be inserted into the main intravenous line close to the venipuncture site. The American College of Obstetricians and Gynecologists (1999a) recommends a number of oxytocin regimens for labor stimulation ([Table 22-2](#)). Until about 15 years ago, only variations of low-dose protocols were used in the United States. In 1984, O'Driscoll and colleagues described a protocol for the active management of labor that called for oxytocin at a starting dosage of 6 mU/min and advanced in 6-mU/min increments. Following this, various trials during the 1990s compared high-dose (4 to 6 mU/min) versus conventional low-dose (0.5 to 1.5 mU/min) regimens both for labor induction and for augmentation.

At Parkland Hospital, Satin and colleagues (1992) evaluated an oxytocin regimen using an initial and incremental dosage of 6 mU/min compared with one using 1 mU/min. Increases at 20-minute intervals were provided as needed. Among 1112 women undergoing induction, the 6-mU/min regimen resulted in a shorter mean admission-to-delivery time, fewer failed inductions, and no cases of neonatal sepsis. Among 1676 women who had labor augmentation, those who received the 6-mU/min regimen had a shorter duration-to-delivery time, fewer forceps deliveries, fewer cesarean deliveries for dystocia, and decreased intrapartum chorioamnionitis or neonatal sepsis. With this protocol, uterine hyperstimulation is managed by oxytocin discontinuation followed by resumption when indicated and at half the stopping dosage. Thereafter, the dosage is increased at 3 mU/min when appropriate instead of the usual 6-mU/min increase for women without hyperstimulation. No adverse neonatal effects were observed.

Xenakis and colleagues (1995) reported benefits using an incremental oxytocin regimen starting at 4 mU/min. Merrill and Zlatnik (1999) randomized 1307 women for labor induction (816) or augmentation (491) to incremental oxytocin given at either 1.5 or 4.5 mU/min. Women randomized to the 4.5 mU/min dosage had significantly decreased mean durations of induction-to-second-stage labor and induction-to-delivery. Nulliparas randomized to the 4.5 mU/min dosage had a lower cesarean delivery rate for dystocia compared with those at 1.5 mU/min dosage ¶— 5.9 versus 11.9 percent.

Thus, benefits favor higher-dose regimens as compared with lower dosages of 0.5 to 1.5 mU/min. In 1990, routine usage of the 6-mU/min oxytocin beginning and incremental dosage was incorporated at Parkland Hospital and continues through today. At the University of Alabama at Birmingham, a 2-mU/min beginning and incremental oxytocin regimen is used. In both cases, these dosages are used for either labor induction or augmentation.

Interval Between Incremental Dosing. Intervals to increase oxytocin dosages vary from 15 to 40 minutes (see [Table 22-2](#)). Satin and colleagues (1994) addressed this aspect with a 6-mU/min regimen providing increases at either 20- or 40-minute intervals. Women assigned to the 20-minute interval regimen for labor augmentation had a significant reduction in the rate of cesarean delivery for dystocia compared with that of the 40-minute interval regimen ¶— 8 versus 12 percent. In women with labor induction, however, uterine hyperstimulation was significantly more frequent with the 20-minute regimen. Other investigators report incremental increases at even more frequent intervals. Frigoletto and associates (1995) and Xenakis and co-workers (1995) began oxytocin at 4 mU/min with increases as needed every 15 minutes. Merrill and Zlatnik (1999) started with 4.5 mU/min with increases every 30 minutes. Lopez-Zeno and colleagues (1992) began at 6 mU/min with increases every 15 minutes. Thus, there are a number of acceptable oxytocin protocols that appear somewhat dissimilar. But are they? A comparison of protocols from two of our institutions follows.

1. The current Parkland Hospital protocol begins oxytocin at 6 mU/min, with 6-mU/min increases every 40 minutes, but employs flexible dosing based on hyperstimulation.
2. At the University of Alabama at Birmingham, oxytocin for labor induction or augmentation is begun at 2 mU/min and is increased as needed every 15 minutes to 4, 8, 12, 16, 20, 25, and 30 mU/min.

These two regimens, while at first appearing disparate, are similar, viz., if there is no uterine activity, either regimen is delivering 12 mU/min by 45 minutes into the infusion.

Maximal Dosage. The *maximal* effective dose of oxytocin to achieve adequate contractions in all cases is not known. Wen and colleagues (2001) studied 1151 consecutive nulliparas in spontaneous labor or undergoing labor induction and found that the likelihood of progression to a vaginal delivery decreases at and beyond an oxytocin dosage of 36 mU/min. At a dosage of 72 mU/min, however, half of the nulliparas were delivered vaginally. Thus, if contractions are not adequate \leq less than 200 Montevideo units \leq and if the fetal status is reassuring and labor has arrested, an oxytocin infusion dose greater than 48 mU/min has no apparent risks.

Risks Versus Benefits. Unless the uterus is scarred, uterine rupture associated with oxytocin infusion is rare, even in parous women (see [Chap. 35](#), p. 837). Flannely and associates (1993) reported no uterine ruptures with or without oxytocin in 27,829 nulliparas. There were eight instances of overt uterine rupture during labor in 48,718 parous women \leq only one of these was associated with oxytocin use.

Oxytocin has amino-acid homology similar to arginine vasopressin. Thus, not surprisingly, it has significant antidiuretic action and when infused at 20 mU/min or more, renal free water clearance decreases markedly. If aqueous fluids are infused in appreciable amounts along with oxytocin, *water intoxication* can lead to convulsions, coma, and even death.

Uterine Contraction Pressures. Contraction forces in spontaneously laboring women range from 90 to 390 Montevideo units. The latter are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window and adding the pressures generated by each contraction. Caldeyro-Barcia and associates (1950) and Seitchik and colleagues (1984) found that the mean or median spontaneous uterine contraction pattern resulting in a progression to a vaginal delivery was between 140 and 150 Montevideo units (see [Chap. 18](#), p. 466). However, in the management of active-phase arrest of labor, and with no contraindication to intravenous oxytocin, decisions must be made with knowledge of the safe upper range of uterine activity. Hauth and coworkers (1986) described an effective and safe protocol for oxytocin augmentation for active-phase arrest with which over 90 percent of women achieved an average of at least 200 to 225 Montevideo units. Hauth and associates (1991) later reported that nearly all women in whom arrest of active-phase labor persisted despite oxytocin were able to generate more than 200 Montevideo units. Importantly, despite no labor progression, there were no adverse maternal or newborn effects following cesarean delivery. More data are needed regarding the precise safety and efficacy of contraction patterns in subgroups of women with a prior cesarean delivery, with twins, or with an overdistended uterus.

Duration of Oxytocin Administration. The American College of Obstetricians and Gynecologists (1989, 1995a) has defined arrest in first-stage labor as a completed latent phase along with contractions exceeding 200 Montevideo units for more than 2 hours without cervical change. There are only sparse data to support a more accurate duration to define active-phase arrest. Some investigators have addressed this issue. Arulkumaran and associates (1987) extended the 2-hour limit to better define failed augmentation. Using a 4-hour limit, they reported a cesarean delivery rate of only 1.3 percent in women who continued to have adequate contractions and progressive cervical dilatation of at least 1 cm/hr. In women without progressive cervical dilatation who were allowed another 4 hours of labor, half were delivered vaginally. Rouse and colleagues (1999) prospectively managed 542 women at term with active-phase arrest. Women with other complications were not included. The protocol included an intent to achieve a sustained pattern of at least 200 Montevideo units for a *minimum* of 4 hours. This time frame was extended to 6 hours if activity of 200 Montevideo units or greater could not be sustained. Almost 92 percent of these women were delivered vaginally.

Rouse and colleagues (2001) extended these observations in 501 spontaneously laboring women at term with active-phase arrest. Using the same protocol, the cesarean delivery rate was only 12 percent. Montevideo units were measured for a total of 1643 hours in these 469 women with arrest of labor in the active phase. Most women with more than 2 hours of labor arrest, but who had sustained uterine activity of 200 Montevideo units or greater, achieved vaginal delivery. These data support the contention that it is safe and effective to allow an active-phase arrest of 4 hours.

Zhang and collaborators (2002) analyzed labor duration from 4 cm to complete dilatation in 1329 nulliparas at term. They found that before dilatation of 7 cm was reached, lack of progress for more than 2 hours was not uncommon in those who delivered vaginally. Alexander and colleagues (2002) reported that epidural analgesia prolonged active labor by 1 hour compared with duration of the active phase as defined by Friedman (1955). Consideration of these changes in the management of labor, especially in nulliparas, may safely reduce the cesarean delivery rate.

AMNIOTOMY. A common indication for amniotomy includes the need for direct monitoring of the fetal heart rate or uterine contractions, or both. To minimize the risk of cord prolapse when membranes are ruptured artificially, care should be taken to avoid dislodging the fetal head. Fundal or suprapubic pressure, or both, may reduce the risk of cord prolapse. Some clinicians prefer to rupture membranes during a contraction. If the vertex is not well applied to the lower uterine segment, a gradual egress of amniotic fluid can be accomplished by several membrane punctures with a 26-gauge needle held with a ring forceps and with direct visualization using a vaginal speculum. The fetal heart rate should be assessed before and immediately after amniotomy.

Elective Amniotomy. Membrane rupture with the intention of accelerating labor is commonly performed. In the investigations presented in [Table 22-3](#), amniotomy at about 5 cm accelerated spontaneous labor by 1 to 2 hours. This procedure was performed without increasing the overall cesarean delivery rate or the use of oxytocin stimulation. Although mild and moderate cord compression patterns were increased following amniotomy, cesarean delivery for fetal distress was not increased. Most importantly, there were no adverse perinatal effects.

Amniotomy Induction. Artificial rupture of the membranes can be used to induce labor, but it implies a commitment to delivery. The main disadvantage of amniotomy when used alone for labor induction is the unpredictable and occasionally long interval to the onset of contractions. In a randomized trial, Bakos and Backstrom (1987) found that amniotomy alone or combined with oxytocin was superior to oxytocin alone. Mercer and colleagues (1995) randomized 209 women undergoing oxytocin induction to amniotomy either at 1 to 2 cm dilatation (early amniotomy) or at 5 cm (late amniotomy). Early amniotomy was associated with significantly shorter labor by approximately 4 hours. There was, however, an increased incidence of chorioamnionitis (23 percent) and cord-compression patterns (12 percent) with early amniotomy.

Amniotomy Augmentation. It is common practice to perform amniotomy when labor is abnormally slow. Rouse and coworkers (1994) found that amniotomy with oxytocin augmentation for arrested active-phase labor shortened the time to delivery by 44 minutes compared with that of oxytocin alone. A drawback was that it significantly increased chorioamnionitis. As an adjunct to oxytocin infusion, however, amniotomy did not affect the route of delivery.

ACTIVE MANAGEMENT OF LABOR

This term describes a codified approach to the management of labor, which is discussed in detail in [Chapter 17](#) (see p. 439).

23. Forceps Delivery and Vacuum Extraction

INTRODUCTION

The precise incidence of operative vaginal delivery in the United States is unknown, but forceps or vacuum delivery was coded on the birth certificate as the method of delivery for 8 percent of the vaginal births in the United States in 2002 (Martin and colleagues, 2003). Although operative vaginal delivery is still taught in almost all residency programs, there is controversy surrounding this method of delivery (American College of Obstetricians and Gynecologists, 2000; Hankins and colleagues, 1999).

FORCEPS DELIVERY

True forceps were first devised in the late 16th or beginning of the 17th century. The reader is referred to the 19th and earlier editions of *Williams Obstetrics* regarding their history.

DESIGN OF FORCEPS. These instruments basically consist of two crossing branches. Each branch has four components: blade, shank, lock, and handle. Each blade has two curves. The *cephalic curve* conforms to the shape of the fetal head, and the *pelvic curve* corresponds more or less to the axis of the birth canal ([Fig. 23-1](#)). Some varieties are *fenestrated* or *pseudofenestrated* to permit a firmer hold on the fetal head.

The blades are connected to the handles by the *shanks*, which are either parallel as in Simpson forceps, or crossing as in Tucker-McLane forceps. The common method of articulation, the *English lock*, consists of a socket located on the shank at the junction with the handle, into which fits a socket similarly located on the opposite shank ([Figs. 23-1](#) and [23-2](#)). A *sliding lock* is used in some forceps, such as Kielland forceps ([Fig. 23-3](#)).

Figure 23-1. Simpson forceps. Note the ample pelvic curve in the single blade above and the cephalic curve evident in the articulated blades below. The fenestrated blade and the wide shank in front of the English-style lock characterize the Simpson forceps.

Figure 23-2. Tucker-McLane forceps. The blade is solid and the shank is narrow.

Figure 23-3. Kielland forceps. The characteristic features are the sliding lock, minimal pelvic curvature, and light weight.

CLASSIFICATION OF FORCEPS DELIVERIES. A current classification (American College of Obstetricians and Gynecologists, 2000; American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002) for forceps and vacuum operations is summarized in [Table 23-1](#). This classification emphasizes the two most important discriminators of risk for both mother and infant: station and rotation. Station is measured in 0 to 5 centimeters, although some clinicians prefer to divide the lower pelvis into thirds 1+, 2+, and 3+, corresponding to +2 cm, +4 cm, and +5 cm, respectively. Deliveries are categorized as outlet, low, and midpelvic procedures. High operations are those in which instruments are applied above 0 station, and thus before engagement. These have no place in contemporary obstetrics.

INCIDENCE OF FORCEPS DELIVERY. In general, there has been a decline in operative vaginal deliveries with a parallel increase in cesarean deliveries over the past two decades (DiMarco and associates, 2000). In a study from the United States National Hospital Discharge Survey, Kozak and Weeks (2002) reported that the cesarean delivery rate expressed per 100 deliveries had increased from 16.5 in 1980 to 22.9 in 2000. During this same time period, forceps delivery expressed per 100 vaginal deliveries had decreased from 17.7 to 4.0, while the vacuum delivery rate increased from 0.7 to 8.4. Chang and colleagues (2002) studied almost 20,000 deliveries from 1977 to 1999 and reported that the rate of forceps delivery decreased over time while the rate of vacuum delivery increased. These authors also evaluated the impact of gender of the attending physician on operative vaginal delivery rates. The authors concluded that gender per se did not have a significant impact on either the forceps or vacuum delivery rate, when controlled for the year in which the procedure was performed.

TRAINING. In a survey of both residency and fellowship training programs by Hankins and colleagues (1999), it was found that residents are still taught operative vaginal delivery with forceps or vacuum, or both. For example, both residents and fellows were expected to be proficient with both instruments for outlet procedures. Importantly, fewer than half of the residency directors expected proficiency with midforceps delivery. Thus, although resident experience obviously varies among programs, it is doubtful that the majority of residents graduating today are adequately trained or skilled in the art of midpelvic delivery with either forceps or vacuum.

EFFECTS OF REGIONAL ANALGESIA ON INSTRUMENTAL DELIVERY.

Epidural analgesia may be associated with failure of spontaneous rotation to an occiput anterior position, as well as slowing of second-stage labor and decreasing maternal expulsive efforts. For example, Kaminski and associates (1987) documented persistent occiput posterior positions in 27 percent of women given epidural analgesia compared with only 8 percent of those not given epidural analgesia. A number of randomized studies have been performed at Parkland Hospital to ascertain the effects of labor analgesia. Five trials that included 2703 nulliparous women were recently analyzed by Sharma and colleagues (2004). Women given epidural analgesia had a twofold increased rate of forceps delivery compared with those given intravenous analgesia—13 versus 7 percent. Similarly, in their meta-analysis of epidural versus opioid analgesia, Halpern and colleagues (1998) reported that women receiving epidural analgesia were twice as likely to have an instrumental delivery. Both studies are consistent with a comprehensive systematic review performed by Lieberman and O'Donoghue (2002).

FUNCTION OF FORCEPS. Although the most important function of forceps is traction, forceps may be invaluable for rotation, particularly for occiput transverse and posterior positions. In general, Simpson forceps are used to deliver the fetus with a molded head, as is common in nulliparous women. The Tucker-McLane instrument is often used for the fetus with a rounded head, which more characteristically is seen in multiparas. In most situations, however, either instrument is appropriate.

Forces Exerted by the Forceps. The force produced by the forceps on the fetal skull is a complex function of pull and compression by the forceps and friction produced by the maternal tissues. It is impossible to ascertain the amount of force exerted by forceps for an individual patient.

INDICATIONS FOR FORCEPS. Termination of the second stage of labor by forceps delivery or vacuum extraction is indicated in any condition threatening the mother or fetus that is likely to be relieved by delivery (American College of Obstetricians and Gynecologists, 2000). Some maternal indications include heart disease, pulmonary injury or compromise, intrapartum infection, certain neurological conditions, exhaustion, or prolonged second-stage labor. The latter is defined by the American College of Obstetricians and Gynecologists (2002) as more than 3 hours with, and more than 2 hours without, regional analgesia in the nulliparous woman. In the parous woman, a prolonged second stage is defined as more than 2 hours with, and more than 1 hour without, regional analgesia. Shortening of second-stage labor for maternal reasons should generally be accomplished with either outlet or low forceps. Fetal indications for operative vaginal delivery with either forceps or vacuum include prolapse of the umbilical cord, with the other requisites for instrument delivery present; premature separation of the placenta; or a nonreassuring fetal heart rate pattern.

Elective and Outlet Forceps. Forceps generally should not be used electively until the criteria for outlet forceps have been met. The fetal head must be on the perineal floor with the sagittal suture no more than 45 degrees from the anteroposterior diameter. In these circumstances, forceps delivery is a simple and safe operation (Carmona and colleagues, 1995; Hagadorn-Freathy and associates, 1991). Carmona and associates (1995) reported no differences in maternal or infant outcomes with term pregnancies randomized to spontaneous or elective outlet forceps delivery. There is, however, no evidence that use of prophylactic forceps is beneficial in the otherwise normal term labor and delivery.

PROPHYLACTIC OUTLET FORCEPS FOR LOW-BIRTHWEIGHT FETUSES. Fairweather (1981) reported no significant differences in outcomes in neonates who weighed 500 to 1500 g and who were delivered spontaneously or by outlet forceps. Schwartz and colleagues (1983) reported similar findings. Currently, it would appear that there is no obvious advantage to routine outlet forceps delivery of a small fetus.

Prerequisites for Forceps Application. There are at least six prerequisites for successful application of forceps:

1. The head must be engaged. Extensive caput succedaneum formation and molding sometimes make determination of the station of the fetal head difficult. When difficulties of station assignment occur, it is important to realize that a "low-forceps" procedure may actually be a more difficult midforceps operation.
2. The fetus must present as a vertex or by the face with the chin anterior.
3. The position of the fetal head must be precisely known.
4. The cervix must be completely dilated.
5. The membranes must be ruptured.
6. There should be no suspected cephalic-pelvic disproportion.

PREPARATION FOR FORCEPS DELIVERY. Although pudendal block analgesia may prove adequate for outlet forceps operations, either regional analgesia or general anesthesia usually is preferred for low-forceps or midpelvic procedures. The bladder should be emptied.

Forceps Application. Forceps are constructed so that their cephalic curve is closely adapted to the sides of the fetal head (Fig. 23-4). The biparietal diameter of the fetal head corresponds to the greatest distance between the appropriately applied blades. Consequently, the head of the fetus is perfectly grasped only when the long axis of the blades corresponds to the occipitomenal diameter. Thus, the major portion of the blade is lying over the face, while the concave margins of the blades are directed toward either the sagittal suture (occiput anterior position) or the face (occiput posterior position). Applied as such, the forceps should not slip, and traction may be applied most advantageously, as illustrated in Figure 23-5. With most forceps, if one blade is applied over the brow and the other over the occiput, the instrument cannot be locked, or if locked, the blades slip off when traction is applied (Fig. 23-6). For these reasons, the forceps must be applied directly to the sides of the fetal head along the occipitomenal diameter.

Identification of Position. Knowledge of the exact position of the fetal head is essential to a proper cephalic application. With the head low in the pelvis, determination of position is made by examination of the sagittal suture and the fontanelles. When the head is at a higher station, an absolute determination can be made by locating the posterior ear.

Figure 23-4. The fetus is presenting as vertex with occiput anterior crowning. The application of the left blade of the Simpson forceps is shown. Next, the right blade is applied and the blades are articulated.

Figure 23-5. Occiput anterior. Delivery by outlet forceps (Simpson). The direction of gentle traction for delivery of the head is indicated.

Figure 23-6. Incorrect application of forceps, one blade over the occiput and the other over the brow. Forceps cannot be locked and the head is extended with tendency of blades to slip off with traction.

OUTLET FORCEPS DELIVERY. Delivery by outlet forceps of the occiput anterior fetal head is illustrated in [Figures 23-7, 23-8, 23-9, 23-10, 23-11, 23-12](#) and [23-13](#). In such circumstances, the small (posterior) fontanel is directed toward the symphysis pubis. The forceps, if applied to the sides of the pelvis, grasp the head ideally. The forceps are applied as follows: Two or more fingers of the right hand are introduced inside the left posterior portion of the vulva and into the vagina beside the fetal head. The handle of the left branch is then grasped between the thumb and two fingers of the left hand and the tip of the blade is gently passed into the vagina between the fetal head and the palmar surface of the fingers of the right hand ([Figs. 23-7](#) and [23-8](#)). For application of the right blade, two or more fingers of the left hand are introduced into the right, posterior portion of the vagina to serve as a guide for the right blade, which is held in the right hand and introduced into the vagina as described for the left blade. After positioning, the branches are articulated.

Appropriateness of Application. For the occiput anterior position, appropriately applied blades are equidistant from the sagittal suture. In the occiput posterior position, the blades are equidistant from the midline of the face and brow.

Traction. When it is certain that the blades are placed satisfactorily, then gentle, intermittent, horizontal traction is exerted until the perineum begins to bulge. If necessary, rotation to occiput anterior is performed before traction is applied ([Figs. 23-9](#) and [23-10](#)). With traction, as the vulva is distended by the occiput, an episiotomy may be performed if indicated ([Fig. 23-11](#)).

More horizontal traction is applied, and the handles are gradually elevated, eventually pointing almost directly upward as the parietal bones emerge ([Fig. 23-12](#)). As the handles are raised, the head is extended. During upward traction, the four fingers should grasp the upper surface of the handles and shanks, while the thumb exerts the necessary force on their lower surface. During the birth of the head, spontaneous delivery should be simulated as closely as possible. Traction should therefore be intermittent, and the head should be allowed to recede in intervals, as in spontaneous labor. Except when urgently indicated, as in severe fetal bradycardia, delivery should be sufficiently slow, deliberate, and gentle to prevent undue head compression. It is preferable to apply traction only with each uterine contraction.

After the vulva has been well distended by the head, the delivery may be completed in several ways. Some clinicians keep the forceps in place to control the advance of the head. However, the thickness of the blades adds to the distention of the vulva, thus increasing the likelihood of laceration or necessitating a large episiotomy. In such cases, the forceps may be removed and delivery completed by the modified Ritgen maneuver ([Fig. 23-13](#)). If the forceps are removed prematurely, the modified Ritgen maneuver may prove to be a tedious and inelegant procedure.

Figure 23-7. The left handle of the Simpson forceps is held in the left hand. The blade is introduced into the left side of the pelvis between the fetal head and fingers of the operator's right hand.

Figure 23-8. Continued insertion of left blade. Note the arc of the handles as they rotate to be applied to the mother's left.

Figure 23-9. Forceps have been locked. Vertex is rotated from left occiput anterior

to occiput anterior (*arrow*).

Figure 23-10. The vertex is now occiput anterior and the forceps are symmetrically placed and articulated.

Figure 23-11. Horizontal traction.

Figure 23-12. Upward traction (*arrow*) is applied as the head is delivered. Forceps may be disarticulated after head is delivered.

Figure 23-13. Forceps have been disarticulated and removed, and modified Ritgen maneuver (*arrow*) is used to complete delivery of the head.

LOW- AND MIDFORCEPS OPERATIONS. When the head lies above the perineum, the sagittal suture usually occupies an oblique or transverse diameter of the pelvis. In such cases, the forceps should always be applied to the sides of the head.

Left Occiput Anterior Position. The right hand, introduced into the left posterior segment of the vagina, should identify the posteriorly located left ear. At the same time, the right hand serves as a guide for introduction of the left branch of the forceps, which is held in the left hand and applied over the left ear. Two fingers of the left hand are then introduced into the right posterior portion of the pelvis.

The right branch of the forceps, held in the right hand, is then introduced along the left hand as a guide. It must then be applied over the anterior ear of the fetus by gently sweeping the blade anteriorly until it lies directly opposite the blade that was introduced first.

Right Occiput Anterior Position. In right positions, the blades are introduced similarly but in opposite directions. After the blades have been applied to the sides of the head, the left handle and shank lie above the right. Consequently, the forceps do not immediately articulate. Locking of the branches is easily effected, however, by rotating the left around the right to bring the lock into proper position.

Occiput Transverse Positions. If the occiput is in a transverse position, the forceps are introduced similarly, with the first blade applied over the posterior ear and the second rotated anteriorly to a position opposite the first. In this case, one blade lies in front of the sacrum and the other behind the symphysis. Simpson or Tucker-McLane forceps (see [Figs. 23-1](#) and [23-2](#)), or one of their modifications, or the specialized Kielland forceps (see [Fig. 23-3](#)) may be used.

Rotation from Anterior and Transverse Positions. When the occiput is obliquely anterior, it gradually rotates spontaneously to the symphysis pubis as traction is exerted. When it is directly transverse, however, a rotary motion of the forceps is required. Rotation counterclockwise from the left side toward the midline is required when the occiput is directed toward the left, and in the reverse direction when it is directed toward the right side of the pelvis. Infrequently, when forceps are used in transverse positions in anteroposteriorly flattened (platypelloid) pelvises, rotation should not be attempted until the fetal head has reached or approached the pelvic floor. Regardless of the original position of the head, delivery eventually is accomplished by exerting traction downward until the occiput appears at the vulva. After this, the rest of the operation is completed as previously described.

OCCIPUT POSTERIOR POSITIONS. Prompt delivery may at times become necessary when the small (occipital) fontanel is directed toward one of the sacroiliac synchondroses, viz., in right occiput posterior or left occiput posterior positions. When delivery is required in either instance, the head is often imperfectly flexed. In some cases, when the hand is introduced into the vagina to locate the posterior ear, the occiput rotates spontaneously toward the anterior, indicating that manual rotation of the fetal head might easily be accomplished.

Manual Rotation. A hand with the palm upward is inserted into the vagina and the fingers are brought in contact with the side of the fetal head that is to be rotated toward the anterior position, while the thumb is placed over the opposite side of the head. With the occiput in a right posterior position, the left hand is used to rotate the occiput anteriorly in a clockwise direction; the right hand is used for the left occiput posterior position. The head must not be disengaged during rotation.

After the occiput has reached the anterior position, labor may be allowed to continue, or forceps can be used. First one blade is applied to that side of the head that is held by the fingers that are maintaining the occiput in the anterior position. The other blade is immediately applied and delivery accomplished.

Forceps Delivery of Occiput Posterior. If manual rotation cannot be easily accomplished, application of the blades to the head in the posterior position and delivery from the occiput posterior position may be the safest procedure (Fig. 23-14). In many cases, the cause of the persistent occiput posterior position and of the difficulty in accomplishing rotation is an anthropoid pelvis, the architecture of which predisposes to posterior delivery and opposes rotation. When the occiput is directly posterior, horizontal traction should be applied until the base of the nose is under the symphysis. The handles should then be slowly elevated until the occiput gradually emerges over the anterior margin of the perineum. Then, the forceps are directed in a downward motion, and the nose, face, and chin successively emerge from the vulva.

Occiput posterior delivery causes greater distention of the vulva, and a large episiotomy may be needed. Pearl and associates (1993) retrospectively reviewed 564 occiput posterior deliveries. These were compared with 1068 controls. The occiput posterior group had a higher incidence of severe perineal lacerations and extensive episiotomy compared with that of the occiput anterior group. Within the occiput posterior group, operative delivery was associated with a higher incidence of severe perineal lacerations (35 versus 16 percent), vaginal lacerations (18 versus 7 percent), and episiotomy (95 versus 74 percent) than was spontaneous delivery. Consequences of these perineal tears are discussed in Chapter 17 (see p. 435). The infants delivered from the occiput posterior position had a higher incidence of Erb (1 percent) and facial nerve (2 percent) palsies than did those delivered from the occiput anterior position.

Forceps Rotations of Occiput Oblique Posterior. Tucker-McLane, Simpson, or Kielland forceps may be used to rotate the fetal head. The oblique occiput may be rotated 45 degrees to the posterior position or 135 degrees to the anterior position (Fig. 23-15). If rotation is performed with Tucker-McLane or Simpson forceps, the head must be flexed, but this is not necessary with Kielland forceps because they have a more straightened pelvic curve. In rotating the occiput anteriorly with Tucker-McLane or Simpson forceps, the pelvic curvature, originally directed upward, at the completion of rotation is inverted and directed posteriorly. Attempted delivery with the instrument in that position is likely to cause vaginal sulcus tears and sidewall lacerations. To avoid such trauma, it is essential to remove and reapply the instrument as described below.

Figure 23-14. Occiput directly posterior. Low forceps (Simpson) delivery as an occiput posterior. (O = occiput, S = symphysis.) The *arrow* illustrates the point at which time the head should be flexed after the bregma passes under the symphysis. It is evident that to prevent serious perineal lacerations, an extensive episiotomy is most often required.

Figure 23-15. Rotation of obliquely posterior occiput to sacrum (A) and symphysis pubis (B).

FORCEPS ROTATION OF OCCIPUT TRANSVERSE. Specialized skill and training are essential when performing this technically difficult operative vaginal procedure. Either standard forceps, such as pseudofenestrated Simpson, or specialized forceps, such as Kielland, are employed. The latter have a sliding lock and almost no pelvic curve (see Fig. 23-3). On each handle is a small knob that indicates the direction of the occiput. The station of the fetal head must be accurately ascertained to be at, or preferably below, the level of the ischial spines, especially in the presence of extreme molding.

Kielland described two methods of applying the anterior blade. In the *wandering* or *gliding* method, the anterior blade is introduced at the side of the pelvis over the brow or face. The blade is then arched around the brow or face to an anterior position, with the handle of the blade held close to the opposite maternal buttock throughout the maneuver. The second blade is introduced posteriorly and the branches are locked. The second method is the *direct* or *classical* application, in which the anterior blade is introduced first with its cephalic curve directed upward, curving under the symphysis. After it has entered sufficiently far into the uterine cavity, it is turned on its axis through 180 degrees to adapt the cephalic curvature to the head. The reader is referred to the second edition of *Operative Obstetrics* (Gilstrap, 2002) for a more detailed description of the technical aspects of Kielland forceps procedures.

FORCEPS DELIVERY OF FACE PRESENTATION. In the face presentation, with the chin directed toward the symphysis mentum anterior forceps occasionally are used to effect vaginal delivery. The blades are applied to the sides of the head along the occipitomenal diameter, with the pelvic curve directed toward the neck. Downward traction is exerted until the chin appears under the symphysis. Then, by an upward movement, the face is slowly extracted, with the nose, eyes, brow, and occiput appearing in succession over the anterior margin of the perineum (Fig. 23-16). Forceps should not be applied to the mentum posterior presentation, because vaginal delivery is impossible as such.

Figure 23-16. Face presentation, mentum (chin) anterior. Delivery with outlet

forceps (Simpson).

MORBIDITY FROM FORCEPS OPERATIONS

Maternal Morbidity. When considering maternal morbidity from operative vaginal delivery, it is important to compare it with the morbidity from cesarean delivery and not to that from spontaneous vaginal delivery. Some generalizations can be made:

1. Elective outlet forceps with rotations not exceeding 45 degrees are associated with little, if any, increase in maternal morbidity (Carmona and colleagues, 1995).
2. Maternal injury increases significantly with rotations of greater than 45 degrees and at higher stations (Hagadorn-Freathy and associates, 1991; Hankins and Rowe, 1996).
3. The need for blood transfusions is increased with operative vaginal delivery, viz., vacuum extraction (6.1 percent) and forceps (4.2 percent), compared with 1.4 percent with uncomplicated cesarean delivery (Sherman and co-workers, 1993).

LACERATIONS AND EPISIOTOMY. The very conditions that lead to the indications for operative vaginal delivery also increase the need for episiotomy. That said, women randomized to delivery with low forceps had no increase in perineal lacerations relative to those delivering spontaneously (Carmona and colleagues, 1995). Conversely, in a retrospective study of over 2 million vaginal deliveries, Handa and colleagues (2001) found a strong association between anal sphincter laceration and operative vaginal delivery. Hagadorn-Freathy and co-workers (1991) reported rates for third- and fourth-degree episiotomy extensions and vaginal lacerations of 13 percent for outlet forceps, 22 percent for low forceps with less than 45 degrees rotation, 44 percent for low forceps with more than 45 degrees rotation, and 37 percent for midforceps deliveries. Similarly, Bofill and colleagues (1996a, 1996b) found a significant association of moderate and severe perineal injuries with indicated operative deliveries, use of forceps versus vacuum extractor, the need for episiotomy, and delivery from other than outlet station.

Robinson and colleagues (1999) studied perineal trauma in 323 women delivered with forceps or vacuum extraction. The incidence of perineal trauma associated with the combination of episiotomy and forceps delivery was not significantly higher than that with forceps delivery alone—46 versus 55 percent, respectively. Vacuum extraction, however, significantly increased such trauma—35 versus 9 percent—with and without episiotomy, respectively. Others report less perineal trauma with the vacuum extractor. Specifically, Low and co-workers (1993) reported vaginal lacerations in 4.3 percent and fourth-degree episiotomy extensions in 1.6 percent of women undergoing vacuum delivery. Loghis and co-workers (1992) reported anal sphincter involvement in 3 percent of vacuum deliveries and vaginal vault extensions in 2.5 percent.

Ecker and colleagues (1997) reported a significant decrease in the episiotomy rate over a 10-year period from 1984 to 1994 for both forceps (96 to 30 percent) and vacuum deliveries (89 to 39 percent). During the same time period, there was a decrease in fourth-degree but no change in third-degree lacerations. In a review of over 34,000 vaginal births by Goldberg and colleagues (2002), episiotomy rates decreased significantly from 70 percent in 1983 to 19 percent in 2000. Forceps deliveries, however, were associated with higher episiotomy rates as well as third- and fourth-degree lacerations compared with those of spontaneous delivery.

URINARY AND RECTAL INCONTINENCE. There are now a number of studies that indicate that even spontaneous vaginal delivery will be followed by urinary and fecal incontinence in some women. In some, incontinence is temporary and improves with time. In others, it persists and may worsen over time. Extensive episiotomies or lacerations, especially of the anal sphincter, are more likely to cause problems with incontinence than spontaneous vaginal delivery alone (Pollack and associates, 2004; Pregazzi and colleagues, 2002). Because forceps deliveries are associated with an increased incidence of episiotomy, episiotomy with second- or third-degree extension, or deep lacerations, it is not surprising that use of forceps has been associated in some reports with a higher rate of incontinence (Eason and colleagues, 2002; Fitzpatrick and colleagues, 2003; Viktrup and Lose, 2001). Thus, the anterior compartment (responsible for bladder function) or the posterior compartment (responsible for anal function) or both may be involved.

Short-term effects of forceps and vacuum deliveries, especially midcavity deliveries, include postpartum urinary retention and bladder dysfunction (Carley and coworkers, 2002). Arya and colleagues (2001) reported that incontinence after forceps delivery was more likely to persist than incontinence associated with vacuum or spontaneous delivery.

Anal sphincter dysfunction, although associated with spontaneous delivery, also is increased with instrumental vaginal delivery, episiotomy extensions, and deep lacerations. Specifically, Eason and colleagues (2000, 2002) evaluated 949 Canadian women 3 months after delivery. Three percent had fecal incontinence, over one fourth had incontinence of flatus, and both were more common in women who had had anal sphincter injuries and forceps delivery. Sultan and colleagues (1993) reported defecatory symptoms in 38 percent of women after forceps delivery, 12 percent following vacuum delivery, and 4 percent delivered spontaneously with either a mediolateral episiotomy or second-degree lacerations. In another study, Sultan and co-workers (1994) reported that half of women who had third-degree tears had anal incontinence or fecal urgency. Endosonographic sphincter defects were seen in 85 percent of those who had a third-degree tear compared with one third of control women without a sphincter tear. In a French study, de Parades and colleagues (2004) identified sonographic sphincter defects in only 13 percent of women with or without an episiotomy or laceration following forceps delivery. Muscle injury is responsible for most anal dysfunction, however, pudendal nerve damage also plays a role (Tetzschner and colleagues, 1998).

Although the short-term effects on anorectal function associated with operative vaginal delivery are of concern, it is unclear what role these have in long-term morbidity. For example, in a 34-year follow-up after forceps delivery, Bollard and colleagues (2003) reported that significant fecal and urinary incontinence was not associated with forceps delivery. In a follow-up of

primiparous women 3 to 4 years after delivery, Schraffordt Koops and colleagues (2003) found no difference in fecal incontinence according to the method of vaginal delivery— "normal," forceps, or vacuum. Rieger and associates (1997) documented anal sphincter dysfunction in women following spontaneous delivery. Peschers and colleagues (2003) found that both urinary and anal incontinence symptoms were common after vaginal delivery, occurring in 28 to 42 percent of women, but that vacuum delivery did not increase the risk above that of spontaneous vaginal delivery.

Other factors have been associated with fecal incontinence in older women. Some of these are high parity, menopause, prior hysterectomy, and irritable bowel syndrome (Donnelly and colleagues, 1998; Jackson and associates, 1997). In a 30-year follow-up study, Nygaard and co-workers (1997) documented incontinence of flatus in 31, 43, and 36 percent of women who had experienced a disrupted sphincter, an episiotomy, or cesarean delivery, respectively. Several other investigators have documented sphincter dysfunction in women undergoing cesarean delivery (Fynes and co-workers, 1998; MacArthur and colleagues, 1997).

FEBRILE MORBIDITY. Postpartum metritis is more frequent, and often more severe, in women following cesarean delivery compared with that following operative vaginal delivery (Robertson and colleagues, 1990).

Perinatal Morbidity. Operative vaginal delivery, especially if performed from the midpelvic level, may be associated with increased neonatal morbidity (Table 23-2). Towner and colleagues (1999) studied 583,340 term nulliparous women delivered in California between 1992 and 1994. The third delivered by cesarean, forceps, or vacuum were compared with those delivered spontaneously (Table 23-3). The incidence of intracranial hemorrhage was highest in infants delivered by vacuum, forceps, or cesarean after labor had started. These investigators concluded that abnormal labor was the common risk factor.

White and associates (1996) found a significant association of facial nerve palsy with forceps delivery compared with that following spontaneous or cesarean delivery. Gilbert and co-workers (1999), using the same California data cited above, found that delivery with forceps (3.4-fold) or vacuum (2.7-fold) significantly increased the risk for brachial plexus injury compared with that of spontaneous delivery.

MORBIDITY FROM MIDFORCEPS DELIVERIES. Numerous studies have described the association of neonatal morbidity and midforceps operations. Several factors must be considered when interpreting these results. First and foremost, most were conducted prior to the redefined classification of forceps in 1988 by the American College of Obstetricians and Gynecologists (2000). Thus, midforceps were not defined clearly and included deliveries from relatively high stations (0 to +1), as well as difficult rotations. Second, spontaneous vaginal deliveries are not appropriate controls for midforceps. Finally, there is no uniformity in the criteria used to define immediate fetal morbidity.

There are a few studies that used the updated 1988 classification. Specifically, Robertson and associates (1990) reported significantly higher neonatal morbidity in the midforceps group compared with that of cesarean delivery.

Hagadorn-Freathy and colleagues (1991) designed a prospective investigation to test the validity of the 1988 classification on stratifying fetal risk. They classified 357 forceps deliveries by both the old and new systems and compared outcomes. One example was that facial nerve palsy developed in 1.3 percent of infants delivered by outlet forceps and 3.2 percent of those delivered by midforceps using the 1965 classification. This compared with rates of 0.9 percent for outlet forceps, 1.7 percent for low forceps, and 9.2 percent for midforceps using the 1988 classification. Thus, the 1988 classification can be used to usefully discriminate among the risks associated with outlet, low-, and midpelvic forceps deliveries. Because of increased maternal and neonatal morbidity compared with that of low-forceps operations, midforceps deliveries are seldom performed now.

Long-Term Infant Morbidity. Over decades of their use, forceps have been at the center of an evolving controversy regarding possible long-term infant morbidity. Particularly controversial has been the possible association between forceps delivery and decreased measures of intelligence. Some of the early studies used data from the Collaborative Perinatal Project. In one, Broman and co-workers (1975) controlled for socioeconomic status, race, and gender. They reported that infants delivered by midforceps had slightly higher intelligence scores at 4 years of age compared with those of children delivered spontaneously. Using the same database, Friedman and associates (1977, 1984), analyzed intelligence assessments at no less than 7 years of age. They concluded that children delivered by midforceps had lower mean intelligence quotients (IQs) compared with children delivered by outlet forceps. In yet another report from this same database, Dierker and colleagues (1986) compared long-term outcomes of children delivered by midforceps with those of children delivered by cesarean after dystocia. Clearly, this is the most appropriate control group. The investigators reported that neurodevelopmental disability was not associated with delivery by midforceps.

There are other studies concerning long-term morbidity of midforceps deliveries. In one, Nilsen (1984) evaluated 18-year-old men when they were drafted into the Norwegian Army. The study found that those delivered by Kielland forceps had higher intelligence scores than those delivered spontaneously, by vacuum extraction, or by cesarean. Similar data reported by Seidman and colleagues (1991) from more than 52,000 Israeli Defense Forces draftees are shown in Table 23-4. In a collaborative study of over 3000 school-aged children, Wesley and colleagues (1992) found no significant differences in standardized intelligence scores at age 5 years according to the method of delivery. Assessment included 1746 children delivered spontaneously, 1192 children delivered by either low- or midforceps or vacuum operations, and 114 delivered by midforceps or vacuum extraction.

CONCLUSIONS REGARDING MORBIDITY FROM FORCEPS. It is clear that the greatest risk is incurred with true midforceps operations and when rotations of greater than 45 degrees are performed. Most studies in which morbid events were reported were from an era when cesarean delivery rates were still around 5 percent. Thus, they undoubtedly included many forceps deliveries that would, in all likelihood, never be attempted today.

The impact of epidural analgesia on the incidence of low- and midforceps deliveries cannot be discounted (Lieberman and O'Donoghue, 2002). The majority of such cases result from inadequate maternal expulsive forces against a relaxed pelvic sling, and thus they are not usually associated with either relative or absolute cephalopelvic disproportion.

Although it is prudent in these cases to allow a longer second stage of labor, in some women and under some circumstances,

delivery is indicated sooner. Low-forceps rotations for epidural-associated labor abnormalities are likely to be safer than the same operation performed in women with prolonged labor or midpelvic arrest unassociated with conduction analgesia.

It seems reasonable to conclude that outlet and low-forceps operations with rotation of 45 degrees or less, classified by the scheme proposed by the American College of Obstetricians and Gynecologists (2000), can be performed with safety for both mother and fetus if the basic guidelines set forth in this chapter are carefully observed.

TRIAL OF FORCEPS AND FAILED FORCEPS. If an attempt at operative vaginal delivery is anticipated to be difficult, the attempt should be considered a trial. With an operating room both equipped and staffed for immediate cesarean delivery, the trial may proceed. If a satisfactory application of the forceps cannot be achieved, then the procedure is abandoned and delivery accomplished by use of either vacuum extraction or cesarean. Once application has been achieved, gentle downward pulls are made on the forceps. If there is no descent, the procedure is abandoned. In some situations, vacuum extraction may be successful (Ezenagu and colleagues, 1999). If not deemed safe, or if it also fails to effect vaginal delivery, then cesarean delivery is performed.

In a study of 122 women who had a trial of midcavity forceps or vacuum extraction in a setting with full preparations to proceed to cesarean section, Lowe (1987) found no significant difference in immediate neonatal or maternal morbidity compared with that of 42 women delivered for similar indications by cesarean without such a trial of instrumentation. Conversely, neonatal morbidity was higher in 61 women who had "unexpected" forceps or vacuum failure in which there was no prior preparation for immediate cesarean delivery. Williams and colleagues (1991) reported good outcomes for both mother and infant with use of alternate or sequential forceps and vacuum delivery. They achieved an overall vaginal delivery rate of 97 percent in 99 women, all 35 weeks or greater, who had indications for assisted vaginal delivery. We agree with the American College of Obstetricians and Gynecologists (2000), which cautions that these trials are attempted only if the clinical assessment is highly suggestive of a successful outcome.

VACUUM EXTRACTION

In the United States, the device is referred to as the vacuum extractor, whereas in Europe it is commonly referred to as a *ventouse* (from French, literally, *soft cup*). The theoretical advantages of the vacuum extractor over forceps include the avoidance of insertion of space-occupying steel blades within the vagina and of the requirement for precise positioning over the fetal head; the ability to rotate the fetal head without impinging on maternal soft tissues; and the decreased intracranial pressure during traction. All previously described instruments were unsuccessful until Malmstrom (1954) applied a new principle, viz., traction on a metal cap designed so that the suction creates an artificial caput, or *chignon*, within the cup that holds firmly and allows adequate traction.

As with forceps choice, the decision to use a metal or a soft cup appears regional. In the United States, the metal cup generally has been replaced by newer soft cup vacuum extractors. As emphasized by Duchon and associates (1998), however, high-pressure vacuum generates large amounts of force regardless of the cup used. The Silastic cup vacuum device is a reusable instrument with a soft, 65-mm-diameter cup. The Mityvac instrument uses a disposable 60-mm-diameter cup (Fig. 23-17), and the CMI Tender Touch uses a 62-mm cup (Fig. 23-18). Bofill and associates (1996b) reported good results with the Mityvac M-cup.

Loghis and colleagues (1992) compared results of 200 women delivered using a metal cup with those of 200 women in whom a pliable cup was used. No differences were found in the rate of birth canal trauma (11 versus 13 percent), major neonatal scalp trauma (6.5 percent versus 5.5 percent), neonatal jaundice (15.5 percent versus 13.5 percent), or Apgar scores. Kuit and co-workers (1993) found the only advantage of the soft cups was a lower incidence of scalp injury. In this study, both rigid and pliable cups had an associated episiotomy extension rate of 14 percent. Vaginal lacerations were 16 percent with rigid cups and 10 percent with pliable cups. Johanson and Menon (2000a) analyzed results from nine randomized trials. They found that soft cups had a higher failure rate (1.65 times) but were associated with less scalp injury (0.45 times) than rigid cups. In a review, Vacca (2002) concluded that randomized trials indicate fewer scalp lacerations with the soft cup, but that the rate of cephalohematomas and subgaleal hemorrhage were similar between soft and rigid cups.

INDICATIONS AND PREREQUISITES. Generally, the indications and prerequisites for the use of the vacuum extractor for delivery are the same as for forceps delivery (American College of Obstetricians and Gynecologists, 2000). The tendency to attempt vacuum deliveries at stations higher than is usually attempted with forceps is worrisome (Broekhuizen and colleagues, 1987). In a recent review of vacuum extraction, Kosca and Gimovsky (2002) concluded that contraindications to vacuum extraction include operator inexperience, inability to assess fetal position, high station, and suspicion of cephalopelvic disproportion. Relative contraindications for delivery using vacuum extraction include face or other nonvertex presentations, fetal coagulopathy, known macrosomia, and recent scalp blood sampling. Generally, vacuum extraction is reserved for fetuses 34 weeks or older.

TECHNIQUE. Proper cup placement is the most important determinant of success in vacuum extraction. The center of the cup should be over the sagittal suture and about 3 cm in front of the posterior fontanelle toward the face. Anterior placement on the fetal cranium ☩— near the anterior fontanelle rather than over the occiput ☩— will result in cervical spine extension unless the fetus is small. Similarly, asymmetrical placement relative to the sagittal suture may worsen asynclitism. Cup placement for elective use in occiput anterior positions is seldom difficult. In contrast, when the indication for delivery is failure to descend caused by occipital malposition, with or without asynclitism or deflexion, cup placement can be very difficult (Lucas, 1994).

Entrapment of maternal soft tissue predisposes the mother to lacerations and hemorrhage and virtually assures cup "pop-off." The full circumference of the cup should be palpated both before and after the vacuum has been created, as well as prior to traction. When using rigid cups, it is recommended that the vacuum be created gradually by increasing the suction by 0.2 kg/cm² every 2 minutes until a negative pressure of 0.8 kg/cm² is reached. With soft cups, negative pressure can be increased to 0.8 kg/cm² over as little as 1 minute (Hankins and associates, 1995; Kuit and colleagues, 1993). Some authors suggest that 0.6 kg/cm² is the optimal peak pressure (Lucas, 1994). Listed in [Table 23-5](#) are conversions of various units of pressures used by different instruments.

Traction should be intermittent and coordinated with maternal expulsive efforts. Traction may be initiated by using a two-handed technique, viz., the fingers of one hand are placed against the suction cup, while the other hand grasps the handle of the instrument. A theoretical advantage of the vacuum cup is that it usually will detach prior to creating tractive forces sufficient to cause fetal injury. Vacuums offer no advantage for avoidance of shoulder dystocia. Manual torque to the cup should be avoided as it may cause cephalohematomas and, with metal cups, "cookie-cutter"-type scalp lacerations. Vacuum extraction should be considered a trial, and without early and clear evidence of descent toward delivery, an alternate delivery approach should be considered. As a general guideline, progressive descent should accompany each traction attempt. Neither data nor consensus are available regarding the number of pulls required to effect delivery, the maximum number of cup detachments that can be tolerated, or optimal total duration of the procedure. A cup pop-off due to technical failure or less than optimal placement should not be equated with a pop-off under ideal conditions of exact cup placement and optimal vacuum maintenance. The former may merit either several additional attempts at placement and delivery or, alternatively, a trial of forceps (Ezenagu and colleagues, 1999; Williams and co-workers, 1991). Conversely, the latter situation is highly suggestive of relative or absolute disproportion or asynclitism. As with forceps procedures, there should be a willingness to abandon attempts at vacuum extraction if satisfactory progress is not made (American College of Obstetricians and Gynecologists, 2000).

COMPLICATIONS. Complications of the vacuum extractor include scalp lacerations and bruising, subgaleal hematomas, cephalohematomas, intracranial hemorrhage, neonatal jaundice, subconjunctival hemorrhage, clavicular fracture, shoulder dystocia, injury of sixth and seventh cranial nerves, Erb palsy, retinal hemorrhage, and fetal death (Broekhuizen and associates, 1987; Galbraith, 1994; Govaert and colleagues, 1992). Significant scalp injuries, hematomas, and resulting hyperbilirubinemia are more common with the metal cup instruments compared with the soft cup devices (American College of Obstetricians and Gynecologists, 2000; Johanson and Menon, 2000a).

In a review by Plauche (1979) of the Malmstrom vacuum extractor, scalp injury ranged from 0.8 to 33 percent, cephalohematoma from 1 to 26 percent, and subgaleal hemorrhage from 0 to 10 percent. Similar results have been reported by Benjamin and Khan (1993) and Kuit and associates (1993). Conversely, Berkus and associates (1985), found no increase in serious neonatal morbidity, including retinal hemorrhage, for the Silastic vacuum extractor compared with that associated with spontaneous delivery.

The Food and Drug Administration (FDA) issued a Public Health Advisory in 1998 regarding the possible association of vacuum-assisted delivery with serious fetal complications, including death. During a 4-year period, the FDA received reports of nine serious fetal injuries and 12 newborn deaths, which was a significant increase over the preceding 11 years. In a response to this advisory, the American College of Obstetricians and Gynecologists (1998) issued a Committee Opinion recommending the continued use of vacuum-assisted delivery devices when appropriate. They estimated that there is approximately one adverse event per 45,455 vacuum extractions per year. Mikovsky and Watson (2001) reviewed obstetrical vacuum extraction.

RECOMMENDATIONS REGARDING VACUUM DELIVERY. Considering the 1998 FDA Public Health Advisory, the following recommendations seem reasonable:

1. The classification of vacuum deliveries should be the same as that utilized for forceps deliveries (including station).
2. The same indications and contraindications utilized for forceps deliveries should be applied to vacuum-assisted deliveries.
3. The vacuum should not be applied to an unengaged vertex, that is, above 0 station.
4. The individual performing or supervising the procedure should be an experienced operator.
5. The operator should be willing to abandon the procedure if it does not proceed easily or if the cup pops off more than three times.

COMPARISON OF VACUUM EXTRACTION WITH FORCEPS

There have been numerous studies comparing vacuum extraction with forceps deliveries. Vacca and associates (1983) conducted a randomized, prospective study comparing metal cup vacuum extraction with forceps delivery. They reported a higher frequency of maternal trauma and blood loss in the forceps group, but an increase in the incidence of neonatal jaundice in the vacuum group. Bofill and colleagues (1996b) randomized 637 women to forceps versus vacuum extraction with the Mityvac M-cup. There were significantly more third- and fourth-degree lacerations (29 versus 12 percent) in the forceps-delivered group. Conversely, the incidence of shoulder dystocia and cephalohematomas was doubled in the vacuum group.

Other investigators have found decreased maternal trauma and similar neonatal morbidity in infants delivered by vacuum compared with forceps (Berkus, 1985; Broekhuizen, 1987; Dell, 1985; Williams, 1991, and all their colleagues). Infants delivered with forceps have more marks and bruising from the instrument (Johnson and associates, 2004). Although retinal hemorrhage occasionally is seen with vacuum usage, it has no apparent long-term effects. Johanson and Menon (2000b) analyzed 10 randomized trials and confirmed that vacuum extraction was associated with less maternal but more fetal trauma, for example, cephalohematoma and retinal hemorrhage.

The data are sparse regarding long-term neurological outcome in newborns delivered by vacuum extraction. In the report of an 18-year follow-up by Nilsen (1984), the mean intelligence score of 38 male infants delivered by vacuum was not different from the national average. Seidman and associates (1991) reported in their adjusted analysis a higher mean IQ score at age 17 in those delivered by vacuum or forceps compared with spontaneous delivery (see [Table 23-4](#)). Johanson and colleagues (1999) performed a 5-year follow-up of a randomized trial of forceps versus vacuum delivery in over 600 women. Almost half in each group reported urinary incontinence or fecal urgency. These authors also reported that there were no significant differences in child development in the two groups.

24. Breech Presentation and Delivery

INTRODUCTION

When the buttocks of the fetus enter the pelvis before the head, the presentation is *breech*. The term probably derives from the same word as *britches*, which described a cloth covering the loins and thighs. As shown in [Table 24-1](#), breech presentation is more common remote from term. Most often, however, before the onset of labor the fetus turns spontaneously to a cephalic presentation, so that breech presentation persists in only about 3 to 4 percent of singleton deliveries. Specifically, the annual rate of breech presentation at delivery in nearly 150,000 infants delivered at Parkland Hospital in the 10-year period ending in 2002 was 3.6 percent.

ETIOLOGY

As term approaches, the uterine cavity usually accommodates the fetus in a longitudinal lie with the vertex presenting. Factors other than gestational age that appear to predispose to breech presentation include hydramnios, uterine relaxation associated with great parity, multiple fetuses, oligohydramnios, hydrocephaly, anencephaly, previous breech delivery, uterine anomalies, and pelvic tumors. Fianu and Vaclavinkova (1978) provided sonographic evidence of a much higher prevalence of placental implantation in the cornual-fundal region for breech presentation (73 percent) than for vertex presentations (5 percent). The frequency of breech presentation also is increased with placenta previa, but only a small minority of breech presentations are associated with a previa. No strong correlation has been shown between breech presentation and a contracted pelvis.

COMPLICATIONS

In the persistent breech presentation, an increased frequency of the following complications can be anticipated:

1. Perinatal morbidity and mortality from difficult delivery.
2. Low birthweight from preterm delivery, growth restriction, or both.
3. Prolapsed cord.
4. Placenta previa.
5. Fetal, neonatal, and infant anomalies.
6. Uterine anomalies and tumors.

DIAGNOSIS

The varying relations between the lower extremities and buttocks of breech presentations form the categories of frank, complete, and incomplete breech presentations. With a *frank breech* presentation, the lower extremities are flexed at the hips and extended at the knees, and thus the feet lie in close proximity to the head ([Fig. 24-1](#)). A *complete breech* presentation differs in that one or both knees are flexed ([Fig. 24-2](#)). With *incomplete breech* presentation, one or both hips are not flexed and one or both feet or knees lie below the breech, such that a foot or knee is lowermost in the birth canal ([Fig. 24-3](#)). Footling breech is an incomplete breech with one or both feet below the breech.

Figure 24-1. Frank breech presentation.

Figure 24-2. Complete breech presentation.

Figure 24-3. Double-footling breech presentation in labor with membranes intact. Note possibility of umbilical cord (C) accident at any instant, especially after rupture of membranes.

ABDOMINAL EXAMINATION. Use of the Leopold maneuvers to diagnose presentation is discussed in [Chapter 17](#) (see p. 412) and shown in [Figure 17-8](#). Its accuracy has been reported to be high by some investigators (Lydon-Rochelle and colleagues, 1993) but not others (Thorp and co-workers, 1991). Typically, with the first Leopold maneuver, the hard, round, readily ballotable fetal head is found to occupy the fundus. The second maneuver indicates the back to be on one side of the abdomen and the small parts on the other. On the third maneuver, if engagement has not occurred — the intertrochanteric diameter of the fetal pelvis has not passed through the pelvic inlet — the breech is movable above the pelvic inlet. After engagement, the fourth maneuver shows the firm breech to be beneath the symphysis. Fetal heart sounds usually are heard loudest slightly above the umbilicus, whereas with engagement of the fetal head, the heart sounds are loudest below the umbilicus.

Figure 17-8. Longitudinal lie. Left occiput anterior position (LOA) (Leopold maneuvers).

VAGINAL EXAMINATION. With the frank breech presentation, both ischial tuberosities, the sacrum, and the anus usually are palpable, and after further descent, the external genitalia may be distinguished. Especially when labor is prolonged, the buttocks may become markedly swollen, rendering differentiation of face and breech very difficult — the anus may be mistaken for the mouth and the ischial tuberosities for the malar eminences. Careful examination, however, should prevent this error, because the finger encounters muscular resistance with the anus, whereas the firmer, less yielding jaws are felt through the mouth. Furthermore, the finger, upon removal from the anus, sometimes is stained with meconium. The mouth and malar eminences form a triangular shape, whereas the ischial tuberosities and anus are in a straight line. The most accurate information, however, is based on the location of the sacrum and its spinous processes, which establishes the diagnosis of position and variety.

In complete breech presentations, the feet may be felt alongside the buttocks, and in footling presentations, one or both feet are inferior to the buttocks. In footling presentations, the foot can readily be identified as right or left on the basis of the relation to the great toe. When the breech has descended farther into the pelvic cavity, the genitalia may be felt.
