IMAGING TECHNIQUES. Ideally, *ultrasound* should be used to confirm a clinically suspected breech presentation and to identify, if possible, any fetal anomalies. If cesarean delivery is planned, additional imaging is not indicated. If, however, vaginal delivery is considered, the type of breech presentation and the degree of flexion or deflexion of the head is important. Ultrasound also may supply this additional information (Fontenot and associates, 1997; Rojansky and colleagues, 1994). *Computed tomographic (CT) scanning* also can be used and will provide pelvic measurements and configuration at lower doses of radiation than standard radiography (see [Chap. 20](#), p. 504). *Magnetic resonance imaging (MRI)* provides reliable information about pelvic capacity and architecture without ionizing radiation, but it is not always readily available (van Loon and colleagues, 1997).

The role of x-ray pelvimetry in deciding the mode of delivery for breech presentation is controversial (Morrison and co-authors, 1995). Cheng and Hannah (1993) reviewed 15 studies of breech delivery at term in which either x-ray or CT pelvimetry was used as one of the criteria for allowing vaginal delivery. They concluded that although the utility of x-ray pelvimetry was difficult to assess because "permissible" pelvic dimensions varied among studies, in most there was no correlation between pelvic measurements and labor outcome. One study demonstrated that the incidence of complicated labor rose with decreasing pelvic capacity (Ohlsen, 1975). Van Loon and colleagues (1997) reported that although MRI pelvimetry did not significantly lower the overall cesarean rate or improve neonatal outcomes, its use was associated with a lower rate of emergency cesarean delivery.

PROGNOSIS

Both mother and fetus are at greater risk with breech presentation compared with cephalic presentation, but to nowhere near the same degree. In an analysis of 57,819 pregnancies in the Netherlands, Schutte and colleagues (1985) reported that even after correction for gestational age, congenital defects, and birthweight, perinatal mortality was higher in breech infants. They concluded that breech presentation may not be coincidental, but rather is a consequence of poor fetal quality. Nelson and Ellenberg (1986) observed that one third of children with cerebral palsy who were in a breech presentation at birth also had major noncerebral malformations. Finally, Krebs and associates (1999) reported that cerebral palsy in breech-presenting fetuses was not related to the mode of delivery. Thus, obstetrical intervention will not eliminate all mortality and long-term morbidity associated with breech presentation.

MATERNAL MORBIDITY. Because of the greater frequency of operative delivery, including cesarean delivery, there is higher maternal morbidity and slightly higher mortality for pregnancies complicated by persistent breech presentation (Collea and co-authors, 1980). This risk likely is increased even more with emergency surgery instead of elective cesarean delivery (Bingham and Lilford, 1987). Labor length is similar to that with cephalic presentation (Hall and Kohl, 1956).

PERINATAL MORBIDITY AND MORTALITY. The prognosis for the fetus in a breech presentation is considerably worse than when in a vertex presentation. The major contributors to perinatal loss are preterm delivery, congenital anomalies, and birth trauma. Thirty years ago, Brenner and associates (1974) reported that at every stage of gestation and in the neonatal period, neonatal deaths were significantly greater among breeches. Congenital abnormalities were identified in 6.3 percent of breech deliveries compared with 2.4 percent of nonbreech deliveries. Contemporaneous

outcomes, in which careful assessment is made before vaginal delivery is attempted and cesarean delivery rates generally exceed 60 percent, are much improved. Albrechtsen and colleagues (1997) reported that perinatal mortality in 45,579 breech deliveries decreased from 9 percent in the period from 1967 through 1976 to 3 percent in 1987 through 1994. Su and colleagues (2003) reported that avoiding labor augmentation and having an experienced obstetrician present at birth significantly reduces the risk of adverse perinatal outcomes for breech fetuses who undergo vaginal birth.

VAGINAL DELIVERY

Delivery of the breech draws the umbilicus and attached cord into the pelvis, which compresses the cord. Therefore, once the breech has passed beyond the vaginal introitus, the abdomen, thorax, arms, and head must be delivered promptly. This involves delivery of successively less readily compressible parts. With a term fetus, some degree of head molding may be essential for it to negotiate the birth canal successfully. Thus, in certain cases:

1. Delivery may be delayed many minutes while the aftercoming head accommodates to the maternal pelvis, resulting in hypoxia and acidemia, which can become severe; or
2. Delivery may be forced, causing trauma from compression, traction, or both.

With a preterm fetus, the disparity between the size of the head and buttocks is even greater than with a larger fetus. At times, the buttocks and lower extremities of the preterm fetus will pass through the cervix and be delivered, and yet the cervix will not be dilated adequately for the head to escape without trauma (Bodmer and associates, 1986). In this circumstance, *Duhrssen incisions* of the cervix, as shown in [Figure 24-4](#), may be lifesaving. Another mechanical problem with breech delivery is entrapment of the fetal arm behind the neck (nuchal arm), which complicates up to 6 percent of vaginal breech deliveries and is associated with increased neonatal mortality (Cheng and Hannah, 1993).

The frequency of cord prolapse is increased when the fetus is small or when the breech is not frank. In the report by Collea and colleagues (1978), the incidence with frank breech presentation was about 0.5 percent, which is similar to 0.4 percent reported for cephalic presentations (Barrett, 1991). In contrast, the incidence of cord prolapse with complete breech presentation was 5 percent, and it was 15 percent with footling breeches. Soernes and Bakke (1986) confirmed earlier observations that umbilical cord length is significantly shorter in breech presentations. Moreover, multiple coils of cord entangling the fetus are more common with breech presentations (Spellacy and associates, 1966). These umbilical cord abnormalities likely play a role both in the development of breech presentation and in the relatively high incidence of a nonreassuring fetal heart rate pattern in labor.

Apgar scores, especially at 1 minute, of vaginally delivered breech infants are generally lower than those of breech infants born by elective cesarean delivery (Flanagan and co-workers, 1987). Compared with cephalic deliveries, umbilical artery blood pH and bicarbonate are lower, and P_{CO_2} is higher (Christian and Brady, 1991). Socol and colleagues (1988), however, concluded that although cesarean delivery improved Apgar scores, it did not improve acid-base status. Flanagan and co-workers (1987) emphasized that ultimate infant outcome for breech birth was not worsened by these significant differences in Apgar scores or acid-base status at birth.

Figure 24-4. Duhrssen incisions at 10 o'clock (already cut) and 2 o'clock (being cut with bandage scissors) to relieve entrapped aftercoming head. Infrequently, an additional incision is required at 6 o'clock. The incisions are so placed as to minimize bleeding from the laterally located cervical branches of the uterine artery. After delivery, the incisions are repaired as described on page 835 (see Fig. 35-27).

UNFAVORABLE PELVIS. Because there is no time for molding of the aftercoming head, a moderately contracted pelvis that had not previously caused problems in delivery of an average-size cephalic fetus might prove dangerous with a breech. Rovinsky and colleagues (1973) urged not only accurate measurements of the pelvic dimensions but also precise evaluation of the pelvic architecture rather than reliance on pelvic indexes. Gynecoid (round) and anthropoid (elliptical) pelvises are favorable configurations, but platypelloid (anteroposteriorly flat) and android (heart-shaped) pelvises are not (see [Chap. 2](#), p. 35).

HYPEREXTENSION OF THE FETAL HEAD. In perhaps 5 percent of term breech presentations, the fetal head may be in extreme hyperextension ([Fig. 24-5](#)). These presentations have been referred to as the *stargazer fetus*, and in Britain as the *flying fetus*. With such hyperextension, vaginal delivery may result in injury to the cervical spinal cord. In general, marked hyperextension after labor has begun is considered an indication for cesarean delivery (Svenningsen and associates, 1985).

Figure 24-5. Radiograph of a fetus presenting as a complete breech and with a markedly hyperextended cervical spine (*arrow*) and head.

LABOR INDUCTION AND AUGMENTATION. Induction of labor in women with a breech

presentation is defended by some clinicians and condemned by others. Brenner and associates (1974) found no significant differences in perinatal mortality and Apgar scores between infants with induced versus spontaneous labor. In oxytocin-augmented labor, however, infant mortality rates were higher and Apgar scores were lower. Fait and colleagues (1998) reported that 12 of 23 women with a breech presentation and an unripe cervix who underwent induction had a successful vaginal delivery with no neonatal complications. At Jackson Memorial Hospital in Miami, oxytocin is used in a manner similar to that for vertex presentations (Diro and associates, 1999). At Parkland Hospital, cesarean delivery is preferred to oxytocin induction or augmentation when there is a viable fetus. Induction may be attempted by amniotomy alone for pregnancies otherwise suitable for a trial of vaginal delivery. At the University of Alabama at Birmingham, oxytocin is employed only if clinical factors are favorable for vaginal delivery, and CT pelvimetry confirms an adequate pelvis.

FOOTLING BREECH. The possibility of compression of a prolapsed cord or a cord entangled around the extremities as the breech fills the pelvis is a threat to the fetus (see [Fig. 24-3](#)).

TERM FETUS. Cheng and Hannah (1993) conducted a systematic search of the world literature regarding term breech delivery and found reports published between 1966 and 1992. A total of 24 studies encompassing 11,721 women were selected because these compared *planned* vaginal with *planned* cesarean delivery for the term, singleton breech fetus. The corrected perinatal mortality rate ranged from 0 to 48 per 1000 births. All but two of the 77 perinatal deaths were in women allowed to deliver vaginally. The main causes of death were head entrapment, cerebral injury and intracranial hemorrhage, cord prolapse, and severe asphyxia. The overall neonatal mortality and morbidity resulting from trauma were increased significantly in the planned vaginal delivery groups, with a typical odds ratio of 3.86. Similarly, Gifford and co-workers (1995b) performed a meta-analysis of outcomes after term breech delivery. Although acknowledging the many methodological limitations of extant studies, they observed that a trial of labor was associated with an increased risk of perinatal injury or death.

Only two of the 24 reports reviewed by these investigators were randomized trials, and both were from the same institution. Collea and colleagues (1980) reported the results of 208 women with frank breech fetuses at term. Almost half of these women were excluded from further consideration because of possible fetopelvic disproportion based on x-ray pelvimetry. A total of 60 infants eventually were delivered vaginally and all survived, although two sustained brachial plexus injuries. There were no perinatal deaths, but half of the 148 women who had cesarean deliveries experienced significant morbidity compared with only 7 percent of 60 women who were delivered vaginally.

Gimovsky and colleagues (1983) studied 105 nonfrank breech fetuses and reported similar findings. Although these two trials concluded that vaginal breech delivery was relatively safe, only 110 fetuses were actually allowed a trial of labor. As emphasized by Eller and Van Dorsten (1995), this small number does not provide sufficient statistical power to demonstrate differences in uncommon adverse outcomes such as perinatal death and birth injury. Lindqvist and associates (1997), in a nationwide Swedish Registry study from 1991 and 1992, found similar mortality with vaginal compared with cesarean delivery. The opposite conclusion was reached by Rietberg and colleagues (2003) in their study of almost 34,000 term breech births in the Netherlands from 1995 to 1999. After the study by Hannah and colleagues (2000) showed increased neonatal morbidity and mortality, elective cesarean breech delivery in the Netherlands doubled from 31 to 62 percent in 2000 and 2001, respectively (Molkenboer and associates, 2003).

PRETERM FETUS. The aftercoming head of a preterm fetus may be trapped by a cervix that is sufficiently effaced and dilated to allow passage of the thorax but not of the less-compressible head. The consequences of vaginal delivery in this circumstance all too often have been both hypoxia and physical trauma, both of which are especially deleterious to the preterm infant.

There are no randomized studies regarding delivery of the preterm breech fetus. Penn and colleagues (1996) attempted such a study in 26 hospitals in England and discontinued the trial after 17 months because only 13 women could be recruited. Retrospective studies have yielded conflicting results. Bowes and colleagues (1979) and Main and co-workers (1983) found that preterm infants undergoing cesarean delivery had a better prognosis. Others have concluded that vaginal delivery did not significantly increase perinatal mortality (Olshan and co-workers, 1984; Rosen and Chik, 1984; Westgren and co-workers, 1985a). In another study, Wolf and colleagues (1999) compared preterm breech fetuses delivered at two tertiary care facilities in the Netherlands. At one center, vaginal delivery was preferred and the cesarean delivery rate was only 17 percent. At the other center, the cesarean delivery rate was 85 percent. These investigators found no difference in 2-year survival without disability or handicap.

The National Institute of Child Health and Human Development Neonatal Research Network (Malloy and co-workers, 1991) analyzed data from 437 very-low-birthweight breech infants admitted to seven neonatal intensive care centers. After adjusting for several variables, the risk of intraventricular hemorrhage and neonatal death was not significantly affected by the mode of delivery for fetuses weighing less than 1500 g. A similar analysis was reported from the Netherlands by Gravenhorst and co-workers (1993). Perinatal follow-up data were collected on 899 singleton, nonanomalous infants of less than 32 weeks' gestation, with birthweights of less than 1500 g. These investigators could not conclusively resolve whether cesarean delivery was advantageous compared with vaginal delivery of infants.

CURRENT STATUS OF VAGINAL BREECH DELIVERY. In 2002, 87 percent of breech fetuses in the United States were delivered by cesarean (Martin and colleagues, 2002). The number of skilled operators with the ability to safely select and vaginally deliver breech fetuses continues to dwindle. Medicolegal concerns make it difficult to train residents to perform such deliveries, and two groups of investigators who have attempted trials of breech delivery concluded that such studies were likely impossible (Penn and Steer, 1990; Zlatnik, 1993).

As mentioned earlier, Hannah and colleagues (2000) reported results from a multinational randomized trial of planned vaginal versus planned cesarean delivery for women with a term breech presentation. A total of 2083 women were randomized: 1041 to planned cesarean and 1042 to planned vaginal delivery. In the planned vaginal delivery group, 57 percent were actually delivered vaginally. Overall, planned cesarean delivery was associated with a reduction in perinatal mortality from 13 per 1000 to 3 per 1000 and a reduction in "serious" neonatal morbidity from 3.8 to 1.4 percent. Maternal complications were similar

between the groups.

On the basis of this international trial, the American College of Obstetricians and Gynecologists (2001) has concluded that, except in cases of "advanced labor" and "imminent delivery," which are not otherwise defined, women with persistent singleton breech presentation at term should undergo a planned cesarean delivery. We have taken issue with this mandate (Hauth and Cunningham, 2002). Our objections center on the College's reliance on the trial of Hannah and colleagues (2000). A number of similar criticisms were discussed in a series of correspondence to the editor of *The Lancet, Obstetrics & Gynecology*, and the *British Medical Journal* (Apuzzio and associates, 2002; Biswas, 2001; Cunha-Filho and Passos, 2001; Leung and Pun, 2001; Premru-Srsen, 2001; Somerset, 2002; Stuart, 2001; Uchida and Murakami, 2001). These issues include that (1) among the 1025 women enrolled from countries with low perinatal mortality rates, perinatal deaths were infrequent and did not differ significantly between groups—none in 514 women in the planned cesarean compared with 3 of 511 in the planned vaginal delivery group; (2) most components included in the "serious" neonatal morbidity composite do not actually portend long-term disability; (3) fewer than 10 percent of women in the trial underwent pelvimetry using radiography, CT scanning, or MRI; and (4) in over 30 percent of participants, the attitude of the fetal head was determined only by clinical methods.

At least three contemporary single-center studies support a trial of vaginal delivery for selected breech-presenting term fetuses. Irion and associates (1998) reported significantly fewer maternal complications, but no difference in corrected neonatal morbidity or mortality between 385 attempted vaginal breech deliveries—70 percent of whom were delivered vaginally—compared with that of 320 planned cesarean deliveries. Giuliani and associates (2002) reported that in their institution vaginal breech delivery was achieved in half of 699 consecutive, term breech-presenting fetuses, with no short- or long-term differences in outcome for infants delivered vaginally compared with those delivered by cesarean. Alarab and associates (2004) reported no serious adverse neonatal outcomes in 146 term breech infants— one fourth of all their breeches—who were delivered vaginally during 3 1/2 years in their institution.

Based on reports such as these, as well as our collective experiences at Parkland Hospital and the University of Alabama at Birmingham Hospital, women with selected frank breech presentations continue to be offered a trial of vaginal delivery on an individualized basis and with approval of the attending faculty. In these women, fetal weight is estimated to be between 2000 and 3500 g. Under these conditions, between 10 and 20 percent of singleton breeches are delivered vaginally.

Recommendations for Delivery. A diligent search for any other complication, actual or anticipated, that might justify cesarean delivery has become a feature of most philosophies for managing breech delivery. Cesarean delivery is commonly but not exclusively used in the following circumstances:

1. A large fetus.
2. Any degree of contraction or unfavorable shape of the pelvis.
3. A hyperextended head.
4. When delivery is indicated in the absence of spontaneous labor (some clinicians use oxytocin augmentation).
5. Uterine dysfunction (some use oxytocin augmentation).
6. Incomplete or footling breech presentation.
7. An apparently healthy and viable preterm fetus with the mother in either active labor or in whom delivery is indicated.
8. Severe fetal growth restriction.
9. Previous perinatal death or children suffering from birth trauma.
10. A request for sterilization.
11. Lack of an experienced operator.

TECHNIQUES FOR BREECH DELIVERY

LABOR AND SPONTANEOUS DELIVERY. There are fundamental differences between labor and delivery in cephalic and breech presentations. With a cephalic presentation, once the head is delivered, the rest of the body typically follows without difficulty. With a breech, however, successively larger and very much less compressible parts of the fetus are born. Spontaneous complete expulsion of the fetus who presents as a breech, as subsequently described, is seldom accomplished successfully. Therefore, as a rule, vaginal delivery requires skilled participation by the obstetrician for a favorable outcome.

Engagement and descent usually take place with the bitrochanteric diameter in one of the oblique pelvic diameters. The anterior hip usually descends more rapidly than the posterior hip, and when the resistance of the pelvic floor is met, internal rotation of 45 degrees usually follows, bringing the anterior hip toward the pubic arch and allowing the bitrochanteric diameter to occupy the anteroposterior diameter of the pelvic outlet. If the posterior extremity is prolapsed, however, it rotates to the symphysis pubis rather than the anterior hip.

After rotation, descent continues until the perineum is distended by the advancing breech, and the anterior hip appears at the vulva. By lateral flexion of the fetal body, the posterior hip then is forced over the perineum, which retracts over the buttocks, thus allowing the infant to straighten out when the anterior hip is born. The legs and feet follow the breech and may be born spontaneously or with aid.

After the birth of the breech, there is slight external rotation, with the back turning anteriorly as the shoulders are brought into relation with one of the oblique diameters of the pelvis. The shoulders then descend rapidly and undergo internal rotation, with

the bisacromial diameter occupying the anteroposterior plane. Immediately following the shoulders, the head, which is normally sharply flexed upon the thorax, enters the pelvis in one of the oblique diameters and then rotates in such a manner as to bring the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.

The breech may engage in the transverse diameter of the pelvis, with the sacrum directed anteriorly or posteriorly. The mechanism of labor in the transverse position differs only in that internal rotation occurs through an arc of 90 rather than 45 degrees. Infrequently, rotation occurs in such a manner that the back of the infant is directed posteriorly instead of anteriorly. Such rotation should be prevented if possible. Although the head may be delivered by allowing the chin and face to pass beneath the symphysis, the slightest traction on the body may cause extension of the head, which increases the diameter of the head that must pass through the pelvis.

METHODS OF VAGINAL DELIVERY. There are three general methods of breech delivery through the vagina:

1. *Spontaneous breech delivery.* The infant is expelled entirely spontaneously without any traction or manipulation other than support of the infant.
2. *Partial breech extraction.* The infant is delivered spontaneously as far as the umbilicus, but the remainder of the body is extracted or delivered with operator traction and assisted maneuvers, with or without maternal expulsive efforts.
3. *Total breech extraction.* The entire body of the infant is extracted by the obstetrician.

The three varieties of breech presentation are illustrated in [Figures 24-1](#), [24-2](#), and [24-3](#). Because the technique of breech extraction differs in a complete, incomplete, and frank breech, these are considered subsequently in two separate sections.

MANAGEMENT OF LABOR. During labor, both mother and fetus are at considerably increased risk compared with that of a woman with a cephalic presentation (Kunzel, 1994). A rapid assessment should be made to establish the status of the membranes, labor, and fetal condition. Close surveillance of fetal heart rate and uterine contractions is begun at admission. Immediate recruitment of the necessary nursing, obstetrical, and anesthesia team to accomplish a vaginal or abdominal delivery also should be accomplished. The nursery is notified. A venous catheter is inserted and an infusion begun as soon as the woman arrives in the labor suite. Emergency induction of anesthesia, or hemorrhage from lacerations or from uterine atony, are but two of many reasons that may require immediate intravenous access for the administration of medications, fluids, or blood.

Stage of Labor. Assessment of cervical dilatation and effacement and the station of the presenting part are essential for planning the route of delivery. If labor is too far advanced, there may not be sufficient time to obtain x-ray pelvimetry. This alone, however, should not force the decision for cesarean delivery. Biswas and Johnstone (1993) found that among 267 term breech presentations, satisfactory progress in labor was the best indicator of pelvic adequacy. Nwosu and colleagues (1993) reported similar findings.

Fetal Condition. The presence or absence of gross fetal abnormalities, such as hydrocephaly or anencephaly, can be rapidly ascertained with the use of sonography or radiography. Such efforts will help to ensure that a cesarean delivery is not performed under emergency conditions for an anomalous infant with no chance of survival. If vaginal delivery is planned, the fetal head should not be extended (see [Fig. 24-5](#)). As discussed, it is possible to ascertain head flexion and to exclude extension with sonography (Fontenot and colleagues, 1997; Rojansky and co-workers, 1994).

Fetal Monitoring. Guidelines for monitoring the high-risk fetus are applied as discussed in [Chapter 17](#) (p. 427). Thus, the fetal heart rate is recorded at least every 15 minutes. Most clinicians prefer continuous electronic monitoring of fetal heart rate and uterine contractions.

When membranes are ruptured, either spontaneously or artificially, the risk of cord prolapse is appreciably increased. Therefore, a vaginal examination should be performed following rupture to check for cord prolapse. Special attention should be directed to the fetal heart rate for the first 5 to 10 minutes following membrane rupture, to detect occult cord prolapse.

Additional help is required for managing labor and delivery of a breech presentation. For labor, one-on-one nursing is ideal because of the risk of cord prolapse or occlusion, and physicians must be readily available should there be an emergency.

Route of Delivery. Discussions with the woman and planning for the route of delivery may have taken place before admission. If not, they are now accomplished as soon as possible. The choice of abdominal or vaginal delivery is based on the type of breech, flexion of the head, fetal size, quality of uterine contractions, and size of the maternal pelvis (see p. 571). The woman should be informed about all relevant facts and uncertainties before delivery. The obstetrician should consider, and usually abide by, the preferences of the informed parents (Kunzel, 1994).

Timing of Delivery. In general, the capability to proceed with immediate breech extraction when the buttocks or feet appear at the vulva is necessary. This is important because persistent fetal bradycardia is prone to develop from cord compression with further fetal descent through the birth canal. It is essential that the delivery team include:

1. An obstetrician skilled in the art of breech extraction.
2. An associate to assist with the delivery.
3. Anesthesia personnel who can assure adequate analgesia or anesthesia when needed.
4. An individual trained to resuscitate the infant.

Delivery is easier, and in turn, morbidity and mortality are probably lower, when the breech is allowed to deliver spontaneously to the umbilicus. If a nonreassuring fetal heart rate pattern develops before this time, however, a decision must be made

whether to perform manual extraction or cesarean delivery. For a favorable outcome with any breech delivery, at the very minimum, the birth canal must be sufficiently large to allow passage of the fetus without trauma. The cervix must be fully dilated, and if not, then a cesarean delivery nearly always is the more appropriate method of delivery when suspected fetal compromise develops.

ASSISTED FRANK BREECH DELIVERY. The frank breech should ideally be allowed to deliver without assistance to at least the level of the umbilicus. Unless there is considerable relaxation of the perineum, an episiotomy should be made. The episiotomy is an important adjunct to any type of breech delivery. As the breech progressively distends the perineum, the posterior hip will deliver, usually from the 6 o'clock position, and often with sufficient pressure to evoke passage of thick meconium at this point (Fig. 24-6). The anterior hip then delivers, followed by external rotation to the sacrum anterior position (Fig. 24-7). The mother should be encouraged to continue to push, as the cord is now drawn well down into the birth canal and likely is being compressed with resultant fetal bradycardia. As the fetus continues to descend, the legs are sequentially delivered by splinting the medial aspect of each femur with the operator's fingers positioned parallel to each femur and by exerting pressure laterally so as to sweep each leg away from the midline.

Following delivery of the legs, the fetal bony pelvis is grasped with both hands, using a cloth towel moistened with warm water. The fingers should rest on the anterior superior iliac crests and the thumbs on the sacrum, minimizing the chance of fetal abdominal soft tissue injury (Fig. 24-8). Maternal expulsive efforts are used in conjunction with continued gentle downward operator rotational traction to effect delivery of the fetus. Gentle downward traction is combined with an initial 90-degree rotation of the fetal pelvis through one arc and then a 180-degree rotation to the other to effect delivery of the scapulas and arms (Figs. 24-9 and 24-10).

The depicted rotational and downward traction maneuvers will decrease the occurrence of persistent nuchal arms, which can complicate all vaginal breech deliveries, prevent further descent, and increase fetal-newborn trauma and morbidity. These maneuvers are frequently most easily effected with the operator at the level of the maternal pelvis and with one knee on the floor. When the scapulas are clearly visible, delivery is then completed as subsequently described for the complete or incomplete breech.

Figure 24-6. The posterior hip of the frank breech is delivering over the perineum. A generous midline episiotomy has been cut.

Figure 24-7. The anterior hip has now delivered and external rotation has occurred. The fetal thighs remain in flexion, with extension at the knees.

Figure 24-8. Delivery of the body. The hands are applied, but not above the pelvic girdle. Gentle downward rotational traction is accomplished until the scapulas are clearly visible.

Figure 24-9. Clockwise rotation of the fetal pelvis 90 degrees brings the sacrum from anterior to left sacrum transverse. Simultaneously, the application of gentle downward traction effects delivery of the scapula.

Figure 24-10. Counterclockwise rotation from sacrum anterior to right sacrum transverse along with gentle downward traction effects delivery of the right scapula.

FRANK BREECH EXTRACTION. At times, extraction of a frank breech may be required and can be accomplished by moderate traction exerted by a finger in each groin and facilitated by a generous episiotomy (Fig. 24-11). If

moderate traction does not effect delivery of the breech, then vaginal delivery can be accomplished only by breech decomposition. This procedure involves manipulation within the birth canal to convert the frank breech into a footling breech. The procedure is accomplished more readily if the membranes have ruptured recently, and it becomes extremely difficult if considerable time has elapsed since escape of amniotic fluid. In such cases, the uterus may have become tightly contracted over the fetus, and pharmacological relaxation by general anesthesia, intravenous magnesium sulfate, or a beta-mimetic such as terbutaline (250 µg subcutaneously) may be required.

Breech decomposition is accomplished by the maneuver attributed to Pinard (1889). It aids in bringing the fetal feet within reach of the operator. As shown in [Figure 24-12](#), two fingers are carried up along one extremity to the knee to push it away from the midline. Spontaneous flexion usually follows, and the foot of the fetus is felt to impinge on the back of the hand. The fetal foot then may be grasped and brought down.

Figure 24-11. Extraction of a frank breech using fingers in groins.

Figure 24-12. Frank breech decomposition using the Pinard maneuver. Two fingers are inserted along one extremity to the knee, which is then pushed away from the midline after spontaneous flexion traction is used to deliver a foot into the vagina.

COMPLETE OR INCOMPLETE BREECH EXTRACTION. During total extraction of a complete or incomplete breech, the hand is introduced through the vagina and both feet of the fetus are grasped. The ankles are held with the second finger lying between them and, with gentle traction, the feet are brought through the vulva. If difficulty is experienced in grasping both feet, first one foot should be drawn into the vagina but not through the introitus, and then the other foot is advanced in a similar fashion ([Fig. 24-13](#)). Now both feet are grasped and pulled through the vulva simultaneously.

As the legs begin to emerge through the vulva, downward gentle traction is then continued. As the legs emerge, successively higher portions are grasped, first the calves and then the thighs ([Fig. 24-14](#)). When the breech appears at the vulva, gentle traction is applied until the hips are delivered. As the buttocks emerge, the back of the infant usually rotates to the anterior. The thumbs are then placed over the sacrum and the fingers over the hips, and assisted breech delivery is effected, as described previously (see [Fig. 24-8](#)). As the scapulas become visible, the back of the infant tends to turn spontaneously toward the side of the mother to which it was originally directed ([Fig. 24-15](#)).

A cardinal rule in successful breech extraction is to employ steady, gentle, downward rotational traction until the lower halves of the scapulas are delivered outside the vulva, making no attempt at delivery of the shoulders and arms until one axilla becomes visible. Failure to follow this rule frequently will make an otherwise easy procedure difficult. The appearance of one axilla indicates that the time has arrived for delivery of the shoulders. It makes little difference which shoulder is delivered first, and there are two methods for delivery of the shoulders.

In the first method, with the scapulas visible, the trunk is rotated in such a way that the anterior shoulder and arm appear at the vulva and can easily be released and delivered first. In [Figure 24-15](#), the operator is shown rotating the trunk of the fetus counterclockwise to deliver the right shoulder and arm. The body of the fetus is then rotated in the reverse direction to deliver the other shoulder and arm.

In the second method, if trunk rotation is unsuccessful, the posterior shoulder must be delivered first. The feet are grasped in one hand and drawn upward over the inner thigh of the mother toward which the ventral surface of the fetus is directed. In this manner, leverage is exerted on the posterior shoulder, which slides out over the perineal margin, usually followed by the arm and hand ([Fig. 24-16](#)). Then, by depressing the body of the fetus, the anterior shoulder emerges beneath the pubic arch, and the arm and hand usually follow spontaneously ([Fig. 24-17](#)). Thereafter, the back tends to rotate spontaneously in the direction of the symphysis. If upward rotation fails to occur, it is effected by manual rotation of the body. Delivery of the head may then be accomplished.

Unfortunately, the process is not always so simple, and it is sometimes necessary first to free and deliver the arms. These maneuvers are less likely to be required if rotational traction is employed and attempts to deliver the shoulders until an axilla becomes visible are avoided. **Attempts to free the arms immediately after the costal margins emerge should be avoided.**

There is more space available in the posterior and lateral segments of the normal pelvis than elsewhere. Therefore, in difficult cases, the posterior arm should be freed first. Because the corresponding axilla is already visible, upward traction on the feet is continued, and two fingers of the other hand are passed along the humerus until the elbow is reached (see [Fig. 24-16](#), inset). The fingers are placed parallel to the humerus and used to splint the arm, which is swept downward and delivered through the vulva. To deliver the anterior arm, depression of the body of the infant is sometimes all that is required to allow the anterior arm to slip out spontaneously. In other instances, the anterior arm can be swept down over the thorax using two fingers as a splint. Occasionally, however, the body must be held with the thumbs over the scapulas and rotated to bring the undelivered shoulder near the closest sacrosciatic notch. The legs then are carried upward to bring the ventral surface of the infant to the

opposite inner thigh of the mother. Subsequently, the arm can be delivered as described previously. If the arms have become extended over the head, their delivery, although more difficult, usually can be accomplished by the maneuvers just described. In so doing, particular care must be taken by the operator to carry the fingers up to the elbow and to use them as a splint to prevent fracture of the humerus.

As discussed earlier, one or both fetal arms occasionally may be found around the back of the neck (nuchal arm) and impacted at the pelvic inlet. In this situation, delivery is more difficult. If the nuchal arm cannot be freed in the manner described, extraction may be facilitated, especially with a single nuchal arm, by rotating the fetus through half a circle in such a direction that the friction exerted by the birth canal will serve to draw the elbow toward the face ([Fig. 24-18](#)). Should rotation of the fetus fail to free the nuchal arm(s), it may be necessary to push the fetus upward in an attempt to release it. If the rotation is still unsuccessful, the nuchal arm often is extracted by hooking a finger(s) over it and forcing the arm over the shoulder, and down the ventral surface for delivery of the arm. In this event, fracture of the humerus or clavicle is very common.

Figure 24-13. Complete breech extraction begins with traction on the feet and ankles.

Figure 24-14. Complete breech extraction continues with traction on the thighs. A warm, moist towel is most often applied over the fetal parts to reduce slippage from vernix as traction is applied.

Figure 24-15. As breech extraction continues, the scapulas become visible and the body rotates, usually to the side of the mother to which it was originally directed.

Figure 24-16. As breech extraction continues, upward traction is employed, effecting delivery of the posterior shoulder. This is followed by delivery of the posterior arm (*inset*).

Figure 24-17. Breech extraction continues with delivery of the anterior shoulder by downward traction. The anterior arm then may be freed the same way as the posterior arm in [Figure 24-16](#).

Figure 24-18. Reduction of nuchal arm being accomplished by rotating the fetus through half a circle counterclockwise so that the friction exerted by the birth canal will draw the elbow toward the face.

DELIVERY OF THE AFTERCOMING HEAD. The fetal head may be extracted with forceps or by one of the following maneuvers.

Mauriceau Maneuver. The index and middle finger of one hand are applied over the maxilla, to flex the head, while the fetal body rests on the palm of the hand and forearm ([Fig. 24-19](#)). The forearm is straddled by the fetal legs. Two fingers of the other hand then are hooked over the fetal neck, and grasping the shoulders, downward traction is applied until the suboccipital region appears under the symphysis. Gentle suprapubic pressure simultaneously applied by an assistant helps keep the head flexed. The body then is elevated toward the maternal abdomen, and the mouth, nose, brow, and eventually the occiput emerge successively over the perineum. **It is emphasized that with this maneuver, the operator uses both hands simultaneously and in tandem to exert continuous downward gentle traction simultaneously on the fetal neck and**

on the maxilla. At the same time, appropriate suprapubic pressure applied by an assistant is helpful in delivery of the head (see [Fig. 24-19](#)).

Prague Maneuver. Rarely, the back of the fetus fails to rotate to the anterior. When this occurs, rotation of the back to the anterior may be achieved by using stronger traction on the fetal legs or bony pelvis. If the back still remains oriented posteriorly, extraction may be accomplished using the Mauriceau maneuver and delivering the fetus back down. If this is impossible, the fetus still may be delivered using the modified Prague maneuver, which, as practiced today, consists of two fingers of one hand grasping the shoulders of the back-down fetus from below while the other hand draws the feet up over the maternal abdomen ([Fig. 24-20](#)).

Forceps to Aftercoming Head. Specialized forceps can be used to deliver the aftercoming head. *Piper forceps*, shown in [Figure 24-21](#), or divergent *Laufe forceps* may be applied electively or when the Mauriceau maneuver cannot be accomplished easily. The blades of the forceps should not be applied to the aftercoming head until it has been brought into the pelvis by gentle traction, combined with suprapubic pressure, and is engaged. Suspension of the body of the fetus in a towel effectively holds the fetus and helps keep the arms out of the way.

Figure 24-19. Delivery of the aftercoming head using the Mauriceau maneuver. Note that as the fetal head is being delivered, flexion of the head is maintained by suprapubic pressure provided by an assistant, and simultaneously by pressure on the maxilla (*inset*) by the operator as traction is applied.

Figure 24-20. Delivery of the aftercoming head using the modified Prague maneuver necessitated by failure of the fetal trunk to rotate anteriorly.

Figure 24-21. Piper forceps for delivery of the aftercoming head. Note the direction of movement shown by the arrows. **A.** The fetal body is elevated using a warm towel and the left blade of the forceps is applied to the aftercoming head. **B.** The right blade is applied with the body still elevated. **C.** Forceps delivery of the aftercoming head.

ENTRAPMENT OF THE AFTERCOMING HEAD. Occasionally, especially with small preterm fetuses, the incompletely dilated cervix will not allow delivery of the aftercoming head. With gentle traction on the fetal body, the cervix, at times, may be manually slipped over the occiput. If this is not successful, then *Duhrssen incisions* (see [Fig. 24-4](#)) are usually necessary.

Some investigators have recommended intravenous nitroglycerin \approx typically 100 μ g \approx to provide cervical relaxation for relief of head entrapment (Dufour and colleagues, 1997; Wessen and associates, 1995). There is, however, no compelling evidence of its efficacy for this purpose.

Replacement of the fetus higher into the vagina and uterus, followed by cesarean delivery, can be used successfully to rescue an entrapped breech that cannot be delivered vaginally. Steyn and Pieper (1994) described use of the *Zavanelli maneuver* \approx cesarean delivery after replacement of the infant back into the uterus \approx to deliver a healthy 2590-g infant with head entrapment. Sandberg (1999) reviewed 11 breech deliveries in which this maneuver was used.

In some countries, *symphysiotomy* is used to widen the anterior pelvis. In his review, Menticoglou (1990) reported that its use has been associated with good infant outcomes in 80 percent of reported cases. Lack of operator training and the potential to cause serious maternal injury explain its rare use in this country (Goodwin and colleagues, 1997).

ANALGESIA AND ANESTHESIA. Continuous epidural analgesia, as described in [Chapter 19](#), is advocated by some as ideal for women in labor with a breech presentation (Kunzel, 1994; Mokriski, 1994). Confino and colleagues (1985) reviewed the outcomes of 371 nonanomalous singleton breech fetuses delivered vaginally. About 25 percent of these women had been given continuous epidural analgesia, and oxytocin augmentation was necessary to effect delivery in half of them. Although first-stage labor was not longer than in a control group not given epidural analgesia, the second stage was prolonged significantly in women whose fetuses weighed more than 2500 g. It was doubled if the fetus weighed more than 3500 g. Chadha and associates (1992) observed similar effects on labor and an increased incidence of cesarean delivery. These potential disadvantages must be weighed against the advantages of better pain relief and, importantly, increased pelvic relaxation should extensive manipulation be required to effect delivery.

Analgesia for episiotomy and intravaginal manipulations that are needed for breech extraction usually can be accomplished with pudendal block and local infiltration of the perineum. Nitrous oxide plus oxygen inhalation provides further relief from pain. If general anesthesia is required, it can be induced quickly with thiopental plus a muscle relaxant and maintained with nitrous oxide.

Anesthesia for breech decomposition and extraction must provide sufficient relaxation to allow intrauterine manipulations. Although successful decomposition has been accomplished using epidural or spinal analgesia, increased uterine tone may render the operation more difficult. Under such conditions, general anesthesia with a halogenated agent may be required to relax the uterus as well as to provide analgesia.

MORBIDITY AND MORTALITY

MATERNAL INJURIES. Complicated vaginal breech deliveries are associated with increased maternal risks. Manual manipulations within the birth canal increase the risk of infection. Intrauterine maneuvers, especially with a thinned lower uterine segment, or delivery of the aftercoming head through an incompletely dilated cervix may cause rupture of the uterus, lacerations of the cervix, or both. Such manipulations also may lead to extensions of the episiotomy and deep perineal tears. Anesthesia sufficient to induce appreciable uterine relaxation may cause uterine atony and, in turn, postpartum hemorrhage.

FETAL INJURIES. Fracture of the humerus and clavicle cannot always be avoided, and fracture of the femur may be sustained during difficult breech extractions ([Fig. 24-22](#)). Such fractures are associated with both vaginal and cesarean deliveries (Awwad and colleagues, 1993; Vasa and Kim, 1990). Neonatal perineal tears have been reported as a complication of spinal electrode use (Freud and associates, 1993). Hematomas of the sternocleidomastoid muscles occasionally develop after delivery, although they usually disappear spontaneously. More serious problems, however, may follow separation of the epiphyses of the scapula, humerus, or femur. There is no evidence that the incidence of congenital hip dislocations is increased by vaginal delivery of a breech (Clausen and Nielsen, 1988). Bartlett and colleagues (2000) studied early motor development of breech- and control cephalic-presenting infants. They concluded that the mode of delivery did not explain the excess neuromotor impairment detected in breech infants.

Paralysis of the arm may follow pressure on the brachial plexus by the fingers in exerting traction, but more frequently it is caused by overstretching the neck while freeing the arms. Geutjens and colleagues (1996) described 36 newborns with brachial plexus injury following vaginal breech delivery. In 80 percent, there was avulsion of the upper cervical spine roots. This injury cannot be treated by microsurgical nerve grafting and carries a worse prognosis for shoulder function. When the fetus is extracted forcibly through a contracted pelvis, spoon-shaped depressions or actual fractures of the skull may result. Occasionally, even the fetal neck may be broken when great force is employed. Testicular injury, in some cases severe enough to result in anorchia, may occur following vaginal breech delivery (Tiwary, 1989).

Figure 24-22. Midshaft right femoral fracture showing posterior displacement and lateral angulation. Injury occurred with extraction at cesarean delivery. (From Awwad and associates, 1993, with permission.)

VERSION

Version is a procedure in which the fetal presentation is altered by physical manipulation, either substituting one pole of a longitudinal presentation for the other or converting an oblique or transverse lie into a longitudinal presentation. According to whether the head or breech is made the presenting part, the operation is designated *cephalic* or *podalic version*, respectively. In *external version*, the manipulations are performed exclusively through the abdominal wall; in *internal version*, they are accomplished inside the uterine cavity.

EXTERNAL CEPHALIC VERSION. Once very popular, external version has received renewed interest in the past two decades, coincidental with the widespread availability of ultrasound, electronic fetal monitoring, and effective tocolytic agents. In the United States, Van Dorsten and co-workers (1981) rekindled interest in this procedure. And more recently, in conjunction with their recommendation of vaginal delivery for breech, the American College of Obstetricians and Gynecologists (2001) recommended that efforts be made to reduce breech presentation by external cephalic version whenever possible.

The success rate for external cephalic version has ranged from 35 to 85 percent, with an average of about 60 percent (American College of Obstetricians and Gynecologists, 2000). Zhang and co-authors (1993) reviewed 25 selected reports on external cephalic version published between 1980 and 1991. They reported an average success rate of 65 percent. Moreover, they observed that after successful version, almost all fetuses remain cephalic. They estimated that despite version attempts, 37 percent of women identified to have a late pregnancy breech ultimately will require cesarean delivery. Interestingly, several reports suggest that after successful version, the risk of cesarean delivery does not completely revert to the institutional baseline risk for vertex presentations, and that dystocia, malpresentation, and nonreassuring fetal heart patterns may be more common after successful version (Chan and colleagues, 2004; Vezina and associates, 2004).

Application of a policy of external cephalic version has been associated with reductions in the cesarean delivery rate at various institutions. Morrison and co-workers (1986) attempted external cephalic version in 2.3 percent of all pregnancies at the University of Mississippi Medical Center from 1982 to 1984. Compared with the preceding 3 years, they decreased vaginal breech deliveries from 1.8 to 1.1 percent of all pregnancies, and cesarean deliveries for breeches from 2.8 to 1.6 percent. Ben-Arie and colleagues (1995) reported that introduction of an external version protocol at their institution decreased breech presentation at term from 3.9 to 2.4 percent. Decision analysis models suggest that routine use of external cephalic version would reduce not only cesarean births but also costs (Gifford and associates, 1995a; Pollack and Yaffe, 2002).

Indications. In general, when a breech presentation is recognized prior to labor in a woman who has reached 36 weeks' gestation, external cephalic version should be considered. After this point, the likelihood of spontaneous version is low (Hickok and colleagues, 1992; Westgren and co-workers, 1985b). Moreover, if version results in the need for immediate delivery, complications of iatrogenic preterm delivery generally are not severe. An additional consideration in timing the version is that

although earlier attempts are more likely to be successful, they also are more likely to be associated with spontaneous reversion to breech (Kornman and associates, 1995; van Veelen and colleagues, 1989).

Version should not be attempted if there is a contraindication to vaginal delivery. Examples include placenta previa or nonreassuring fetal status. A prior uterine incision is a relative contraindication, although in small studies external version was not associated with uterine rupture in women who had previously undergone cesarean delivery (de Meeus and associates, 1998; Flamm and co-workers, 1991; Schachter and colleagues, 1994). At the University of Alabama at Birmingham, decisions about version in women with a prior cesarean incision are individualized with an awareness that repeat cesarean is generally a safe operation. At Parkland Hospital, we do not attempt external version in these women. Obviously, larger studies are needed to better characterize risks versus benefits.

Factors Associated with Successful Version. Increasing parity is the most consistent factor associated with success of external cephalic version (Zhang and colleagues, 1993). In another study, Hellstrom and co-workers (1990) identified only 3 of 16 variables to be associated with successful external version. The most important factor was parity, followed by fetal presentation, and then the amount of amniotic fluid. Version was more successful in a parous woman who has an unengaged fetus surrounded by a normal amount of amniotic fluid. Boucher and associates (2003) reported a direct relationship between the amniotic fluid index and successful external cephalic version in a prospective observational study of 1361 women who underwent a trial of version. Lau and associates (1997) identified three variables that predicted *failed* version. These were an engaged presenting part, difficulty in palpating the fetal head, and a uterus tense to palpation. In the presence of all three, there were no successes; with two, success was less than 20 percent, however if none was present, the success rate was 94 percent.

Gestational age is also important and earlier attempts increase the chance of success but are associated with an increased rate of spontaneous reversion (Westgren and colleagues, 1985b). Other reported determinants of failed version include diminished amniotic fluid volume, maternal obesity, anterior placenta, cervical dilatation, descent of the breech into the pelvis, and anterior or posterior positioning of the fetal spine (Fortunato and colleagues 1988; Newman and colleagues, 1993).

Transverse Lie. Women with a transverse lie usually are excluded from analyses of breech version because the overall success rate approaches 90 percent (Newman and colleagues, 1993).

Technique. External cephalic version should be carried out in an area that has ready access to a facility equipped to perform emergency cesarean deliveries (American College of Obstetricians and Gynecologists, 2000). Real-time ultrasonic examination is performed to confirm nonvertex presentation and adequacy of amniotic fluid volume, to rule out obvious fetal anomalies if not done previously, and to identify placental location. External monitoring is performed to assess fetal heart rate reactivity. D-immune globulin is given if indicated.

A "forward roll" of the fetus usually is attempted first. As shown in [Figure 24-23](#), each hand grasps one of the fetal poles, and the buttocks are elevated from the maternal pelvis and displaced laterally. The buttocks are then gently guided toward the fundus, while the head is directed toward the pelvis. If the forward roll is unsuccessful, then a "backward flip" is attempted. Version attempts are discontinued for excessive discomfort, persistently abnormal fetal heart rate, or after multiple failed attempts. The nonstress test is repeated after version until a normal test result is obtained.

Tocolysis. Most investigators recommend uterine relaxation with a tocolytic agent, usually terbutaline 250 µg given subcutaneously. Although some have shown a benefit to tocolysis, others have not. Robertson and associates (1987) used ritodrine, Tan and colleagues (1989) used salbutamol, and Yanny and associates (2000) used glyceryl trinitrate—all to no avail. Indeed, in a placebo controlled trial of 99 women, the use of sublingual nitroglycerin was associated with a lower rate of successful version than placebo—48 versus 63 percent—and a higher rate of complications such as hypotension (Bujold and colleagues, 2003). Conversely, in another randomized trial, Fernandez and co-workers (1996) reported that subcutaneous terbutaline significantly increased the success rate of version. It was 27 percent in the control group and 52 percent in the terbutaline group. Marquette and colleagues (1996) reported a benefit of ritodrine infusion, but only in nulliparas. Policies at the University of Alabama at Birmingham and at Parkland Hospital are to administer 250 µg of terbutaline subcutaneously to most women prior to attempted version.

Conduction Analgesia. Some investigators have reported increased success with version when epidural analgesia is used. In a prospective randomized trial, Schorr and co-workers (1997) found that epidural analgesia given with terbutaline tocolysis was successful in 60 percent of cases, compared with 30 percent in cases in which only terbutaline was given. Mancuso and collaborators (2000) randomized 108 women and reported a success rate of 59 percent with epidural versus one of 33 percent without. Neiger and associates (1998) used epidural analgesia after failed versions and reported 56-percent success.

Not all have reported improved success with conduction analgesia. Dugoff and colleagues (1999) randomized 102 women to be given terbutaline, with or without spinal analgesia. The success rates were almost identical, 44 and 42 percent, respectively. Delisle and associates (2001) reported that spinal analgesia did not improve the success rate of external cephalic version in their randomized trial. According to the American College of Obstetricians and Gynecologists (2000), there is not enough consistent evidence to recommend conduction analgesia routinely.

Other Methods. There are some unconventional interventions with reported efficacy that emphasize our lack of understanding regarding the persistence of the breech presentation. Cardini and Weixen (1998) performed a randomized clinical trial to evaluate *moxibustion*—burning the herbal preparation *moxa* to generate heat to stimulate acupuncture point BL67—to promote spontaneous breech version. Women in the intervention group experienced significantly increased fetal movements and more often had a cephalic presentation at delivery. Mehl (1994) prospectively matched 100 women with a breech presentation at 37 to 40 weeks to evaluate *hypnosis* with suggestions for relaxation. Significantly more fetuses of women in the intervention group (81 percent) converted to vertex than in the control group (48 percent). In another study that at least intuitively is comprehensible, Johnson and Elliott (1995) used *acoustic stimulation* to startle breech fetuses to shift their spines laterally for successful manual version attempts.

Complications. Risks of external version include placental abruption, uterine rupture, amniotic fluid embolism, fetomaternal hemorrhage, isoimmunization, preterm labor, fetal distress, and fetal demise. According to Zhang and colleagues (1993), there have been no reported fetal deaths in the United States resulting directly from external version since 1980. Reported nonfatal

complications include fetal heart rate decelerations in almost 40 percent of fetuses and fetomaternal hemorrhage in 4 percent (Phelan and co-workers, 1984; Stine and colleagues, 1985). Scattered case reports have indicated some uncommon complications. Petrikovsky and colleagues (1987) reported a case of fetal brachial plexus injury after successful external version. Stine and co-workers (1985) reported a maternal death due to an amniotic fluid embolism. Rare severe complications notwithstanding, Collaris and Oei (2004) concluded, based on a systematic review of 44 studies, which included 7377 patients from 1990 to 2002, that external cephalic version is a safe procedure for mother and fetus.

Figure 24-23. External cephalic version.

INTERNAL PODALIC VERSION. This maneuver is used only for delivery of a second twin. It consists of the insertion of a hand into the uterine cavity to turn the fetus manually. The operator seizes one or both feet and draws them through the fully dilated cervix while using the other hand to transabdominally push the upper portion of the fetal body in the opposite direction. The operation is followed by breech extraction and is discussed in detail in [Chapter 39](#) (see p. 940).

25. Cesarean Delivery and Peripartum Hysterectomy

INTRODUCTION

Cesarean delivery is defined as the birth of a fetus through incisions in the abdominal wall (laparotomy) and the uterine wall (hysterotomy). This definition does not include removal of the fetus from the abdominal cavity in the case of rupture of the uterus or in the case of an abdominal pregnancy. In some cases, and most often because of emergent complications such as intractable hemorrhage, abdominal hysterectomy is indicated following delivery. When performed at the time of cesarean delivery, the operation is termed *cesarean hysterectomy*. If done within a short time after vaginal delivery, it is termed *postpartum hysterectomy*.

HISTORICAL BACKGROUND

The origin of the term *cesarean* is obscure, and three principal explanations have been suggested.

In the first, according to legend, Julius Caesar was born in this manner, with the result that the procedure became known as the Caesarean operation. Several circumstances weaken this explanation. First, the mother of Julius Caesar lived for many years after his birth in 100 bc, and as late as the 17th century, the operation was almost invariably fatal. Second, the operation, whether performed on the living or the dead, is not mentioned by any medical writer before the Middle Ages. Historical details of the origin of the family name Caesar are found in the monograph by Pickrell (1935).

The second explanation is that the name of the operation is derived from a Roman law, supposedly created in the 8th century bc by Numa Pompilius, ordering that the procedure be performed upon women dying in the last few weeks of pregnancy in the hope of saving the child. This *lex regia* — king's rule or law — later became the *lex caesarea* under the emperors, and the operation itself became known as the caesarean operation. The German term *Kaiserschnitt* — Kaiser cut — reflects this derivation.

The third explanation is that the word *caesarean* was derived sometime in the Middle Age from the Latin verb *caedere*, to cut. This explanation seems most logical, but exactly when it was first applied to the operation is uncertain. Because *section* is derived from the Latin verb *seco*, which also means *cut*, the term *caesarean section* seems tautological — thus *cesarean delivery* is used. In the United States, the *ae* in the first syllable of *caesarean* is replaced with the letter e. In the United Kingdom, Australia, and most commonwealth nations, the *ae* is retained.

From the time of Virgil's Aeneas to Shakespeare's Macduff, poets repeatedly have referred to persons "untimely ripped" from their mother's womb. Ancient historians such as Pliny, moreover, say that Scipio Africanus, the conqueror of Hannibal, as well as Martius and Julius Caesar were all born by cesarean. In regard to Julius Caesar, Pliny adds that it was from this circumstance that the surname arose by which the Roman emperors were known. Birth in this extraordinary manner, as described in ancient mythology and legend, was believed to confer supernatural powers and elevated the heroes so born above ordinary mortals.

In evaluating these references to abdominal delivery in antiquity, it is pertinent that no such operation is even mentioned by Hippocrates, Galen, Celsus, Paulus, Soranus, or any other medical writer of those periods. If cesarean delivery actually was employed, it is particularly surprising that Soranus, whose extensive work written in the 2nd century ad covers all aspects of obstetrics, does not refer to it.

Several references to abdominal delivery appear in the Talmud between the 2nd and 6th centuries ad, but whether they had any background in terms of clinical usage is conjectural. There can be no doubt, however, that cesarean delivery in dead women was first practiced soon after the Christian Church gained dominance, as a measure directed at baptism of the child. Confidence in the validity of some of these early reports is rudely shaken, however, when they glibly state that a living, robust child was obtained 8 to 24 hours after the death of the mother.

Cesarean deliveries in the living were first recommended, and the current name of the operation used, in the celebrated work of Francois Rousset (1581) entitled *Traite Nouveau de l'Hysterotomotokie ou l'Enfantement Cesaerien*. Rousset had never performed or witnessed the operation, and his information was based chiefly on letters from friends. He reported 14 successful cesarean deliveries, a fact in itself difficult to accept. When it is further stated that 6 of the 14 operations were performed on the same woman, the credulity of the most gullible is exhausted!

The apocryphal nature of most early reports on cesarean delivery is stressed because many of them have been accepted without question. Authoritative statements by dependable obstetricians about early use of the operation, however, did not appear in the literature until the mid-17th century. An example is the classical work of the French obstetrician, Francois Mauriceau, first published in 1668. This shows without doubt that the operation was employed on the living in rare and desperate cases, and that it was usually fatal. Details of the history of cesarean deliveries are found in Fasbender's classic text (1906).

The appalling maternal mortality rate of cesarean delivery continued until the beginning of the 20th century. In Great Britain and Ireland, the maternal death rate from the operation in 1865 was 85 percent. In Paris, during the 90 years ending in 1876, not a single mother survived cesarean delivery. Harris (1879) noted that as late as 1879, cesarean deliveries actually were more successful when performed by the patient herself or when the abdomen was ripped open by the horns of a bull! He found nine such cases in the literature with five recoveries, and contrasted them with 12 cesarean deliveries performed in New York City during the same period, with only one recovery.

The turning point in the evolution of cesarean operations came in 1882, when Max Sanger, then a 28-year-old assistant of Crede at Leipzig, introduced suturing of the uterine wall. The long neglect of so simple an expedient had not been from oversight, but stemmed from a deeply rooted belief that sutures in the uterus were superfluous as well as harmful by virtue of serving as the site for severe infection. In meeting these latter objections, Sanger, who had himself used sutures in only one case, documented their value not from the sophisticated medical centers of Europe but from frontier America. There, in

outposts from Ohio to Louisiana, 17 cesarean deliveries had been reported in which silver wire sutures had been used, with the survival of eight mothers — an extraordinary record in those days. Thus, hemorrhage was the first and most serious problem to be solved. The review by Eastman (1932) details these findings.

Although the introduction of uterine sutures reduced mortality from the operation from hemorrhage, generalized peritonitis remained the dominant cause of death. Hence, various types of operations were devised to combat this scourge. The earliest was the Porro procedure (1876), which combined subtotal cesarean hysterectomy with marsupialization of the cervical stump. The first extraperitoneal operation was described by Frank in 1907. With various modifications, this technique was introduced by Latzko (1909) and Waters (1940), and it was employed until recent years.

In 1912, Kronig contended that the main advantage of the extraperitoneal technique was that the uterine incision was covered by peritoneum. To accomplish this, he cut through the vesical reflection of the peritoneum from one round ligament to the other and separated it and the bladder from the lower uterine segment. Then, through a vertical median incision, the child was extracted by forceps. The uterine incision was then closed and buried under the vesical peritoneum. With minor modifications, this low-segment technique was introduced into the United States by Beck (1919) and popularized by DeLee (1922) and others. A particularly important modification was recommended by Kerr in 1926, who preferred a transverse rather than a longitudinal uterine incision.

Boley (1991) and Sewell (1993) have provided extensive reviews of the history of cesarean delivery.

CESAREAN DELIVERY

CONTEMPORARY STATUS OF CESAREAN DELIVERY

Frequency. From 1965 through 1988, the cesarean delivery rate in the United States rose progressively from only 4.5 percent of all deliveries to almost 25 percent (U.S. Public Health Service, 1991). Most of this increase took place in the 1970s and early 1980s and occurred throughout the western world (Fig. 25-1). Between 1989 and 1996 the annual rate of cesarean delivery decreased in the United States (Fig. 25-2). This was due in large part to an increased rate of *vaginal birth after cesarean* (VBAC) and to a lesser extent, a small decrease in the primary cesarean rate (see Fig. 25-2). Since 1996, however, the total cesarean rate has increased every year, and in 2002 it was 26.1 percent, the highest rate ever recorded in the United States.

From these figures, it is apparent that the 1991 U.S. Public Health Service goal of an overall cesarean delivery rate of 15 percent by the year 2000 was not achieved. More recently, the American College of Obstetricians and Gynecologists Task Force on Cesarean Delivery Rates (2000) recommended two benchmarks for the United States for the year 2010:

1. A cesarean rate of 15.5 percent for nulliparous women at 37 weeks or more with a singleton cephalic presentation.
2. A vaginal birth rate after a prior cesarean of 37 percent in women at 37 weeks or more with a singleton cephalic presentation who had one prior low-transverse cesarean delivery. The U.S. Department of Health and Human Services (2000) has established similar goals for 2010.

The reasons why the cesarean rate quadrupled between 1965 and 1988 and its continued rise are not completely understood, but some explanations include the following:

1. Women are having fewer children, thus, a greater percentage of births are among *nulliparas*, who are at increased risk for cesarean delivery.
2. The average *maternal age* is rising, and older women, especially nulliparas, are at increased risk of cesarean delivery (Fig. 25-3).
3. The use of *electronic fetal monitoring* is widespread. This technique is associated with an increased cesarean delivery rate compared with intermittent fetal heart rate auscultation (see Chap. 18, p. 444). Although cesarean delivery performed primarily for "fetal distress" comprises only a minority of all such procedures, in many more cases concern for an abnormal, or "nonreassuring," fetal heart rate tracing lowers the threshold for cesarean deliveries performed for abnormal progress of labor.
4. The vast majority of fetuses presenting as *breech* are now delivered by cesarean (see Chap. 24, p. 571).
5. The incidence of *midpelvic forceps and vacuum deliveries* has decreased (see Chap. 23, p. 548).
6. Rates of *labor induction* continue to rise, and induced labor, especially among nulliparas, increases the risk of cesarean delivery (see Chap. 22, p. 536).
7. The prevalence of *obesity* has risen dramatically, and obesity also increases the risk of cesarean delivery (see Chap. 43, p. 1011).
8. Concern for *malpractice litigation* has contributed significantly to the present cesarean delivery rate. More than a decade ago, it was reported that failure to perform a cesarean delivery and thus avoid adverse neonatal neurological outcome or cerebral palsy was the dominant obstetrical claim in the United States (Physicians Insurance Association of America, 1992). Although more recent data are aggregated differently, they suggest that this picture has changed little. Specifically, in 2001 a brain-damaged infant was the claim responsible for 40 percent of all medicolegal indemnity paid by obstetricians-gynecologists (Physicians Insurance Association of America, 2002). This reality is especially troubling in view of the well-documented lack of association between cesarean delivery and any reduction in childhood neurological problems. According to Foley and colleagues (2002), the incidence of neither neonatal seizures nor cerebral palsy diminished as the rate of cesarean delivery increased (see also Chap. 29, p. 654).
9. Some elective cesarean deliveries are now performed due to concern over pelvic floor injury associated with vaginal birth (Nygaard and Cruikshank, 2003).

Indications. As shown in [Table 25-1](#), repeat cesarean deliveries and those performed for dystocia have been the leading indications in both the United States and other western industrialized countries. Although it is not possible to catalog comprehensively all appropriate indications for cesarean delivery, over 85 percent are performed because of prior cesarean delivery, dystocia, fetal distress, or breech presentation.

PRIOR CESAREAN DELIVERY. Management of the woman with a prior cesarean delivery is discussed in [Chapter 26](#).

DYSTOCIA. Some form of dystocia is the most frequent indication for cesarean delivery in the United States. An analysis of dystocia as a contributing factor to the cesarean rate is difficult, however, because of the heterogeneity inherent in the condition (see [Chap. 20](#), p. 496). Indeed, there are 16 different ICD-9 (2003) codes applicable to cesarean delivery performed for a labor abnormality! Descriptive terms vary from more precise definitions promulgated by Friedman (1978) — *secondary arrest of dilatation*, *arrest of descent* — to more ambiguous and commonly used terms such as *cephalopelvic disproportion* and *failure to progress*.

FETAL DISTRESS. Electronic fetal monitoring was employed in 85 percent of labors in the United States in 2002 (Martin and colleagues, 2003). Its use increases the cesarean delivery rate, perhaps by as much as 40 percent (Thacker and associates, 2001). Unfortunately, despite initial optimism, it has become well established that management based on electronic monitoring is no better in reducing the risk of cerebral palsy or perinatal death than that based on intermittent heart rate auscultation. Indeed, the performance of cesarean delivery per se may have no bearing on the neurodevelopmental prognosis of the infant. Scheller and Nelson (1994), in a report from the National Institutes of Health, and Lien and associates (1995) presented data specifically refuting any association between cesarean delivery and either cerebral palsy or seizures.

Pertinent to the diagnosis of fetal distress are the recommendations of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) that facilities giving obstetrical care have the capability of initiating a cesarean delivery within 30 minutes of the decision to operate. Misinterpretations of this guideline are common. Specifically, this recommendation addresses facilities and does not govern clinical decision making. There is no nationally recognized standard of care that codifies an acceptable time interval for performance of cesarean delivery. In most instances, operative delivery is not necessary within this 30-minute time frame. Indeed, Bloom and co-workers (2001) from the National Institute of Child Health and Human Development (NICHD) Maternal-Fetal Medicine Units Network reported that 69 percent of 7450 cesareans performed in labor commenced more than 30 minutes after the decision to operate. Moreover, Chauhan and co-workers (1997) and MacKenzie and Cooke (2002) reported that failure to achieve a cesarean delivery decision-to-incision time of less than 30 minutes was not associated with a negative impact on neonatal outcome. On the other hand, when faced with an acute, catastrophic deterioration in fetal condition, cesarean delivery usually is indicated as rapidly as possible and purposeful delays of any time period would be inappropriate.

BREECH PRESENTATION. Management of the breech-presenting fetus is discussed in [Chapter 24](#). Concern for fetal injury, as well as the infrequency with which a breech presentation meets criteria for a trial of labor, make it likely that its contribution to the overall cesarean delivery rate will remain relatively static.

Figure 25-1. Percentage of deliveries by cesarean: Selected countries, 1970-1978. (From Smith, 1987, with permission.)

Figure 25-2. Total and primary cesarean and vaginal birth after cesarean (VBAC) rates: United States, 1989-2001. The total rate is expressed as the percent of all live births by cesarean delivery (CD). The primary cesarean rate is per 100 live births to women who have not had a previous cesarean. The rate of VBAC delivery is calculated per 100 live births to women with a previous cesarean delivery. (Data from Hamilton and associates, 2003.)

Figure 25-3. Primary cesarean delivery rates by maternal age and birthweight among nulliparous women in Washington State, 1987-1990. (From Parrish and co-workers, 1994, with permission.)

METHODS TO DECREASE CESAREAN DELIVERY RATES. Several investigators have documented the feasibility of achieving significant reductions in institutional cesarean delivery rates without increased perinatal morbidity or mortality (DeMott, 1990; DeMuylder, 1990; Porreco, 1990; Pridjian, 1991; Sanchez-Ramos, 1990, and all of their co-workers). Programs aimed at reducing the number of cesarean deliveries generally are focused on educating physicians, peer reviewing, encouraging a trial of labor after prior transverse cesarean delivery, and restricting cesarean deliveries for dystocia only to women who meet strictly defined criteria. In a recent randomized study from 34 Latin American hospitals, Althabe and colleagues (2004) reported that a mandatory second opinion was associated with a small but significant reduction in the cesarean delivery rate without an adverse effect on maternal or perinatal morbidity.

MATERNAL MORTALITY AND MORBIDITY. In the United States, maternal death attributable solely to cesarean delivery is rare. In 1980, Frigoletto and colleagues reported a series of 10,000 consecutive operations with

no maternal deaths. In 1988, Sachs and associates observed only seven deaths as a direct result of more than 121,000 cesarean deliveries performed between 1976 and 1984.

Even so, larger data sets attest to the mortality risks. In a population-based case-control study from North Carolina, which encompassed the 7-year period from 1992 to 1998, cesarean delivery was associated with an almost fourfold risk of death, even after controlling for pregnancy complications (Harper and colleagues, 2003). In another study, Hall and Bewley (1999) compiled data from over 2 million births in the United Kingdom from 1994 through 1996. They showed that whereas emergency cesarean delivery was associated with an almost ninefold risk of maternal death relative to that of vaginal delivery, even elective cesarean delivery was associated with an almost threefold risk ([Table 25-2](#)). In a recent Network study, Landon and associates (2004) reported a fivefold increased maternal death rate in women with a failed versus successful vaginal delivery who underwent a trial of labor after a prior cesarean delivery.

Maternal morbidity is increased dramatically with cesarean compared with that of vaginal delivery. Principal sources are puerperal infection, hemorrhage, and thromboembolism (Burrows and associates, 2004). Not all morbidity is immediate, and Lydon-Rochelle and colleagues (2000) reported that rehospitalization in the 60 days following cesarean delivery was nearly twice as common as after vaginal delivery—17 versus 10 hospitalizations per 1000 women delivered. Rajasekar and Hall (1997) reported that the incidence of bladder laceration with cesarean operation was 1.4 per 1000 procedures, and the incidence of ureteral injury was 0.3 per 1000. Although bladder injury was immediately identified, the diagnosis of ureteral injury often was delayed. Uterine infection is relatively common after cesarean delivery. The diagnosis and management of pelvic and wound infections following cesarean delivery are discussed in [Chapter 31](#). As discussed in [Chapter 43](#) (see p. 1011), morbidity associated with cesarean delivery is increased dramatically in obese women.

All of these morbidities, as well as the increased recovery time, result in a twofold increase in costs for cesarean versus vaginal delivery (Henderson and associates, 2001).

PATIENT CHOICE CESAREAN DELIVERY. As cesarean delivery has become safer and more commonly performed, and women have taken a more active role in their obstetrical care, it has been argued that women should be able to choose to undergo elective cesarean delivery (Harer, 2000). The issue is currently quite contentious. Putative reasons for this choice include avoidance of pelvic floor injury during vaginal birth, reduction in the risk of fetal injury, and convenience (Al-Mufti and colleagues, 1997). Conversely, the motivation of physicians in offering this choice, its medical rationale from both a maternal and fetal-neonatal standpoint, and even the concept of informed free choice have been questioned (Wagner, 2000).

Bewley and Cockburn (2002a, 2000b) found the concept of elective cesarean delivery to lack both ethical and medical merit. Clearly, and usually only with the benefit of hindsight, it can be said that some women and infants who have undergone difficult vaginal birth may have been better served by cesarean delivery instead. In most cases, however, clinically robust means of prospectively identifying otherwise uncomplicated pregnancies in which the woman or her fetus-infant would benefit from elective cesarean delivery are lacking. Minkoff and Chervenak (2003) and Minkhoff and colleagues (2004) concluded that although current evidence does not support routine elective cesarean delivery, it *does* ethically support an obstetrical decision to accede to an *informed* patient's request for such a delivery. At this time, we conclude that it is difficult to justify a *laissez faire* approach to this major operation.

TECHNIQUE FOR CESAREAN DELIVERY. With minor variations, surgical performance of cesarean delivery is comparable worldwide.

Abdominal Incisions. Usually either a midline vertical or a suprapubic transverse incision is used. Only in especial circumstances would a paramedian or midtransverse incision be employed.

Vertical Incision. An infraumbilical midline vertical incision is quickest to make. The incision should be of sufficient length to allow delivery of the infant without difficulty. Therefore, its length should correspond with the estimated fetal size. Sharp dissection is performed to the level of the anterior rectus sheath, which is freed of subcutaneous fat to expose a strip of fascia in the midline about 2 cm wide. Some surgeons prefer to incise the rectus sheath with the scalpel throughout the length of the fascial incision. Others prefer to make a small opening and then incise the fascial layer with scissors. The rectus and the pyramidalis muscles are separated in the midline by sharp and blunt dissection to expose transversalis fascia and peritoneum.

The transversalis fascia and preperitoneal fat are dissected carefully to reach the underlying peritoneum. The peritoneum near the upper end of the incision is opened carefully, either bluntly, or by elevating it with two hemostats placed about 2 cm apart. The tented fold of peritoneum between the clamps is then examined and palpated to be sure that omentum, bowel, or bladder is not adjacent. In women who have had previous intra-abdominal surgery, including cesarean delivery, omentum or bowel may be adherent to the undersurface of the peritoneum. The peritoneum is incised superiorly to the upper pole of the incision and downward to just above the peritoneal reflection over the bladder.

Transverse Incisions. With the modified *Pfannenstiel incision*, the skin and subcutaneous tissue are incised using a lower transverse, slightly curvilinear incision. The incision is made at the level of the pubic hairline and is extended somewhat beyond the lateral borders of the rectus muscles. After the subcutaneous tissue has been separated from the underlying fascia for 1 cm or so on each side, the fascia is incised transversely the full length of the incision. Sequentially, first the superior and then the inferior edge of the fascia is grasped with suitable clamps and elevated by the assistant as the operator separates the fascial sheath from the underlying rectus muscles either bluntly or sharply. Blood vessels coursing between the muscles and fascia are clamped, cut, and ligated, or they are fulgurated with electrocautery. Meticulous hemostasis is imperative. The fascial separation is carried near enough to the umbilicus to permit an adequate midline longitudinal incision of the peritoneum. The rectus muscles are then separated in the midline to expose the underlying peritoneum. The peritoneum is opened as discussed earlier.

The cosmetic advantage of the transverse skin incision is apparent. Whether it is stronger and less likely to undergo dehiscence is debated (Hendrix and co-workers, 2000). There definitely are some disadvantages in its use. Exposure in some women is not as optimal as with a vertical incision, and the latter can more easily be extended to increase exposure— a particular advantage if the woman is obese. With repeat cesarean delivery, reentry through a Pfannenstiel incision usually is

more time consuming and difficult because of scarring.

When a transverse incision is desired and more room is needed, the *Maylard incision* provides a safe option (Ayers and Morley, 1987; Giacalone and colleagues, 2002). In this incision, the rectus muscles are divided sharply or with electrocautery. The incision also may be especially useful in women with significant scarring resulting from previous transverse incisions.

Uterine Incisions. Most often the incision is made in the lower uterine segment transversely as described by Kerr in 1926. Occasionally, a low-segment vertical incision as described by Kronig in 1912 may be used. The so-called *classical incision* is a vertical incision into the body of the uterus above the lower uterine segment and reaching the uterine fundus. This incision is seldom used today. For most cesarean deliveries, the transverse incision is the operation of choice. Its advantages are that it (1) is easier to repair, (2) is located at a site least likely to rupture during a subsequent pregnancy, and (3) does not promote adherence of bowel or omentum to the incisional line. If the fetus is not presenting by the vertex, if there are multiple fetuses, or if the fetus is very immature and the woman has had no labor, a lower-segment vertical or even a classical incision may, at times, prove to be advantageous.

TECHNIQUE FOR TRANSVERSE CESAREAN INCISION. Commonly, the uterus is found to be dextrorotated so that the left round ligament is more anterior and closer to the midline than the right. With thick meconium or infected amniotic fluid, some surgeons prefer to lay a moistened laparotomy pack in each lateral peritoneal gutter to absorb fluid and blood that escape from the opened uterus. The rather loose reflection of peritoneum above the upper margin of the bladder and overlying the anterior lower uterine segment—the *bladder flap*—is grasped in the midline with forceps and incised transversely with a scalpel or scissors (Fig. 25-4). Scissors are inserted between the vesicouterine serosa and myometrium of the lower uterine segment and are pushed laterally from the midline, and then withdrawn while partially opening the blades intermittently, to separate a 2-cm-wide strip of serosa, which is then incised. As the lateral margin on each side is approached, the scissors are directed somewhat more cephalad (Fig. 25-5). The lower flap of peritoneum is elevated, and the bladder is gently separated by blunt or sharp dissection from the underlying myometrium (Fig. 25-6). In general, the separation of bladder should not exceed 5 cm in depth and usually should be less. It is possible, especially with an effaced, dilated cervix, to dissect downward so deeply as inadvertently to expose and then enter the underlying vagina rather than the lower uterine segment.

The uterus is entered through the lower uterine segment about 1 cm below the upper margin of the peritoneal reflection. It is important to place the uterine incision relatively higher in women with advanced or complete cervical dilatation to minimize both lateral extension of the incision into the uterine arteries and unintended entry into the vagina. This is done by using the vesicouterine serosal reflection as a guide.

The uterine incision can be made by a variety of techniques. Each is initiated by using a scalpel to transversely incise the exposed lower uterine segment for 1 to 2 cm in the midline. This must be done carefully to avoid injury to the fetus (Fig. 25-7). Skin laceration was the most common fetal injury seen with 37,110 cesarean deliveries in the Network study reported by Alexander and colleagues (2005). Careful blunt entry using hemostats or fingertip to split the muscle may be helpful. Once the uterus is opened, the incision can be extended by cutting laterally and then slightly upward with bandage scissors. Alternatively, when the lower uterine segment is thin, the incision can be extended by simply spreading the incision, using lateral and upward pressure applied with each index finger (Fig. 25-8). Although Rodriguez and associates (1994) reported that blunt and sharp extensions of the initial uterine incision are equivalent in terms of safety and postoperative complications, Magann and colleagues (2002) reported that sharp dissection increased blood loss and the need for transfusion. **It is very important to make the uterine incision large enough to allow delivery of the head and trunk of the fetus without either tearing into or having to cut into the uterine arteries and veins that course through the lateral margins of the uterus.** If the placenta is encountered in the line of incision, it must be either detached or incised. When the placenta is incised, fetal hemorrhage may be severe; thus, delivery and cord clamping should be performed as soon as possible in such cases.

Delivery of the Infant. In a cephalic presentation, a hand is slipped into the uterine cavity between the symphysis and fetal head, and the head is elevated gently with the fingers and palm through the incision, aided by modest transabdominal fundal pressure (Fig. 25-9). After a long labor with cephalopelvic disproportion, the fetal head may be tightly wedged in the birth canal. Upward pressure exerted by a hand in the vagina by an assistant will help to dislodge the head and allow its delivery above the symphysis. To minimize fetal aspiration of amniotic fluid, exposed nares and mouth are aspirated with a bulb syringe before the thorax is delivered. The shoulders then are delivered using gentle traction plus fundal pressure (Fig. 25-10). The rest of the body readily follows.

After the shoulders are delivered, an intravenous infusion containing about two ampules or 20 units of oxytocin per liter of crystalloid is infused at 10 mL/min until the uterus contracts satisfactorily, after which the rate can be reduced. Bolus doses of 5 to 10 units are avoided because of associated hypotension. Munn and colleagues (2001) studied a much higher initial concentration using a solution of 80 units of oxytocin in 500 mL of crystalloid, which was infused at about 17 mL/min. They reported that this approach significantly reduced the need for additional uterotonic agents.

The cord is clamped, and the infant is given to the team member who will conduct resuscitative efforts as needed. The uterine incision is observed for any vigorously bleeding sites. These should be promptly clamped with Pennington or ring forceps, or similar instruments. The placenta is then delivered unless it has already done so spontaneously. Many surgeons prefer manual removal, but spontaneous delivery with some cord traction (Fig. 25-11) has been shown to reduce the risk of puerperal metritis (Atkinson and colleagues, 1996; Lasley and associates, 1997). Fundal massage, begun as soon as the fetus is delivered, reduces bleeding and hastens placental delivery.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) recommend that "a qualified person who is skilled in neonatal resuscitation should be in the operative delivery room, with all equipment needed for neonatal resuscitation, to care for the neonate." Based on their comparison of 834 cesarean deliveries with 834 low-risk vaginal deliveries, Jacob and Phenninger (1997) reported that, with regional analgesia, there is rarely a need for vigorous infant resuscitation after elective repeat cesarean delivery or cesarean delivery for dystocia without fetal heart rate abnormalities, and that a pediatrician may not be necessary at such deliveries. At Parkland Hospital, pediatric nurse practitioners attend uncomplicated, scheduled cesarean deliveries.

Repair of the Uterus. After delivery of the placenta, the uterus may be lifted through the incision onto the draped abdominal wall and the fundus covered with a moistened laparotomy pack. Although some clinicians prefer to avoid it, uterine exteriorization often has advantages that outweigh any disadvantages. For example, the relaxed, atonic uterus can be recognized quickly and massage applied. The incision and bleeding points are visualized more easily and repaired, especially if there have been extensions laterally. Adnexal exposure is superior, and thus tubal sterilization is easier. The principal disadvantage is from discomfort and vomiting caused by traction in cesarean deliveries performed under regional analgesia. Neither febrile morbidity nor blood loss appears to be increased in women undergoing uterine exteriorization prior to repair (Hershey and Quilligan, 1978; Wahab and co-workers, 1999).

Immediately after delivery and inspection of the placenta, the uterine cavity is inspected and either suctioned or wiped out with a gauze pack to remove avulsed membranes, vernix, clots, and other debris. The upper and lower cut edges and each lateral angle of the uterine incision are examined carefully for bleeding. Individually clamped large vessels are best ligated with a suture ligature. Concern has been expressed by some clinicians that sutures through the decidua may lead to endometriosis in the hysterotomy scar, but this is a rare.

The uterine incision is then closed with one or two layers of continuous 0 or number 1 absorbable suture. Chromic suture is used by most surgeons, but some prefer synthetic nonabsorbable sutures. Hauth and colleagues (1992) randomized 906 women to either one- or two-layer closure using 1-0 chromic gut. A continuous locking one-layer closure required less operative time and fewer additional hemostatic sutures. In a follow-up report of 164 women delivered subsequently, the type of uterine closure did not significantly affect several maternal and fetal complications in the next pregnancy (Chapman and associates, 1997). Similarly, Durnwald and Mercer (2003) reported no uterine ruptures in 182 women who underwent a trial of labor after single-layer closure compared with four ruptures in 340 women (1.2 percent) after double-layer closure. By contrast, Bujold and associates (2002) reported that single-layer closure was associated with a fourfold increased risk of uterine rupture during a subsequent trial of labor. Further study of this issue is needed (see [Chap. 26](#), p. 611).

The initial suture is placed just beyond one angle of the uterine incision. A running-lock suture is then carried out, with each suture penetrating the full thickness of the myometrium ([Fig. 25-12](#)). It is important to select carefully the site of each stitch and to avoid withdrawing the needle once it penetrates the myometrium. This minimizes the perforation of unligated vessels and subsequent bleeding. The running-lock suture is continued just beyond the opposite incision angle. Especially when the lower segment is thin, satisfactory approximation of the cut edges usually can be obtained with one layer of suture. If approximation is not satisfactory after a single-layer continuous closure, or if bleeding sites persist, then more sutures are required. Either another layer of sutures may be placed so as to achieve approximation and hemostasis, or individual bleeding sites can be secured with figure-of-eight or mattress sutures.

Traditionally, serosal edges overlying the uterus and bladder have been approximated with a continuous 2-0 chromic catgut suture. Multiple randomized trials suggest that omission of this step causes no postoperative complications (Grundsell, 1998; Hull and Varner, 1991; Irion, 1996; Nagele, 1996; Pietrantonio, 1991, and all their associates). Specifically, not approximating the bladder flap is unlikely to increase adhesion formation or long-term morbidity (Roset and colleagues, 2003; Tulandi and Al-Jaroudi, 2003). Data are conflicting as to whether nonclosure of peritoneum decreases postoperative discomfort and need for analgesia (Chanrachakul and colleagues, 2002; Rafique and colleagues, 2002).

If tubal sterilization is to be performed, it is now done as described in [Chapter 33](#) (see p. 752).

Abdominal Closure. All packs are removed, and the paracolic gutters and cul-de-sac are emptied of blood and amniotic fluid using gentle suction. Some surgeons irrigate the gutters and cul-de-sac, especially in the presence of infection or meconium. A small randomized trial by Harrigill and colleagues (2003) supports that this step is not necessary in low-risk women who undergo cesarean delivery in the absence of amnionitis. After the sponge and instrument counts are found to be correct, the abdominal incision is closed in layers. As previously discussed, many surgeons omit the parietal peritoneal closure because it serves little purpose. If there is distended bowel in the incision site, however, we find that peritoneal closure may help to protect the bowel when fascial sutures are placed. As each layer is closed, bleeding sites are located, clamped, and ligated. The rectus muscles are allowed to fall into place, and the subfascial space is meticulously checked for hemostasis. With significant diastasis, the rectus muscles may be approximated with one or two figure-of-eight sutures of 0 or number 1 chromic. The overlying rectus fascia is closed either with interrupted 0 nonabsorbable sutures that are placed lateral to the fascial edges and no more than 1 cm apart, or by continuous, nonlocking suture of a long-lasting absorbable or permanent type.

The subcutaneous tissue usually need not be closed separately if it is less than 2 cm in thickness, and the skin is closed with vertical mattress sutures of 3-0 or 4-0 silk or equivalent suture, with a running 4-0 subcuticular stitch using semipermanent suture, or with skin clips. If the subcutaneous tissue is at least 2 cm thick, it should be closed. In a randomized prospective study of more than 1400 women undergoing cesarean delivery, Bohman and colleagues (1992) reported a significantly decreased frequency of superficial wound disruption when the subcutaneous layer was approximated. Based on their systematic review of six studies, Chelmos and colleagues (2004) concluded that suturing the subcutaneous tissue at cesarean delivery decreases the risk of wound disruption by 34 percent in women with fat thickness greater than 2 cm.

Figure 25-4. The loose vesicouterine serosa is grasped with the forceps. The hemostat tip points to the upper margin of the bladder. The retractor is firmly positioned against the symphysis. (m. = muscle.)

Figure 25-6. Cross section showing dissection of the bladder off the uterus to expose the lower uterine segment.

Figure 25-5. The loose serosa above the upper margin of the bladder is elevated and incised laterally.

Figure 25-7. The myometrium is incised carefully to avoid cutting the fetal head.

Figure 25-8. After entering the uterine cavity, the incision is extended laterally with bandage scissors (**A**) or with the fingers, as shown in **B**.

Figure 25-9. A. Immediately after incising the uterus and rupturing the fetal membranes, the fingers are insinuated between the symphysis pubis and the fetal head until the posterior surface is reached. The head is lifted carefully anteriorly and, as necessary, superiorly to bring it from beneath the symphysis forward through the uterine and abdominal incisions. **B.** As the fetal head is lifted through the incision, pressure usually is applied to the uterine fundus through the abdominal wall to help expel the fetus.

Figure 25-10. The shoulders are delivered, and oxytocin infusion is begun.

Figure 25-11. Placenta bulging through the uterine incision as the uterus contracts.

Figure 25-12. The cut edges of the uterine incision are approximated with a running-lock suture.

TECHNIQUE FOR CLASSICAL CESAREAN INCISION. Occasionally it is necessary to use a classical incision for delivery. Some indications are:

1. Difficulty in exposing or safely entering the lower uterine segment because the bladder is densely adherent from previous surgery, a myoma occupies the lower uterine segment, or the cervix has been invaded by cancer.
2. Transverse lie of a large fetus, especially if the membranes are ruptured and the shoulder is impacted in the birth canal. A fetus presenting as a back-down transverse lie may be particularly difficult to deliver through a transverse incision.
3. Some cases of placenta previa with anterior implantation, especially in the case where the placenta has grown through a prior uterine incision (placenta percreta).

4. Certain cases in which the fetus is very small, especially if breech, and the lower uterine segment is not thinned out.
5. Massive maternal obesity precluding safe access to the lower uterine segment.

Uterine Incision. A vertical uterine incision is initiated with a scalpel beginning as low as possible, depending on how well the lower segment is thinned out. If adhesions, insufficient exposure, a tumor, or placenta percreta preclude development of a bladder flap, then the incision is made above the level of the bladder. Once uterine entry is made with the scalpel, the incision is extended cephalad with bandage scissors until it is sufficiently long to permit delivery of the fetus. Numerous large vessels that bleed profusely are commonly encountered within the myometrium.

Uterine Repair. One method employs a layer of continuous 0 or 1-0 chromic catgut to approximate the deeper halves of the incision. The outer half of the uterine incision is then closed with similar suture, using either a continuous stitch or figure-of-eight sutures. No unnecessary needle tracts should be made lest myometrial vessels are perforated with subsequent hemorrhage or hematomas. To achieve good approximation and to prevent the suture from tearing through the myometrium, it is helpful to have an assistant compress the uterus on each side of the wound toward the midline as each suture is placed and tied. The edges of the uterine serosa, if not already so, are approximated with continuous 2-0 chromic catgut. The operation is completed as described earlier.

POSTMORTEM CESAREAN DELIVERY. At times, cesarean delivery is performed on a woman who has just died, or who is expected to do so momentarily. The issue of cesarean delivery to aid in cardiopulmonary resuscitation of the mother is further discussed in [Chapter 42](#) (see p. 1002).

PERIPARTUM HYSTERECTOMY

Hysterectomy performed at or following delivery may be lifesaving if there is severe obstetrical hemorrhage. It can be carried out in conjunction with cesarean delivery or following vaginal delivery. One measure of its incidence is from the Maternal-Fetal Medicine Units Network centers. In that study of almost 29,000 cesarean deliveries, Shellhaas and colleagues (2001) reported that hysterectomy was performed in 1 in every 200 cesarean deliveries. Overall, hysterectomy was performed in 1 in every 950 deliveries. During the 9-year period ending with 2002, during which there were almost 129,500 deliveries at Parkland Hospital, peripartum hysterectomy was performed once in every 500 deliveries. The incidence was 1 in 135 for 26,700 cesarean deliveries and about 1 in 1850 for vaginal deliveries. These numbers are similar to those of Kastner and co-workers (2002), who reported an overall rate of peripartum hysterectomy of 1.4 per 1000 deliveries. Similarly, Forna and associates (2004) cited a rate of 0.8 per 1000 deliveries at Grady Hospital.

INDICATIONS. The majority of procedures are performed to arrest hemorrhage from intractable uterine atony, lower-segment bleeding associated with the uterine incision or placental implantation, or a laceration of major uterine vessels. Placenta accreta, often in association with repeat cesarean delivery, and uterine atony are the most common indications today for cesarean or postpartum hysterectomy (Kastner and associates, 2002; Shellhaas and colleagues, 2001). These conditions are discussed in [Chapter 35](#) (see p. 809). Large myomas may preclude satisfactory hysterotomy closure and thus necessitate hysterectomy. Elective indications for peripartum hysterectomy include large or symptomatic myomas and severe cervical dysplasia or carcinoma in situ.

Major complications of peripartum hysterectomy are increased blood loss and the possibility of urinary tract damage. An important factor affecting the complication rate is whether the operation is performed as an elective procedure or as an emergency. As shown in [Table 25-3](#), morbidity associated with emergency hysterectomy is substantively increased. Seago and associates (1999) reported that the rate of intraoperative and postoperative complications among 100 women who underwent planned cesarean hysterectomy was not increased when compared with that of a control group of 37 women who underwent cesarean delivery followed by hysterectomy performed within 6 months.

Although pelvic vessels are appreciably hypertrophied, hysterectomy usually is facilitated by the ease of development of tissue planes in pregnant women. Blood loss is usually appreciable because hysterectomy performed for hemorrhage almost always is torrential. Indeed, as shown in [Table 25-3](#), 90 percent of women undergoing emergency peripartum hysterectomy required transfusions.

TECHNIQUE FOR PERIPARTUM HYSTERECTOMY. Supracervical or total hysterectomy is performed using standard operative techniques. Initially, placement of a self-retaining retractor such as a Balfour is not necessary. Satisfactory exposure is best obtained with cephalad traction on the uterus by an assistant, along with hand-held retractors such as a Richardson or Deaver. The bladder flap is deflected downward to the level of the cervix if possible. After cesarean delivery and placental removal, if the hysterotomy is bleeding appreciably, either it can be sutured, or Pennington or sponge-forceps can be applied for hemostasis. If bleeding is minimal, neither maneuver is necessary.

The round ligaments close to the uterus are divided between Heaney or Kocher clamps and doubly ligated. Either 0 or number 1 sutures can be used. The incision in the vesicouterine serosa that was made to mobilize the bladder is extended laterally and upward through the anterior leaf of the broad ligament to reach the incised round ligaments ([Fig. 25-13](#)). The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tubes, utero-ovarian ligaments, and ovarian vessels ([Fig. 25-14A](#)). These vessels then are doubly clamped close to the uterus and divided, and the lateral pedicle is doubly ligated ([Fig. 25-14B](#)). The posterior leaf of the broad ligament is divided inferiorly toward the uterosacral ligaments ([Fig. 25-15](#)). Next, the bladder and attached peritoneal flap are again deflected and dissected from the lower uterine segment and retracted out of the operative field ([Fig. 25-16](#)). If the bladder flap is unusually adherent, as it may be after previous cesarean incisions, careful sharp dissection may be necessary.

Special care is necessary from this point on to avoid injury to the ureters, which pass beneath the uterine arteries. To help accomplish this, the assistant places constant traction on the uterus in the direction away from the side on which the uterine vessels are being ligated. The ascending uterine artery and veins on either side are identified near their origin. These pedicles

are then doubly clamped immediately adjacent to the uterus, divided, and doubly suture ligated. As shown in [Figure 25-17](#), we prefer to use three heavy clamps, incise the tissue between the most medial and two lateral clamps, and then ligate the two pedicles in the clamps lateral to the uterus.

In cases of profuse hemorrhage, it may be more advantageous to rapidly double clamp and divide all of the vascular pedicles between clamps to gain hemostasis and then return to suture ligate all of the pedicles.

Supracervical Hysterectomy. To perform a subtotal hysterectomy, it is necessary only to amputate the body of the uterus at this level. The cervical stump may be closed with continuous or interrupted chromic sutures. Subtotal hysterectomy is often all that is necessary to stop hemorrhage and may be the more prudent operation for selected women (Jones, 1999; Kastner, 2002; Learman, 2003; Munro, 1997, and their associates).

Total Hysterectomy. Even if total hysterectomy is planned, we find it in many cases technically easier to finish the operation after amputating the uterine fundus and placing Ochsner or Kocher clamps on the stump for traction and hemostasis. Self-retaining retractors also are placed at this time. To remove the cervix, it is necessary to mobilize the bladder much more extensively in the midline and laterally. This will help carry the ureters caudad as the bladder is retracted beneath the symphysis and also will prevent laceration or suturing of the bladder during cervical excision and vaginal cuff closure. Before cesarean delivery, the bladder is dissected free for about 2 cm below the lowest margin of the cervix to expose the uppermost part of the vagina. If the cervix is effaced and dilated appreciably, after delivery the cervicovaginal junction may be identified by a vertical uterine incision made anteriorly in the midline, either through the hysterotomy incision or through an incision made at the level of the ligated uterine vessels. A finger is directed inferiorly through the incision to identify the free margin of the dilated, effaced cervix and the anterior vaginal fornix, and the contaminated glove replaced. Another useful method to identify the cervical margins is to place four metal skin clips or brightly colored sutures at 12, 3, 6, and 9 o'clock positions on the cervical edges prior to hysterectomy.

The cardinal ligaments, uterosacral ligaments, and the many large vessels these ligaments contain are doubly clamped systematically with Heaney-type curved clamps, Ochsner-type straight clamps, or similar instruments ([Fig. 25-18](#)). The clamps are placed as close to the cervix as possible, taking care not to include excessive tissue in each clamp. The tissue between the pair of clamps is incised and the distal pedicle suture ligated. These steps are repeated until the level of the lateral vaginal fornix is reached. In this way, the descending branches of the uterine vessels are clamped, cut, and ligated as the cervix is dissected from the cardinal ligaments posteriorly.

Immediately below the level of the cervix, a curved clamp is placed across the lateral vaginal fornix, and the tissue is incised medially to the clamp ([Fig. 25-19](#)). The excised lateral vaginal fornix can be simultaneously doubly ligated and sutured to the stump of the cardinal ligament. The entire cervix is then excised from the vagina. The cervix is inspected to ensure that it has been completely removed, and the vagina is then repaired. Each of the angles of the lateral vaginal fornix is secured to the cardinal and uterosacral ligaments ([Fig. 25-20](#)). Following this step, some surgeons prefer to close the vagina using figure-of-eight chromic catgut sutures. Others achieve hemostasis by using a running-lock stitch of chromic catgut suture placed through the mucosa and adjacent endopelvic fascia around the circumference of the vaginal cuff ([Fig. 25-21](#)). The open vagina may promote drainage of fluids that would otherwise accumulate and contribute to hematoma formation and infection.

If a self-retaining retractor has not already been placed, some clinicians choose to insert the instrument at this point. The bowel is then packed out of the field and all sites of incision are examined carefully for bleeding. One technique is to perform a systematic bilateral survey from the fallopian tube and ovarian ligament pedicles to the vaginal vault and bladder flap. Bleeding sites are ligated with care to avoid the ureters.

Some clinicians choose to reperitonealize the pelvis. One method employs a continuous chromic suture starting with the tip of the ligated pedicle of fallopian tube and ovarian ligament, which is inverted retroperitoneally. Sutures are then placed continuously to approximate the leaves of the broad ligament, bury the stump of the round ligament, and to join the cut edge of the vesicouterine peritoneum over the vaginal vault posteriorly to the cut edge of peritoneum above the cul-de-sac. This action is then repeated on the other side. The abdominal wall normally is closed in layers, as previously described.

Oophorectomy. Most studies indicate that in 5 percent of postpartum hysterectomies, one adnexum will have to be removed to stop bleeding (Plauche, 1995). That said, during any hysterectomy, a decision as to the fate of the ovaries must be made. For women who are approaching menopause, the decision is not difficult, but few women who undergo cesarean hysterectomy are of this age.

Figure 25-13. The incision in the vesicouterine serosa is extended laterally and upward through the anterior leaf of the broad ligament to reach the incised round ligaments.

Figure 25-14. A. The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tube, utero-ovarian ligaments, and ovarian vessels. **B.** These then are doubly clamped close to the uterus and divided.

Figure 25-15. The posterior leaf of the broad ligament is divided inferiorly toward

the uterosacral ligament.

Figure 25-16. The bladder is further dissected from the lower uterine segment by blunt dissection with pressure directed toward the lower segment and not the bladder. Sharp dissection may be necessary.

Figure 25-17. A. The uterine artery and veins on either side are doubly clamped immediately adjacent to the uterus and divided. **B, C.** The vascular pedicle is doubly suture ligated.

Figure 25-18. The cardinal ligaments are clamped, incised, and ligated.

Figure 25-19. A curved clamp is placed across the lateral vaginal fornix below the level of the cervix and the tissue incised medially to the point of the clamp.

Figure 25-20. The lateral angles of the vaginal cuff are secured to the cardinal and uterosacral ligaments.

Figure 25-21. A running-lock suture is placed through the edge of the vaginal mucosa, circumferentially.

PERIPARTUM MANAGEMENT

PREOPERATIVE CARE. If cesarean delivery is planned, a sedative, such as secobarbital, 100 mg, may be given at bedtime the night before the operation. In general, no other sedatives, narcotics, or tranquilizers are administered until after the infant is born. Oral intake is stopped at least 8 hours before surgery. The woman scheduled for repeat cesarean delivery typically is admitted the day of surgery and evaluated by the obstetrician and the anesthesiologist. The hematocrit is rechecked, as is the indirect Coombs test. If the latter is positive, then availability of compatible blood must be assured. An antacid, such as Bicitra, 30 mL, is given shortly before placement of conduction analgesia or induction with general anesthesia. This minimizes the risk of lung injury from gastric acid should aspiration occur (see [Chap. 19](#), p. 490). An indwelling bladder catheter is placed. If hair obscures the operative field it should be removed the day of surgery by clipping or shaving. If shaving is performed the night before surgery, the risk of wound infection is increased.

INTRAVENOUS FLUIDS. Requirements for intravenous fluids, including blood during and after cesarean delivery, can vary considerably. The woman of average size with a hematocrit of 30 percent or more and a normally expanded blood and extracellular fluid volume most often will tolerate blood loss up to 2000 mL without difficulty. Unappreciated bleeding through the vagina during the procedure, bleeding concealed in the uterus after its closure, or both, commonly lead

to underestimation. Although blood loss averages about 1500 mL with elective cesarean hysterectomy, it is quite variable (Pritchard, 1965). Intravenously administered fluids consist of either lactated Ringer solution or a similar crystalloid solution with 5 percent dextrose. Typically, 1 to 2 L are infused during and immediately after the operation. Throughout the procedure, and subsequently while in the recovery area, the blood pressure and urine flow are monitored closely.

PREVENTION OF POSTOPERATIVE INFECTION. Febrile morbidity is frequent after cesarean delivery. A large number of randomized trials have demonstrated that a single dose of an antimicrobial agent given at the time of cesarean delivery will serve to decrease infection morbidity significantly. This is true of high-risk laboring patients as well as those undergoing elective cesarean delivery (American College of Obstetricians and Gynecologists, 2003). For women in labor or with ruptured membranes, most clinicians recommend a single 2-g dose of a β -lactam drug—either a cephalosporin or an extended-spectrum penicillin—after delivery of the infant. Postoperative pelvic infection is the most frequent cause of febrile morbidity and develops in up to 20 percent of these women despite peripartum prophylactic antimicrobials (Goepfert and associates, 2001). In general, infection rates are higher among government-funded and indigent patients. Treatment of uterine infection and its complications are discussed in [Chapter 31](#).

RECOVERY SUITE. Postoperatively, the amount of bleeding from the vagina must be monitored closely, and the uterine fundus must be identified frequently by palpation to assure that the uterus is remaining firmly contracted. Unfortunately, as conduction analgesia fades or the woman awakens from general anesthesia, palpation of the abdomen is likely to produce considerable discomfort. This can be made more tolerable by giving an effective analgesic intravenously, such as meperidine, 75 to 100 mg, or morphine, 10 to 15 mg. A thick dressing with an abundance of adhesive tape over the abdomen interferes with fundal palpation and massage and later causes discomfort as the tape is removed. Deep breathing and coughing are encouraged. Once the mother is fully awake, bleeding is minimal, blood pressure is satisfactory, and urine flow is at least 30 mL/hr, she may be sent to her room.

SUBSEQUENT CARE

Analgesia. For the woman of average size, meperidine, 75 to 100 mg, is given intramuscularly as often as every 3 hours as needed for discomfort, or morphine sulfate, 10 to 15 mg, is similarly administered. An antiemetic, such as promethazine, 25 mg, usually is given along with the narcotic. Intravenous meperidine or morphine via a patient-controlled pump is an even more effective alternative to bolus therapy in the immediate postoperative period. The pump typically is programmed to deliver a continuous infusion of drug, which the woman can supplement with intermittent boluses, the frequency of which are determined by the "lock-out" interval ([Table 25-4](#)). In a recent trial at Parkland Hospital (Yost and colleagues, 2004), morphine provided superior pain relief to meperidine and was associated with significantly higher rates of breast feeding continuation and infant rooming-in.

Vital Signs. After transfer to her room, the patient is assessed at least hourly for 4 hours and thereafter, at intervals of 4 hours. Blood pressure, pulse, temperature, uterine tone, urine output, and amount of bleeding are evaluated.

Fluid Therapy and Diet. Unless there has been pathological constriction of the extracellular fluid compartment from severe preeclampsia, vomiting, fever, or prolonged labor without adequate fluid intake, or there is sepsis or significant blood loss, the puerperium is characterized by excretion of fluid that was retained during pregnancy. Moreover, with the typical cesarean delivery, significant extracellular fluid sequestration in bowel wall and lumen does not occur, unless it was necessary to pack the bowel away from the operative field or peritonitis develops. Thus, the woman who undergoes cesarean delivery rarely develops fluid sequestration in the so-called third space. Quite the contrary, she normally begins surgery with a physiologically enlarged extravascular volume acquired during pregnancy that she mobilizes and excretes after delivery. Therefore, large volumes of intravenous fluids during and subsequent to surgery are not needed to replace sequestered extracellular fluid. As a generalization, 3 L of fluid should prove adequate during the first 24 hours after surgery. If urine output falls below 30 mL/hr, however, then the woman should be reevaluated promptly. The cause of the oliguria may range from unrecognized blood loss to an antidiuretic effect from infused oxytocin.

Bladder and Bowel Function. The bladder catheter most often can be removed by 12 hours postoperatively or, more conveniently, the morning after surgery. Subsequent ability to empty the bladder before overdistention develops must be monitored as with vaginal delivery.

In uncomplicated cases, solid food may be offered within 8 hours of surgery (Burrows and associates, 1995; Kramer and colleagues, 1996). Although some degree of adynamic ileus follows virtually every abdominal operation, in most cases of cesarean delivery, it is negligible. Symptoms include abdominal distention and gas pains, and an inability to pass flatus or stool. The pathophysiology of postoperative ileus is complex and involves hormonal, neural, and local factors that are incompletely understood (Livingston and Passaro, 1990). If associated with otherwise unexplained fever, an unrecognized bowel injury may be responsible. Treatment for ileus has changed little over the past several decades and involves intravenous fluid and electrolyte supplementation. If severe, nasogastric decompression is necessary. Frequently, a 10-mg bisacodyl rectal suppository provides appreciable relief.

Ambulation. In most instances, by the day after surgery, the woman should get briefly out of bed with assistance at least twice. Ambulation can be timed so that a recently administered analgesic will minimize the discomfort. By the second day she may walk without assistance. Early ambulation lowers the risk of venous thrombosis and pulmonary embolism (see [Chap. 47](#)).

Wound Care. The incision is inspected each day, and the skin sutures or clips often can be removed on the fourth day after surgery. However, if there is concern for superficial wound separation, as in the obese patient, the suture or clips should remain in place for 7 to 10 days if they are not causing appreciable skin irritation. By the third postpartum day, bathing by shower is not harmful to the incision. In addition to increasing the risk of wound separation, thick subcutaneous tissue—greater than 3 cm—increases the risk of wound infection (Vermillion and associates, 2000).

Laboratory. The hematocrit is routinely measured the morning after surgery. It is checked sooner when there was unusual blood loss or when there is oliguria or other evidence to suggest hypovolemia. If the hematocrit is decreased significantly from the preoperative level, the measurement is repeated and a search is instituted to identify the cause of the decline. If the

hematocrit stabilizes, the mother can ambulate without any difficulty, and if there is little likelihood of further blood loss, iron therapy is preferred to transfusion.

Breast Care. Breast feeding can be initiated the day of surgery. If the mother elects not to breast feed, a binder that supports the breasts without marked compression usually will minimize discomfort (see [Chap. 30](#), p. 699).

Hospital Discharge. Unless there are complications during the puerperium, the mother generally is discharged on the third or fourth postpartum day (see [Chap. 30](#), p. 706). Strong and associates (1993) have presented data suggesting that discharge on day 2 may be appropriate for properly selected and motivated women. The mother's activities during the first week should be restricted to self-care and care of her baby with assistance. Brooten and colleagues (1994) successfully combined early discharge with nurse specialist transitional home care. In many cases, it may be advantageous to perform an initial postpartum evaluation during the first to third week after delivery to search for puerperal complications discussed in [Chapters 30](#) and [32](#).

SECTION IV - LABOR AND DELIVERY
25. Cesarean Delivery and Peripartum Hysterectomy
INTRODUCTION

26. Prior Cesarean Delivery

INTRODUCTION

There are few issues in modern obstetrics that have been as controversial as the management of the woman with a prior cesarean delivery. For many decades, a scarred uterus was believed to contraindicate labor out of fear of uterine rupture. In 1916, Cragin made his famous, oft-quoted, and now seemingly excessive pronouncement, "Once a cesarean, always a cesarean." We must remember that when this statement was made, the so-called classical vertical uterine incision was used almost universally. It was not until 1921 that the Kerr transverse incision was recommended. Among Cragin's contemporaries, there were some who did not totally agree with his pronouncement. Writing in the fourth edition of *Williams Obstetrics*, J. Whitridge Williams (1917) termed the statement "an exaggeration." Now, 18 editions and nearly 90 years later, the controversy continues.

The year 1978 was another milestone in the history of prior cesarean delivery. Merrill and Gibbs (1978) reported from the University of Texas at San Antonio that subsequent vaginal delivery was safely attempted in 83 percent of their patients with prior cesarean deliveries. This report served to rekindle interest in vaginal birth after prior cesarean at a time when only 2 percent of American women who had previously undergone cesarean birth were planning vaginal delivery. The report was timely because during this same period, the rates of cesarean delivery in the United States were beginning to increase at an unprecedented rate. Between 1980 and 1988, for example, the rate jumped from 17 to 25 percent—a remarkable 50-percent increase in less than a decade. Meanwhile, evidence had accrued that uterine rupture was infrequent and rarely catastrophic. Thus, in an effort to address this escalation, the American College of Obstetricians and Gynecologists (1988) recommended that, in the absence of a contraindication, a woman with one previous low-transverse cesarean delivery be counseled to attempt labor in a subsequent pregnancy. Accordingly, the frequency of vaginal birth after cesarean, commonly referred to as *VBAC* and pronounced *vee back*, increased significantly in the United States. As shown in [Figure 26-1](#), by 1996 almost 30 percent of women with a prior cesarean were being delivered vaginally. In 1991, Dr. Roy Pitkin, former editor of *Obstetrics & Gynecology*, wrote that "...without question, the most remarkable change in obstetric practice over the last decade was management of the woman with prior cesarean delivery."

Figure 26-1. Total and primary cesarean delivery rate and vaginal birth after previous cesarean (VBAC) rate: United States, 1989-2002. (Reproduced from Hamilton and associates, 2003.)

TRIAL OF LABOR VERSUS REPEAT CESAREAN DELIVERY

RISKS AND BENEFITS. Beginning in 1989, as the number of women with prior cesareans attempting vaginal delivery increased, there were a number of reports from around the United States and Canada that suggested that VBAC might be riskier than anticipated (Leveno, 1999). This led Scott (1991) to suggest an "alternative viewpoint on mandatory trial of labor," based on adverse experiences with 12 women in Utah who suffered uterine rupture during a trial of labor. Two women required hysterectomy, there were three perinatal deaths, and two infants suffered significant long-term neurological impairment. Porter and colleagues (1998) subsequently reported that there were 26 uterine ruptures in Salt Lake City between 1990 and 1996 and that 23 percent of the infants were dead or damaged as a result of intrapartum asphyxia. Reports such as these raised serious concern about the safety of this practice and contributed to heightened controversy (Flamm, 1997). These concerns resulted in fewer women with a prior cesarean incision attempting vaginal delivery, which led to a corresponding increase in the overall cesarean delivery rate, again seen in [Figure 26-1](#).

MAGNITUDE OF RISK. Although uterine rupture and its associated complications clearly are increased with a trial of labor, some investigators have argued that these factors should weigh only minimally in the decision to attempt VBAC because the absolute risk of these complications is quite low. For example, Landon and collaborators (2004) from the Maternal-Fetal Medicine Units (MFMU) Network compared the outcomes of nearly 18,000 women who attempted a trial of labor with those of more than 15,000 women who were delivered by elective repeat cesarean. As shown in [Table 26-1](#), although the risk of uterine rupture was higher among the women undergoing a trial of labor, the absolute risk was small. Specifically, the risk of uterine rupture was 7 per 1000. In comparison, however, there were no uterine ruptures in the elective cesarean delivery group. Moreover, the rates of stillbirth and hypoxic ischemic encephalopathy were significantly greater in the trial of labor group.

Smith and associates (2002) measured the risks of intrapartum and neonatal death associated with a trial of labor compared with those of a planned repeat cesarean delivery using a database linking all maternity hospitals in Scotland. Their analysis involved 313,238 term singleton deliveries that were registered between 1992 and 1997 and included 24,529 births from women with a prior cesarean delivery. The risk of delivery-related perinatal death was approximately 1.3 per 1000 among the 15,515 women with a prior cesarean who attempted a vaginal delivery. Although the absolute risk was again small, this rate was *11 times greater* than the risk of perinatal death associated with a planned repeat cesarean.

The results of these and other investigations, including two large systematic reviews by Chauhan and colleagues (2003) and Mozurkewich and Hutton (2000), are congruent. Collectively, they suggest that the absolute risk of uterine rupture attributable to a trial of labor resulting in death or injury to the fetus is about 1 per 1000. The major controversy surrounding the management of women with a prior cesarean thus stems from the question: *Is a 1 per 1000 risk of having an otherwise healthy fetus die or be damaged as a result of a trial of labor acceptable?*

MATERNAL MORBIDITY. Another potential argument in support of VBAC has been that a trial of labor is

associated with reduced risks for the mother compared with those of a repeat cesarean delivery. Maternal *mortality* does not appear to differ significantly between women undergoing a trial of labor compared with that of an elective repeat cesarean (Landon and co-workers, 2004; Mozurkewich and Hutton, 2000). Estimates of maternal *morbidity*, however, have produced conflicting results. In the meta-analysis by Mozurkewich and Hutton (2000), women undergoing a trial of labor were about half as likely to require a blood transfusion or hysterectomy compared with those undergoing an elective repeat cesarean delivery. Conversely, in the MFMU Network study cited earlier, Landon and co-workers (2004) observed that the risks of transfusion and infection were significantly greater for women attempting a trial of labor (see [Table 26-1](#)). McMahon and associates (1996), in a population-based study of 6138 women, found that major complications—hysterectomy, uterine rupture, or operative injury—were almost twice as common in women undergoing a trial of labor compared with those of those undergoing an elective second cesarean delivery. Moreover, compared with a successful trial of labor, the risk of these major complications was fivefold greater in women whose attempt at a vaginal delivery failed.

COSTS. Analyses from Northwestern Hospital in Chicago support the safety of VBAC as well as its cost effectiveness in women with one or two prior low-transverse uterine incisions (Grobman and associates, 2000; Socol and Peaceman, 1999). By applying a mathematical model to a hypothetical cohort of 100,000 pregnant women whose only prior delivery was through a low-transverse cesarean incision, a policy of routine repeat cesarean for a second birth was calculated to result in an increased cost of \$179 million. Similarly, DiMaio and colleagues (2002) estimated that total hospital costs for mother and newborn were nearly \$1100 higher for each elective repeat cesarean compared with that of those who attempted vaginal delivery. Conversely, Clark and colleagues (2000) concluded that "when costs as opposed to charges are considered and the cost of long-term care for neurologically injured infants is taken into account, trial of labor after previous cesarean is unlikely to be associated with a significant cost saving for the health care system."

ELECTIVE REPEAT CESAREAN DELIVERY. As described in [Chapter 25](#) (see p. 592), compared with vaginal delivery, cesarean birth is associated with increased risks, including anesthesia, hemorrhage, damage to the bladder and other organs, pelvic infection, scarring, and other less frequent events. In spite of these potential concerns, an elective repeat cesarean is considered by many women to be preferable to attempting a trial of labor. Frequent reasons for this preference include the convenience of a scheduled delivery and the fear of a prolonged and potentially dangerous labor. Abitbol and associates (1993) studied such preferences by analyzing the results of a program in which women who were candidates for a trial of labor were able to elect their route of delivery following extensive counseling. Information was provided in three separate sessions concerning advantages and disadvantages of VBAC and repeat cesarean delivery. Of the 312 women studied, 125 (40 percent) opted for a repeat cesarean. There were no complications in the elective cesarean group compared with two unanticipated fetal deaths in the VBAC group. All women were interviewed on the day of discharge regarding their delivery experience. Of the women delivered by scheduled cesarean, 93 percent reported that they were satisfied with their choice. This compared with only 53 percent of women who elected a trial of labor and 80 percent of those who had an uncomplicated trial of labor.

Fetal Maturity. If elective repeat cesarean delivery is planned, it is essential that the fetus be mature. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have established guidelines for timing an elective operation. According to these criteria, elective delivery may be considered and fetal maturity assumed if at least one of the criteria outlined in [Table 26-2](#) is met. In all other instances, fetal pulmonary maturity must be documented by amniotic fluid analysis before elective repeat cesarean is undertaken (see [Chap. 29](#), p. 651). Alternatively, the onset of spontaneous labor is awaited.

CANDIDATES FOR A TRIAL OF LABOR

As the foregoing discussion makes clear, a plurality of positions exists regarding the optimal management of the woman with a prior cesarean delivery. Specifically, through 2003, more than 1000 citations were available in the literature—and no randomized trials—addressing subsequent attempts at vaginal delivery. In 1998 and 1999, the American College of Obstetricians and Gynecologists issued updated practice bulletins supporting VBAC but also urging a more cautious approach. In part, their recommendation reads:

It has become apparent that VBAC is associated with a small but significant risk of uterine rupture with poor outcomes for both mother and infant.... These developments, which have led to a more circumspect approach to trial of labor by even the most ardent supporters of VBAC, illustrate the need to reevaluate VBAC recommendations.

Several factors are pertinent to the evaluation of women for a trial of labor to attempt VBAC. The most recent recommendations of the American College of Obstetricians and Gynecologists (2004) for selecting appropriate candidates are listed in [Table 26-3](#). Summarized in the following sections are these and other considerations for the evaluation and management of the woman with a prior cesarean delivery. Such evaluation is particularly challenging given the lack of randomized studies. Indeed, based on their recent review of 100 published studies, Hashima and co-workers (2004) concluded that little high-quality data are available to guide clinical decisions regarding selection of women who are likely to have a successful trial of labor. Following a review of more than 600 articles, Guise and colleagues (2004) reached a similar conclusion.

TYPE OF PRIOR UTERINE INCISION. Women with a transverse scar confined to the lower uterine segment have the lowest risk of symptomatic scar separation during a subsequent pregnancy ([Table 26-4](#)). The highest rates of rupture have been reported for incisions extending into the fundus—the classical incision ([Fig. 26-2](#)). Importantly, in about one third of women, the classical scar will rupture before the onset of labor. Not infrequently, rupture may take place several weeks before term. In a review of 157 women with a prior classical cesarean, Chauhan and colleagues (2002) reported that one woman had a complete uterine rupture prior to the onset of labor and 15 (9 percent) others suffered a uterine dehiscence (see p. 615). Similarly, we have encountered a term abdominal pregnancy in a woman whose prior classical incision had separated weeks to months before she was delivered by repeat cesarean.

In women with uterine malformations who have undergone cesarean delivery, the risks for uterine rupture in a subsequent pregnancy may be as high as with a classical incision. Specifically, Ravasia and associates (1999) reported the risk of

subsequent rupture to be 8 percent in women with unicornuate, bicornuate, didelphic, and septate uterine malformations (see [Chap. 40](#), p. 953).

The risk of uterine rupture in women with a prior vertical incision that did not extend into the fundus is controversial. Martin and co-authors (1997) and Shipp and colleagues (1999) reported that these low-vertical uterine incisions did not have an increased risk for rupture when compared with that of low-transverse incisions. The American College of Obstetricians and Gynecologists (2004) concluded that, although there is limited evidence, women with a prior vertical incision in the lower uterine segment without fundal extension may be candidates for VBAC. This is in contrast to prior classical or T-shaped uterine incisions, which are considered contraindications to VBAC. It seems reasonable to us that, given the very few conditions that call for vertical incisions— for example, preterm delivery with a poorly developed lower uterine segment— these incisions almost invariably extended into the active segment. The unanswered question is: How far upward does the incision have to extend before the risk of rupture is equivalent to a true classical incision? Thus, when preparing an operative report following a vertical uterine incision, it is essential to document its exact extent in a manner that cannot be misunderstood by subsequent surgeons.

Women who have previously sustained a uterine rupture are at increased risk for recurrence. Those with a rupture confined to the lower segment have been reported to have a 6-percent recurrence risk in subsequent labor, whereas those whose prior rupture included the upper uterus have a 32-percent recurrence risk (Reyes-Ceja and associates, 1969; Ritchie, 1971). We are of the view that women with prior uterine ruptures or classical or T-shaped incisions ideally are delivered by cesarean on achievement of fetal pulmonary maturity and prior to the onset of labor, and that such women should be warned of the hazards of unattended labor and signs of possible uterine rupture.

Figure 26-2. Ruptured vertical cesarean section scar (*arrow*) identified at time of repeat cesarean delivery early in labor; asterisks indicate some of the sites of densely adherent omentum.

CLOSURE OF PRIOR INCISION. As discussed in [Chapter 25](#) (see p. 597), the low-transverse uterine incision typically is closed in one or two layers. Whether the risk of subsequent uterine rupture is related to the number of layers is controversial. Chapman (1997) and Tucker (1993) and their associates found no relationship between a one- and two-layer closure and risk of subsequent uterine rupture. Although Durnwald and Mercer (2003) also found no increased risk of rupture, uterine dehiscence was more common after single-layer closure. In contrast, Bujold and co-workers (2002) reviewed the operative records of 1980 women who underwent a trial of labor, including 23 (1.2 percent) who experienced uterine rupture. They found that a single-layer closure was associated with nearly a fourfold increased risk of rupture compared with a double-layer closure. The latter consisted of a running-lock suture followed by a running, nonlocking imbricating suture. In response, Vidaeff and Lucas (2003) argued that experimental models of wound healing have not demonstrated any advantages with a double-layer closure. Because of potentially confounding variables inherent in this type of retrospective study, they concluded that the evidence is insufficient to routinely recommend a double-layer closure. There should be further study of the relationship between closure technique and subsequent uterine rupture. This is especially true given the limited available information regarding healing and scarring of cesarean incisions.

Healing of the Cesarean Incision. Williams (1921) believed that the uterus heals by regeneration of the muscular fibers and not by development of scar tissue. Certainly, upon inspection of the unopened uterus at repeat cesarean delivery, there is usually no trace of the former incision, or at most, an almost invisible linear scar. Also, when the uterus is removed and fixed in formalin, there often is no visible scar, or only a shallow vertical furrow in the external and internal surfaces of the anterior uterine wall is seen, with no trace of scar tissue between them.

On the other hand, Schwarz and co-workers (1938) concluded that healing was mainly by fibroblast proliferation. They studied the uterine incision site some days after cesarean incision and observed that as the scar shrinks, connective tissue proliferation becomes less obvious. If the cut surfaces of the uterus are closely apposed, the proliferation of connective tissue is minimal, and the normal relation of smooth muscle to connective tissue gradually is reestablished. Even when the healing is so poor that marked thinning has resulted, the remaining tissue often is entirely muscular.

INTERDELIVERY INTERVAL. It seems logical to assume that the risk of uterine rupture would be increased if the hysterotomy scar did not have sufficient time to heal. Studies of uterine scar healing using magnetic resonance imaging suggest that complete uterine involution and restoration of anatomy may require at least 6 months (Dicle and colleagues, 1997). To explore this issue further, Shipp and associates (2001) retrospectively examined the relationship between interdelivery interval and uterine rupture in 2409 women with one prior cesarean delivery. There were 29 (1.4 percent) cases of uterine rupture. They found that interdelivery intervals of 18 months or less were associated with a threefold increased risk of symptomatic uterine rupture compared with that of those over 18 months.

NUMBER OF PRIOR CESAREAN INCISIONS. The risk of uterine rupture increases with the number of previous cesarean deliveries. Miller and colleagues (1994) studied 12,707 women undergoing a trial of labor after cesarean delivery. They reported rupture rates of 0.6 percent and 1.8 percent for women with one and two prior cesarean deliveries, respectively. Similarly, in the MFMU Network study by Landon and co-investigators (2004a), uterine rupture was twice as high in women with multiple prior cesareans compared with that of those with only one— 1.4 versus 0.7 percent. Caughey and colleagues (1999) compared uterine rupture rates in 3757 women with one prior cesarean delivery with those of 134 women who had two prior cesarean incisions. Although women with a classical incision usually were delivered by elective repeat cesarean, the type of prior uterine incision was not specified. The rate of uterine rupture was increased nearly fivefold in women with two previous cesarean deliveries compared with that of those only with one— 3.7 versus 0.8 percent.

Any previous vaginal delivery, either before or following a cesarean birth, significantly improves the prognosis for a subsequent successful VBAC, with either spontaneous or induced labor (Caughey and colleagues, 1998; Grinstead and Grobman, 2004; Hendler and co-workers, 2004). Prior vaginal delivery also lowers the risk of subsequent uterine rupture (Zelop and associates, 2000). Indeed, the most favorable prognostic factor is prior vaginal delivery. The American College of Obstetricians and Gynecologists (2004) has recently taken the position that for women with two prior low-transverse cesarean deliveries, only those with a prior vaginal delivery should be considered for VBAC.

INDICATION FOR PRIOR CESAREAN DELIVERY. The success rate for a trial of labor depends to some extent on the indication for the previous cesarean delivery. Generally, about 60 to 80 percent of trials of labor after prior cesarean birth result in vaginal delivery (American College of Obstetricians and Gynecologists, 2004). In a large series reported by Wing and Paul (1999), 91 percent of women whose first cesarean was for breech presentation had a successful VBAC. When fetal distress was the original indication, the success rate was 84 percent. In those with dystocia as the original indication, Impey and O'Herlihy (1998) reported that even when the strictest criteria are used to diagnose dystocia, a VBAC rate of 68 percent can be achieved.

Hoskins and Gomez (1997) analyzed VBAC success rates in 1917 women in relation to cervical dilation achieved before the original cesarean delivery was performed for dystocia. For women whose cesarean was performed at 5 cm or less, the VBAC success rate was 67 percent. It was 73 percent when the cervix was dilated 6 to 9 cm. The success rate of vaginal delivery fell to 13 percent when dystocia was diagnosed during the second stage. These latter findings seem counterintuitive and, indeed, Bujold and Gauthier (2001) reported a 75-percent VBAC success rate in women who had undergone a prior cesarean for second-stage dystocia.

FETAL MACROSOMIA. It would seem that increasing fetal size would increase the risk of uterine rupture with VBAC. This, however, remains unproven. Zelop and associates (2001) compared the outcomes of 2749 women undergoing a trial of labor at term. There were 29 (1.1 percent) uterine ruptures. Although not statistically significant, the rate of uterine rupture for women whose infants weighed at least 4000 g was 1.6 percent compared with that of 1.0 percent for those whose infants weighed less. The rate of uterine rupture was even greater (2.4 percent) when the birthweight exceeded 4250 g. Similarly, Elkousy and colleagues (2003) found that for women attempting VBAC who had no previous vaginal deliveries, the relative risk of uterine rupture more than doubled when the birthweight was at least 4000 g.

MATERNAL OBESITY. Carroll and colleagues (2003) found that as maternal weight increased, the rate of VBAC success decreased. In their study, only 4 of 30 women (13 percent) undergoing a trial of labor who weighed more than 300 pounds delivered vaginally. Their observations that puerperal infection was higher in obese women attempting a trial of labor was confirmed by Edwards and associates (2003). Maternal obesity is detailed in [Chapter 43](#).

LABOR AND DELIVERY CONSIDERATIONS

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have formulated the following guidelines for women with a prior cesarean who have chosen a trial of labor:

1. Prompt evaluation of the laboring patient must be performed.
2. Continuous electronic monitoring of fetal heart rate and uterine contractions should be considered (see [Chap. 18](#), p. 444).
3. Personnel familiar with the potential complications of a trial of labor should be vigilant for nonreassuring fetal heart rate patterns and inadequate progress of labor.
4. Attempts should be limited to institutions with physicians immediately available to provide emergency care.

Lavin and co-workers (2002) surveyed all hospitals in Ohio to determine the number that actually had an obstetrician, anesthesia coverage, and a surgical team immediately available—defined as present in the hospital—when a woman was attempting a trial of labor. A complete complement was available in 15, 63, and 100 percent of level I, II, and III institutions, respectively. Because VBAC deliveries were equally distributed among the institutions, the investigators concluded that many women may be attempting VBAC under less than optimal conditions. They recommended that there is a need to examine staffing and referral patterns.

INFORMED CONSENT. No woman should be mandated to undergo a trial of labor. Instead, the risks and benefits of a trial of labor versus a repeat cesarean delivery should be discussed with any woman with a prior uterine incision. The ultimate decision to attempt a vaginal delivery should be made by the informed patient and her physician. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) recommend that the following issues be addressed:

1. Advantages of a successful vaginal delivery, for example, shorter postpartum hospital stay; less painful, more rapid recovery; and others.
2. Contraindications to a trial of labor, for example, prior classical cesarean, placenta previa, and others.
3. Risk of uterine rupture (approximately 1 percent).
4. Increased risk of uterine rupture with more than one prior cesarean delivery, attempts at cervical ripening or labor induction, macrosomia, and oxytocin augmentation.
5. In the event of rupture, there is a 10- to 25-percent risk of significant adverse fetal sequelae.
6. Although catastrophic uterine rupture leading to perinatal death or permanent neonatal injury is rare, occurring less often

than 1 per 1000 VBAC attempts, it does occur despite the best available resources.

CERVICAL RIPENING AND LABOR STIMULATION. Any attempt to induce cervical ripening or to induce or augment labor increases the risk of uterine rupture in women undergoing a trial of labor.

Oxytocin. Use of oxytocin to induce or augment labor has been implicated in uterine ruptures in women attempting VBAC. Turner (1997) observed that 13 of the 15 uterine ruptures reported at the Coombe Hospital in Dublin between 1982 and 1991 occurred in women with prior cesareans who had been given an oxytocic agent, usually for *induction* of labor. In contrast, cautious use of intravenous oxytocin to *augment* labor in women with prior cesarean at this hospital was rarely associated with uterine rupture.

Zelop and associates (1999) analyzed uterine ruptures at Brigham and Women's Hospital after induced or augmented labor in women with one prior cesarean delivery. Rupture occurred in 2.3 percent of those induced compared with 1 and 0.4 percent of those whose labor was augmented or was spontaneous, respectively. They urged caution when using oxytocin for labor stimulation in these women. Goetzl and associates (2001) examined the relationship between the total oxytocin dose and duration of induction and the risk of uterine rupture. Although not significant, oxytocin dose and duration correlated directly with uterine rupture. The investigators concluded, however, that the differences in the dose or patterns of oxytocin use were not substantial enough to develop safer induction protocols.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have concluded that oxytocin may be used for both labor induction and augmentation with close patient monitoring in women with a prior cesarean delivery undergoing a trial of labor (see [Chap. 22](#), p. 537).

EXPERIENCES AT PARKLAND HOSPITAL. Our experience with uterine ruptures led us to the decision to discontinue the use of oxytocin in women with prior cesarean deliveries. Between 1986 and 1990, a trial of labor was undertaken by 2044 of the 7049 women with prior cesarean deliveries. Of these women, 1482 (73 percent) delivered vaginally. Uterine rupture with part of the fetus extruded outside of the uterus occurred in three women, for a rate of 1.5 per 1000. In another 307 women who received oxytocin during their trial of labor, three uterine ruptures (10 per 1000) occurred. These events prompted a reappraisal of our use of oxytocin and the adoption of a more conservative approach.

Prostaglandins. Several prostaglandin preparations commonly are employed for cervical ripening or labor induction. Recent evidence indicates that their use in women attempting VBAC substantively increases the risk of uterine rupture. For example, Ravasia and colleagues (2000) compared the rupture rates between 172 such women given prostaglandin E₂ gel and 1544 similar women in spontaneous labor. The rate of uterine rupture was significantly greater in the women treated with prostaglandin E₂ gel than in those having spontaneous labor—2.9 percent versus 0.5 percent.

There are only a few reports describing the use of the prostaglandin E₁ analogue misoprostol in women with a prior cesarean delivery. Wing and colleagues (1998) prematurely terminated their randomized study of oxytocin versus misoprostol for labor induction in women with previous cesarean delivery after 2 of the first 17 women randomized to misoprostol experienced a uterine rupture. Sciscione and co-workers (1998) described a case of uterine rupture following misoprostol administration in a woman attempting VBAC. The editors of the *Australian and New Zealand Journal of Obstetrics and Gynaecology* published the report for the stated purpose of warning other investigators of the potential hazards of studying misoprostol in women with a prior cesarean delivery.

Lydon-Rochelle and associates (2001) performed a retrospective, population-based study in Washington State from 1987 through 1996. They included all primiparous women who delivered a live singleton infant by cesarean and who also delivered a second child during the study period. Of the 20,095 women included, 13,115 (65 percent) underwent a trial of labor. As shown in [Table 26-5](#), the risk of uterine rupture was nearly 16-fold greater for women undergoing induction of labor with prostaglandins compared with that of a repeated cesarean delivery without labor. Based in large part on the results of this study, the American College of Obstetricians and Gynecologists (2002, 2004) discourage the use of prostaglandin cervical ripening agents for the induction of labor in these women. They further recommend that if induction of labor in a woman with a prior cesarean delivery is necessary for a clear and compelling clinical indication, the potential increased risk of uterine rupture with prostaglandin use should be discussed with the patient and documented.

As also shown in [Table 26-5](#), Lydon-Rochelle and colleagues (2001) found a threefold risk of uterine rupture associated with spontaneous labor alone compared with the risk associated with elective repeat cesarean delivery. Based on these findings, Greene (2001) editorialized that elective repeat cesarean is the safest route of delivery for the infant.

EPIDURAL ANALGESIA. The use of epidural analgesia for labor in women with a prior cesarean delivery was debated in the past because it was thought that such a technique might mask the pain of uterine rupture. As evidence accrued, however, it was found that less than 10 percent of women with scar separation experience pain and bleeding. Instead, fetal heart rate decelerations are the most likely sign of rupture (Flamm and associates, 1990). Several studies attest to the safety of properly conducted epidural analgesia for labor (Farmer and colleagues, 1991; Flamm and associates, 1994). Moreover, vaginal delivery rates are similar among women who receive an epidural for labor compared with those who do not (Flamm and co-workers, 1988; Stovall and colleagues, 1987). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) have concluded that epidural analgesia may safely be used during a trial of labor. They further recommend that the anesthesia service be notified whenever a woman with a prior cesarean is admitted in active labor.

UTERINE SCAR EXPLORATION. Although some obstetricians routinely document the integrity of the old scar by palpation following successful vaginal delivery, such uterine exploration is felt by others to be unnecessary. Currently, it is not known what effect documentation of an asymptomatic scar has on subsequent reproduction or route of delivery. There is general agreement, however, that surgical correction of a scar dehiscence is necessary only if significant bleeding is encountered. Asymptomatic separations do not generally require exploratory laparotomy and repair.

EXTERNAL CEPHALIC VERSION. Limited data suggest that external cephalic version for breech

presentation may be as successful for women with a prior cesarean as for women without such a history (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002). Breech presentation and external cephalic version are addressed in [Chapter 24](#) (see p. 581).

UTERINE RUPTURE

CLASSIFICATION. Uterine rupture typically is classified as either *complete* (all layers of the uterine wall separated) or *incomplete* (uterine muscle separated but visceral peritoneum is intact). Incomplete rupture is also commonly referred to as *uterine dehiscence*. As expected, morbidity and mortality are appreciably greater when rupture is complete. Currently, the greatest risk factor for either complete or incomplete uterine rupture is prior cesarean delivery. Indeed, in a review of all cases of uterine rupture in Nova Scotia between 1988 and 1997, Kieser and Baskett (2002) reported that 92 percent occurred in women with a prior cesarean birth. Other causes of uterine rupture are discussed in [Chapter 35](#) (see p. 837).

DIAGNOSIS. Prior to circulatory collapse from hemorrhage, the symptoms and physical findings may appear bizarre unless the possibility of uterine rupture is kept in mind. For example, hemoperitoneum from a ruptured uterus may result in irritation of the diaphragm with pain referred to the chest—leading one to the diagnosis of pulmonary or amniotic fluid embolism instead of uterine rupture. Few women experience cessation of contractions following uterine rupture, and the use of intrauterine pressure catheters has not been shown to assist reliably in the diagnosis (Rodriguez and associates, 1989). Instead, the most common electronic fetal monitoring finding tends to be sudden, severe heart rate decelerations that may evolve into late decelerations, bradycardia, and undetectable fetal heart action (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002). In the Nova Scotia study cited earlier, 57 percent of the diagnoses were based primarily on fetal heart rate abnormalities (Kieser and Baskett, 2002). Finally, in a recent comparison of fetal heart rate characteristics in 36 cases of uterine rupture versus 100 matched controls, Ridgeway and co-workers (2004) found that bradycardia was the only finding that differentiated uterine rupture from a successful trial of labor.

In a minority of women, the appearance of uterine rupture is identical to that of placental abruption. In most, however, there is remarkably little appreciable pain or tenderness. Also, because most women in labor are treated for discomfort with either narcotics or lumbar epidural analgesia, pain and tenderness may not be readily apparent. The condition usually becomes evident because of signs of fetal distress and occasionally because of maternal hypovolemia from concealed hemorrhage.

In some cases in which the fetal presenting part has entered the pelvis with labor, loss of station may be detected by pelvic examination. If the fetus is partly or totally extruded from the site of uterine rupture, abdominal palpation or vaginal examination may be helpful to identify the presenting part, which will have moved away from the pelvic inlet. A firm contracted uterus may at times be felt alongside the fetus.

PROGNOSIS. With rupture and expulsion of the fetus into the peritoneal cavity, the chances for intact fetal survival are dismal, and reported mortality rates range from 50 to 75 percent. Fetal condition depends on how much placenta is intact, although this likely decreases over minutes. If the fetus is alive at the time of rupture, the only chance of continued survival is afforded by immediate delivery, most often by laparotomy. Otherwise, hypoxia from both placental separation and maternal hypovolemia is inevitable. If rupture is followed by total placental separation, then very few infants will be salvaged.

The maternal prognosis is much better and rupture is seldom fatal. If untreated, however, most women would die from hemorrhage or, less often, later from infection.

Hysterectomy Versus Repair. In cases of scar separation without bleeding following VBAC, exploratory laparotomy is not indicated. With frank rupture during a trial of labor, however, hysterectomy may be required. In two reports by McMahon (1996) and Miller (1997) and their colleagues, 10 to 20 percent of such women required hysterectomy for hemostasis. In selected cases, suture repair with uterine preservation may be performed. Sheth (1968) described outcomes from a series of 66 women in whom repair of a uterine rupture was elected rather than hysterectomy. In 25 instances, the repair was accompanied by tubal sterilization. Thirteen of the 41 mothers who did not have tubal sterilization had a total of 21 subsequent pregnancies, and uterine rupture recurred in four instances. Hysterectomy is described in [Chapter 25](#) (see p. 599), and other techniques to control obstetrical hemorrhage are detailed in [Chapter 35](#) (see p. 809).

27. Abnormalities of the Placenta, Umbilical Cord, and Membranes

INTRODUCTION

With the basic understanding of the process of implantation and placental development presented in [Chapter 3](#) (see p. 51), it is much easier to visualize the development of abnormal placental types. Much of the ever-growing knowledge of primary placental pathology was stimulated by a nucleus of placental pathologists that includes, amongst others, Benirschke, Driscoll, Fox, Naeye, and Salafia. For a detailed account of these disorders, the reader is referred to the Fourth Edition of *Pathology of the Human Placenta* (Benirschke and Kaufmann, 2000).

PLACENTAL ABNORMALITIES

In general, placental and fetal size and weight roughly correlate in a linear fashion. There is also evidence that fetal growth depends on placental weight, which is less with small-for-gestational age infants (Heinonen and colleagues, 2001). According to Mathews and associates (2004), this is not dependent on nutrients (see [Chap. 38](#), p. 895).

ABNORMAL SHAPE OR IMPLANTATION. There are a number of variations of placental shape or implantation, and some have significant clinical impact.

Multiple Placentas with a Single Fetus. The placenta occasionally is separated into lobes. When the division is incomplete and the vessels of fetal origin extend from one lobe to the other before uniting to form the umbilical cord, the condition is termed *placenta bipartita* or *bilobata* ([Fig. 27-1](#)). Fox (1978) cited its incidence to be at about 1 in every 350 deliveries. If the two or three distinct lobes are separated entirely, and the vessels remain distinct, the condition is designated *placenta duplex* or *placenta triplex*.

Succenturiate Lobes. This variation describes one or more small accessory lobes that develop in the membranes at a distance from the periphery of the main placenta, to which they usually have vascular connections of fetal origin. It is a smaller version of the bilobed placenta, and although its incidence has been cited by Benirschke and Kaufmann (2000) to be as high as 5 percent, we have encountered these very infrequently. The accessory lobe may sometimes be retained in the uterus after delivery and may cause serious hemorrhage. In some cases, an accompanying vasa previa may cause dangerous fetal hemorrhage at delivery (see p. 627 and also [Chap. 35](#), p. 819).

Membranaceous Placenta. Very rarely, all of the fetal membranes are covered by functioning villi, and the placenta develops as a thin membranous structure occupying the entire periphery of the chorion. This finding is called *placenta membranacea* and also is referred to as *placenta diffusa*. Diagnosis often can be made using sonography. It may occasionally give rise to serious hemorrhage because of associated placenta previa or accreta.

Ring-Shaped Placenta. In fewer than 1 in 6000 deliveries, the placenta is annular in shape, and sometimes a complete ring of placental tissue is present. This development may be a variant of membranaceous placenta. Because of tissue atrophy in a portion of the ring, a horseshoe shape is more common. These abnormalities appear to be associated with a greater likelihood of antepartum and postpartum bleeding and fetal growth restriction.

Fenestrated Placenta. In this rare anomaly, the central portion of a discoidal placenta is missing. In some instances, there is an actual hole in the placenta, but more often the defect involves only villous tissue with the chorionic plate intact. Clinically, it may be mistakenly considered to indicate that a missing portion of placenta has been retained in the uterus.

Extrachorial Placentation. When the chorionic plate, which is on the fetal side of the placenta, is smaller than the basal plate, which is located on the maternal side, the placental periphery is uncovered and leads to the common designation of *extrachorial placenta* ([Fig. 27-2](#)). If the fetal surface of such a placenta presents a central depression surrounded by a thickened, grayish-white ring, it is called a *circumvallate placenta*. The ring is composed of a double fold of amnion and chorion, with degenerated decidua and fibrin in between. Within the ring, the fetal surface presents the usual appearance, except that the large vessels terminate abruptly at the margin of the ring. When the ring does not have the central depression with the fold of membranes, the condition is described as a *circummarginate placenta* (see [Fig. 27-2](#)). There is an increased risk with circumvallate placentas of antepartum hemorrhage — both from placental abruption and from fetal hemorrhage — as well as of preterm delivery, perinatal mortality, and fetal malformations (Benirschke, 1974; Lademacher and co-workers, 1981). Adverse clinical outcomes with circummarginate placentas are less well defined.

Placenta Accreta, Increta, and Percreta. These abnormalities are serious variations in which trophoblastic tissues invade the myometrium to varying depths. They are much more likely with placenta previa or with implantation over a prior uterine incision or perforation. Torrential hemorrhage is a frequent complication (see [Chap. 25](#), p. 599, and [Chap. 35](#), p. 830).

Figure 27-1. Bilobed placenta with marginal insertion of the umbilical cord. There also is partial velamentous insertion of the cord with the fetal vessels traversing the membranes to reach the smaller placental lobe on the right.

Figure 27-2. Circumvallate (*left*) and circummarginate (*right*) varieties of extrachorial placentas.

DEGENERATIVE PLACENTAL LESIONS. Degenerative lesions may result from trophoblast aging, or impairment of uteroplacental circulation with infarction. Deposition of calcium salts is heaviest on the maternal surface in the basal plate. Further deposition occurs along the septa, and both increase as pregnancy progresses. It is more extensive in smokers whose placentas also have reduced fetal capillary diameters (Larsen and co-workers, 2002). Extensive calcification is found in 10 to 15 percent of all placentas at term ([Fig. 27-3](#)). This can be seen with sonography, and Spirt and colleagues (1982) reported that by 33 weeks more than half of placentas have some degree of calcification. It is difficult to correlate the degree of calcium deposition with pregnancy outcome (Benirschke and Kaufmann, 2000).

Figure 27-3. A. Placental calcification is evident as gray plaques on the maternal surface of the placenta. **B.** A radiograph of the same placenta emphasizes the extensive calcification.

CIRCULATORY DISTURBANCES. Placental perfusion may be impaired by disruption of uterine vessels, placental vessels, or the intervillous space (Becroft and associates, 2004).

Placental Infarctions. These are the most common placental lesions, and their presence is a continuum from normal changes to extensive and pathological involvement. For example, Salafia and associates (2000) identified infarcts in 10 percent of 500 consecutive placentas from uncomplicated term pregnancies. Almost 90 percent were located at the placental margin and 90 percent were less than 1 cm. These types of limited infarctions result from occlusion of the maternal uteroplacental circulation and usually represent normal aging. Around the edge of nearly every term placenta there is a dense yellowish-white fibrous ring representing a zone of degeneration and necrosis, which is an incidental finding.

Thus, although these infarcts are "normal," if they are numerous, placental insufficiency may develop. When they are thick, centrally located, and randomly distributed, as shown in [Figure 27-4](#), they may be associated with preeclampsia or lupus anticoagulant (Benirschke and Kaufmann, 2000; Many and colleagues, 2001). These conspicuous lesions arise after occlusion of the decidual artery interrupts blood flow to the intervillous space. Necrosis of villous tissue develops from ischemia. Histopathological features include fibrinoid degeneration of the trophoblast, calcification, and ischemic infarction. If decidual artery occlusion is followed by hemorrhage, then *placental abruption* results.

Another type of infarct is found underneath the chorionic plate. These yellowish-white fibrous lesions are usually pyramidal shaped and range from 2 mm to 3 cm across the base. These *subchorionic infarcts* extend downward with their apices in the intervillous space. Similar lesions may be noted about the intercotyledonary septa. Occasionally these lesions meet and form a column of cartilage-like material extending from the maternal surface to the fetal surface. Less frequently, round or oval islands of similar tissue occupy the central portions of the placenta.

Maternal Floor Infarction. This uteroplacental vasculopathy differs from the previously described infarctions in that there are not large areas of villous infarction. Instead, fibrinoid deposition occurs within the decida basalis and usually is confined to the placental floor. The fibrin, however, can extend into the intervillous space to envelop the villi, which then atrophy. According to Benirschke and Kaufmann (2000), and as shown in [Figure 27-5](#), there frequently is massive net-like fibrin deposition throughout the placenta. It is an uncommon lesion, and Adams-Chapman and colleagues (2002) identified it in 6 per 1000 deliveries. The etiopathogenesis of these lesions is not well defined, although in some cases it is associated with thrombophilia (Katz, 2002; Sebire, 2002, 2003; van der Molen, 2000; Ward, 2000, and all their colleagues). These lesions are considered in further detail in [Chapter 47](#) (see p. 1074).

There is no doubt that maternal floor infarction is associated with fetal growth restriction, abortion, and stillbirths. It is not associated with preeclampsia or placental abruption. There also appears to be an increased incidence of central nervous system injury and neurodevelopmental sequelae in these infants (Adams-Chapman and associates, 2002).

Placental Vessel Thrombosis. When a stem artery from the fetal circulation in the placenta is occluded, it produces a sharply demarcated area of avascularity. Fox (1978) found such single-artery thrombosis in 5 percent of placentas from normal pregnancies and in 10 percent of those from diabetic women. He estimated that thrombosis of a single stem artery will deprive only 5 percent of the villi of their blood supply. Despite this, Benirschke and Kaufmann (2000) found these lesions to be frequently associated with fetal growth restriction and stillbirth.

Figure 27-4. A. Placental infarcts. (A = chorioamniotic membrane; B = fibrin deposited locally beneath the chorion; C = normal placental tissue.) In this instance, the infarct was unusually extensive and most likely contributed to fetal death. **B.** Generalized fibrin deposition with little normal tissue remaining.

Figure 27-5. Section through a 32-week placenta showing maternal floor infarction associated with antiphospholipid antibody syndrome. There is marked thickening of the basal plate, fibrous septa, and massive perivillous fibrin deposition. (From Sebire and colleagues, 2002, with permission.)

HYPERTROPHIC LESIONS OF THE CHORIONIC VILLI. Striking enlargement of the chorionic villi is commonly seen in association with severe erythroblastosis and fetal hydrops. It also has been described in maternal diabetes, fetal congestive heart failure, and maternal-fetal syphilis (Sheffield and colleagues, 2002). Many of these conditions are discussed in [Chapter 29](#).

MICROSCOPIC PLACENTAL ABNORMALITIES. Beginning after 32 weeks, clumps of syncytial nuclei are found to project into the intervillous space. These projections are called *syncytial knots* and likely represent apoptosis, although some are artifacts of tangential sectioning of villi (Benirschke and Kaufmann, 2000). The number of *cytotrophoblastic* cells becomes progressively reduced as pregnancy advances. By term, such cells are few and inconspicuous. In some maternal or fetal disorders, numerous cytotrophoblastic cells are found in placentas. Some examples include gestational hypertension, diabetes, and erythroblastosis fetalis.

PLACENTAL INFLAMMATION. Changes that are now recognized as various forms of degeneration and necrosis were formerly described under the term *placentitis*. For example, small placental cysts with grumous contents were formerly thought to be abscesses. Nonetheless, especially in cases of preterm and prolonged membrane rupture, bacteria invade the fetal surface of the placenta. This occurrence is discussed in the section on chorioamnionitis (see p. 625).

TUMORS OF THE PLACENTA

Gestational Trophoblastic Disease. These pregnancy-related trophoblastic proliferative abnormalities are discussed in [Chapter 11](#).

Chorioangioma (Hemangioma). Various angiomatous tumors ranging widely in size have been described. Because of the resemblance of their components to the blood vessels and stroma of the chorionic villus, the term *chorioangioma*, or *chorangioma*, has been considered the most appropriate designation. These are the only benign tumors of the placenta (Benirschke and Kaufmann, 2000). They most likely are hamartomas of primitive chorionic mesenchyme and have an incidence of about 1 percent. Larger chorioangiomas, such as those shown in [Figure 27-6](#), may be suspected on the basis of certain sonographic findings.

Small growths are usually asymptomatic, but large tumors may be associated with hydramnios or antepartum hemorrhage. Fetal death and malformations are uncommon complications, although there may be a correlation with low birthweight. Stiller and Skafish (1986) described a case with multiple placental chorioangiomas in which a blood group A fetus bled acutely into her O group mother. The mother showed evidence of acute hemolysis without anemia, and the fetus developed a sinusoidal heart rate pattern frequently seen with severe anemia. We have identified an unusual case of severe iron deficiency anemia in the neonate as the consequence of chronic fetal-to-maternal bleeding from multiple small chorioangiomas. Large tumors provide an arteriovenous shunt that can lead to fetal heart failure.

Tumors Metastatic to the Placenta. Malignant tumors rarely metastasize to the placenta. Of those that do, melanoma accounts for nearly one third of reported cases, and leukemias and lymphomas comprise another third (Dildy and associates, 1989; Read and Platzter, 1981). Tumor cells usually are confined within the intervillous space. In a fourth, the fetus will have metastases. Even so, malignant cells seldom proliferate to cause clinical disease (Altman and associates, 2003; Baergen and colleagues, 1997b).

Embolic Fetal Brain Tissue. Fetal brain tissue occasionally is seen embolized to the placenta or fetal lungs (Baergen and associates, 1997a; Gardiner, 1956). It usually has been described with "traumatic" deliveries. This phenomenon is not without precedent because brain tissue has been found in pulmonary veins following head trauma in older children and adults.

Figure 27-6. Placenta (p) and a discrete 450-g chorioangioma (c) connected to the placenta by a vascular stalk (*arrow*). The 34-week fetus was identified by sonography to have marked hydrothorax. Demonstrated in cord blood were severe hypofibrinogenemia, thrombocytopenia, hypoprothrombinemia, and microangiopathic hemolysis. The infant had cardiomegaly, heart failure, pleural effusion, and hepatomegaly. After several cardiac arrests the infant succumbed 3 days after birth.

ABNORMALITIES OF THE MEMBRANES

MECONIUM STAINING. The presence of meconium in amniotic fluid is relatively common—it was identified in 12 percent of more than 175,000 liveborn infants by Wiswell and Bent (1993). Benirschke and Kaufmann (2000) described visible meconium-stained placentas in 18 percent of nearly 13,000 consecutive deliveries. The incidence of meconium staining at Parkland Hospital has been remarkably constant, and of almost 250,000 women delivered during the past 20 years, about 20 percent had meconium identified during labor or at delivery. From their review, Ghidini and Spong (2001) cited meconium staining in a median of 14 percent of pregnancies.

Preterm fetuses seldom pass meconium. It is uncommon prior to 38 weeks, after which it increases to 25 to 30 percent after 42 weeks ([Table 27-1](#)). Staining of the amnion can be obvious within 1 to 3 hours after meconium passage (Miller and colleagues, 1985). Although more prolonged exposure results in staining of the chorion, umbilical cord, and decidua, according to Benirschke and Kaufmann (2000), meconium passage cannot be timed or dated accurately.

In its global sense, meconium passage is associated with increased perinatal morbidity and mortality. Fujikura and Klionsky (1975) identified meconium-stained membranes or fetuses in about 10 percent of 43,000 liveborn infants in the Collaborative

Study of Cerebral Palsy. The neonatal mortality rate was 3.3 percent in the group with meconium-stained membranes compared with 1.7 percent in those without such staining. Nathan and co-workers (1994) reviewed perinatal outcomes at Parkland Hospital in more than 8000 women delivered in whom meconium was identified intrapartum. Outcomes were compared with those of more than 34,500 pregnancies with clear amniotic fluid. Perinatal mortality was increased significantly in the meconium group: 1.5 versus 0.3 per 1000. Severe fetal acidemia—cord arterial pH less than 7.0—was significantly more common with meconium-stained fluid: 7 versus 3 per 1000. Moreover, cesarean delivery was doubled in the meconium group: 14 versus 7 percent. These global findings are not applicable to individual cases, but despite this, meconium has assumed great importance in many medicolegal pursuits. Benirschke and Kaufmann (2000) aptly conclude that the legal profession overemphasizes the importance of meconium passage without appreciating its complexity.

Neonatal morbidity and mortality associated with meconium is characterized by the *meconium aspiration syndrome*, which develops in about 10 percent of exposed infants (Ghidini and Spong, 2001). Severe disease requires ventilatory assistance and has a mortality rate of about 10 percent. Although it is commonly held that meconium aspiration syndrome is primarily the result of aspiration of thick, tenacious meconium, Ghidini and Spong (2001) concluded from their review that thin meconium also was associated with respiratory insufficiency.

One serious maternal risk is that meconium associated with amniotic fluid embolism greatly increases maternal mortality from cardiorespiratory failure and consumptive coagulopathy (see [Chap. 35](#), p. 845). Jazayeri and colleagues (2002) also have shown a fourfold risk of puerperal metritis with meconium-stained amniotic fluid.

CHORIOAMNIONITIS. Inflammation of the fetal membranes usually is a manifestation of intrauterine infection. It frequently is associated with prolonged membrane rupture and long labor. Grossly, infection is characterized by clouding of the membranes as shown in [Figure 27-7](#). There also may be a foul odor, depending on bacterial species and concentration. When mono- and polymorphonuclear leukocytes infiltrate the chorion, the resulting microscopical finding is designated *chorioamnionitis*. These cells are maternal in origin. Conversely, if leukocytes are found in amniotic fluid (*amnionitis*), or the umbilical cord (*funisitis*), the cells are fetal in origin (Goldenberg and co-workers, 2000). Before 20 weeks, almost all polymorphonuclear leukocytes are maternal in origin, but later the inflammatory response is both maternal and fetal (Sampson and colleagues, 1997). Microscopic evidence for inflammation of these structures is much more common in preterm deliveries.

According to some investigators, these findings of inflammation may be nonspecific and are not always associated with other evidence of fetal or maternal infection. For example, Yamada and colleagues (2000) found that meconium-stained fluid is a chemoattractant for leukocytes. Conversely, Benirschke and Kaufmann (2000) believe that microscopic chorioamnionitis is always due to infection.

Management of overt clinical chorioamnionitis is antimicrobial administration and expedient delivery (see [Chap. 36](#), p. 866). Occult chorioamnionitis, caused by a wide variety of microorganisms, frequently is cited as a possible explanation for many otherwise unexplained cases of ruptured membranes, preterm labor, or both. Often, however, it is impossible to verify which occurred first (see [Chap. 6](#), p. 178, and [Chap. 36](#), p. 859).

Figure 27-7. Chorioamnionitis in a diamniotic dichorionic placenta. Placenta from Twin A on the left was located near the fundus and has a normal luster. Placenta from Twin B has indistinct features caused by clouding of the membranes due to inflammatory exudate. (From Benirschke and Kaufmann, 2000, with permission.)

OTHER ABNORMALITIES. Small *amniotic cysts* lined by typical amniotic epithelium occasionally are formed. The common variety results from fusion of amniotic folds, with subsequent fluid retention.

Amnion nodosum are tiny, light tan, creamy nodules in the amnion made up of vernix caseosa with hair, degenerated squames, and sebum. They result from oligohydramnios and are most commonly found in fetuses with renal agenesis, prolonged preterm ruptured membranes, or in the placenta of the donor fetus with twin-to-twin transfusion syndrome (Benirschke and Kaufmann, 2000).

Amniotic bands are caused when disruption of the amnion leads to formation of bands or strings that entrap the fetus and impair growth and development of the involved structure. Fetal conditions that appear to be the consequence of this phenomenon, including intrauterine amputations, are considered in [Chapter 29](#) (see p. 685).

UMBILICAL CORD ABNORMALITIES

The cord develops in close association with the amnion, as described in [Chapter 3](#) (see p. 68). The cord serves a vital function, but it unfortunately is susceptible to entanglement, compression, and occlusion. Collins and Collins (2000) reported a 1-percent incidence of potentially harmful cord complications.

LENGTH. Cord length at term has appreciable variation, and extremes range from no cord (achordia) to lengths up to 300 cm. Short umbilical cords may be associated with adverse perinatal outcomes such as fetal growth restriction, congenital malformations, intrapartum distress, and a twofold risk of death (Kraakowiak and associates, 2004). Excessively long cords are more likely to cause complications such as prolapse. In a study of more than 20,000 placentas, Baergen and colleagues (2001) reported a mean length of 37 cm. They defined excessively long cords to be more than two standard deviations, which was 70 cm or longer. In a retrospective analysis, they compared 926 fetuses with long cords with 200 controls who had normal-length cords. Pregnancies involving a fetus with a long cord were associated with maternal systemic disease and delivery complications. There were more cases of cord entanglement, fetal distress, fetal anomalies, and respiratory distress. Perinatal mortality was increased nearly threefold, albeit with borderline statistical significance.

Determinants of cord length are intriguing. Animal studies and observational studies in human pregnancy support the concept that cord length is influenced positively by both the volume of amniotic fluid and fetal mobility. Heredity is a factor, and 9 percent of women with an excessively long cord in the study by Baergen and colleagues (2001) had such a finding in a subsequent pregnancy. Miller and associates (1981) identified the cord to be shortened appreciably when there had been either chronic fetal constraint from oligohydramnios or decreased fetal movement, such as with Down syndrome or limb dysfunction.

CORD COILING. In most cases, the umbilical vessels course through the cord in a spiraled manner. Several authors have observed a significant increase in various adverse outcomes in fetuses with hypocoiled cords. Some of these are meconium staining, preterm birth, and fetal distress (Strong and colleagues, 1993, 1994). Shen-Schwarz and associates (1996) reported an association between "absent" cord twisting and marginal and velamentous cord insertion. Rana and associates (1995) found a higher incidence of preterm delivery and cocaine abuse in women with hypercoiled cords.

SINGLE UMBILICAL ARTERY. Identification of a *two-vessel cord* is an important observation. **About one fourth of all infants with only one umbilical artery have associated congenital anomalies.** In a review of nearly 350,000 deliveries, Heifetz (1984) found an incidence of a single artery to be 0.63 percent in liveborns, 1.92 percent in neonates with perinatal death, and 3 percent in twins. The incidence is increased considerably in women with diabetes, epilepsy, preeclampsia, antepartum hemorrhage, oligohydramnios, and hydramnios (Leung and Robson, 1989). Two-vessel cords were identified in 1.5 percent of 879 fetuses aborted spontaneously (Byrne and Blanc, 1985). Over half of these had serious malformations, most associated with chromosomal abnormalities.

In many cases, a single umbilical artery is detected by routine ultrasound screening. Hill and co-workers (2001) reported that the number of cord vessels could be quantified ultrasonically in almost 98 percent of cases studied between 17 and 36 weeks. The fetal prognosis depends on whether the two-vessel cord is associated with other abnormalities or whether it is an isolated finding. Coexistent fetal anomalies detected by ultrasound have been reported to be from 10 and 50 percent.

Perinatal prognosis is better when a two-vessel umbilical cord is an *isolated sonographic finding*. In one study, Parilla and colleagues (1995) reported no adverse outcomes in 50 such fetuses. In another report, Budorick and co-workers (2001) found no abnormal karyotypes and only one echocardiographic abnormality in 31 fetuses with a two-vessel cord as an isolated finding. Gossett and associates (2002) reported that 74 such fetuses all had normal echocardiography. Conversely, Catanzarite (1995) described 46 fetuses with this isolated ultrasonographic finding, two of whom had lethal chromosomal abnormalities and a third, a tracheoesophageal fistula.

When a two-vessel cord is a *nonisolated finding*, as many as half of fetuses are aneuploid (Budorick and associates, 2001). There are a number of associated anomalies, and Pavlopoulos and colleagues (1998) reported renal aplasia, limb-reduction defects, and atresia of hollow organs in such fetuses, suggesting a vascular etiology.

Goldkrand and colleagues (1999) performed Doppler velocimetry in 45 fetuses with a two-vessel cord and 124 normal controls. Although velocity indices were all in the normal range, beginning at 26 weeks they were lower in affected fetuses than in those fetuses with normal cords. These investigators later measured blood flow and found that the single artery had volumetric blood flow equal to a normal cord with two arteries (Goldkrand and associates, 2001). They concluded that growth restriction did not occur in anatomically normal fetuses with a single artery. Raio and colleagues (1999) reported an association between a single artery and a reduction of Wharton jelly.

FOUR-VESSEL CORD. Careful inspection may disclose a venous remnant in 5 percent of cases (Fox, 1978). The significance is unknown.

ABNORMALITIES OF CORD INSERTION. The umbilical cord usually is inserted at or near the center of the fetal surface of the placenta.

Furcate Insertion. In this rare anomaly, the umbilical vessels separate from the cord substance before their insertion into the placenta. Because vessels lose cushioning, they are prone to twisting and thrombosis.

Marginal Insertion. Cord insertion at the placental margin is sometimes referred to as a *Battledore placenta*. It is found in about 7 percent of term placentas (Benirschke and Kaufmann, 2000). With the exception of the cord being pulled off during delivery of the placenta, it is of little clinical significance.

Velamentous Insertion. This insertion is of considerable importance. The umbilical vessels separate in the membranes at a distance from the placental margin, which they reach surrounded only by a fold of amnion (Figs. 27-1 and 27-8). Benirschke and Kaufmann (2000) reviewed almost 195,000 deliveries and found an average incidence of 1.1 percent. Velamentous insertion occurs much more frequently with twins, and Feldman and associates (2002) identified it in 28 percent of triplets.

Vasa Previa. This finding is associated with velamentous insertion when some of the fetal vessels in the membranes cross the region of the cervical os below the presenting fetal part. Lee and co-workers (2000) attempted to view the internal cervical os with sonography in nearly 94,000 women studied in the second or third trimester. Vasa previa was identified in 18, for an incidence of 1 in about 5200 pregnancies. About half were associated with velamentous insertion and the rest divided between marginal cord insertions and bilobed or succenturiate-lobed placentas (Figs. 27-1 and 27-9). Occasionally, the examiner will be able to palpate or directly visualize a tubular fetal vessel in the membranes overlying the presenting part. Because of a low sensitivity for imaging vasa previa with ultrasound, color Doppler examination is recommended when these are suspected (Harris and Alexander, 2000; Lee and associates, 2000; Nomiya and colleagues, 1998). In a study of 155 cases by Oyelese and associates (2004), prenatal diagnosis was associated with increased survival 97 versus 44 percent.

With vasa previa, there is considerable potential fetal danger because membrane rupture may be accompanied by tearing of a fetal vessel with exsanguination. In their review, Fung and Lau (1998) found that a low-lying placenta was a risk factor in 80

percent of cases. They also found that antenatal diagnosis was associated with decreased fetal mortality compared with discovery at delivery. Oyelese and colleagues (1999) recommended transvaginal ultrasound with color Doppler for women with risk factors. These included a bilobed, succenturiate, or low-lying placenta; multifetal pregnancy; or pregnancy resulting from in vitro fertilization.

In a prospective study of 45 women with a third-trimester placenta previa, Megier and colleagues (1999) found that 3 of 20 previas located over the internal os also had a vasa previa. In an 8-year survey of more than 90,000 women who had gray-scale ultrasonography, Lee and colleagues (2000) utilized endovaginal and Doppler studies to confirm vasa previa in women whose initial ultrasound showed an "echogenic parallel or circular line near the cervix" (see [Fig. 27-9](#)). They were able to detect vasa previa in asymptomatic women as early as the midtrimester.

Whenever there is hemorrhage antepartum or intrapartum, the possibility of vasa previa and a ruptured fetal vessel exists. Unfortunately, the amount of fetal blood that can be shed without killing the fetus is relatively small. Thus, in many cases, fetal death is virtually instantaneous. One approach to detecting fetal blood is to smear the blood on glass slides, stain the smears with Wright stain, and examine for nucleated red cells, which normally are present in cord blood but not maternal blood.

Figure 27-8. Velamentous insertion of the cord. The placenta and membranes have been inverted to expose the amnion. Part of the fetal surface of the placenta appears at the bottom of the photograph. Note the large fetal vessels extending from the cord insertion and within the membranes. Finally, note the proximity of the vessels to the site of membrane rupture.

Figure 27-9. Grey-scale ultrasonographic scans showing vasa previa. The left figure is a midline sagittal view of the cervix, bladder, and fetal head at 34 weeks' gestation. The aberrant vessel is seen as an echogenic circular structure overlying the internal os. The right figure is a parasagittal view from another woman at 28 weeks. The aberrant vessel (*arrowhead*) is seen as a linear echogenic structure that courses along the amnion adjacent to the cervix. (From Lee and colleagues, 2000, with permission.)

CORD ABNORMALITIES CAPABLE OF IMPEDING BLOOD FLOW. Several mechanical and vascular abnormalities of the umbilical cord are capable of impairing fetal-placental blood flow.

Knots. *False knots*, which result from kinking of the vessels to accommodate to the length of the cord, should be distinguished from *true knots*, which result from active fetal movements. In nearly 17,000 deliveries in the Collaborative Study on Cerebral Palsy, Spellacy and co-workers (1966) found an incidence of true knots of 1.1 percent. The incidence is especially high in monoamniotic twins. Venous stasis may lead to mural thrombosis and fetal hypoxia, causing death or neurological morbidity. Collins and Collins (2000) estimate a 6 percent incidence of stillbirths when true knots are found.

Loops. The cord frequently becomes coiled around portions of the fetus, usually the neck. This is more likely with longer cords. Several large studies have reported one loop of nuchal cord in 20 to 34 percent of deliveries; two loops in 2.5 to 5 percent; and three loops in 0.2 to 0.5 percent (Kan and Eastman, 1957; Sornes, 1995; Spellacy and associates, 1966). Fortunately, coiling of the cord around the neck is an uncommon cause of antepartum fetal death or neurological damage (Clapp and colleagues, 2003; Nelson and Grether, 1998).

Such entwined cords, however, may cause intrapartum complications. As labor progresses and there is fetal descent, contractions may compress the cord vessels. This causes fetal heart rate decelerations that persist until the contraction ceases (see [Chap. 18](#), p. 453). In labor, 20 percent of fetuses with a nuchal cord have moderate or severe variable heart rate decelerations, and they also are more likely to have a lower umbilical artery pH (Hankins and colleagues, 1987).

TORSION AND STRICTURES. Torsion of the cord is rare. It results from fetal movements during which the cord normally becomes twisted. Occasionally, the torsion is so marked that fetal circulation is compromised. Cord stricture is more serious, and most infants with this finding are stillborn. The stricture is associated with an extreme focal deficiency in Wharton jelly. In monoamniotic twinning, a significant fraction of the high perinatal mortality rate is attributed to entwining of the umbilical cords before labor.

HEMATOMA. These accumulations of blood are associated with short cords, trauma, and entanglement (Benirschke and Kaufmann, 2000). They may result from the rupture of a varix, usually of the umbilical vein, with effusion of blood into the cord ([Fig. 27-10](#)). Hematomas also may be caused by umbilical vessel venipuncture.

Figure 27-10. Hematoma of the umbilical cord.

CYSTS. Cord cysts occasionally are found along the course of the cord and are designated true and false, according to their origin. True cysts are quite small and may be derived from remnants of the umbilical vesicle or the allantois. False cysts, which may attain considerable size, result from liquefaction of Wharton jelly. Such cysts that are detected by sonography are difficult to identify precisely.

PATHOLOGICAL EXAMINATION

The development of placental pathology as a discipline has renewed interest in placental examination. In many cases, expert evaluation will help to elucidate the etiopathogenesis of some perinatal outcomes. Although most authorities agree that routine placental examination by a pathologist is not indicated, there still is debate as to which placentas should be submitted. For example, the College of American Pathologists recommends routine examination for a comprehensive and imposing list of maternal, perinatal, and placental conditions (Langston and colleagues, 1997). Conversely, the American College of Obstetricians and Gynecologists (1993) concluded that there are insufficient data to support all of these recommendations. The major concerns are that pathological examination is costly and time consuming and would exhaust resources that could be better spent.

Certainly, all agree that the placenta and cord — including the number of vessels — should be examined grossly following all deliveries. The decision to request pathological examination will depend on clinical and placental findings. The possible correlation(s) of specific placental findings with both short- and long-term neonatal outcomes is unclear at this time.

Although it is our opinion that routine placental examination by a pathologist cannot be justified, there are some obstetrical and perinatal conditions in which placental findings are helpful. For example, when performed in conjunction with fetal autopsy, it may prove useful in determining the cause of stillbirth (see [Chap. 29](#), p. 677). Porter (2000) recommends formal pathological placental examination in the following circumstances: (1) perinatal death, (2) preterm delivery, (3) fetal growth abnormalities, (4) fetal malformations, (5) hydrops, (6) any other fetal disorders, (7) multiple pregnancy, (8) maternal disorders, and (9) gross placental lesions. The protocol used at Parkland Hospital is that the placenta is sent for pathological examination whenever the neonatal resuscitation team is called. The placenta also is examined in all cases of stillborn infants or if there are obvious abnormalities. Thus, the indications are similar to those of Porter (2000). The specimen is accompanied by a completed data sheet with pertinent clinical information.

SECTION V - FETUS AND NEWBORN

28. The Newborn Infant

INTRODUCTION

At birth, the infant is subjected to rapid and profound physiological changes. Survival depends on a prompt and orderly conversion to air breathing. For efficient interchange of oxygen and carbon dioxide, the fluid-filled alveoli of the lungs must expand with air, the air must be exchanged by appropriate respiratory motion, and perfusion must be established.

INITIATION OF AIR BREATHING

STIMULI TO BREATHE AIR. The newborn begins to breathe and cry almost immediately after birth, indicating the establishment of active respiration. Factors that appear to influence the first breath of air include:

1. *Physical stimulation*, such as handling the infant during delivery.
2. *Deprivation of oxygen and accumulation of carbon dioxide*, which serve to increase the frequency and magnitude of breathing movements both before and after birth (Dawes, 1974).
3. *Compression of the thorax* during the second stage of labor and vaginal birth, which has been found to force an amount of fluid from the respiratory tract equivalent to about one fourth of the ultimate functional residual capacity (Saunders and Milner, 1978).

Aeration of the newborn lung is not the inflation of a collapsed structure, but instead, the rapid replacement of bronchial and alveolar fluid by air. After delivery, the residual alveolar fluid is cleared through the pulmonary circulation and, to a lesser degree, through the pulmonary lymphatics (Chernick, 1978). Delay in removal of fluid from the alveoli probably contributes to the syndrome of *transient tachypnea of the newborn*. As fluid is replaced by air, the compression of the pulmonary vasculature is reduced considerably and, in turn, resistance to blood flow is lowered. With the fall in pulmonary arterial blood pressure, the ductus arteriosus normally closes.

High negative intrathoracic pressures are required to bring about the initial entry of air into the fluid-filled alveoli. Normally, from the first breath after birth, progressively more residual air accumulates in the lung, and with each successive breath, lower pulmonary opening pressure is required. In the normal mature infant, by about the fifth breath, pressure-volume changes achieved with each respiration are very similar to those of the adult. Thus, the breathing pattern shifts to regular, deeper inhalations from the shallow episodic inspirations characteristic of the fetus and described in [Chapter 15](#) (see p. 376). The presence of surfactant, synthesized by type II pneumocytes, lowers surface tension in the alveoli and thereby prevents the collapse of the lung with each expiration. Lack of sufficient surfactant, common in preterm infants, leads to the prompt development of *respiratory distress syndrome* (see [Chap. 29](#), p. 650).

MANAGEMENT OF DELIVERY

IMMEDIATE CARE. Before and during delivery, careful considerations must be given to several determinants of neonatal well-being that include:

1. Health status of the mother.
2. Prenatal complications, including any suspected fetal malformations.
3. Labor complications.
4. Gestational age.
5. Duration of labor and ruptured membranes.
6. Types, amounts, times, and routes of administration of medications.
7. Type and duration of anesthesia.
8. Any difficulty with delivery.

With delivery of the head, either vaginally or by cesarean, the face should be wiped and the mouth and nares suctioned. A soft rubber syringe or its equivalent is quite suitable. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) recommend that at least one person whose primary responsibility is the neonate and who is capable of initiating resuscitation attend every delivery. Either that person or someone else who is immediately available should have the skills required to perform complete resuscitation.

NEWBORN RESUSCITATION. As many as 10 percent of newborn infants require some degree of active resuscitation to stimulate breathing (Kattwinkel, 2000). This is perhaps related to the observation that the risk of death for newborns delivered at home in Washington state between 1989 and 1996 was nearly twice that of those delivered in hospitals (Pang and co-workers, 2002). When deprived of oxygen, either before or after birth, infants demonstrate a well-defined sequence of events leading to apnea. As shown in [Figure 28-1](#), oxygen deprivation results initially in a transient period of rapid

breathing. If such deprivation persists, however, breathing stops and the infant enters a stage of apnea known as *primary apnea*. This stage is accompanied by a fall in heart rate and loss of neuromuscular tone. Simple stimulation and exposure to oxygen will usually reverse primary apnea. If oxygen deprivation and asphyxia persist, however, the infant will develop deep gasping respirations, followed by *secondary apnea*. This latter stage is associated with a further decline in heart rate, falling blood pressure, and loss of neuromuscular tone. Infants in secondary apnea will not respond to stimulation and will not spontaneously resume respiratory efforts. Unless ventilation is assisted, death will occur. **Clinically, primary and secondary apnea are indistinguishable; thus, secondary apnea must be assumed and resuscitation of the apneic infant must be started immediately.**

Resuscitation Protocol. The following is a summary of the guidelines for neonatal resuscitation recommended by the American Academy of Pediatrics and the American Heart Association (Kattwinkel, 2000). These guidelines have been endorsed by the American College of Obstetricians and Gynecologists in the *Guidelines for Perinatal Care* (2002). Of note, Wiswell (2003) recently has provided an excellent review summarizing some of the evidence and controversies underlying these guidelines.

BASIC STEPS. As shown in [Figure 28-2](#), the infant is first placed in a warm environment to minimize heat loss. Next, the airway is cleared. If the delivery is complicated by meconium and the infant is not vigorous, endotracheal intubation is recommended as subsequently discussed so that the airway can be suctioned before further resuscitative efforts are performed. The infant is then dried and stimulated after which respiratory effort, heart rate, and color are assessed. In most instances, the infant will take a breath within a few seconds of birth and cry within half a minute. If the infant is breathing, the heart rate is greater than 100 beats/min, and the skin of the central portion of the body and mucus membranes is pink, then routine supportive care is provided.

VENTILATION. The presence of apnea, gasping respirations, or bradycardia beyond 30 seconds after delivery should prompt administration of *positive-pressure ventilation* ([Fig. 28-3](#)). The recommended assisted ventilation rate is 40 to 60 breaths per minute and 30 per minute if chest compressions also are being delivered. Adequate ventilation is indicated by bilateral rise of the chest and auscultation of breath sounds as well as improvement in heart rate and color. If ventilation is inadequate, the infant's head position should be checked (see [Fig. 28-3](#)), secretions cleared, and if necessary, inflation pressure increased.

Fetal failure to establish effective respirations may result from a variety of complications, including the following:

1. Fetal hypoxemia or acidosis from any cause.
2. Drugs administered to the mother.
3. Fetal immaturity.
4. Upper airway obstruction.
5. Pneumothorax.
6. Other lung abnormalities, either intrinsic (e.g., hypoplasia) or extrinsic (e.g., diaphragmatic hernia).
7. Aspiration of amniotic fluid contaminated with meconium.
8. Central nervous system developmental abnormality.
9. Septicemia.

ENDOTRACHEAL INTUBATION. If bag-and-mask ventilation is ineffective or prolonged, endotracheal intubation should be performed. Other indications include the need for chest compressions or tracheal administration of medications or special circumstances such as extremely low birthweight or congenital diaphragmatic hernia. A laryngoscope with a straight blade $\#$ —size 0 for preterm infants, size 1 for term infants $\#$ —is introduced at the side of the mouth and then directed posteriorly toward the oropharynx ([Fig. 28-4](#)). The laryngoscope is next moved gently into the space between the base of the tongue and the epiglottis. Gentle elevation of the tip of the laryngoscope will raise the epiglottis and expose the glottis and the vocal cords. The endotracheal tube is then introduced through the vocal cords. Gentle cricoid pressure may be useful. The suggested tube size and depth of insertion are shown in [Table 28-1](#).

Several steps are taken to ensure that the tube is positioned in the trachea and not the esophagus: observing symmetrical chest wall motion; listening for equal breath sounds, especially in the axillae; and listening for an absence of breath sounds or a gurgling sound over the stomach. Given that meconium, blood, mucus, and particulate debris in amniotic fluid or in the birth canal may have been inhaled prior to delivery, any foreign material encountered in the tracheal tube should be suctioned immediately.

The resuscitator, using an appropriate ventilation bag attached to the tracheal tube, should deliver puffs of oxygen-rich air into the tube at 1- to 2-second intervals with a force adequate to gently lift the chest wall. Pressures of 25 to 35 cm H₂O typically will expand the alveoli without causing a pneumothorax or pneumomediastinum.

CHEST COMPRESSIONS. If the heart rate remains below 60 beats/min despite adequate ventilation with 100-percent oxygen for 30 seconds, chest compressions are initiated. Compressions are delivered on the lower third of the sternum at a depth sufficient to generate a palpable pulse. A 3:1 ratio of compressions to ventilations is recommended, with 90 compressions and 30 breaths to achieve approximately 120 events each minute. The heart rate is reassessed every 30 seconds, and chest compressions are continued until the spontaneous heart rate is at least 60 beats/min.

MEDICATIONS AND VOLUME EXPANSION. Administration of epinephrine is indicated when the heart rate remains below 60 beats/min after a minimum of 30 seconds of adequate ventilation and chest compressions. Epinephrine is particularly indicated in the presence of asystole. The recommended intravenous or endotracheal dose is 0.1 to 0.3 mL/kg of a 1:10,000 solution. This is repeated every 3 to 5 minutes as indicated.

Volume expansion should be considered when blood loss is suspected, the infant appears to be in shock, or the response to resuscitative measures is inadequate. An isotonic crystalloid solution, such as normal saline or Ringer lactate, is recommended. Symptomatic anemia may require transfusion of red blood cells. The initial dose of either type of volume expander is 10 mL/kg given by slow intravenous push over 5 to 10 minutes.

The routine use of *sodium bicarbonate* during neonatal resuscitation is controversial (Kette and associates, 1991). The hyperosmolarity and CO₂-generating properties of bicarbonate may be detrimental to myocardial and cerebral function. If sodium bicarbonate is used during prolonged arrests unresponsive to other therapy, it should be administered only after establishment of adequate ventilation and circulation.

Naloxone is a narcotic antagonist indicated for reversal of respiratory depression in a newborn infant whose mother received narcotics within 4 hours of delivery. Adequate ventilation should always be established prior to naloxone administration. The recommended dose of naloxone is 0.1 mg/kg of a 1.0-mg/mL solution. Because the duration of action of narcotics may exceed that of naloxone, continued monitoring of respiratory function is essential, and repeat doses may be necessary to prevent recurrent apnea. Based on their systematic review of nine studies, McGuire and Fowlie (2003) concluded that prophylactic naloxone administration, in the absence of respiratory depression, does not confer any clinical benefits.

Discontinuation of Resuscitation. As expected, infants with cardiopulmonary arrest who do not respond promptly to resuscitation are at great risk for mortality and, if they survive, severe morbidity. For example, Haddad and associates (2000) described 33 infants born without cardiac or respiratory effort that persisted for at least the first 5 minutes of life and in whom resuscitation was attempted. Of the 11 survivors, five had clinical or radiological signs of neurological injury, four were lost to follow-up, and only two had normal neurological development. Given the poor prognosis, the American Academy of Pediatrics and American Heart Association (Kattwinkel, 2000) advise that discontinuation of resuscitative efforts may be appropriate if resuscitation after cardiopulmonary arrest does not result in spontaneous circulation within 15 minutes. Furthermore, resuscitation of newborns after 10 minutes of asystole is very unlikely to result in neurologically intact survival.

METHODS USED TO EVALUATE NEWBORN CONDITION

APGAR SCORE. A useful clinical tool to identify those neonates who require resuscitation as well as to assess the effectiveness of any resuscitative measures is the Apgar scoring system (Apgar, 1953). As shown in [Table 28-2](#), each of the five easily identifiable characteristics—heart rate, respiratory effort, muscle tone, reflex irritability, and color—is assessed and assigned a value of 0 to 2. The total score, based on the sum of the five components, is determined 1 and 5 minutes after delivery.

The 1-minute Apgar score reflects the need for immediate resuscitation. The 5-minute score, and particularly the change in score between 1 and 5 minutes, is a useful index of the effectiveness of resuscitative efforts. The 5-minute Apgar score also has prognostic significance for neonatal survival, because survival is related closely to the condition of the infant in the delivery room (Apgar and associates, 1958). In an analysis of more than 150,000 infants delivered at Parkland Hospital, Casey and associates (2001b) assessed the contemporaneous significance of the 5-minute score for predicting survival during the first 28 days of life. They found that in term infants the risk of neonatal death was approximately 1 in 5000 for those with Apgar scores of 7 to 10, as compared with approximately 1 in 4 for those with scores of 3 or less. Low 5-minute scores were comparably predictive of neonatal death in preterm infants. They concluded that the Apgar scoring system is as relevant for

the prediction of neonatal survival today as it was almost 50 years ago.

There have been attempts to use Apgar scores to define asphyxial injury and to predict subsequent neurological outcome — uses for which the Apgar score was never intended. Such associations are especially difficult to measure given that both asphyxial injury and low Apgar scores are infrequent outcomes. For example, according to U.S. birth certificate records for the year 2002, only 1.4 percent of newborns had a 5-minute score below 7 (Martin and co-workers, 2003). Similarly, in a population-based study of more than 1 million term infants born in Sweden between 1988 and 1997, the incidence of 5-minute Apgar scores of 3 or less was approximately 2 per 1000 (Thorngren-Jerneck and Herbst, 2001).

Despite the methodological challenges, erroneous definitions of asphyxia by many groups were established solely based upon low Apgar scores. The promulgation of such definitions prompted the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics to issue a joint statement in 1986 on the use and misuse of the Apgar score that was reaffirmed in 1996. Important caveats regarding Apgar score interpretation addressed in this statement include the following:

1. Because certain elements of the Apgar score are partially dependent on the physiological maturity of the infant, a healthy preterm infant may receive a low score only because of immaturity (Amon and associates, 1987; Catlin and co-workers, 1986).
2. Given that Apgar scores may be influenced by a variety of factors including, but not limited to, fetal malformations, maternal medications, and infection, to equate the presence of a low Apgar score solely with asphyxia or hypoxia represents a misuse of the score.
3. Correlation of the Apgar score with adverse future neurological outcome increases when the score remains 3 or less at 10, 15, and 20 minutes, but still does not indicate the cause of future disability (Freeman and Nelson, 1988; Nelson and Ellenberg, 1981).
4. The Apgar score alone cannot establish hypoxia as the cause of cerebral palsy (see [Chap. 29](#), p. 655). A neonate who has had an asphyxial insult proximate to delivery that is severe enough to result in acute neurological injury should demonstrate all of the findings listed in [Table 28-3](#).

UMBILICAL CORD BLOOD ACID-BASE STUDIES. Blood taken from umbilical vessels may be used for acid-base studies to assess the metabolic status of the fetus. Blood collection is performed following delivery by immediately isolating a 10- to 20-cm segment of cord with two clamps near the neonate and two clamps nearer the placenta. The importance of clamping the cord is underscored by the fact that delays of 20 to 30 seconds can alter both the P_{CO_2} and pH (Lievart and deJong, 1984). The cord is then cut between the two proximal and two distal clamps. *Arterial blood* is drawn from the isolated segment of cord into a 1- to 2-mL commercially prepared plastic syringe containing lyophilized heparin or a similar syringe that has been flushed with a heparin solution containing 1000 U/mL. The needle is capped and the syringe transported, on ice, to the laboratory. Although efforts should be made to transport the blood promptly, neither the pH nor P_{CO_2} change significantly in blood kept at room temperature for up to 60 minutes (Duerbeck and associates, 1992). Chauhan and colleagues (1994) developed mathematical models allowing reasonable prediction of birth acid-base status in properly collected cord blood samples analyzed as late as 60 hours after delivery.

Fetal Acid-Base Physiology. The fetus produces carbonic and organic acids. Carbonic acid (H_2CO_3) is formed by oxidative metabolism of CO_2 . The fetus can rapidly clear CO_2 through the placental circulation, and when H_2CO_3 accumulates in fetal blood without an increase in organic acids, the result is *respiratory acidemia*. Organic acids primarily are formed by anaerobic metabolism and include lactic and β -hydroxybutyric acids. These organic acids are cleared slowly from fetal blood, and when they accumulate without an increase in H_2CO_3 , the result is *metabolic acidemia*. With the development of metabolic acidemia, bicarbonate (HCO_3^-) decreases because it is used to buffer the organic acid. An increase in H_2CO_3 accompanied by an increase in organic acid (seen as a decrease in HCO_3^-) is known as a *mixed respiratory-metabolic acidemia*.

In the fetus, respiratory and metabolic acidemia, and ultimately tissue acidosis, are most likely part of a progressively worsening continuum. This is different from the adult pathophysiology, in which distinct conditions result in either respiratory (pulmonary disease) or metabolic (diabetes) acidemia. In the fetus, the placenta serves as both the lungs and, to a certain degree, the kidneys. One principal cause of developing acidemia in the fetus is a decrease in uteroplacental perfusion. This results in the retention of CO_2 (respiratory acidemia), and if protracted and severe enough, it ultimately leads to a mixed or metabolic acidemia.

Assuming that maternal pH and blood gases are normal, the actual pH of fetal blood is dependent on the proportion of carbonic and organic acids as well as the amount of bicarbonate, which is the major buffer in blood. This can best be illustrated by the Henderson-Hasselbach equation:

$$pH = pK + \log \frac{[\text{base}]}{[\text{acid}]} \text{ or, } pH = pK + \log \frac{HCO_3^-}{H_2CO_3}$$

For clinical purposes, HCO_3^- represents the metabolic component and is reported in mEq/L. The H_2CO_3 concentration represents the respiratory component and is reported as the P_{CO_2} in mmHg. Thus:

$$pH = pK + \log \frac{\text{metabolic } (HCO_3^- \text{ mEq/L})}{\text{respiratory } P_{CO_2} (\text{mm Hg})}$$

Delta base is a calculated number used as a measure of the change in buffering capacity of bicarbonate (HCO_3^-). For example, bicarbonate concentration will be decreased with a metabolic acidemia as it is consumed in order to maintain a normal pH. A

base deficit occurs when HCO_3^- concentration decreases to below normal levels, and a *base excess* occurs when HCO_3^- values are above normal. Importantly, a mixed respiratory-metabolic acidemia with a large base deficit and a low HCO_3^- (less than 12 mEq/L) is more often associated with a depressed neonate than is a mixed acidemia with a minimal base deficit and a more nearly normal HCO_3^- (American College of Obstetricians and Gynecologists, 1995; Gilstrap and Cunningham, 1994; Ross and Gala, 2002). A nomogram for calculating the delta base has been published by Siggaard-Anderson (1963).

Clinical Diagnosis of Significant Acidemia. Fetal oxygenation and pH generally decline during the course of normal labor (Dildy and co-workers, 1994). Normal umbilical cord blood pH and blood gas values at delivery in term newborns are summarized in [Table 28-4](#). Similar values have been measured in preterm infants (Dickinson and co-workers, 1992; Ramin and associates, 1989; Riley and Johnson, 1993). Using data from over 19,000 deliveries, the lower limits of normal pH in the newborn have been found to range from 7.04 to 7.10 (Boylan and Parisi, 1994). Thus, these values should be considered to define neonatal acidemia. Most fetuses will tolerate intrapartum acidemia with a pH as low as 7.00 without incurring neurological impairment (Freeman and Nelson, 1988; Gilstrap and associates, 1989). Indeed, Goldaber and associates (1991) found that there were significantly more neonatal deaths and infants with neurological dysfunction if a pH cutoff value of less than 7.00 was used ([Table 28-5](#)).

Another important prognostic consideration is the direction of pH change from birth to the immediate neonatal period. Casey and co-workers (2001a) found that the risk of seizures during the first 24 hours of life was reduced fivefold if a cord pH below 7.2 normalized within 2 hours after delivery.

In the fetus, *metabolic acidemia* develops when oxygen deprivation is of sufficient duration and magnitude to require anaerobic metabolism for fetal cellular energy needs. Low and associates (1997) defined fetal acidosis as a base deficit of greater than 12 mmol/L and severe fetal acidosis as a base deficit greater than 16 mmol/L. In the study of over 150,000 newborn infants cited earlier, Casey and associates (2001b) defined metabolic acidemia using umbilical cord blood gas cutoffs that were 2 standard deviations below the mean. Using this criteria, metabolic acidosis was defined as an umbilical artery blood pH less than 7.00 accompanied by a Pco_2 of no more than 76.3 mm Hg, HCO_3^- concentration of no more than 17.7 mmol/L, and base deficit of no more than 10.3 mEq/L. According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002), the precise umbilical cord blood pH value that defines *chemically* significant acidemia is not known; however, umbilical artery blood pH values less than 7.00 with a metabolic component and a base deficit of 10 mEq/L or more realistically represent clinically significant metabolic acidosis.

Metabolic acidemia is associated with a high rate of multiorgan dysfunction, and in rare cases such hypoxia-induced metabolic acidemia may be so severe as to cause subsequent neurological impairment. In fact, a fetus without such acidemia cannot by definition have suffered recent hypoxic-induced injury (see [Table 28-3](#)). Even severe metabolic acidosis, however, is poorly predictive of subsequent neurological impairment in the term infant. Although metabolic acidosis was associated with an increase in immediate neonatal complications in a group of infants with depressed 5-minute Apgar scores, Socol and colleagues (1994) found no difference in umbilical artery blood gas measurements among those individuals who developed cerebral palsy and those with subsequent normal neurological outcome. In very-low-birthweight infants—those less than 1000 g—newborn acid-base status may be more closely linked to long-term neurological outcome (Gaudier and co-workers, 1994; Low and associates, 1995). In contrast, Casey and associates (2001b) measured the association between metabolic acidemia, low Apgar scores, and neonatal death in term and preterm infants. Relative to infants with a 5-minute Apgar score of at least 7, the risk of neonatal death was more than 3200-fold greater in term infants with metabolic acidemia and 5-minute scores of 3 or less ([Table 28-6](#)).

Respiratory acidemia generally develops as a result of an acute interruption in placental gas exchange with subsequent CO_2 retention. Transient umbilical cord compression is the most common antecedent factor in the development of fetal respiratory acidemia. In general, respiratory acidemia does not reflect an insult of potential harm to the fetus. Low and co-workers (1994) found no increase in newborn complications after respiratory acidosis. The degree to which pH is affected by Pco_2 , the respiratory component of the acidosis, can be calculated by the following relationship: 10 additional units of Pco_2 will lower the pH by 0.08 units (Eisenberg and colleagues, 1987). Thus in a mixed respiratory-metabolic acidemia, the benign respiratory component can be calculated as follows:

During labor, an acute cord prolapse occurred and the fetus was delivered by cesarean 20 minutes later. The umbilical artery pH at birth was 6.95, with a Pco_2 of 89 mm Hg. To calculate the degree to which the cord compression and subsequent impairment of CO_2 exchange affected the pH, the relationship given earlier is applied: 89 mm Hg–49 mm Hg (normal newborn $\text{Pco}_2=40$ mm Hg (excess CO_2)). To correct pH: $(40 \div 10) \times 0.08 = 0.32$; $6.95 + 0.32 = 7.27$. Therefore, the pH prior to cord prolapse was approximately 7.27, well within normal limits.

Recommendations for Cord Blood Gas Determinations. A cost-effectiveness analysis for universal cord blood gas measurements has not been conducted. In some centers, cord gas analysis is performed in all infants at birth. The American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2002) recommend that cord blood gas and pH analyses be used in select neonates with low Apgar scores to distinguish metabolic acidemia from hypoxia or other causes that might result in a low Apgar score. Although umbilical cord acid-base blood determinations have a low predictability for either immediate or long-term adverse neurological outcome, they are helpful to exclude intrapartum events that may cause acidosis (Gilstrap and Cunningham, 1994).

PREVENTIVE CARE

EYE INFECTION PROPHYLAXIS. A little more than a century ago, it was estimated that as many as 80 percent of children in institutions for the blind had *gonococcal ophthalmia neonatorum* resulting from passage through the birth canal of a mother infected with gonorrhea (Schneider, 1984). In 1884, Crede, a German obstetrician, introduced the practice of instilling into each eye immediately after birth one drop of a 1-percent solution of silver nitrate, which was later washed out with saline. As a result, blindness due to neonatal infection from *Neisseria gonorrhoeae* was largely eliminated.

Since that time, a variety of antimicrobials have also proven to be effective, and prophylaxis against gonococcal ophthalmia neonatorum is now mandatory for all neonates, including those born by cesarean delivery (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002). Current recommendations by the Centers for Disease Control and Prevention (2002a) include a single application of aqueous silver nitrate (1 percent), erythromycin ophthalmic ointment (0.5 percent), or tetracycline ophthalmic ointment (1 percent). For infants born to mothers with untreated gonorrhea, single-dose ceftriaxone, 25 to 50 mg/kg, is given intramuscularly or intravenously, not to exceed 125 mg.

The problem of providing adequate neonatal prophylaxis against *chlamydial conjunctivitis* is much more complex. It is estimated that 12 to 25 percent of infants born vaginally to mothers with an active chlamydial infection will develop conjunctivitis (Teoh and Reynolds, 2003). Although it is reasonable to expect that tetracycline and erythromycin ophthalmic ointments applied at birth should reduce the incidence of chlamydial conjunctivitis, results with these agents and silver nitrate solution have been disappointing. In a study from Kenya, Isenberg and colleagues (1995) showed that 2.5-percent povidone-iodine solution was superior to either 1-percent silver nitrate solution or 0.5-percent erythromycin ointment in preventing chlamydial conjunctivitis. According to the Centers for Disease Control and Prevention (2002a), topical prophylaxis against chlamydial conjunctivitis is inadequate, and any case of conjunctivitis in an infant less than 1 month old should prompt consideration for chlamydial infection.

HEPATITIS B IMMUNIZATION. In 1991, the Centers for Disease Control and Prevention recommended routine immunization of all newborns against hepatitis B prior to hospital discharge. In 1999, routine vaccination of low-risk newborns was suspended because of concerns that the vaccine contained *thimerosal*, a mercury-containing preservative (Clark and co-workers, 2001). A thimerosal-free hepatitis B vaccine became available several months later and the Centers for Disease Control and Prevention (2002a) recommended it for newborn prophylaxis. Use of the vaccine does not appear to increase the number of febrile episodes, sepsis evaluations, or adverse neurological sequelae (Lewis and associates, 2001). If the mother is hepatitis B surface-antigen positive, the neonate should be passively immunized with hepatitis B immune globulin (see [Chap. 49](#), p. 1131).

VITAMIN K. To prevent vitamin K-dependent hemorrhagic disease of the newborn, which is discussed in [Chapter 29](#) (see p. 676), routine intramuscular administration of single-dose vitamin K within 1 hour of birth is recommended by the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2002).

UNIVERSAL NEWBORN SCREENING. Newborn screening programs began in the early 1960s when Dr. Robert Guthrie developed a test for phenylketonuria (PKU) and a system for collection and transport of blood samples on filter paper (Guthrie and Susi, 1963). Since that time, the term *newborn screening* has referred to biochemical testing for inherited disorders, generally metabolic in origin, that are usually correctable by either drug or dietary interventions (Therrell, 2001). In 2000, all states required mandatory screening for PKU and congenital hypothyroidism and many states required testing for several other disorders, including galactosemia, maple syrup urine disease, homocystinuria, sickle cell disease, and congenital adrenal hyperplasia (American Academy of Pediatrics Newborn Screening Task Force, 2000; March of Dimes, 2002). Using a cost-benefit analysis, Schoen and co-workers (2002) concluded that newborn screening compared favorably with other mass screening programs, including those for breast and prostate cancer. The American College of Obstetricians and Gynecologists (2003) has concluded that newborn screening programs provide an important public health benefit and has advised obstetricians to inform expectant families of the newborn screening process.

ROUTINE NEWBORN CARE

ESTIMATION OF GESTATIONAL AGE. An estimate of the gestational age of the newborn may be made very soon after delivery ([Fig. 28-5](#)). The relationship between gestational age and birthweight should be used to identify neonates at risk for complications (McIntire and colleagues, 1999). For example, neonates who are either small- or large-for-gestational age are at increased risk for hypoglycemia and polycythemia, and measurements of blood glucose and hematocrit are indicated (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002).

Figure 28-5. Ballard score for estimating gestational age. (Reproduced from Ballard and co-workers, 1991, with permission.)

SKIN CARE. Following delivery, excess vernix, as well as blood and meconium, should be gently wiped off. Any remaining vernix is readily absorbed and disappears entirely within 24 hours. The first bath should be postponed until the temperature of the neonate has stabilized.

UMBILICAL CORD. Loss of water from the Wharton jelly leads to mummification of the umbilical cord shortly after birth. Within 24 hours, the cord stump loses its characteristic bluish-white, moist appearance and soon becomes dry and black. Within several days to weeks, the stump sloughs, leaving a small, granulating wound, which after healing forms the umbilicus. Separation usually takes place within the first 2 weeks, with a range of 3 to 45 days (Novack and colleagues, 1988). The umbilical cord dries more quickly and separates more readily when exposed to air, thus, a dressing is not recommended.

Serious umbilical infections sometimes are encountered. The most likely offending organisms are *Staphylococcus aureus*, *Escherichia coli*, and group B streptococcus. Because the umbilical stump in such cases may present no outward sign of infection, the diagnosis may be elusive. Strict aseptic precautions should be observed in the immediate care of the cord. In a

randomized study of 766 newborns, Janssen and co-workers (2003) showed that triple-dye applied to the cord was superior to soap and water care in preventing colonization and exudate formation.

FEEDING. In many hospitals, infants begin breast feeding in the delivery room. Most term infants thrive best when fed at intervals of every 2 to 4 hours. Preterm or growth-restricted infants require feedings at shorter intervals. In most instances, a 3-hour interval is satisfactory. The proper length of each feeding depends on several factors, such as the quantity of breast milk, the readiness with which it can be obtained from the breast, and the avidity with which the infant nurses. It is generally advisable for the infant to nurse for 5 minutes at each breast for the first 4 days, or until the mother has a supply of milk. After the fourth day, the infant nurses up to 10 minutes on each breast.

A goal established by the U.S. Public Health Service for *Healthy People 2010* is to increase the proportion of mothers who breast feed their infants to 75 percent in the early postpartum period, 50 percent at 6 months, and 25 percent at 12 months (U.S. Department of Health and Human Services, 2000). In 1998, nearly two thirds of mothers chose to breast feed, the highest rate in nearly 30 years, and over 28 percent continued for at least 6 months (American College of Obstetricians and Gynecologists, 2000). Breast feeding is discussed further in [Chapter 30](#) (see p. 699).

Initial Weight Loss. Because most infants actually receive little nutriment for the first 3 or 4 days of life, they progressively lose weight until the flow of maternal milk or other feeding has been established. Preterm infants lose relatively more weight and regain their birthweight more slowly than term infants. Infants who are small-for-gestational age but otherwise healthy regain their initial weight more quickly when fed than preterm infants.

If the normal infant is nourished properly, birthweight usually is regained by the end of the 10th day. Thereafter, the weight typically increases steadily at the rate of about 25 g/day for the first few months. Birthweight doubles by 5 months of age and triples by the end of the first year.

Stools and Urine. For the first 2 or 3 days after birth, the contents of the colon are composed of soft, brownish-green *meconium*. This consists of desquamated epithelial cells from the intestinal tract, mucus, and epidermal cells and lanugo (fetal hair) that have been swallowed along with amniotic fluid. The characteristic color results from bile pigments. During fetal life and for a few hours after birth, the intestinal contents are sterile, but bacteria quickly colonize the bowel.

Meconium stooling is seen in 90 percent of newborns within the first 24 hours, and most of the rest do so within 36 hours. Voiding, although usually occurring shortly after birth, may not occur until the second day. The passage of meconium and urine in the minutes immediately after birth or during the next few hours indicates patency of the gastrointestinal and urinary tracts. Failure of the infant to stool or urinate after these times suggests a congenital defect, such as imperforate anus or a urethral valve. After the third or fourth day, as the consequence of ingesting milk, meconium is replaced by light-yellow homogenous feces with a consistency similar to peanut butter.

ICTERUS NEONATORUM. About one third of all infants, between the second and fifth day of life, develop so-called *physiological jaundice of the newborn*. Serum bilirubin levels at birth are normally 1.8 to 2.8 mg/dL. These levels increase during the next few days but with wide individual variation. Between the third and fourth day, the bilirubin in mature infants commonly exceeds 5 mg/dL, the concentration at which jaundice is usually noticeable. Most of the bilirubin is free, or unconjugated. One cause is immaturity of the hepatic cells, resulting in less conjugation of bilirubin with glucuronic acid leading to reduced excretion in bile ([Chap. 29](#), p. 672). Reabsorption of free bilirubin as the consequence of the enzymatic splitting of bilirubin glucuronide by intestinal conjugase activity in the newborn intestine also appears to contribute significantly to the transient hyperbilirubinemia. In preterm infants, jaundice is more common and usually more severe and prolonged than in term infants, because of even less hepatic enzyme production. Increased erythrocyte destruction from any cause also contributes to hyperbilirubinemia.

CIRCUMCISION. Current scientific evidence suggests that several medical benefits are associated with newborn male circumcision. A review by the American Academy of Pediatrics Task Force on Circumcision (1989) reported that the procedure prevented phimosis, paraphimosis, and balanoposthitis, and it decreased the incidence of penile cancer. The Task Force also cited an increased incidence of cervical cancer among sexual partners of uncircumcised men infected with human papillomavirus. The associations between circumcision and reduced risks of penile human papillomavirus infection and cervical cancer in sexual partners have been corroborated by Castellsague and associates (2002).

The American Academy of Pediatrics (1999), however, has concluded that the existing evidence is insufficient to recommend routine neonatal circumcision, a position that is endorsed by the American College of Obstetricians and Gynecologists (2001). Others have argued that the existing data support a recommendation for routine circumcision (Schoen and associates, 2000). Nevertheless, it is currently recommended that parents should decide what is in the best interest of their own child and should make an informed choice after being given accurate and unbiased information. In 1999, 65 percent of all male infants born in hospitals in the United States were circumcised (Centers of Disease Control and Prevention, 2002b).

Surgical Technique. Newborn circumcision should be performed only on a healthy infant, and some contraindications are listed in [Table 28-7](#). The most commonly used instruments include the Gomco and Mogen clamps and the Plastibell device ([Fig. 28-6](#)). Compared with the Gomco procedure, Kaufman and colleagues (2002) reported that the Mogen technique required less time to perform and was associated with less apparent discomfort for the infant. Regardless of the method used, the goal is to remove enough shaft skin and inner preputial epithelium so that the glans is exposed sufficiently to prevent phimosis. In all techniques, (1) the amount of external skin to be removed must be accurately estimated, (2) the preputial orifice must be dilated to visualize the glans and ensure that it is normal, (3) the inner preputial epithelium must be freed from the glans epithelium, and (4) the circumcision device must be left in place long enough to produce hemostasis before amputating the prepuce (Lerman and Liao, 2001). For a detailed description of surgical techniques see *Operative Obstetrics* (Swaim, 2002).

Anesthesia for Circumcision. The American Academy of Pediatrics (1999) recommends that if circumcision is performed, procedural analgesia should be provided. A variety of techniques for pain relief have been described, including lidocaine-prilocaine topical cream, local analgesia infiltration, and dorsal penile nerve and ring blocks. Stang and colleagues (1988) reported that dorsal penile nerve block reduced behavioral distress and modified adrenocortical stress response in neonates

undergoing circumcision. This observation was confirmed in subsequent clinical studies (Arnett and co-workers, 1990; Fontaine and Toffler, 1991). The results of these studies favor the dorsal penile nerve block and the ring block technique over topical analgesia (Butler-O'Hara, 1998; Hardwick-Smith, 1998; Lander, 1997; Taddio, 1997, and their colleagues). The use of a pacifier dipped in sucrose also appears beneficial (Kaufman and colleagues, 2002).

After appropriate penile cleansing, the *ring block technique* consists of placing a wheal of 1 percent lidocaine at the base of the penis and advancing the needle in a 180-degree arc around the base of the penis first to one side and then the other to achieve a circumferential ring of analgesia. The maximum dose of lidocaine is 1.0 mL. The addition of a buffering agent does not appear to offer a benefit (Newton and co-workers, 1999). **No vasoactive compounds such as epinephrine should ever be added to the local analgesic agent.**

Complications of Circumcision. As with any surgical procedure, there is a risk of bleeding, infection, and hematoma formation. These risks, however, are low (Christakis and colleagues, 2000; Holman and colleagues, 1995). More unusual complications have been reported as isolated cases, including amputation of the distal penile glans during neonatal ritual circumcision (Neulander and colleagues, 1996), infection with human immunodeficiency virus-1 (HIV-1) and other sexually transmitted diseases (Nicoll, 1997), postcircumcision meatal stenosis (Upadhyay and associates, 1998), denudation of the penis (Orozco-Sanchez and Neri-Vela, 1991), penile destruction with electrocautery (Gearhart and Rock, 1989), formation of an epidermal inclusion cyst and urethrocutaneous fistula (Amukele and associates, 2003), and ischemia following the **inappropriate use of lidocaine with epinephrine** (Berens and Pontus, 1990).

ROOMING-IN. A model of maternity care that placed newborns in their mothers' rooms instead of central nurseries, so-called *rooming-in*, first appeared in U.S. hospitals in the early 1940s (Temkin, 2002). In part, rooming-in stems from a trend to make all phases of childbearing as natural as possible and to foster mother-child relationships at an early date. By the end of 24 hours, the mother is generally fully ambulatory. Thereafter, with rooming-in, she can usually provide routine care for herself and her infant. An obvious advantage is her increased ability to assume full care of the infant when she arrives home.

HOSPITAL DISCHARGE. Traditionally, the newborn infant is discharged with its mother, and in most cases, maternal stay has determined that of the infant. In the past decade, the length of stay for the mother following uncomplicated vaginal delivery has declined considerably. Although it is clear that most newborns can be safely discharged within 48 hours, this is not uniformly true. For example, using data from the Canadian Institute for Health Information, Liu and colleagues (2000) examined neonatal readmission rates in over 2.1 million discharges. As the length of hospital stay decreased from 4.2 days in 1990 to 2.7 days in 1997, the readmission rate increased from 27.3 to 38 per 1000 births. Dehydration and jaundice accounted for most of these readmissions. Using Washington state infant discharge data, Malkin and co-workers (2000) found that 28-day mortality was increased fourfold and 1-year mortality increased twofold in infants discharged within 30 hours of birth.

Because of the increased scrutiny regarding short hospital stays, federal legislation — *The Newborns' and Mothers' Health Protection Act of 1996* — was enacted to prohibit insurers from restricting hospital stays for mothers and newborns to less than 2 days for vaginal or 4 days for cesarean deliveries. As a result, the average length of hospital stay for childbirth increased from 2.1 days in 1995 to 2.5 days in 2000. This increase reflected the reduced number of very short hospital stays following childbirth (Hall and Owings, 2002). Mosen and associates (2002) found that implementation of the new legislation was associated with a 6-percent increase in cost; however, neonatal readmission rates within 7 days of discharge decreased by nearly half.

29. Diseases and Injuries of the Fetus and Newborn

INTRODUCTION

The fetus and newborn infant are susceptible to a large number of diseases. Because many disorders have a different presentation and course in term as compared with preterm infants, these age groups are considered separately in this chapter. Illnesses or disorders that are the direct consequence of maternal disease are considered in other chapters pertinent to specific maternal illnesses. Because most perinatal infections arise as a result of maternal infection or colonization, they are considered in [Chapters 58](#) and [59](#).

DISEASES OF THE PRETERM FETUS AND NEWBORN

RESPIRATORY DISTRESS SYNDROME. To provide blood gas exchange after birth, the infant's lungs must rapidly fill with air while being cleared of fluid, and the volume of blood that perfuses the lungs must increase remarkably. Some of the fluid is expressed as the chest is compressed during vaginal delivery, and the remainder is absorbed through the pulmonary lymphatics. Sufficient surfactant, synthesized by type II pneumocytes, is essential to stabilize the air-expanded alveoli by lowering surface tension and thereby preventing lung collapse during expiration (see [Chap. 4](#), p. 109). If surfactant is inadequate, respiratory distress develops, and hyaline membranes form in the distal bronchioles and alveoli. Because of this, respiratory distress in the newborn is also termed *hyaline membrane disease*.

Respiratory distress syndrome (RDS) is generally a disease of preterm neonates, although it can occur in term newborns who have sepsis or meconium aspiration. In recent years, RDS has decreased as a cause of neonatal death in the United States as the result of surfactant therapy and administration of antenatal corticosteroids (Jobe, 2004; Martin, 2004). Boys are more likely to develop RDS than girls, and white infants appear to be more frequently and more severely affected than black infants.

Clinical Course. In typical RDS, tachypnea develops, the chest wall retracts, and expiration is accompanied by a grunt and flaring of the nostrils— a combination called *grunting and flaring*. Grunting is common in the newborn whenever there is uneven expansion of the lungs or lower airway obstruction. Shunting of blood through nonventilated lung areas contributes to hypoxemia and to metabolic and respiratory acidosis. Poor peripheral circulation and systemic hypotension may be evident. The chest radiograph shows a diffuse reticulogranular infiltrate with an air-filled tracheobronchial tree (air bronchogram).

Respiratory insufficiency also can be caused by sepsis, pneumonia, meconium aspiration, pneumothorax, persistent fetal circulation, heart failure, and malformations involving thoracic structures, such as diaphragmatic hernia. Recently, Shulenin and colleagues (2004) described surfactant deficiency due to a mutation of the *ABCA3* gene that is involved in surfactant production. Cardiac decompensation in the early newborn period also can have multiple causes, including patent ductus arteriosus and congenital cardiac malformations.

Pathology. Because of inadequate surfactant production, the alveoli are not stable and low pressures cause collapse on end expiration. Nutrition of the lung cells is compromised by hypoxia and systemic hypotension. There may be partial maintenance of the fetal circulation, leading to pulmonary hypertension and a relative right-to-left shunt. Eventually, there is ischemic necrosis of the cells lining the airway. When oxygen therapy is initiated, the pulmonary vascular bed dilates and the shunt (if there is one) reverses. Protein-filled fluid leaks into the alveolar ducts, and the cells lining the alveolar ducts slough. Hyaline membranes composed of fibrin-rich protein and cellular debris line the dilated alveoli and terminal bronchioles, and the epithelium underlying the membrane becomes necrotic.

Treatment. The most important factor influencing survival is admission to a neonatal intensive care unit, which dramatically reduces the number of RDS deaths. Although hypoxemia is indicative of the need for oxygen, excess oxygen can damage the pulmonary epithelium and retina.

Over the years, advances in mechanical ventilation technology have improved neonatal survival. For example, the development of *continuous positive airway pressure (CPAP)* brought about an appreciable reduction in the neonatal mortality rate by preventing the collapse of unstable alveoli and allowing high inspired-oxygen concentrations to be reduced, thereby minimizing toxicity. Disadvantages of CPAP include disturbance of the endothelium and epithelium— caused by overstretching and resulting in barotrauma— and impaired venous return (Verbrugge and Lachmann, 1999). *High-frequency oscillatory ventilation* reduces the risk of barotrauma by using a constant, low-distending pressure and small variations or oscillations to promote alveolar patency. This technique allows optimal lung volume to be maintained and CO₂ to be cleared without damaging alveoli. Although mechanical ventilation has undoubtedly improved survival, it is also an important factor in the genesis of *bronchopulmonary dysplasia* (see p. 651).

Postnatal glucocorticoids have been used for many years to prevent chronic lung disease in these infants. The American Academy of Pediatrics (2002) now recommends against their use because of adverse neuropsychological effects apparent by school age. Yeh and colleagues (2004) recently described significantly impaired motor and cognitive function and school performance in exposed neonates.

SURFACTANT TREATMENT. Administration of exogenous surfactant can prevent hyaline membrane disease. Commercially available preparations contain biological or animal surfactants such as human and bovine (Survanta), calf lung surfactant extract (Infasurf), porcine (Curosulf), or synthetic surfactant (Exosulf). Surfactant therapy has been credited for the largest drop in infant mortality observed in 25 years. It has been used for *prophylaxis* of preterm infants at risk for respiratory distress, as well as for *rescue* of those with established disease.

Jobe (1993) summarized the results of 35 randomized controlled studies of surfactant used for either prophylaxis or rescue therapy and found that it reduced the incidence of pneumothorax and death in the first 28 days of life by 31 to 39 percent. When antenatal corticosteroids and surfactant were given together, there was an even greater reduction in overall death rate and deaths due to respiratory distress syndrome. These findings were confirmed by Kari and associates (1994).

Complications. Persistent hyperoxia injures the lung, especially the alveoli and capillaries. High oxygen concentrations given at high pressures can cause *bronchopulmonary dysplasia*, or *oxygen toxicity lung disease*. This is a chronic condition in which alveolar and bronchiolar epithelial damage leads to hypoxia, hypercarbia, and oxygen dependence, followed by peribronchial and interstitial fibrosis. *Pulmonary hypertension* is another frequent complication. If hyperoxemia is sustained, the infant also is at risk of developing *retinopathy of prematurity*, formerly called *retrolental fibroplasia*. When any of these develop, the likelihood of subsequent neurosensory impairment is substantively increased (Schmidt and colleagues, 2003).

Prevention. With the possible exception of progesterone therapy, no method of prevention or treatment of preterm labor significantly reduces its incidence or improves any index of neonatal outcome (see [Chap. 36](#), p. 869). The National Institutes of Health (1994) concluded that antenatal corticosteroid therapy reduced respiratory distress and intraventricular hemorrhage in preterm infants born between 24 and 32 weeks (see p. 653).

AMNIOCENTESIS FOR FETAL LUNG MATURITY. Delivery for fetal indications is necessary when the risks to the fetus from a hostile intrauterine environment are greater than the risk of respiratory distress, even if the fetus is preterm. If this degree of risk is not present and the criteria for elective delivery at term are not met, amniocentesis is used to confirm fetal lung maturity. The technique is similar to that described for second-trimester amniocentesis in [Chapter 13](#) (see p. 328). Several methods can be used to determine the relative concentration of surfactant-active phospholipids:

1. *Lecithin-sphingomyelin (L/S) ratio.* Lecithin (dipalmitoyl phosphatidylcholine) plus phosphatidylinositol and especially phosphatidylglycerol are important in the formation and stabilization of the surface-active layer that prevents alveolar collapse and respiratory distress (see [Chap. 4](#), p. 109). Before 34 weeks, lecithin and sphingomyelin are present in amniotic fluid in similar concentrations. At about 34 weeks, the concentration of lecithin relative to sphingomyelin begins to rise ([Fig. 29-1](#)).

Gluck and co-workers (1971) were the first to report that the risk of neonatal respiratory distress is slight whenever the concentration of lecithin is at least twice that of sphingomyelin (L/S ratio). Conversely, there is increased risk of respiratory distress when this ratio is below 2. Harper and Lorenz (1993) found an immature L/S ratio to be more predictive of the need for ventilatory support than gestational age or birthweight ([Table 29-1](#)). Because lecithin and sphingomyelin are found in blood and meconium, contamination with these substances may confound the results. Blood has an L/S ratio of 1.3 to 1.5, and meconium usually lowers the L/S ratio (Buhi and Spellacy, 1975).

2. *Phosphatidylglycerol.* With some pregnancy complications, respiratory distress may develop despite an L/S ratio greater than 2. With diabetes, for example, some clinicians use a number greater than 2 to define maturity or require the presence of phosphatidylglycerol (Ojomo and Coustan, 1990). Phosphatidylglycerol is believed to enhance the surface-active properties of lecithin and sphingomyelin (see [Chap. 4](#), p. 109). Its identification in amniotic fluid provides more assurance, but not necessarily an absolute guarantee, that respiratory distress will not develop. Because phosphatidylglycerol is not detected in blood, meconium, or vaginal secretions, these contaminants do not confuse its interpretation.

3. *TDx-FLM.* This automated assay measures the surfactant-to-albumin ratio in uncentrifuged amniotic fluid and gives results in approximately 30 minutes. In a study of 374 consecutive amniotic fluid specimens, Steinfeld and associates (1992) reported that a TDx value of 50 or greater predicted fetal lung maturity in 100 percent of cases. Subsequent investigations by Hagen and associates (1993) and Herbert and co-workers (1993) found the TDx-FLM to be equal or superior to the L/S ratio, foam stability index, or phosphatidylglycerol assessment in predicting both positive and negative tests. Eriksen and associates (1996) reported that, in diabetic women, the TDx-FLM test has a sensitivity, specificity, and negative-predictive value for evaluating fetal lung maturity comparable to the L/S ratio. Many hospitals use the TDx-FLM as their first-line test of pulmonary maturity, followed by the L/S ratio in indeterminate samples.

4. *Other tests.* The *foam stability* or *shake test*, introduced by Clements and associates (1972), depends on the ability of surfactant in amniotic fluid, when mixed appropriately with ethanol, to generate stable foam at the air-liquid interface. Problems with the test include errors caused by slight contamination and frequent false-negative test results. The *Lumadex-FSI test*, *fluorescent polarization (microviscometry)*, and *amniotic fluid absorbance at 650-nm wavelength* have all been used with variable success. The *lamellar body count* is a rapid, simple, and accurate method of assessing fetal lung maturity (Welsch and colleagues, 1996). Measurement of the amniotic fluid concentration of *dipalmitoylphosphatidylcholine (DPPC test)* also has been reported to be highly sensitive and specific for predicting respiratory distress (Alvarez and Ludmir, 1996).

Figure 29-1. Changes in mean concentrations of lecithin and sphingomyelin in amniotic fluid during gestation in normal pregnancy. (From Gluck and Kulovich, 1973, with permission.)

RETINOPATHY OF PREMATURITY. Formerly known as *retrolental fibroplasia*, retinopathy of prematurity had become by 1950 the largest single cause of blindness in this country. After the discovery that the etiology of the disease was hyperoxemia, its frequency decreased remarkably.

The retina vascularizes centrifugally from the optic nerve starting at about the fourth month and continuing until shortly after birth. During the time of vascularization, excessive oxygen induces severe retinal vasoconstriction with endothelial damage and vessel obliteration, especially in the temporal portion. Neovascularization results, and the new vessels penetrate the retina and extend into the vitreous, where they are prone to leak proteinaceous material or burst with subsequent hemorrhage. Adhesions then form, which detach the retina. Precise levels of hyperoxemia that can be sustained without causing retinopathy are not known. That said, retinopathy is unlikely if inhaled air has no more than 40-percent oxygen content. Unfortunately, very immature infants who develop respiratory distress often require high oxygen concentrations to maintain life until respiratory function improves. Importantly, if vascular damage results, it increases threefold the likelihood of later death or neurological disability (Schmidt and co-workers, 2003).

INTRAVENTRICULAR HEMORRHAGE. There are four major categories of neonatal intracranial hemorrhage: *subdural hemorrhage* is usually the result of trauma. *Subarachnoid hemorrhage* and *intracerebellar hemorrhage* usually result from trauma in term infants but in preterm infants are commonly due to hypoxia. *Periventricular-intraventricular hemorrhage* results from either trauma or asphyxia in half of term infants but has no discernible cause in 25 percent of cases (Volpe, 1995). In preterm neonates, the pathogenesis of periventricular hemorrhage is multifactorial and includes hypoxic-ischemic events, anatomical factors, coagulopathy, and many others. The prognosis after hemorrhage depends on the location and extent of the bleeding. For example, subdural and subarachnoid hemorrhage often result in minimal, if any, neurological abnormalities. Bleeding into the parenchyma, however, can cause serious permanent damage.

Periventricular-Intraventricular Hemorrhage. When the fragile capillaries in the germinal matrix rupture, there is bleeding into surrounding tissues, which may extend into the ventricular system and brain parenchyma. Unfortunately, it is a common problem in preterm neonates, especially those born before 32 weeks. These lesions also can develop at later gestational ages and occasionally are seen in term neonates.

Most hemorrhages develop within 72 hours of birth, but they have been observed as late as 24 days (Perlman and Volpe, 1986). Almost half are clinically silent. Most small germinal matrix hemorrhages and those confined to the cerebral ventricles resolve without impairment (Weindling, 1995). Large lesions can result in hydrocephalus or *periventricular leukomalacia*, a correlate of cerebral palsy, discussed later. Because intraventricular hemorrhage usually is recognized within 3 days of delivery, its genesis is often erroneously attributed to birth events. It is important to realize that *prelabor* intraventricular hemorrhage also can occur (Achiron and associates, 1993; Nores and associates, 1996).

PATHOLOGY. The primary pathological process is damage to the germinal matrix capillary network, which predisposes to subsequent extravasation of blood into the surrounding tissue. In preterm infants, this capillary network is especially fragile for several reasons:

1. The subependymal germinal matrix provides poor support for the vessels coursing through it.
2. The venous anatomy in this region causes venous stasis and congestion, which makes the vessel susceptible to bursting with increased intravascular pressure.
3. Vascular autoregulation is impaired before 32 weeks (Volpe and Hill, 1987).

Even if extensive hemorrhage or other complications of preterm birth do not cause death, survivors can have major neurodevelopmental handicaps (Papile and co-workers, 1983). DeVries and colleagues (1985) attribute most long-term sequelae of intraventricular-periventricular hemorrhage to cystic areas called *periventricular leukomalacia*. These areas develop most commonly as a result of ischemia and least commonly in direct response to hemorrhage, and are discussed subsequently.

INCIDENCE AND SEVERITY. The incidence of ventricular hemorrhage depends on gestational age at birth. About half of all neonates born before 34 weeks but only 4 percent of those born at term will have some evidence of hemorrhage (Hayden and associates, 1985). Very-low-birthweight infants have the earliest onset of hemorrhage and the greatest likelihood of involvement of parenchymal tissue, and thus the highest mortality rate (Perlman and Volpe, 1986).

The severity of intraventricular hemorrhage can be assessed by ultrasound and computed tomography. Papile and colleagues (1978) devised the most widely used grading scheme to quantify the extent of the lesion and estimate prognosis:

• **Grade I** — hemorrhage limited to the germinal matrix.

• **Grade II** — intraventricular hemorrhage.

• **Grade III** — hemorrhage with ventricular dilatation.

• **Grade IV** — parenchymal extension of hemorrhage.

Jakobi and colleagues (1992) showed that infants with grade I or II intraventricular hemorrhage had over 90 percent survival rate with a 3.2-percent rate of handicap, the same as control infants of the same age but without hemorrhage. The survival rate for infants with grade III or IV hemorrhage, however, was only 50 percent. Vergani and co-workers (1996) confirmed that very preterm infants are at increased risk of sustaining severe intracranial hemorrhage. The latest figures from the Neonatal Research Network (Lemons and colleagues, 2001), indicate that 30 percent of infants born weighing 501 to 1500 g develop intracranial hemorrhage, with 11 percent of cases being grad III or IV.

CONTRIBUTING FACTORS. Events that predispose to germinal matrix hemorrhage and subsequent periventricular leukomalacia are multifactorial and complex. The preterm fetus has fragile intracranial blood vessels that make it particularly susceptible, and preterm birth is frequently associated with infection, which predisposes to tissue ischemia. Luthy and co-workers (1987) reported a threefold increased risk for grade III or IV hemorrhage when the cord arterial pH was less than 7.2. Respiratory distress syndrome and mechanical ventilation are commonly associated factors. Lesko and colleagues (1986) reported that heparin, often used to maintain vascular catheter patency in intensive care units, was associated with a fourfold increased risk of germinal matrix hemorrhage. In a review of 232 infants who weighed less than 1500 g, Wallin and co-workers (1990) reported that associated postnatal factors include respiratory distress and ventilator therapy.

PREVENTION AND TREATMENT. Administration of corticosteroids at least 24 hours before delivery appears to prevent or reduce the incidence and severity of intraventricular hemorrhage. In a consensus statement developed by a panel of the National Institutes of Health (1994), it was concluded that antenatal corticosteroid therapy reduced mortality, respiratory distress, and intraventricular hemorrhage in preterm infants born between 24 and 32 weeks, and that the benefits were additive with those from surfactant therapy. In addition, the consensus panel concluded that the benefits of antenatal steroid therapy probably extend to preterm premature membrane rupture. After a second Consensus Development Conference held by the National Institutes of Health (2000), it was concluded that repeated courses of antenatal steroids should not be given. Data

were considered inadequate to prove any benefit or to document the safety of more than one course (see [Chap. 36](#), p. 868).

The type of corticosteroid administered may be important. Although both betamethasone and dexamethasone cross the placenta in their active form, betamethasone has a longer half-life. This is because it has a larger volume of distribution and is cleared more slowly than dexamethasone (American College of Obstetricians and Gynecologists, 2002). Further, although both medications are associated with a reduced incidence of respiratory distress, only betamethasone has been shown to decrease mortality (Ballard and Ballard, 1995). Consistent with this finding, Cox and associates (1996) found no benefits of dexamethasone with regard to grade III or IV hemorrhage in preterm infants delivered at Parkland Hospital. In another study, Baud and colleagues (1999) found that *betamethasone* decreased the incidence of periventricular leukomalacia, but *dexamethasone* did not. Silver and associates (1996) reported that infants treated with antenatal dexamethasone and born before 30 weeks had fewer grade III and IV hemorrhages after treatment with surfactant, but the comparison group received placebo, not betamethasone.

The efficacy of phenobarbital, vitamin K, vitamin E, or indomethacin in diminishing the frequency and severity of intracranial hemorrhage, when administered either to the neonate or to the mother during labor, remains controversial (Chiswick and colleagues, 1991; Hanigan and colleagues, 1988; Thorp and colleagues, 1995). Data from a variety of sources suggest that magnesium sulfate may prevent the sequelae of periventricular hemorrhage, as discussed on page 658.

It is generally agreed that avoiding significant hypoxia both before and after preterm delivery is of paramount importance (Low and co-workers, 1995). There is presently no convincing evidence, however, that routine cesarean delivery for the preterm fetus presenting cephalic will decrease the incidence of periventricular hemorrhage (Strauss and colleagues, 1985; Tejani and co-workers, 1987; Welch and Bottoms, 1986). For example, Anderson and associates (1992) found no significant difference in the overall *frequency* of hemorrhage in infants whose birthweights were below 1750 g and who were delivered without labor compared with that of those delivered during latent or active labor. Infants delivered of mothers in active labor, however, tended to have more grade III or IV hemorrhages. In contrast, data presented by Ment and associates (1995) suggested a reduction in early intracranial hemorrhage with cesarean delivery.

NECROTIZING ENTEROCOLITIS. This newborn bowel disorder has clinical findings of abdominal distention, ileus, and bloody stools. There is usually radiological evidence of *pneumatosis intestinalis*, which is bowel wall gas formed by invading gas-forming bacteria. Bowel perforation may prompt resection.

The disease is seen primarily in low-birthweight infants but occasionally is encountered in mature neonates. Various causes hypothesized include perinatal hypotension, hypoxia, sepsis, umbilical catheterization, exchange transfusions, and the feeding of cow milk and hypertonic solutions (Kliegman and Fanaroff, 1984). All of these can ultimately lead to occlusive intestinal ischemia. Reperfusion injury also seems to play a role (Czyrko and associates, 1991). Because the disease tends to occur in clusters, some investigators believe that coronaviruses may have an etiological role.

BRAIN DISORDERS. Few events evoke more fear and apprehension in parents and obstetricians than the specter of "brain damage." This term immediately conjures visions of disabling cerebral palsy and hopeless mental retardation. Although most brain disorders or injuries are less horrific, they nevertheless are a major source of psychological and economic damage. The evolution of our understanding of this myriad of brain disorders was presaged by over a century of misconceptions that were accepted by science, medicine, and society.

In 1862, a London orthopedist, William Little, described 47 children with spastic rigidity and concluded that abnormalities of birth could be the cause. Notables such as Sigmund Freud (1897) challenged this view, having observed that abnormal birth processes frequently produced no effects. It was more than 100 years after Little's observations that research was begun in earnest to elucidate the pathophysiology of fetal and neonatal brain damage. The landmark observations of Nelson and Ellenberg (1986a) have subsequently led to the acceptance — except by plaintiff attorneys — that only a relative few of such cases are caused at the time of birth, and that the majority are not preventable.

The persistence, for so many years, of the presumed birth-injury etiology for cerebral damage was one of the major reasons for the escalating rate of cesarean deliveries in the United States through the 1970s and 1980s. Because cause and effect were not related, this increase in cesarean deliveries did not result in any significant decline in the rate of cerebral palsy.

Brain disorders or damage, including the sequela of cerebral palsy, are a complex and multifactorial process caused by a combination of genetic, physiological, environmental, and obstetrical factors. For years the term *birth asphyxia*, indicating a neurological injury during birth, was applied to many infants inappropriately, however, objective definitions have subsequently evolved. To clarify the potential role of intrapartum events in causing permanent neurological injury, the American College of Obstetricians and Gynecologists (1998, 2004) developed a precise definition of birth asphyxia that includes all of these three:

1. Profound metabolic or mixed acidemia (pH of less than 7.0) determined on an umbilical cord arterial blood sample.
2. Persistent Apgar score of 0 to 3 for longer than 5 minutes.
3. Evidence of neonatal neurological sequelae such as seizures, coma, or hypotonia; or dysfunction of one or more of the following systems: cardiovascular, gastrointestinal, hematological, pulmonary, or renal.

When these three factors are associated with brain injury, they suggest that perinatal *hypoxic ischemic encephalopathy* developed. More importantly, their absence associated with brain injury helped to forge the crucial link between antepartum events that cause the majority of cases of cerebral palsy.

Neonatal Encephalopathy. The American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2003) recently convened a task force to review scientific data concerning *neonatal encephalopathy* and cerebral palsy. It defined neonatal encephalopathy as some combination of abnormal consciousness, tone, reflexes, feeding, respiration, or seizures in the term or near-term infant. The Task Force concluded that there were many different causes, which may or may not result in permanent sequelae — cerebral palsy being but one. Moreover, cerebral palsy can be attributed to an intrapartum event only if the affected child develops *hypoxic ischemic encephalopathy*. Further, of the several forms of

cerebral palsy, only the spastic quadriplegic type can result from an acute interruption of blood supply prior to delivery. Hemiparetic or hemiplegic cerebral palsy, spastic diplegia, and ataxia are unlikely to result from an intrapartum event. Purely dyskinetic or ataxic cerebral palsy, especially when accompanied by a learning disorder, usually has a genetic origin (Nelson and Grether, 1998).

Although there is no doubt that some cases of cerebral palsy arise from intrapartum hypoxic-ischemic events, accumulated data indicate that 70 percent of all cases of neonatal encephalopathy result from an event that occurred *prior* to the onset of labor. To address this, the Task Force developed four essential criteria that, if all are present, define an acute intrapartum event sufficient to cause cerebral palsy:

1. Evidence of metabolic acidosis in fetal umbilical arterial blood obtained at delivery: pH of less than 7.0 and base deficit of at least 12 mmol/L.
2. Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks.
3. Cerebral palsy of spastic quadriplegic or dyskinetic type.
4. Exclusion of other possible etiologies such as trauma, coagulation disorders, infections, or genetic disorders.

The Task Force also developed five criteria that, if occurring together, suggest that the supposed insult occurred within 0 to 48 hours of delivery:

1. A sentinel hypoxic event occurring immediately before or during labor.
2. Sudden and sustained fetal bradycardia or the absence of fetal heart rate variability in the presence of persistent, late, or variable decelerations, usually after a hypoxic sentinel event when the fetal heart rate pattern was previously normal.
3. Apgar scores of 0 to 2 beyond 5 minutes.
4. Onset of multisystem dysfunction within 72 hours of birth.
5. Early imaging study showing evidence of acute, nonfocal cerebral abnormality.

Gibbs and colleagues (2004) recently reviewed these criteria and offered 12 suggestions for implementation into practice in an obstetrical-neonatal unit.

Cerebral Palsy. This term refers to a group of conditions that are characterized by chronic movement or posture abnormalities, are cerebral in origin, arise early in life, and are nonprogressive (Nelson, 2003). Epilepsy and mental retardation frequently accompany cerebral palsy but usually are not associated with perinatal asphyxia in the absence of cerebral palsy.

Cerebral palsy is commonly classified by the type of neurological dysfunction (spastic, dyskinetic, or ataxic) as well as the number and distribution of limbs involved (quadriplegia, diplegia, hemiplegia, or monoplegia). The major types and frequencies of cerebral palsy are:

1. *Spastic quadriplegia*, which has a strong association with mental retardation and seizure disorders (20 percent).
2. *Diplegia*, which is common in preterm or low-birthweight infants (30 percent).
3. *Hemiplegia* (30 percent).
4. *Choreoathetoid types* (15 percent).
5. *Mixed varieties* (Freeman and Nelson, 1988; Rosen and Dickinson, 1992).

Significant mental retardation, defined as an intelligence quotient (IQ) of less than 50, is associated with 25 percent of cerebral palsy cases.

INCIDENCE AND EPIDEMIOLOGICAL CORRELATES. The incidence of cerebral palsy in developed countries is approximately 2 per 1000 live births (Clark and Hankins, 2003). Importantly, this rate either has remained essentially unchanged or has increased since the 1950s (Freeman and Nelson, 1988; Torfs and colleagues, 1990). In some countries, the incidence has risen because advances in the care of very preterm infants have improved their survival, but with significant handicap (Stanley and Blair, 1991). From their review of 11 studies published from 1985 through 1990, Rosen and Dickinson (1992) reported that the average cumulative rate for cerebral palsy at ages 5 to 7 years was 2.7 per 1000 live births. For infants less than 2500 g, this rate was 15 per 1000; for survivors who weighed 500 to 1500 g at birth, the rate was 13 to 90 per 1000.

Nelson and Ellenberg (1984, 1985, 1986a, 1986b) have made important contributions to our understanding of cerebral palsy. Their studies included data from the Collaborative Perinatal Project, which followed offspring of almost 54,000 pregnancies until age 7. They found that the important antecedents and most commonly associated risk factors for cerebral palsy were (1) evidence of genetic abnormalities, such as maternal mental retardation, fetal microcephaly, and fetal congenital malformations; (2) birthweight less than 2000 g; (3) gestational age at birth less than 32 weeks; and (4) infection. Obstetrical complications were not strongly predictive of cerebral palsy, and indeed, only about 20 percent of affected children had markers of perinatal asphyxia. By contrast, over half had associated congenital malformations, low birthweight, microcephaly, or another explanation for the brain disorder. They concluded that the causes of most cases of cerebral palsy were unknown, and that no foreseeable single intervention would likely prevent a large proportion of cases.

Torfs and associates (1990) reported similar findings in 0.3 percent of over 19,000 children from the California Child Health and Development Studies database who were diagnosed with cerebral palsy. Of these 55 children, 25 percent had neural-tube

defects or obvious postnatal causes such as infection or injury. The 22 percent with cerebral palsy who had "perinatal asphyxia," defined erroneously as a time-to-cry interval longer than 5 minutes, also had birth defects, gestational risk factors, or both. The strongest predictors of cerebral palsy included a congenital anomaly, low birthweight, low placental weight, or abnormal fetal position such as face presentation, breech, or transverse lie. The latter is often associated with neurological abnormality. These factors were similar to those identified in the Collaborative Perinatal Project ([Table 29-2](#)). Interestingly, low-, mid-, or even high-forceps or cesarean delivery did not correlate with cerebral palsy. Similarly, the Maternal Fetal Medicine Units (MFMU) Network studied nearly 800 infants with birthweights less than 1000 g and showed that only low birthweight and early gestational age correlated with neonatal neurological morbidity (Goepfert and associates, 1996).

Intrapartum Events. The Task Force on Neonatal Encephalopathy determined that only 1.6 cases of cerebral palsy per 10,000 deliveries are attributable solely to intrapartum hypoxia. This finding is supported by many studies. For example, Stanley and Blair (1991) performed a case-control study of all cases of cerebral palsy in Western Australia from 1975 to 1980. They reported that in 92 percent of cases, intrapartum injury as the cause of cerebral palsy was unlikely; in 3.3 percent, it was possible; and in only 4.9 percent was it likely. Phelan and associates (1996) by review of fetal monitor tracings evaluated 209 cases of neonatal neurological impairment and classified 75 percent as nonpreventable.

Consistent with this, data from a variety of sources indicate that continuous electronic fetal monitoring in labor neither predicts nor reduces the risk of cerebral palsy when compared with intermittent auscultation (Clark and Hankins, 2003; Grant and associates, 1989; MacDonald and associates, 1985; Thacker and colleagues, 1995). It was concluded by the American College of Obstetricians and Gynecologists (1995) that "a substantial body of evidence disproves the hypothesis that electronic fetal monitoring would reduce long-term neurological impairment and cerebral palsy in newborns so monitored."

Importantly, there does not appear to be any specific fetal heart rate pattern that predicts cerebral palsy, and a number of studies have found no relationship between the clinician's response to abnormal fetal heart rate patterns and neurological outcome (Melone and associates, 1991; Nelson and co-workers, 1996; Niswander and colleagues, 1984). In fact, an abnormal heart rate pattern in fetuses who ultimately develop cerebral palsy may reflect preexisting neurological abnormality and not ongoing, remedial injury (Phelan and Ahn, 1994). This, in part, accounts for the unchanged incidence of cerebral palsy in the United States, despite a fivefold increase in the cesarean delivery rate since 1965.

Apgar Scores. A variety of data show that Apgar scores alone are generally poor predictors of neurological impairment. Nelson and Ellenberg (1984) studied the interaction between obstetrical complications and a low Apgar score and reported that, in the absence of complications, low Apgar scores alone were not associated with a high level of risk. However, in infants who had 5-minute Apgar scores of 3 or less along with a complicated birth, the incidence of cerebral palsy was increased appreciably. Dijkhoorn and colleagues (1986) reported similar findings. The American College of Obstetricians and Gynecologists (1996) concluded that low Apgar scores at 1 and 5 minutes identify infants who need resuscitation, but that low Apgar scores alone are not evidence for hypoxia sufficient to result in neurological damage (see [Chap. 28](#), p. 637).

Umbilical Cord Blood Gas Studies. As summarized in [Chapter 28](#) (see p. 638), an important part of the definition of neonatal asphyxia is metabolic acidosis. In its absence, significant intrapartum hypoxia or asphyxia generally is excluded. However, when used alone, umbilical cord acid-base determinations have proven no more helpful than the 1- and 5-minute Apgar scores in predicting long-term neurological sequelae. Dijkhoorn and associates (1986) studied 805 term newborns delivered vaginally. They reported that the largest number of neurologically abnormal infants had low Apgar scores but a normal cord arterial pH, indicating that intrapartum hypoxia was not the major cause of neurological morbidity. Other investigators have reported that neither pH measurements nor acidemia alone correlate with long-term neurological outcome in term infants (American College of Obstetricians and Gynecologists, 1992; Fee and associates, 1990).

Data from several studies indicate that a pH of less than 7.0 is the cutoff for clinically significant acidemia (Gilstrap and associates, 1989; Goldaber and associates, 1991). In a later study of more than 150,000 liveborn infants, Casey and co-workers (2001) used umbilical artery pH to assess predictability of neonatal death within 28 days. As the pH fell to 7.0 or less, the likelihood of neonatal death escalated, increasing 1400-fold with a cord pH of 6.8 or lower in term newborns. When the cord pH was 7.0 or less and the 5-minute Apgar score was 0 to 3, the relative risk of neonatal death was 3204!

Nucleated Red Blood Cells. These immature red cells enter the circulation in response to hypoxia or hemorrhage. Their quantification has been proposed as a measure of hypoxia. And, because increased production of nucleated red cells takes place over time, it has been suggested that these counts can be used to measure the duration of hypoxia (Korst and associates, 1996; Naeye and Localio, 1995). Others have not been able to reproduce these findings. Salafia and colleagues (1996) studied 465 preterm newborns and found no correlation between nucleated red cells and hypoxia. Instead, they found these cells to be hematological markers associated with maternal, placental, and newborn infection. Hankins and co-workers (2002) studied 46 fetuses with acute peripartum asphyxia sufficient to result in neonatal encephalopathy. They found that nucleated red cells were elevated in only 41 percent. As summarized by the Task Force on Neonatal Encephalopathy and Cerebral Palsy, the significance of both nucleated erythrocytes and lymphocytes as a marker for hypoxic injury is currently imprecise and unclear.

PERIVENTRICULAR LEUKOMALACIA. This pathological description refers to cystic areas deep in brain white matter that develop after hemorrhagic and ischemic infarction. Tissue ischemia leads to regional necrosis, and because brain tissue does not regenerate, these irreversibly damaged areas appear as echolucent cysts on neuroimaging studies. They generally require at least 2 weeks to develop and have been reported to develop up to 104 days after the initial insult (Goetz and colleagues, 1995). Accordingly, the presence of these cystic areas at birth may help to determine the timing of the hemorrhagic event (Hayakawa and co-workers, 1999).

A variety of clinical and pathological data link severe intraventricular hemorrhage Ⓐ—grade III or IV Ⓑ— and resulting periventricular leukomalacia to cerebral palsy. Grade I or II hemorrhages usually resolve without extensive tissue injury. Luthy and colleagues (1987) reported a 16-fold increased risk of cerebral palsy for low-birthweight infants who had grade III or IV hemorrhage compared with that in infants who had either none or grade I or II hemorrhage. Allan and co-workers (1997) found that the highest rates of cerebral palsy in 505 infants with birthweights between 600 and 1250 g were associated with periventricular leukomalacia (37 percent) and ventriculomegaly (30 percent). DeVries and colleagues (1993) followed 504 infants born at 34 weeks or less. At least two thirds had localized cystic periventricular leukomalacia, and 100 percent of those with extensive cystic areas developed cerebral palsy. Conversely, only 11 percent of those with transient cysts developed

cerebral palsy. Hsu and colleagues (1996) showed that the size of the cyst(s) correlates directly with the risk for cerebral palsy. Fujimoto and colleagues (1994) demonstrated that symmetrical cystic lesions convey the highest risk.

Periventricular leukomalacia is more strongly linked to infection and inflammation than to intraventricular hemorrhage. Zupan and colleagues (1996) studied 753 infants born between 24 and 32 weeks, 9 percent of whom developed periventricular leukomalacia. Those born before 28 weeks, or who had inflammatory events during the last days to weeks before delivery, or both, were at highest risk. Perlman and co-workers (1996) found that periventricular leukomalacia was strongly associated with prolonged membrane rupture, chorioamnionitis, and neonatal hypotension. Spinillo and colleagues (1995, 1998) found a strong association between leukomalacia and a variety of factors, including first-trimester hemorrhage, smoking, urinary infection in labor, preterm labor, low birthweight, neonatal acidosis, meconium staining, and ritodrine therapy for more than 72 hours.

Periventricular Leukomalacia in the Preterm Fetus. Consideration of brain development explains why very preterm infants are most susceptible to intraventricular hemorrhage and periventricular leukomalacia. Before 32 weeks, the vascular anatomy of the brain is composed of two systems, one that penetrates into the cortex—the *ventriculopedal system*—and another that reaches down to the ventricles, but then curves to flow outward—the *ventriculofugal system* (Weindling, 1995). There are no vascular anastomoses connecting these two systems. As a result, the area between these systems, through which the pyramidal tracts pass near the lateral cerebral ventricles, is a watershed area vulnerable to ischemia. Vascular insufficiency before 32 weeks leading to ischemia would affect this watershed area first, and resulting damage of the pyramidal tracts would cause spastic diplegia. After 32 weeks, vascular flow shifts toward the cortex. Thus, hypoxic injury after this time primarily damages the cortical region.

PERINATAL INFECTION. Fetal infection may be the key element in the pathway between preterm birth, intracranial hemorrhage, periventricular leukomalacia, and cerebral palsy (Dammann and Leviton, 1997; Yoon and colleagues, 1997a, 2000, 2001). In the pathway proposed in [Figure 29-2](#), antenatal reproductive tract infection evokes the production of cytokines such as tumor necrosis factor and interleukins-1, -6, and -8. These in turn stimulate prostaglandin production and preterm labor (see [Chap. 36](#), p. 859). Preterm intracranial blood vessels are susceptible to rupture and damage, and the cytokines that stimulate preterm labor also have direct toxic effects on oligodendrocytes and myelin. Vessel rupture, tissue hypoxia, and cytokine-mediated damage result in massive cell death. Glutamate is released, stimulating membrane receptors to allow excess calcium to enter the neurons. High intracellular calcium levels are toxic to white matter, and glutamate may be directly toxic to oligodendroglia (Levene, 1992; Oka and associates, 1993).

Many studies have shown that infection and cytokines can damage the immature brain. Yoon and colleagues (1997a) have shown that inoculation of rabbit embryos with *E coli* causes histological damage in white matter. In another study, these investigators showed that tumor necrosis factor and interleukin-6 were more frequently found in the brains of infants who died with periventricular leukomalacia (Yoon and co-workers, 1997b). Cytokines are strongly linked to white matter lesions even when organisms cannot be demonstrated. In a study of 123 preterm infants, Yoon and colleagues (2000) demonstrated that only 45 percent of amniotic fluid samples from infants who ultimately developed cerebral palsy contained microorganisms. These same fluids had abnormally elevated levels of interleukin-6 and interleukin-8 in 85 percent of cases.

Infection is important, even when separated from preterm birth. Verma and colleagues (1997) compared 285 infants born after preterm labor and 279 infants born after preterm prematurely ruptured membranes with 149 infants who were delivered preterm for other reasons. The incidence and severity of intraventricular hemorrhage and periventricular leukomalacia were highest in those infants with spontaneous labor or membrane rupture, and were increased even more with chorioamnionitis. Grether and Nelson (1997) performed a population-based case-control study of cerebral palsy in affected children whose birthweight was over 2500 g and who had no congenital brain malformations or genetic abnormalities. They found a ninefold increased risk of cerebral palsy after either intrapartum maternal fever or chorioamnionitis, and a 19-fold risk if there was neonatal infection.

Wu and co-workers (2003) recently described a nested case-control study of over 231,500 singleton infants born at 36 weeks or more. They reported a fourfold increased risk of cerebral palsy if clinical chorioamnionitis was identified. Other independent risk factors were growth restriction (fourfold), black ethnicity (3.6-fold), maternal age over 25 years (2.6-fold), and nulliparity (1.8-fold).

PREVENTION. In preterm infants, corticosteroid therapy may reduce the incidence of intraventricular hemorrhage (see p. 653). In addition, prophylaxis or aggressive treatment of infection may protect against neurological injury. Magnesium sulfate is currently being investigated as another neuroprotective agent. In adults, it has been shown to stabilize intracranial vascular tone, minimize fluctuations in cerebral blood flow, reduce reperfusion injury, and block calcium-mediated intracellular damage (Marret and associates, 1995). Magnesium reduces synthesis of cytokines and bacterial endotoxins and thus also may minimize the inflammatory effects of infection (Grether and Nelson, 1997).

Epidemiological evidence suggests that maternal magnesium sulfate therapy has a fetal neuroprotective effect (Schendel and co-workers, 1996). Some have concluded that this effect may be limited to fetuses delivered early for preeclampsia (Grether and colleagues, 2000). In contrast, however, a recent Australian randomized trial of magnesium sulfate given to 1047 women delivering spontaneously before 30 weeks showed that magnesium exposure improved some perinatal outcomes (Crowther and colleagues, 2003). Although the incidence of both neonatal death and cerebral palsy were improved, the study was not sufficiently powered to make these differences statistically significant. As emphasized by Tyson and Gilstrap (2003), although the 17-percent reduction in death and cerebral palsy reported in this study is encouraging, magnesium for these purposes is still investigational. An ongoing trial conducted by the MFMU Network is the *BEAM (Beneficial Effects of Antenatal Magnesium Sulfate) study* (http://www.nichd.nih.gov/about/womenhealth/premature_birth.cfm).

NEURORADIOLOGICAL IMAGING. Computed tomographic (CT) and magnetic resonance imaging (MRI) scans have been used in older children to define the timing of cerebral injury. Wiklund and colleagues (1991a, 1991b) studied children between 5 and 16 years of age with hemiplegic cerebral palsy, 28 of whom were born preterm and 83 born at term. Only 25 percent of these children had CT findings that were considered normal. In those who had been delivered at term, periventricular atrophy was present in 37 percent and maldevelopment in 17 percent, thus suggesting a *prenatal* injury in over half of cases. In contrast, as many as 70 percent of those delivered preterm had findings that confirmed an insult in early *postnatal* life. Cortical and subcortical injury suggestive of a perinatal injury was found in 19 percent.

Nelson and Lynch (2004) recommend MRI to best identify and characterize neonatal strokes. Truwit and colleagues (1992) performed MRI scans in 40 patients with cerebral palsy. The predominant finding in 80 percent of those born preterm was evidence of periventricular white matter damage. This indicated hypoxic ischemic injury, although its exact chronology was difficult to determine. In contrast, 50 percent of those born at term had findings consistent with antenatal brain damage, including polymicrogyria consistent with midpregnancy injury, and isolated periventricular leukomalacia. In 25 percent of these cases, MRI findings, coupled with clinical events, were suggestive of hypoxic ischemic injury at birth.

Cranial ultrasound also provides useful information. The development of periventricular leukomalacia is shown in [Figure 29-3](#). In this case, because cysts take days to weeks to develop, an ultrasound examination performed on day 1 was critical in diagnosing *antenatal* brain injury. Intraventricular hemorrhage was found to be a secondary insult that developed in the nursery. Sometimes head ultrasound reveals findings different but complementary to those of CT scanning. A grade III intraventricular hemorrhage diagnosed at birth by CT scan is shown in [Figure 29-4A](#). A cranial ultrasound examination done the same day, however, also identified periventricular leukomalacia, thus documenting injury well before birth ([Fig. 29-4B](#)).

Neonatal MRI also has been instructive (Battin and associates, 1998; Fedrizzi and colleagues, 1996; Okumura and colleagues, 1997). It also has been used to help determine the most likely time of brain insult in children with cerebral palsy (Jaw and co-workers, 1998).

NEONATAL ENCEPHALOPATHY IN TERM INFANTS. Mature infants also can suffer neurological insults, resulting in permanent compromise. As discussed on page 654, neonatal encephalopathy is a defined syndrome of disturbed neurological function consisting of difficulty in initiating and maintaining respiration, depressed tone and reflexes, subnormal level of consciousness, and frequently seizures. It generally is believed to be the consequence of a hypoxic-ischemic insult, although the timing of the insult is not always known. *Mild encephalopathy* is generally defined as hyperalertness, irritability, jitteriness, and hypertonia and hypotonia; *moderate encephalopathy* includes lethargy, severe hypertonia, and occasional seizures; and *severe encephalopathy* is defined by coma, multiple seizures, and recurrent apnea.

Severe encephalopathy is a more important predictor of cerebral palsy and future cognitive defects than either mild or moderate types (Robertson and Finer, 1985). Poor postnatal brain growth is an early sign of neurological compromise. In one study, Cordes and colleagues (1994) performed serial head circumference measurements of 54 term infants with hypoxic-ischemic encephalopathy. They found that a decrease in the expected head circumference of more than 3.1 percent in the first 4 months of life predicted microcephaly. Permanent impairment was predictable with 90 percent specificity.

MENTAL RETARDATION. Severe mental retardation has a prevalence of 3 per 1000 children. Etiological factors are shown in [Table 29-3](#). Some genetic causes are discussed in [Chapter 12](#). Isolated mental retardation, without epilepsy or cerebral palsy, is associated with perinatal hypoxia in very few cases (Nelson and Ellenberg, 1984, 1985, 1986a, 1986b).

SEIZURE DISORDERS. Although these may accompany cerebral palsy, isolated seizure disorders or epilepsy usually are not caused by perinatal hypoxia. Nelson and Ellenberg (1986b) determined that the major predictors of seizure disorders were fetal malformations— cerebral and noncerebral, family history of seizures, and neonatal seizures.

Figure 29-2. Schematic representation of the hypothesized pathway between maternal or intrauterine infection, preterm birth, and cerebral palsy. (Courtesy of Dr. Robert Goldenberg.)

Figure 29-3. Preterm infant delivered at 27 weeks because of placental abruption. **A.** Ultrasound scan of the head performed on the first postnatal day shows small bilateral cysts in the periventricular white matter and bilateral germinal-matrix hemorrhages. These findings indicate a much older lesion than one caused by perinatal asphyxia. **B.** Repeat ultrasound of the same infant on day 3 of life showed bilateral intraventricular hemorrhage and a large intraparenchymal echodensity on the right. (Courtesy of Dr. Jeffrey Perlman.)

Figure 29-4. This term infant was born depressed. **A.** Computed tomographic (CT) scan demonstrates a grade III intraventricular hemorrhage. **B.** Ultrasound scan confirmed intraventricular hemorrhage and in addition, bilateral cystic periventricular leukomalacia was seen, which was not observed on the CT scan. These findings documented a severe antenatal brain insult of 4 to 5 weeks' duration. (From Perlman and Cunningham, 1993.)

INFANT OUTCOME IN EXTREME PREMATURE BIRTH. All of the concerns previously described are amplified in infants born at 22 to 25 weeks. Currently, depending on many factors, this gestational age range is considered the limit of viability. Not only is the mortality rate in this age group high, but survivors frequently have devastating neurological, ophthalmological, gastrointestinal, or pulmonary injury. The largest study to date of such infants was conducted by the National Institutes of Health-sponsored Human Development Neonatal Research Network (Lemons and colleagues, 2001). Investigators from 14 tertiary care centers collected data from 1995 and 1996 on 4438 infants who weighed 501 to 1500 grams at birth. The study was limited to liveborn infants and therefore, likely underestimated mortality at the lowest gestational ages. Infants were followed only to hospital discharge. Of the entire cohort, 71 percent were exposed to antenatal steroids and 62 percent to antenatal antimicrobials. After delivery, half were treated with surfactant therapy and one fourth were given corticosteroids for lung disease.

This study provides the most accurate, current data on the outcome of extremely preterm infants. Not surprisingly, the chance of survival until discharge was directly proportional to both gestational age at birth and birthweight (Figs. 29-5 and 29-6). For example, only 25 percent of infants born at 21 to 23 weeks survived, whereas more than 90 percent of those born at 28 weeks or later survived. Also, the incidence of long-term morbidity, including chronic lung disease, grade III or IV intracranial hemorrhage, and necrotizing enterocolitis, was inversely proportional to birthweight and age (Table 29-4). The incidence of chronic morbidity decreased from 63 percent in survivors who weighed 501 to 750 grams at birth, to less than 10 percent in those weighing 1250 to 1500 grams. Hoekstra and co-workers (2004) studied long-term outcomes in 675 survivors born between 23 and 26 weeks. They identified intraventricular hemorrhage and chronic lung disease as being important markers for poor outcomes.

Information on the long-term outcome of similar very-low-birthweight infants was provided by Wood and associates (2000). These investigators followed 283 of 308 survivors born at 25 or fewer completed weeks. Formal assessment at a median of 30 months showed that half had neurological disability. In half of these cases or 25 percent of the total group the disability was severe.

Figure 29-5. Mortality before discharge by gestational age among infants born in Neonatal Research Network Centers during 1995 and 1996. Data are expressed as a percentage of infants who died, and 95-percent confidence intervals are shown between bars for each group. (From Lemons and colleagues, 2001, with permission.)

Figure 29-6. Mortality before discharge by birthweight among infants born in Neonatal Research Network Centers during 1995 and 1996. Data are expressed as a percentage of infants who died, and 95-percent confidence intervals are shown between bars for each 100-g interval. (From Lemons and co-workers, 2001, with permission.)

ANEMIA. After 35 weeks, the mean cord hemoglobin concentration is about 17 g/dL and values below 14 g/dL are abnormal. During the first several hours of life, the hemoglobin value may rise by as much as 20 percent due to delayed cord clamping, resulting in an appreciable volume of blood being expressed from the placenta through the cord into the infant. Alternatively, if the placenta is cut or torn, a fetal vessel is perforated or lacerated, or the infant is held well above the level of the placenta for some time before cord clamping, the hemoglobin concentration may fall after delivery.

Fetal-to-Maternal Hemorrhage. Fetal red cells in the maternal circulation can be identified by use of the acid elution principle first described by Kleihauer, Brown, and Betke, or any of several modifications. Fetal erythrocytes contain hemoglobin F, which is more resistant to acid elution than hemoglobin A. After exposure to acid, only fetal hemoglobin remains. Fetal red cells can then be identified by uptake of a special stain and quantified on a peripheral smear (Fig. 29-7). This test is very accurate unless the maternal red cells carry excess fetal hemoglobin as the result of a hemoglobinopathy.

During all pregnancies, very small volumes of blood cells escape from the fetal intravascular compartment across the placental barrier into the maternal intervillous space. This observation is important for several reasons. It is the cause of maternal red cell isoimmunization, as discussed on page 663. Routine fetal-to-maternal cell transfer may someday serve as the basis for a screening test for fetal aneuploidy using maternal peripheral blood (see Chap. 13, p. 331). There is also evidence that persistence of fetal cells in certain maternal tissues, and the immune response they incite, may be the instigating factor in certain autoimmune diseases such as thyroid failure and scleroderma (see Chap. 54, p. 1210).

Choavaratana and colleagues (1997) performed serial Kleihauer-Betke tests in 2000 pregnant women and found that, although the *incidence* of fetal-maternal hemorrhage in each trimester was high, the *volume transfused* from fetus to mother was very small (Table 29-5). Large hemorrhages are uncommon, and Bowman (1985) reported that only 21 of 9000 women had fetal hemorrhage at delivery exceeding 30 mL. Other events that may cause sufficient hemorrhage to incite isoimmunization are shown in Table 29-6.

D-positive fetal red blood cells in D-negative maternal blood can be detected by the rosette test. Maternal red cells are mixed with anti-D antibodies, which coat any fetal (D-positive) cells present in the sample. Indicator red cells bearing the D-antigen are then added, and rosettes form around the fetal cells as the indicator cells attach to them by the antibodies. Rosettes indicate that fetal D-positive cells are present.

If the fetus becomes severely anemic, a sinusoidal heart rate pattern may develop (see Chap. 18, p. 451). Although this pattern is not pathognomonic of fetal anemia, it should prompt immediate evaluation. In general, anemia occurring gradually or chronically, as in isoimmunization, is better tolerated by the fetus than anemia that develops acutely. Chronic anemia may not produce fetal heart rate abnormalities until the fetus is moribund. In contrast, significant acute hemorrhage is poorly tolerated by the fetus and often causes profound neurological fetal impairment.

Acute maternal-fetal hemorrhage results in fetal hypotension, diminished perfusion of vital organs, ischemia, and cerebral infarction. As a result, after an acute hemorrhage, subsequent obstetrical management usually will not change the outcome. De Alemida and Bowman (1994) described 27 cases of fetal-maternal hemorrhage exceeding 80 mL. Despite appropriate management, almost half of these infants died or developed spastic diplegia. In one study, severe fetal-to-maternal hemorrhage caused 5 percent of fetal deaths (Samadi and colleagues, 1996). Although the etiology of such hemorrhage is often undetermined, placental abruption usually is seldom the cause. That said, trauma such as vehicular accidents can cause placental tearing or "fracture," with significant fetal hemorrhage (see Chap. 42, p. 999). The fetal effects of acute hemorrhage also are illustrated by monozygotic twinning. After the death of one monozygotic twin, acute hemorrhage from the living twin into the low-resistance circulation of the dead twin can cause such rapid and severe damage that even immediate

cesarean delivery does not improve outcome (see [Chap. 39](#), p. 930).

Once fetal-maternal hemorrhage is recognized, the volume of fetal blood lost can be quantified. The volume may influence obstetrical management and is essential to determining the appropriate dose of D-immunoglobulin when the woman is D-negative.

Using basic physiological principles, the amount of fetal hemorrhage may be calculated from the results of a Kleihauer-Betke (KB) stain using the formula:

$$\text{Fetal blood volume} = \frac{\text{MBV} \times \text{maternal Hct} \times \% \text{ fetal cells in KB}}{\text{Newborn Hct}}$$

where MBV = maternal blood volume (about 5000 mL in normal-sized normotensive women at term) and Hct = hematocrit. Thus for 1.7-percent positive KB-stained cells in a woman of average size with a hematocrit of 35 percent giving birth to a term infant weighing 3000 g and whose hematocrit is 0.5:

$$\text{Fetal blood volume} = \frac{5000 \times 0.35 \times 0.017}{.05} = 60 \text{ mL}$$

The fetal-placental blood volume at term is 125 mL/kg, which is 375 mL for this 3000-g fetus. Thus, this fetus has lost 30 mL of red cells over time into the maternal circulation. This is equivalent to 60 mL of whole blood, because the hematocrit is 50 percent.

Figure 29-7. Massive fetal-to-maternal hemorrhage. After acid-elution treatment, fetal red cells rich in hemoglobin F stain darkly (*upper arrow*), whereas maternal red cells with only very small amounts of hemoglobin F stain lightly (*lower arrow*).

ISOIMMUNIZATION. In 1892, Ballantyne established clinicopathological criteria for the diagnosis of hydrops fetalis. In 1932, Diamond, Blackfan, and Baty reported that the fetal anemia in this syndrome was characterized by numerous circulating erythroblasts. Subsequently, the Rhesus factor was discovered by Landsteiner and Weiner in 1940, and Levine and associates confirmed in 1941 that erythroblastosis was due to maternal isoimmunization against paternally inherited fetal factors. The subsequent development of effective maternal prophylaxis was attributed to Finn and associates (1961) in England, and Freda and co-workers (1963) in the United States.

Over 400 red cell antigens have been identified to date. Although some of them are immunologically and genetically important, many are so rare as to be of little clinical significance. Blood banks do not routinely test for any red cell antigen other than the Rhesus and ABO antigens. Any individual who lacks a specific red cell antigen may produce an antibody when exposed to that antigen. Such antibodies can prove harmful to the individual in the case of a blood transfusion or to a fetus during pregnancy. Accordingly, blood banks routinely screen for antibodies.

The vast majority of humans carry at least one red cell antigen inherited from their father but lacking in their mother. Although the mother could be sensitized if enough fetal erythrocytes reached her circulation to elicit an immune response, isoimmunization is actually rare for the following reasons: (1) low prevalence of red cell antigens; (2) insufficient transplacental passage of fetal antigens or maternal antibodies; (3) maternal-fetal ABO incompatibility, leading to rapid clearance of fetal cells before they elicit an immune response; (4) variable antigenicity; and (5) variable maternal immune response to the antigen, with some antigens provoking only minimal response. Considering all these factors, it is not surprising that there is only an overall 2-percent chance of D-isoimmunization by 6 months postpartum, and that isoimmunization does not always lead to erythroblastosis fetalis.

The incidence of sensitization to red cell antigens at each stage of pregnancy has been studied most extensively in D-negative women. A D-negative woman delivered of a D-positive, ABO-compatible infant has a likelihood of isoimmunization of 16 percent; 2 percent will be immunized by the time of delivery, 7 percent will have anti-D antibody by 6 months postpartum, and the remaining 7 percent will be "sensitized" (Bowman, 1985). In sensitized women, anti-D antibodies are produced at such a low level that they are not detected during or after the index pregnancy but instead are identified early in a subsequent pregnancy.

ABO Blood Group System. Although incompatibility for the major blood group antigens A and B is the most common cause of hemolytic disease in the newborn, the resulting anemia is usually very mild. About 20 percent of all infants have an ABO maternal blood group incompatibility, but only 5 percent are clinically affected. ABO incompatibility is different from CDE incompatibility for several reasons:

1. ABO disease frequently is seen in firstborn infants because most group O women have anti-A and anti-B isoagglutinins antedating pregnancy. These antibodies are attributed to exposure to bacteria displaying similar antigens.
2. Most species of anti-A and anti-B antibodies are immunoglobulin M (IgM), which cannot cross the placenta and therefore cannot gain access to fetal erythrocytes. In addition, fetal red cells have fewer A and B antigenic sites than adult cells and are thus less immunogenic. There is no need to monitor antenatal hemolysis with amniocentesis, and no justification for early delivery.
3. The disease is invariably milder than D-isoimmunization and rarely results in significant anemia. Affected infants typically have neonatal anemia and jaundice, which can be treated with phototherapy, and not erythroblastosis fetalis.

4. As a result, ABO isoimmunization is a disease of pediatric rather than obstetrical concern.

ABO isoimmunization can affect future pregnancies but, unlike CDE disease, rarely becomes progressively more severe. Katz and co-workers (1982) identified a recurrence rate of 87 percent, of whom 62 percent required treatment, most often limited to phototherapy.

Although there is no need for antenatal monitoring, careful neonatal observation is essential because hyperbilirubinemia may require treatment. Treatment usually consists of phototherapy or simple or exchange transfusion with O-negative blood. The usual criteria for diagnosis of neonatal hemolysis due to ABO incompatibility are as follows: (1) the mother is blood group O, with anti-A and anti-B antibodies in her serum, whereas the fetus is group A, B, or AB; (2) jaundice develops within the first 24 hours; (3) there are varying degrees of anemia, reticulocytosis, and erythroblastosis; (4) the Coombs test is positive, although rapid clearance of antibody and antibody-coated cells can result in a negative test; and (5) there has been careful exclusion of other causes of hemolysis.

CDE (Rhesus) Blood Group System. This system includes five red cell proteins or antigens: c, C, D, e, and E. No "d" antigen has been identified, and Rh- or D-negativity is defined as the absence of the D-antigen. There are, however, D-antigen variants that cause hemolytic disease (Bush and associates, 2003; Cannon and colleagues, 2003). The CDE antigens are of considerable clinical importance because most D-negative individuals become immunized after a single exposure. The CDE genes are located on the short arm of chromosome 1 and are inherited as a group, independent of other blood group genes. Like many genes, their incidence varies according to racial origin. Native Americans, Inuits, and Chinese and other Asiatic peoples are almost all D-positive (99 percent). Approximately 92 to 93 percent of African Americans are D-positive, but only 87 percent of Caucasians carry the D-antigen. Of all racial and ethnic groups studied thus far, the Basques show the highest incidence of D-negativity (34 percent).

The C-, c-, E-, and e-antigens have lower immunogenicity than the D-antigen, but they can cause erythroblastosis fetalis. All pregnant women should be tested routinely for the presence or absence of D-antigen on their erythrocytes and for irregular antibodies in their serum. Barss and colleagues (1988) have argued convincingly that this need be done only once during each pregnancy in D-positive women.

Other Blood Group Incompatibilities. Because the routine administration of anti-D immunoglobulin prevents most cases of anti-D-isoimmunization, proportionately more cases of significant antenatal hemolytic disease are now caused by more rare red cell antigens. Such sensitization is suggested by a positive indirect Coombs test performed to screen for abnormal antibodies in maternal serum ([Table 29-7](#)).

Several large studies indicate that anti-red cell antibodies are found in 1 percent of pregnancies (Bowell and colleagues, 1986a; Howard and colleagues, 1998). Most of these antibodies (40 to 60 percent) are directed against the CDE genes, with anti-D being most common, followed by anti-E, anti-c, and anti-C. Anti-Kell antibodies are also frequent. Fortunately, one fourth of these antibodies are from the Lewis system, which does not cause hemolysis because Lewis antigens do not develop on erythrocytes until a few weeks after birth.

KELL ANTIGEN. About 90 percent of Caucasians are Kell negative. Kell type is not routinely determined, and 90 percent of cases of anti-Kell sensitization result from transfusion with Kell-positive blood. As with CDE antigens, Kell sensitization also can occur as the result of maternal-fetal incompatibility (Mayne and associates, 1990). Maternal Kell sensitization is different from D-sensitization because anti-Kell antibodies also attach to fetal erythrocyte precursor cells directly in the bone marrow, thus preventing a hemopoietic response to anemia. This process can cause a more rapid and severe anemia than with anti-D-sensitization (Weiner and Widness, 1996). Because fewer erythrocytes are produced, there is less hemolysis and less amniotic fluid bilirubin. As a result, severe anemia may not be predicted by either the maternal anti-Kell titer or the level of amniotic fluid bilirubin. Caine and Mueller-Heubach (1986) described 13 Kell-sensitized pregnancies with a Kell-positive fetus. Five of these resulted in hydrops or perinatal death, despite favorable amniotic fluid studies 1 week before delivery. Bowman and colleagues (1992a) reviewed 20 Kell-sensitized pregnancies, in which exchange transfusions were required in four and four fetuses died.

Because of this disparate severity of Kell sensitization, some investigators recommend evaluation when the maternal anti-Kell titer is 1:8 or greater, as discussed subsequently. In addition, Weiner and Widness (1996) suggest that the initial evaluation be accomplished by cordocentesis instead of amniocentesis, because fetal anemia from Kell sensitization is usually more severe than indicated by the amniotic fluid bilirubin level.

OTHER ANTIGENS. Kidd (Jk^a), Duffy (Fy^a), c-, E-, and to a lesser extent C-antigens can all cause erythroblastosis as severe as that associated with sensitization to D-antigen (see [Table 29-7](#)). Two Duffy antigens have been identified, Fy^a and Fy^b, and some African Americans lack both. Fy^a is the most immunogenic. The Kidd system also has two antigens, Jk^a and Jk^b, with the population distribution as follows: Jk (a+b-), 26 percent; Jk (a-b+), 24 percent; and Jk (a+b+), 50 percent (Alper, 1977). Most cases of isoimmunization to these antigens occur after blood transfusions.

After sensitization to D-antigen, sensitization to the C-antigen is the next most common cause of clinically significant isoimmunization. Although anti-C-isoimmunization most commonly results from previous pregnancies, those fetuses whose mothers have been transfused are more likely to have moderate to severe hemolysis (Bowell and associates, 1986b; Wenk and colleagues, 1986). A third of fetuses with either anti-C or anti-Ce alloimmunization described by Bowman and colleagues (1992b) had hemolysis but none had severe disease. In contrast, Hackney and co-workers (2004) reported that 12 of 46 anti-c isoimmunized fetuses had serious hemolysis, and 8 of these 12 required fetal transfusions.

If an IgG red cell antibody is detected and there is any doubt as to its significance, the clinician should err on the side of caution and the pregnancy should be evaluated. As shown in [Table 29-7](#), many rare or *private antigens* have been associated with severe isoimmunization (Rouse and Weiner, 1990).

Immune Hydrops. The abnormal collection of fluid in more than one area of the fetal body, such as ascites and pleural effusion, is termed *hydrops*. Its causes usually are categorized as immune — such as isoimmunization — and nonimmune.

In immune hydrops, excessive and prolonged hemolysis causes anemia, which stimulates marked erythroid hyperplasia of the bone marrow as well as extramedullary hematopoiesis in the spleen and liver with eventual hepatic dysfunction (Nicolini and associates, 1991). There may be cardiac enlargement and pulmonary hemorrhage. Fluid collects in the fetal thorax, abdominal cavity, or skin. The placenta is markedly edematous, enlarged, and boggy, with large, prominent cotyledons and edematous villi. Hydrothorax may be so severe as to restrict lung development, which causes pulmonary compromise after birth. Ascites, hepatomegaly, and splenomegaly may lead to severe dystocia. Hydropic changes are easily seen by sonography (Fig. 29-8).

The precise pathophysiology of hydrops remains unknown. Theories about the inciting pathological event include heart failure from profound anemia and hypoxia, portal hypertension due to hepatic parenchymal disruption caused by extramedullary hemopoiesis, and decreased colloid oncotic pressure resulting from liver dysfunction and hypoproteinemia. The data from several studies indicate that in most cases, the degree and duration of anemia is the major factor causing and influencing the severity of ascites. Secondary factors include hypoproteinemia caused by liver dysfunction and capillary endothelial leakage resulting from tissue hypoxia. Both of these factors lead to protein loss and decreased colloid oncotic pressure, and make the hydrops worse. For example, Nicolaidis and colleagues (1985) performed percutaneous umbilical artery blood sampling in 17 severely D-isoimmunized fetuses at 18 to 25 weeks. All fetuses with hydrops had hemoglobin values of less than 3.8 g/dL and plasma protein concentrations less than 2 standard deviations below the normal mean for fetuses of the same age, as well as substantive protein concentrations in ascitic fluid. Conversely, none of the fetuses with hemoglobin values exceeding 4 g/dL were hydropic, even though 6 of 10 also had hypoproteinemia of the same magnitude as the hydropic fetuses. Similarly, Weiner and co-workers (1989) evaluated umbilical venous pressure during 20 antenatal transfusions in isoimmunized pregnancies. They observed that the significantly elevated pressures found in fetuses with immune hydrops normalized within 24 hours of transfusion. Because portal hypertension cannot resolve so rapidly, this suggests that the elevated pressure was actually due to hypoxic myocardial dysfunction, which was reversed by the blood transfusion.

Fetuses with hydrops may die in utero from profound anemia and circulatory failure (Fig. 29-9). One sign of severe anemia and impending death is the sinusoidal fetal heart rate pattern (see Fig. 18-13, p. 451). In addition, hydropic changes in the placenta, leading to placentomegaly, can cause preeclampsia. Because the preeclamptic mother develops severe edema mimicking that of the fetus, this development is referred to as the *mirror syndrome* (see p. 674). The liveborn hydropic infant appears pale, edematous, and limp at birth, and usually requires resuscitation. The spleen and liver are enlarged, and there may be widespread ecchymosis or scattered petechiae. Dyspnea and circulatory collapse are common.

Hyperbilirubinemia. Less severely affected infants may appear well at birth, only to become jaundiced within a few hours. Marked hyperbilirubinemia, if untreated, can cause *kernicterus*, a form of central nervous system damage that specifically affects the basal ganglia and can lead to cerebral palsy. Anemia, in part resulting from impaired erythropoiesis, may persist for many weeks to months in the infant who demonstrates hemolytic disease at birth. In the absence of hypoxia, erythrocyte production normally falls after birth, especially in the preterm infant.

Mortality. Perinatal deaths from hemolytic disease caused by D-isoimmunization have decreased dramatically since adoption of the policy of routine administration of D-immunoglobulin to all D-negative women during or immediately after pregnancy. Survival also has been increased by advances in antenatal and neonatal therapy; the seriously affected fetus can be identified and treated by antenatal transfusions or delivered preterm if necessary (Bowman and colleagues, 1977; Fretts and colleagues, 1992).

Identification of the Isoimmunized Pregnancy. With the exception of ABO incompatibility, which requires only neonatal treatment, the prenatal management of isoimmunization is the same regardless of the inciting antigen. The first step is identifying the woman at risk by performing a blood type and antibody screen at the first prenatal appointment during every pregnancy. Because the antibodies in maternal serum are unbound, they are detected by the *indirect Coombs test*.

In the fetus or neonate, however, the anti-red cell antibodies produced by the mother are absorbed to the D-positive fetal erythrocytes, and thus are identified primarily by the *direct Coombs test*. The absorbed antibodies act as hemolysins, leading to an accelerated rate of red cell destruction. The maternal antibodies detectable in the neonatal circulation at birth gradually disappear over a period of 1 to 4 months. Before these antibodies are cleared, however, they may prevent correct determination of the neonate's blood type; the neonatal red cells may be so thoroughly coated with anti-D antibody that D-antigens are not detectable and the neonate is reported incorrectly to be D-negative.

If the maternal antibody screen reveals the presence of red cell antibodies, they should be identified and their immunoglobulin subtype \mathfrak{R} — either IgG or IgM \mathfrak{R} — determined. Only IgG antibodies are of concern because IgM antibodies cannot cross the placenta or cause fetal hemolysis. If the antibodies are IgG and are known to cause fetal hemolytic anemia (see Table 29-7), the antibody titer should be quantified. A titer above a critical level requires further evaluation. For each antibody, the titer below which the fetus will not die from hemolytic disease is different and is determined individually by each laboratory. For example, the critical titer for anti-D antibodies is usually 1:16; a titer equal to or higher than this indicates the possibility of severe hemolytic disease. Although the critical titers for other antibodies are often assumed to be 1:16 as well, most laboratories have insufficient data to support this assumption. For example, considering two of the more common antibodies, the critical titer for anti-Kell antibody is probably closer to 1:8, whereas the titer for c or E may be 1:32 or higher (see p. 664).

PREDICTING FETAL GENOTYPE. The presence of maternal anti-D antibodies does not necessarily mean that the fetus will be affected or is even D-positive. In a previously sensitized or sensibilized woman, the antibody titer may rise to high levels during a subsequent pregnancy even when the fetus is D-negative, due to the *amnestic response*. Importantly, half of all women with antigen-positive Caucasian husbands can have an antigen-negative baby, because half of all D-positive Caucasian males are heterozygous for D-antigen (Race and Sanger, 1975). In addition, many women sensitized to atypical red cell antigens become immunized after a blood transfusion, and the antigen may not be present on the father's red cells.

For anti-D sensitization, determining whether the father is heterozygous or homozygous for the D-antigen is helpful in determining pregnancy management. The woman whose husband is homozygous for D and thus has a 100 percent chance of having a D-positive infant will be treated differently than the woman whose husband is heterozygous and has only a 50 percent chance of having a positive infant. The most likely paternal genotype \mathfrak{R} — the arrangement of the Rh genes on each paternal chromosome \mathfrak{R} — cannot be determined precisely but can be estimated. The CDE blood group gene locus is located on chromosome 1p34-p36. One gene encodes the C/c and E/e proteins, and a second gene encodes D \mathfrak{R} — recall that there is no "d" gene or gene product. By identifying paternal CDE antigens and considering the most common arrangement of the

corresponding genes in men of his race, the father's presumed genotype can be predicted. For example, if the father is CcDe, he could be either homozygous for D (D,D) or heterozygous (D, "d"). If he is white, there is a 94 percent chance that the arrangement of these alleles is CDe/cde; thus, he has a 94 percent chance of being heterozygous for D and a 47 percent (94 ÷ 2) chance of having a D-negative fetus.

If the woman is sensitized by an atypical antigen, the paternal antigen type will determine whether the fetus is at risk. For example, many women producing anti-Kell antibodies are sensitized from a blood transfusion and have a Kell-negative husband. Determining that the father is Kell-negative eliminates the need to monitor the Kell-negative fetus. **Before paternal testing is pursued, it is imperative that any possibility of nonpaternity be disclosed.**

Management of Isoimmunization. Management is individualized after reviewing the obstetrical history. Accurate pregnancy dating is critical, as is determining the gestational age at which fetal anemia developed in the last pregnancy. Anemia tends to occur earlier and be sequentially more severe with every pregnancy. In the first sensitized pregnancy, a positive antibody screen with a titer below the critical level should be followed with repeat titers at timely intervals, usually monthly. Once the critical titer has been met or exceeded, further evaluation is required.

If this is not the first sensitized pregnancy, maternal antibody titers may not be helpful because they may be elevated simply as the result of the *amnestic* response. In these cases, fetal anemia can be predicted noninvasively using *middle cerebral artery Doppler*. The anemic fetus shunts blood preferentially to the brain to maintain adequate oxygenation. This response can be identified by measuring peak blood flow velocity in the middle cerebral artery (Moise, 2002). In one study, Mari and colleagues (2000) measured middle cerebral artery blood flow serially in 111 fetuses at risk for anemia and in 265 normal fetuses. Doppler was 100-percent sensitive in detection of anemic fetuses, with or without fetal hydrops, and had a false-positive rate of only 12 percent.

If the antibody titer or middle cerebral artery peak blood flow indicate that the fetus is likely to be anemic, then further evaluation is appropriate. Early studies showed that without treatment, isoimmunization has a perinatal mortality rate of about 30 percent (Freda, 1973). With aggressive management, including repeated ultrasound examinations, diagnostic amniocentesis or cordocentesis, and fetal transfusions in selected cases, the perinatal mortality rate is lowered remarkably (Harman and co-workers, 1983; Queenan and colleagues, 1993).

AMNIONIC FLUID EVALUATION. When fetal blood cells undergo hemolysis, breakdown pigments, mostly bilirubin, are present in the supernatant of amniotic fluid. The amount of amniotic fluid bilirubin correlates roughly with the degree of hemolysis and thus indirectly predicts the severity of the fetal anemia. Because the amniotic fluid bilirubin level is low compared with serum levels, the concentration is measured by a continuously recording spectrophotometer and is demonstrable as a change in absorbance at 450 nm, referred to as ΔOD_{450} (Fig. 29-10).

The likelihood that the fetus is anemic is determined by plotting the ΔOD_{450} on a graph, shown in [Figure 29-11](#), that was originated by Liley (1961). He compared ΔOD_{450} measurements with fetal outcome in 101 isoimmunized pregnancies and showed that mild, moderate, or severe fetal anemia could be predicted according to which of three zones the bilirubin level was plotted into. Subsequent studies have correlated these zones with actual fetal hemoglobin concentrations. Optical density values in zone 1 generally indicate a D-negative fetus or one who will have only mild disease. In zone 2, the fetus is at moderate risk. In low zone 2, the expected fetal hemoglobin concentration is between 11.0 and 13.9 g/dL, whereas in upper zone 2, the anticipated hemoglobin level ranges from 8.0 to 10.9 g/dL. Values in zone 3 indicate a severely affected fetus with a hemoglobin level of less than 8.0 g/dL, and without therapy, death is predicted within 7 to 10 days.

A value in zone 3 demands immediate fetal red blood cell transfusion or delivery. Conversely, a value in zone 1 can be followed by a repeated sampling in 2 to 3 weeks and the trend of the two values used to estimate the severity of the hemolytic process. A value in zone 2, however, indicates that severe fetal anemia is possible; this finding should be followed by a repeated sampling within 1 to 2 weeks. If the trend of samples forms a line parallel to the lines on the graph or is decreasing within the zone, either the fetus is unaffected or hemolysis is stable. In these cases, amniocentesis can be repeated at 2- to 3-week intervals until either transfusion or delivery is required (American College of Obstetricians and Gynecologists, 1990). Conversely, if the trend of ΔOD_{450} values is rising within zone 2 or has risen into zone 3, immediate transfusion or delivery is indicated.

Expanded Liley Graph. The original Liley graph was applicable only to pregnancies lasting 27 weeks or more, contemporaneous for the limits of viability at that time. As these limits were expanded, it was necessary to extrapolate the Liley curve back to 18 to 20 weeks. However, this curve cannot simply be extrapolated back to 25 weeks because amniotic fluid bilirubin is normally high at that age. Thus, ΔOD_{450} results plotted on an extrapolated Liley curve do not accurately predict either hemolysis or the fetal hemoglobin level (Nicolaidis and colleagues, 1986).

For these reasons, a number of modified Liley curves have been developed for pregnancies of 27 weeks or less. For example, Queenan and colleagues (1993) examined 845 amniotic fluid samples from 75 D-immunized and 520 unaffected pregnancies and constructed a Liley-type curve that begins at 14 weeks ([Fig. 29-12](#)). In this graph and others, however, the naturally high amniotic fluid bilirubin level at midpregnancy results in a large "indeterminate" zone. In this zone, bilirubin concentrations do not accurately predict fetal hemoglobin. For this reason, when evaluation indicates that there is likely to be severe fetal anemia or hydrops before 25 weeks, many clinicians will forego amniocentesis in favor of fetal blood sampling.

FETAL BLOOD SAMPLING. Cordocentesis is performed as described in [Chapter 13](#) (see p. 330). The risk of fetal loss is about 1.4 percent per procedure. Previously, some clinicians used cordocentesis primarily to evaluate all isoimmunized pregnancies. Advantages were that fetal hemoglobin concentration could be accurately determined and fetal blood typing could be accomplished. Currently, however, using molecular genetic techniques, fetal D-antigen type can be determined by testing fetal DNA obtained from amniocytes (Bennett and associates, 1993). This technique is invaluable, especially for pregnancies in which the father is a presumed heterozygote, because in these cases the fetus could be D-negative and one amniocentesis for fetal D typing and ΔOD_{450} measurement might be the only invasive test needed. Greater than 99-percent sensitivity for fetal D-antigen typing is claimed (Van Den Veyver and colleagues, 1996; Yankowitz and co-workers, 1997). Several reference laboratories are now able to analyze amniocytes for the E-, c-, Kell 1, and Kell 2 (Cellano) antigens, as well.

When the ΔOD_{450} measurement or middle cerebral artery Doppler indicates the possibility of fetal anemia, ultrasonography reveals fetal hepatomegaly or hydrops, or fetal testing indicates physiological stress, management is determined by the gestational age. The mature fetus should be delivered, whereas the preterm fetus can be evaluated using diagnostic cordocentesis and transfusion as necessary. Fetal hemoglobin, hematocrit, reticulocyte count, and indirect Coombs titer also are used to predict the onset of anemia if the fetus is not yet affected (Weiner and associates, 1991a).

Nicolaidis and co-workers (1988) recommend that transfusions be commenced when the hemoglobin is at least 2 g/dL below the mean for normal fetuses of corresponding gestational age. Other clinicians perform transfusions when the fetal hematocrit is below 30 percent, which is 2 standard deviations below the mean at all gestational ages (Weiner and co-workers, 1991b). Fetal intraperitoneal and intraumbilical blood transfusions are discussed in [Chapter 13](#) (see p. 332). Various other treatments, such as plasmapheresis, administration of promethazine or D-positive erythrocyte membranes in enteric capsules, or immunosuppression with corticosteroids have been shown to be ineffective.

DELIVERY. Vaginal delivery at or near term is the goal of management. When management includes serial amniotic fluid ΔOD_{450} measurement or fetal transfusions, fetal well-being should be closely monitored (see [Chap. 15](#)). With appropriate management, extremely preterm delivery usually can be avoided.

NEONATAL CARE AND OUTCOME. Cord blood is obtained for hemoglobin concentration measurement and direct Coombs testing. If the infant is overtly anemic, it is often best to carry out the initial exchange transfusion promptly, with recently collected type-O, D-negative red cells. For infants who are not overtly anemic, the need for exchange transfusion is determined by the rate of increase in bilirubin concentration, the maturity of the infant, and the presence of other complications. Most fetal transfusion survivors develop normally (Bowman, 1978). Grab and colleagues (1999) reported the long-term outcomes of 35 fetuses who had severe isoimmunization or immune hydrops treated with antenatal intravascular transfusions. One had mild psychomotor disabilities at age 1, and another had delayed speech development. However, at up to 6 years of age, none of the survivors, including those with hydrops, had moderate or severe neurological impairment.

Prevention. Anti-D-immunoglobulin is extracted by cold alcohol fractionation and ultra-filtration of plasma containing high-titer D-antibody. Each dose provides 300 μg of D-antibody as determined by radioimmunoassay. It is given to the D-negative nonsensitized mother to prevent sensitization after any pregnancy-related events that could result in fetal-maternal hemorrhage (see [Table 29-6](#)). Up to 2 percent of women with a spontaneous abortion and 5 percent of those undergoing elective termination become isoimmunized without D-immunoglobulin.

ROUTINE ANTEPARTUM ADMINISTRATION. One dose of anti-D immunoglobulin is given prophylactically to all D-negative women at about 28 weeks, and a second dose is given after delivery if the infant is D-positive (American College of Obstetricians and Gynecologists, 1999b). Without such prophylaxis, Bowman and Pollock (1978) showed that 1.8 percent of D-negative women will become isoimmunized by silent fetal-maternal hemorrhage. When such prophylaxis is given, only 0.07 percent of susceptible women are sensitized.

A second dose is required at delivery because the half-life of immunoglobulin is only 24 days and it persists for only 6 weeks. In addition, fetal-maternal hemorrhage is more likely at delivery. Each 300 μg will protect the average-sized mother from fetal hemorrhage of up to 15 mL of D-positive red cells, or 30 mL of fetal whole blood with the usual hematocrit of about 50. The initial dose of 300 μg will produce a weakly positive (1:1 to 1:4) indirect Coombs titer in the mother. As the body mass index increases from over 27 to 40 kg/m^2 , serum antibody levels decrease by 30 to 60 percent (Woelfer and co-workers, 2004). Rarely, a small amount of antibody crosses the placenta and results in a weakly positive direct Coombs test in cord and infant blood. This small amount causes negligible hemolysis.

The risk of acquiring a virus such as the human immunodeficiency virus (HIV) as the result of being treated with anti-D-immunoglobulin is extremely low. Individuals who are antibody- or antigen-positive for various hepatitis viruses are excluded from blood donation, donor plasma is tested, and solvent-detergent viral inactivation and nanofiltration eliminate HIV and other viruses (Centers for Disease Control, 1987; Hong and colleagues, 1998; Misbah and Chapel, 1993).

D-negative women who receive blood products are also at risk of becoming sensitized. Although D-negative women should be given only D-negative red cells, platelet transfusions and plasmapheresis can provide sufficient D-antigen to cause sensitization. This can be prevented by an injection of D-immunoglobulin. **When there is doubt about whether to give anti-D-immunoglobulin, it should be given.** Explicitly, anti-D-immunoglobulin, even if not needed, will cause no harm, however, failing to give it when needed can have severe consequences.

LARGE FETAL-TO-MATERNAL HEMORRHAGE. If there is a large fetal-maternal hemorrhage, one dose of D-immunoglobulin may not be sufficient to neutralize the transfused fetal cells. Ness and colleagues (1987) studied 800 D-negative mothers and reported that the incidence of excessive fetal-maternal transfusion exceeding 30 mL of whole blood, the quantity neutralized by one dose of immunoglobulin, was 1 percent. Another 5.6 percent of these pregnancies had fetal-maternal hemorrhage of between 11 and 30 mL. Thus, at least 1 percent, and perhaps more, of susceptible mothers would have been given insufficient immunoglobulin if not tested. Importantly, they determined that if extra D-immunoglobulin is considered only for women with risk factors such as abdominal trauma, placental abruption, placenta previa, intrauterine manipulation, multiple gestation, or manual removal of the placenta, half of women requiring more than the 300- μg dose would be missed. Stedman and co-workers (1986), utilizing the erythrocyte rosette test, reported similar results. Accordingly, the American Association of Blood Banks (Snyder, 1998) recommends that all D-negative women be tested at delivery with the Kleihauer-Betke or rosette test. The dosage of anti-D-immunoglobulin is calculated from the estimated volume of the fetal-to-maternal hemorrhage described on page 663. One 300- μg ampule is given for each 30 mL of fetal blood to be neutralized. To determine if the Rhogam dose was adequate after it is given, the indirect Coombs test is performed. A positive result indicates that there is excess anti-D-immunoglobulin in the maternal serum, thus demonstrating that the dose was sufficient.

D^u-ANTIGEN. Identification of the D^u-antigen may cause confusion or result in designation of the blood type as "weak D-positive." The D^u-antigen is actually a variant of the D-antigen, and women confirmed to be D^u-positive are therefore D-positive and do not need immunoglobulin (American College of Obstetricians and Gynecologists, 1999b). If a D-negative

woman delivers a D^u-positive infant, she should be given D-immunoglobulin. As before, if there is any doubt about D-antigen status, then immunoglobulin should be given.

MATERNAL-TO-FETAL HEMORRHAGE. It is now recognized that in most pregnancies, small amounts of maternal blood enter the fetal circulation and vice versa. Very rarely, the D-negative fetus is exposed to maternal D-antigen and becomes sensitized as a result. When such a female fetus becomes an adult, she will produce anti-D antibodies indicating sensitization even before or early in her first pregnancy. This mechanism of isoimmunization is called the *grandmother theory* because the fetus in the current pregnancy is jeopardized by antibodies initially provoked by its grandmother's erythrocytes. This scenario accounts for very few cases of D-sensitization. Major blood group (ABO) incompatibility offers appreciable protection against D-sensitization of the fetus. Furthermore, significant maternal-to-fetal hemorrhage is uncommon. D-negative infants born to D-positive mothers are not routinely given D-immunoglobulin prophylaxis.

HYPERBILIRUBINEMIA

Disposal of Bilirubin. Unconjugated or free bilirubin is readily transferred across the placenta from mother to fetus, or vice versa, if the maternal plasma level of unconjugated bilirubin is high. Although bilirubin glucuronide is water soluble and normally is excreted into bile and urine when the plasma level is elevated, unconjugated bilirubin is not excreted this way.

Kernicterus. The great concern over unconjugated hyperbilirubinemia in the newborn, especially if preterm, results from its association with kernicterus. Bilirubin staining of the basal ganglia and hippocampus results in profound degeneration in these regions. Surviving infants show spasticity, muscular incoordination, and varying degrees of mental retardation. There is a positive correlation between unconjugated bilirubin levels above 18 to 20 mg/dL and kernicterus. Despite this, kernicterus may develop at much lower concentrations, especially in very preterm infants.

Factors other than the serum bilirubin concentration that contribute to the development of kernicterus include hypoxia and acidosis. Sepsis contributes to kernicterus. Both hypothermia and hypoglycemia predispose the infant to kernicterus by raising the level of nonesterified fatty acids. These, in turn, compete with bilirubin for binding sites on albumin and inhibit bilirubin conjugation. Although sulfonamides and salicylates also compete for protein-binding sites, and sodium benzoate in injectable diazepam, furosemide, and gentamicin displaces bilirubin from albumin, these drugs are unlikely to lead to kernicterus. Excessive doses of vitamin K analogues may be associated with hyperbilirubinemia. The importance of the serum albumin concentration and the binding sites so provided is obvious.

Physiological Jaundice. By far the most common form of unconjugated nonhemolytic jaundice is so-called physiological jaundice. In the mature infant, the serum bilirubin increases for 3 to 4 days to serum levels of up to 10 mg/dL or so, and then falls rapidly. In preterm infants, the rise is more prolonged and may be more intense.

Treatment. Phototherapy is now widely used to treat hyperbilirubinemia. By some unknown mechanism, light seems to promote hepatic excretion of unconjugated bilirubin. In most instances, phototherapy leads to oxidation of bilirubin, resulting in a lower bilirubin level. Light that penetrates the skin also increases peripheral blood flow, which further enhances photo-oxidation. As much surface area as possible is exposed, the infant is turned every 2 hours, and the temperature is closely monitored to prevent dehydration. The fluorescent bulbs must be the appropriate wavelength, and the eyes should be completely shielded. Serum bilirubin should be monitored for at least 24 hours after discontinuance of phototherapy. Rarely, exchange transfusion is required.

NONIMMUNE HYDROPS FETALIS. Hydrops is defined by the presence of excess fluid in two or more body areas, such as thorax, abdomen, or skin, and is often associated with hydramnios and placental thickening. Because obstetrical ultrasound examination has become routine, hydrops is frequently identified prenatally and in some cases, the etiology is determined. Santolaya and colleagues (1992) identified hydrops in 0.6 percent of 12,572 pregnancies examined with ultrasound, and determined the etiology in 77 percent of cases (Fig. 29-13). Heinonen and colleagues (2000) reported a similar incidence of 1 in 1700, and they were able to determine etiology in 95 percent. In some cases, fetal ascites develops without other features of hydrops and the overall prognosis is better (Favre and co-workers, 2004).

Etiology. A variety of pathogenic mechanisms can lead to hydrops. *Cardiac abnormalities*, either structural defects or arrhythmias, or both, are associated with 20 to 45 percent of cases of nonimmune hydrops (Allan, 1986; Castillo, 1986; Gough, 1986; Santolaya, 1992, and all their co-workers). Fetal heart failure also can result from infection-related myocarditis or hepatitis.

Approximately one third of hydrops cases result from *multiple malformations* or *chromosomal anomalies*. Shulman and colleagues (2000) have reported that the majority of cases of dramatic and extensive subcutaneous edema—so-called *space-suit hydrops*—recognized in the first trimester result from chromosomal abnormalities. Of 30 such fetuses identified at less than 14 weeks of gestation, 87 percent were aneuploid, of which over half involved the sex chromosomes.

About 10 percent of hydrops cases are associated with *twin-to-twin transfusion syndrome* (see Chap. 39, p. 929). In these cases, hydrops can be due to heart failure from volume overload in the recipient twin or myocardial dysfunction from severe anemia in the donor twin. Other causes of severe anemia that can lead to hydrops include parvovirus infection, acute fetal-maternal hemorrhage, or α -thalassemia (American College of Obstetricians and Gynecologists, 1999a). *Inborn errors of metabolism* such as Gaucher disease, GM 1 gangliosidosis, or sialidosis can cause recurrent hydrops (Lefebvre and colleagues, 1999). Rarely, an *anomalous lymph system* can result in lymph accumulating to cause isolated chylothorax or chylous ascites, but these fluid collections do not qualify as hydrops because they involve only one body cavity.

The great variety of causes of hydrops listed by Holzgreve and associates (1984) are presented in Table 29-8. The reported incidence of these causes varies according to the sophistication of the evaluation and the population studied. For example, in San Francisco, which has a large Asian population, 10 percent of hydrops was caused by α -thalassemia (Holzgreve and colleagues, 1984).

Prognosis. Although the outcome for hydrops caused by any of these mechanisms is generally poor, McCoy and colleagues (1995) reviewed 82 cases of nonimmune hydrops attributed to cardiovascular abnormalities (23 percent), aneuploidy (16 percent), thoracic anomalies (13 percent), genetic syndromes (11 percent), anemia and infection (9 percent), twin-to-twin transfusion (6 percent), and idiopathic causes (22 percent). The mortality rate for hydrops evident before 24 weeks was 95 percent. Conversely, fetuses with hydrops who survived to at least 24 weeks, had structurally normal hearts, and were euploid had a survival rate of 20 percent.

Diagnosis. Ultrasound evaluation may provide a diagnosis. Depending on the circumstances, helpful maternal blood tests might include hemoglobin electrophoresis, Kleihauer-Betke test, indirect Coombs test, and serological tests for syphilis, toxoplasmosis, cytomegalovirus, rubella, and parvovirus B19. Cordocentesis is considered for karyotyping, hemoglobin concentration and electrophoresis, evaluation of blood gas and transaminase levels, and serological testing for IgM-specific antibodies to infectious agents. In view of the data from McCoy and associates (1995) described previously, a fetal echocardiogram and karyotype analysis are important in evaluation and predicting prognosis for fetuses who have reached 24 weeks.

Management. In some cases, treatment is possible. Some cardiac arrhythmias can be treated pharmacologically, severe anemia due to fetal-maternal hemorrhage or parvovirus infection can be treated with blood transfusions, and hydrops of one fetus in twin-to-twin transfusion syndrome may resolve with therapeutic amniocentesis (see Chap. 39, p. 929). In most cases, however, hydrops cannot be treated and ultimately proves fatal for the fetus or newborn. In general, when hydrops persists and cardiac abnormalities and aneuploidy have been ruled out, and if the fetus is mature enough that survival is likely, delivery should be accomplished. Very preterm fetuses usually are managed expectantly. Although hydrops usually persists or worsens with time, it occasionally resolves spontaneously (Mueller-Heubach and Mazer, 1983).

Maternal Complications. A unique complication of hydrops is the maternal *mirror syndrome* (Midgley and Hardrug, 2000). Believed to be caused by vascular changes in the swollen, hydropic placenta, it is called the mirror syndrome because the mother develops preeclampsia with severe edema that is similar to that of the fetus. In these situations, preeclampsia often develops early and only rarely resolves with fetal treatment. Duthie and Walkinshaw (1995) described a woman with parvovirus-associated fetal hydrops and severe preeclampsia whose hypertension resolved at 25 weeks when fetal transfusion reversed the fetal hydrops. In many cases, however, treatment is not possible and delivery is necessary. Preterm labor is common because of hydramnios. Postpartum hemorrhage sometimes occurs as the result of sudden decompression of an overdistended uterus, and retained placenta is common.

Figure 29-13. Classification and cause in 76 cases of fetal hvdrons in which the

etiology could be diagnosed by ultrasound. (From Santolaya and associates, 1992, with permission.)

FETAL CARDIAC ARRHYTHMIAS. These abnormal heart rhythms are now recognized frequently because of extensive use of real-time ultrasound and Doppler technology. Whereas most arrhythmias are transient and benign, some tachyarrhythmias, if sustained, can result in congestive heart failure, nonimmune hydrops, and fetal death. Sustained bradycardia, although less often associated with hydrops, may signify underlying cardiac pathology that includes structural lesions or autoimmune myocarditis.

Kleinman and associates (1985) summarized their experience with fetal arrhythmias. Premature atrial contractions accounted for two thirds of all cases. Fortunately, this arrhythmia is benign, is related to immaturity, and usually resolves with further development. Rarely, it converts to a sustained supraventricular tachycardia. If the rate is more than 200 beats/min, it may cause cardiac failure, and thus requires treatment as discussed in [Chapter 13](#) (see p. 332).

The prognosis for the fetus with bradycardia is less promising. Bradycardia typically results either from a major structural abnormality or from congenital heart block, including the long QT syndrome (Lin and co-workers, 2004). If a defect is identified by fetal echocardiography, fetal karyotyping should be offered.

Maternal anti-SS-A (anti-Ro) antibody causes half of cases of congenital heart block by binding to tissue in the conduction tracts (Taylor and colleagues, 1986). Intriguing data from Stevens and colleagues (2003) provides evidence that these myocytes may be from maternal engraftment. Such *microchimerism* is considered to be a cause of maternal disease arising from fetal cell engraftment (see [Chap. 54](#), p. 1210). Tissue inflammation provoked by these antibodies leads to permanent damage, and survivors frequently require a pacemaker at birth. Anti-SS-A antibodies can affix to other cardiac tissues as well, and if there is extensive myocarditis, the prognosis is poor. Brucato and co-workers (2003) reviewed 1825 cases of congenital heart block from 38 studies. They reported that in utero diagnosis is associated with a much poorer prognosis and a higher risk of late-onset dilated cardiomyopathy than when the diagnosis is made in childhood. In addition, the recurrence risk of congenital heart block in subsequent pregnancy is high because congenital cases often are associated with anticardiac antibodies. Many of these women have, or subsequently develop, lupus erythematosus or another connective tissue disease. Conversely, of all the women who produce anti-SS-A, only 1 in 20 have fetuses with cardiac disease (see [Chap. 54](#), p. 1215).

Fetal therapy has been attempted for heart block. Robinson and co-workers (2001) used terbutaline to transiently increase the heart rate of seven fetuses with a ventricular rate below 60. Saleeb and colleagues (1999) reviewed the treatment of 50 fetuses with heart block caused by maternal SS-A and SS-B antibodies. They concluded that fluorinated steroids significantly improved outcome and resulted in the resolution of pleural effusions, ascites, or hydrops in 13 of 18 treated cases.

DISEASES OF THE TERM FETUS AND NEONATE

RESPIRATORY DISTRESS SYNDROME. Term infants can have respiratory complications, although these are much less frequent than in those born preterm. Common causes in term infants include sepsis, especially from group B streptococcal disease and intrauterine-acquired pneumonia; persistent pulmonary hypertension of the newborn; meconium aspiration syndrome; and pulmonary hemorrhage.

Advances in neonatal care have improved the survival rate and decreased the morbidity of these conditions. High-frequency oscillatory ventilation improves oxygenation without high ventilatory pressures, and nitric oxide is a specific pulmonary vasodilator that has no effect on systemic vasculature. A meta-analysis of 11 trials of nitric oxide therapy in term or near-term infants with respiratory failure found that nitric oxide significantly improved oxygenation. Its use reduced mortality as well as the need for extracorporeal membrane oxygenation (Finer and Barrington, 2000). Unfortunately, nitric oxide does not appear to have similar beneficial effects for infants born before 34 weeks (Kinsella and co-workers, 1999).

MECONIUM ASPIRATION SYNDROME. This disorder results from peripartum inhalation of meconium-stained amniotic fluid, leading to a chemical pneumonitis with inflammation of pulmonary tissues, mechanical obstruction of the airways, and hypoxia. In severe cases, it progresses to persistent pulmonary hypertension, other morbidity, and death. Even with prompt and appropriate therapy, seriously affected infants frequently die or suffer long-term neurological sequelae.

Risk Factors. In about 20 percent of pregnancies at term, amniotic fluid is contaminated by meconium. In the past, this was considered a sign of "fetal distress" in response to hypoxia. It is now recognized, however, that in the majority of cases, meconium passage indicates a normally maturing gastrointestinal tract, or occurs as the result of vagal stimulation from umbilical cord compression (Nathan and co-workers, 1994). Passage of meconium into a normal amniotic fluid volume results in light meconium staining, and its aspiration before labor is a relatively common occurrence. In healthy, well-oxygenated fetuses, this diluted meconium is readily cleared from the lungs by normal physiological mechanisms. In some infants, however, the inhaled meconium is not cleared, and meconium aspiration syndrome results. It can occur after normal labor, but is more likely when meconium is thick, the pregnancy is postterm, or the fetus is growth-restricted. Putting these together, pregnancies at highest risk are those in which there is diminished amniotic fluid volume, along with cord compression or uteroplacental insufficiency that may cause meconium passage (Davis and co-workers, 1985; Leveno and colleagues, 1984). In these cases, the meconium remains thick and undiluted, and the compromised fetus cannot clear it.

Prevention. Unfortunately, pathological meconium aspiration cannot be predicted by the fetal heart rate tracing (Dooley and colleagues, 1985). However, Carson and colleagues (1976) reported that the incidence of meconium aspiration syndrome could be reduced by *oropharyngeal suctioning* following delivery of the fetal head, but before delivery of the chest. This maneuver is followed by laryngoscopic visualization of the vocal cords and, when meconium is visualized, additional suctioning of the trachea. In this study, meconium aspiration syndrome was reduced but not eliminated, suggesting that delivery factors are not

solely responsible. In the almost three decades since this report, this combined obstetrical-pediatric delivery protocol has been the standard of care. Despite this, several investigators reported that strict adherence to this protocol does not reduce the incidence of the syndrome below 2.1 percent (Davis and colleagues, 1985; Wiswell and colleagues, 1990). This observation is explicable for a number of reasons. Murphy and associates (1984) have shown that pulmonary hypertension, the main pathological outcome of meconium aspiration, is characterized by abnormal muscularization of the interacinar arteries. These changes begin well before birth, most likely as the result of a recurring antenatal insult. Consequently, they are unaffected by maneuvers at delivery. Cornish and colleagues (1994) used a baboon model to show that intrapartum meconium aspiration, either alone or combined with peripartum asphyxia, did not produce the kind of pathophysiological effects that could lead to long-term damage or death in the human neonate.

Katz and Bowes (1992) concluded from their review that only chronically asphyxiated fetuses develop meconium aspiration syndrome. They postulated that chronic antepartum asphyxia leads to pulmonary vascular damage, pulmonary hypertension, and persistent fetal circulation. In addition, these infants are unable to clear aspirated meconium. Thus, the 2 percent of infants who do not respond to suctioning at delivery are likely to be those who have sustained such antenatal damage. Similarly, Richey and colleagues (1995) found no correlation between markers of acute asphyxia—umbilical artery pH, lactate, or hypoxanthine—and meconium, but did find that one marker of chronic asphyxia—serum erythropoietin—was significantly elevated in newborns with meconium-stained fluid. This observation was confirmed by Bloom and associates (1996).

Amnioinfusion. Amnioinfusion for meconium may be beneficial only when the meconium is thick and there are recurrent variable decelerations (Spong and colleagues, 1994). On the other hand, it probably poses little or no increased risk (Sadovsky and colleagues, 1989; Wenstrom and co-workers, 1995). Unfortunately, it does not benefit fetuses in whom meconium aspiration syndrome has already developed before the onset of labor (Byrne and Gau, 1987; Manning and colleagues, 1978). This technique is discussed in [Chapter 21](#) (p. 532) and described in [Chapter 18](#) (p. 462).

Care of the Neonate. According to guidelines of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002), at delivery the infant's mouth and nares should be carefully suctioned before the shoulders are delivered. A suction bulb is usually adequate. The DeLee trap also can be used, but it should be connected to wall suction and not suctioned by mouth. Although both methods are equally efficacious, even with careful suctioning, 2 to 5 percent of infants with thick meconium develop meconium aspiration syndrome (Locus and colleagues, 1990).

If the infant is depressed, residual meconium in the hypopharynx is removed by suctioning under direct visualization. The trachea is then intubated and meconium suctioned from the lower airway. If the infant is vigorous, there is no evidence that tracheal suctioning is necessary. The stomach can be suctioned of meconium to avoid further meconium aspiration. Although the efficacy of this management in preventing long-term morbidity or mortality is undocumented, it carries little risk when done properly (Yoder, 1994).

HEMORRHAGIC DISEASE OF THE NEWBORN. This disorder is characterized by spontaneous internal or external bleeding, beginning any time after birth. Most hemorrhagic disease results from abnormally low levels of the vitamin K-dependent clotting factors (V, VII, IX, and X), prothrombin, and proteins C and S (Zipursky, 1999). Early bleeding occurs within 48 hours after birth in infants whose mothers took anticonvulsants during pregnancy. In these cases, the depressed factor levels result from their decreased maternal hepatic synthesis, as well as the generally poor transplacental passage of vitamin K. Classical hemorrhagic disease, which becomes apparent from 2 to 5 days after birth, occurs in infants not treated with vitamin K at birth. Late hemorrhage occurs at 2 to 12 weeks in infants who are exclusively breast fed, because breast milk contains very low levels of vitamin K. Other causes include hemophilia, congenital syphilis, sepsis, thrombocytopenia purpura, erythroblastosis, and intracranial hemorrhage.

Prophylaxis. Hemorrhagic disease can be avoided by the intramuscular injection of 1 mg of vitamin K₁ (phytonadione) at delivery. Oral administration is not effective, and maternal administration of vitamin K prior to delivery results in very little transport to the fetus. For treatment of active bleeding, vitamin K is injected intravenously. Reports of an association between the administration of vitamin K to newborns and subsequent development of childhood leukemia have been disproved (Zipursky, 1999).

THROMBOCYTOPENIA. The differential diagnosis of neonatal thrombocytopenia is provided in [Table 29-9](#). Thrombocytopenia tends to be more severe in preterm fetuses, especially those with respiratory distress and hypoxia or sepsis.

Immune Thrombocytopenia. Rarely, antiplatelet IgG is transferred from the mother, causing thrombocytopenia in the fetus-neonate. In these cases, thrombocytopenia is mild and is found in association with maternal autoimmune disease, especially immune thrombocytopenia. Although corticosteroid therapy usually increases maternal platelet levels, it generally does not affect fetal platelets. Despite this, fetal platelet counts are usually high enough to allow vaginal delivery without an increased risk of intrapartum hemorrhage and without need for fetal platelet sampling (see [Chap. 51](#), p. 1158). Importantly, neonatal platelet levels often fall rapidly after birth, reaching a nadir at 48 to 72 hours of life, making close monitoring in the first days of life essential.

Alloimmune (Isoimmune) Thrombocytopenia. This condition differs from immunological thrombocytopenia in several important ways. It is caused by maternal isoimmunization to fetal platelet antigens in a manner similar to D-antigen isoimmunization (see p. 663). Thus, the maternal platelet count is normal and alloimmunization is not suspected until after the birth of an affected child. Another important difference is that alloimmune fetal thrombocytopenia, even in the first affected infant, is frequently severe, and usually develops before the third trimester. It can thus cause fetal intracranial hemorrhage, even as early as 20 weeks.

Alloimmune thrombocytopenia follows maternal isoimmunization, usually against the platelet antigen HPA-1a—formerly called PL A1—which is found in 98 percent of the population. The susceptible mother lacks this common antigen and becomes immunized when exposed to the fetal platelet antigen. Recall that some degree of fetal-maternal hemorrhage occurs in the majority of pregnancies (see [Table 29-5](#)). Based on the incidence of HPA-1a negativity, 1 in 50 pregnancies is at risk.

Yet the incidence of alloimmune thrombocytopenia is only 1 in 5000 to 1 in 10,000 live births (Nicolaidis and Snijders, 1992; Silver and colleagues, 2000). The paucity of expected cases is explained by the fact that fetal-maternal hemorrhage sufficient to provoke an immune response occurs in only 5 to 10 percent of pregnancies. Other antibodies are also important. Davoren and associates (2004) reported that only 79 percent of these mothers had HPA-1a alloimmunization and 16 percent were due to HPA-5b, HPA-3a, and HPA-1b antibodies.

The diagnosis can be made on clinical grounds if the mother has a normal platelet count and there is no evidence of any immunological disorder, and her infant has thrombocytopenia without evidence of other disease. Fetal alloimmune thrombocytopenia recurs in 70 to 90 percent of subsequent pregnancies, is often severe, and usually develops earlier with each successive pregnancy (Silver and associates, 2000). Fortunately, weekly maternal intravenous infusions of immunoglobulin usually result in fetal platelet levels high enough to allow vaginal delivery (see [Chap. 13](#), p. 332).

Preeclampsia and Eclampsia. Fetal thrombocytopenia is not caused by preeclampsia-eclampsia. Pritchard and colleagues (1987) studied a large number of women with hypertension at Parkland Hospital and identified no cases in which neonatal thrombocytopenia correlated with maternal thrombocytopenia (see [Chap. 34](#), p. 773).

POLYCYTHEMIA AND HYPERVISCOSITY. Neonatal polycythemia and blood hyperviscosity occur as the result of chronic hypoxia in utero, from acute transfusion from the placenta or a twin at delivery, or much more rarely, from maternal-fetal hemorrhage. As the hematocrit rises above 65, blood viscosity markedly increases. Signs and symptoms include plethora, cyanosis, and neurological aberrations. Laboratory findings include hyperbilirubinemia, thrombocytopenia, fragmented erythrocytes, and hypoglycemia. Treatment consists of partial exchange transfusion with plasma to lower the hematocrit.

FETAL DEATH

From the foregoing sections, it is apparent that a number of maternal and fetal conditions can result in fetal demise. With advances in obstetrics, clinical genetics, maternal-fetal and neonatal medicine, and perinatal pathology, a number of stillbirths that previously would have been categorized as "unexplained" can now be attributed to specific causes. In many cases, this information makes management of subsequent pregnancies easier. Ultrasound allows rapid confirmation of fetal death, which frequently prompts labor induction in women with a favorable cervix (see [Chap. 22](#), p. 540).

DEFINITION OF FETAL MORTALITY. Stillbirths are much more common with decreasing gestational age. According to Copper and colleagues (1994), almost 80 percent of all stillbirths occur before term, and more than half occur before 28 weeks. Considering this, because statistics on perinatal outcome compiled by the National Center for Health Statistics and others generally include only those dead fetuses and neonates born weighing 500 g or more, the incidence of early stillbirth may actually be even higher than that shown in [Figure 29-14](#).

The stillbirth rate has declined over the past five decades, and the causes of stillbirth also have changed appreciably. Fretts and colleagues (1992) reviewed 709 stillbirths at the Royal Victoria Hospital in Montreal and found that the fetal death rate per 1000 births decreased from 11.5 in the 1960s to 5.1 in the 1980s. The rate due to lethal anomalies declined by almost half between the 1970s and 1980s—from 10.8 to 5.4 per 10,000 births—because deaths of infants with anomalies were "prevented" by early pregnancy terminations. Through the 1980s, commonly recognized causes of fetal death included infection, malformations, fetal growth restriction, and abruptio placentae. Although more than one fourth of all fetal deaths during the 1980s were still unexplained, this number decreased from 38.1 to 13.6 per 10,000 births.

Figure 29-14. Relationship between gestational age and incidence of stillbirth. (From Copper and colleagues, 1994, with permission.)

CAUSES OF FETAL DEATH. These can generally be categorized as fetal, placental, or maternal. In the past, because a definable cause could not always be assigned, there was only mild enthusiasm for necropsy. Currently, however, it is recognized that an autopsy performed by a pathologist with expertise in fetal and placental disorders, assisted by a team including maternal-fetal medicine, genetic, and pediatric specialists, often determines the cause of death. Faye-Petersen (1999), Horn (2004), and their colleagues reviewed autopsies performed by such teams, and found that the cause of death was identified in up to 94 percent. Determining the cause of death of preterm infants appears to be most difficult (Yudkin and colleagues, 1987). Some causes of fetal death or stillbirth identified by autopsy are shown in [Table 29-10](#).

Fetal Causes. Some type of fetal abnormality accounts for 25 to 40 percent of all stillbirths (Fretts and Usher, 1997; Pauli and Reiser, 1994). These abnormalities include congenital anomalies, infections, malnutrition, nonimmune hydrops, and anti-D-isoimmunization.

The reported incidence of *major congenital malformations* in stillborns is highly variable. It depends on whether necropsy was performed and if so, the experience, interest, and training of the pathologist (Cartlidge and co-workers, 1995). The majority of stillbirths attributed to fetal causes in the Wisconsin Stillbirth Service Program had a major structural malformation identified at autopsy (Pauli and Reiser, 1994). Conversely, in a study of 403 stillbirths reported by Copper and colleagues (1994), malformations were identified prenatally in only 5.6 percent. Faye-Petersen and colleagues (1999) found that one third of fetal deaths were caused by structural anomalies, of which neural-tube defects, hydrops, isolated hydrocephalus, and complex congenital heart disease were the most common. Major structural anomalies, hydrops, and aneuploidy are particularly amenable to antenatal diagnosis.

The incidence of stillbirths caused by fetal infection appears to be remarkably consistent. In five studies totaling 2676

stillbirths, 5.6 percent were attributed to infection (Cartlidge, 1995; Copper, 1994; Fretts, 1992; Lammer, 1989; Pauli and Reiser, 1994, and all of their colleagues). Most were diagnosed as "chorioamnionitis" and others as "fetal or intrauterine sepsis." In indigent and inner-city women, congenital syphilis can be a common cause of fetal death. For example, between 5 and 10 percent of stillbirths at Parkland Hospital are attributable to syphilis (see [Chap. 59](#), p. 1302). Other potentially lethal infections include cytomegalovirus, parvovirus B19, rubella, varicella, and listeriosis.

Placental Causes. Placental abnormalities known to cause fetal death are shown in [Table 29-10](#). Many of these deaths could also be categorized as having maternal or fetal causes. For example, placental abruption is associated with gestational hypertension in about half of cases, and could thus be classified as "maternal." In another example, placental insufficiency could result from aneuploidy or infection and thus be considered "fetal." With these caveats in mind, approximately 15 to 25 percent of fetal deaths are attributed to problems of the placenta, membranes, or cord (Alessandri and colleagues, 1992; Fretts and Usher, 1997).

Placental abruption is the most common single identifiable cause of fetal death (see [Chap. 35](#), p. 812). Fretts and Usher (1997) determined abruption to be the cause of death in 14 percent of stillborns. At Parkland Hospital, about 10 percent of third-trimester stillbirths are the consequence of premature placental separation.

Clinically significant *placental* and *membrane infection* rarely occurs in the absence of significant fetal infection. Exceptions include tuberculosis and malaria. In some cases, microscopic examination of the placenta and membranes may help to identify an infectious cause. Chorioamnionitis is characterized by mononuclear and polymorphonuclear leukocytes infiltrating the chorion. Although some clinicians consider these findings to be nonspecific, Benirschke and Kaufmann (2000) believe that microscopic chorioamnionitis is always due to infection (see [Chap. 27](#), p. 625).

Placental infarcts appear as areas of fibrinoid trophoblastic degeneration, calcification, and ischemic infarction from spiral artery occlusion (see [Chap. 27](#), p. 621). Marginal and subchorionic infarcts are common and usually of no import. Fox (1978) found that one fourth of placentas from uncomplicated term deliveries had infarcts. When there is severe hypertension, two thirds of placentas are so involved. Severe preeclampsia, with or without maternal thrombophilia, frequently results in extensive, centralized infarcts (see [Chap. 27](#), p. 621).

Fetal-maternal hemorrhage sufficient to cause fetal death was reported in 4.7 percent of 319 fetal deaths at Los Angeles County Women's Hospital in which Kleihauer-Betke stains of maternal blood had been performed (Samadi and associates, 1996). Such hemorrhage is common with severe maternal trauma (see [Chap. 42](#), p. 999). Twin-to-twin transfusion is a common cause of fetal death in monochorionic multifetal pregnancy (see [Chap. 39](#), p. 929).

Maternal Causes. Although they appear to make only a small contribution to fetal deaths, maternal factors may be underestimated. This is because pathologies with a strong maternal component, such as placental abruption or isoimmunization, often are attributed to placental or fetal causes. *Hypertensive disorders* and *diabetes* are the two most commonly cited maternal diseases, associated with 5 to 8 percent of stillbirths (Alessandri and colleagues, 1992; Fretts and Usher, 1997).

Lupus anticoagulant and *anticardiolipin antibodies* are associated with decidual vasculopathy, placental infarction, fetal growth restriction, recurrent abortion, and fetal death (see [Chap. 54](#), p. 1215). Although women with these autoantibodies clearly are at increased risk for adverse pregnancy outcomes, very few otherwise unexplained stillbirths can be attributed solely to such antibodies (Haddow and co-workers, 1991; Infante-Rivard and associates, 1991). Some hereditary thrombophilias have been linked with placental abruption, fetal growth restriction, and stillbirths (Prochazka and colleagues, 2003; Rey and co-workers, 2003). These disorders are discussed in detail in [Chapter 47](#) (see p. 1074).

EVALUATION OF THE STILLBORN INFANT. Determining the cause of fetal death facilitates the psychological adaptation to a significant loss, helps to assuage the guilt that is part of grieving, makes counseling regarding recurrence more accurate, and may prompt therapy or intervention to prevent a similar outcome in the next pregnancy. Identification of inherited syndromes also provides useful information for other family members.

Clinical Examination. A thorough examination of the fetus, placenta, and membranes should be performed at delivery and recorded in the chart. The details of relevant prenatal events should be provided. Photographs should be taken for the record whenever possible, and a full radiograph of the fetus ☞— a "fetogram" ☞— may be performed. These are especially important in providing anatomical information when the parents decline a full autopsy. The checklist used at Parkland Hospital to format the stillbirth note is outlined in [Table 29-11](#).

Laboratory Evaluation. If autopsy and chromosome studies are performed when indicated, up to 35 percent of stillborn infants are discovered to have major structural anomalies (Faye-Petersen and associates, 1999; Mueller and colleagues, 1983). Another 20 percent have dysmorphic features or skeletal abnormalities (Pauli and Reiser, 1994; Saller and colleagues, 1995). Finally, 8 percent have chromosomal abnormalities. The American College of Obstetricians and Gynecologists (1996) recommends consideration of cytogenetic studies for fetuses with dysmorphic features, inconsistent growth measurements, anomalies, hydrops, or growth restriction. A fetal karyotype also should be performed if either parent is a carrier for a balanced translocation, or if there is a history of recurrent losses or stillbirths in first-degree relatives. Such studies also might be considered in cases in which absolutely no other explanation for the loss is found. If certain types of fetal or placental aneuploidies are detected, such as a chromosome translocation or rearrangement, parental karyotypes also may be indicated.

Appropriate consent must be obtained to take skin and other fetal tissue samples, including fluid obtained by needle postmortem. A total of 3 mL of fetal blood, obtained from the umbilical cord (preferably) or by cardiac puncture is placed into a sterile, heparinized tube for cytogenetic studies. If blood cannot be obtained, a piece of fetal or placental tissue can be substituted, but because it must contain some viable cells that can be stimulated to divide, it cannot be macerated. Skin with attached dermal tissue or fascia from the thigh, inguinal region, or Achilles tendon should measure 1 cm² and be washed with sterile saline prior to placement in saline or sterile cytogenetic medium. Placement in formalin or alcohol prevents cytogenetic analysis by killing any remaining viable cells. A full karyotype may not be possible in cases with prolonged intrauterine retention. Fluorescence in situ hybridization, however, might be used to rule out numerical abnormalities or to look for certain common deletions such as that causing DiGeorge syndrome. Maternal blood should be obtained for Kleihauer-Betke staining,

testing for antiphospholipid antibodies and lupus anticoagulant if indicated, and serum glucose to exclude overt diabetes.

Autopsy. Patients should be encouraged to allow a full autopsy, but valuable information also can be obtained from limited studies. A gross external examination, along with photography, radiography, MRI, bacterial cultures, and selective use of chromosomal and histopathology studies often can aid in determining the cause of death (Brookes and co-workers, 1996; Mueller and colleagues, 1983).

A complete autopsy is much more likely to yield valuable information. An analysis of 400 consecutive fetal deaths in Wales found that autopsy altered the presumed cause of death in 13 percent and provided new information in another 26 percent (Cartlidge and Stewart, 1995). Studies from Alabama and New York found that autopsy results changed the recurrence risk estimates and parental counseling in approximately one fourth of cases (Faye-Petersen and colleagues, 1999; Saller and associates, 1995).

In many centers, maternal records and autopsy findings are reviewed on a monthly basis by a stillbirth committee composed of maternal-fetal medicine specialists, neonatologists, clinical geneticists, and perinatal pathologists. If possible, the cause of death is assigned based on available evidence. Most importantly, parents should then be contacted and offered counseling regarding the cause of death, the recurrence risk if any, and strategies to avoid recurrence in future pregnancies.

PSYCHOLOGICAL ASPECTS. Fetal death is psychologically traumatic for the woman and her family. Further stress results from an interval of more than 24 hours between the diagnosis of fetal death and the induction of labor, not seeing her infant for as long as she desires, and having no tokens of remembrance (Radestad and colleagues, 1996). The woman experiencing a stillbirth or even an early miscarriage is at increased risk for postpartum depression and should be closely monitored (see [Chap. 55](#), p. 1243).

PREGNANCY AFTER PREVIOUS STILLBIRTH. Fortunately, there are very few conditions associated with recurrent stillbirth. Other than hereditary disorders, only maternal conditions such as diabetes, chronic hypertension, or hereditary thrombophilia increase risk of recurrence. Several studies have cited rates of recurrent stillbirth that range from 0 to 8 percent, depending on the specific population studied (Freeman, 1985; Samueloff, 1993; Surkan, 2004; Weeks, 1995, and all their colleagues). Losses that occur early in the pregnancy are associated with a higher risk of subsequent adverse outcomes than those that occur late in gestation. Goldenberg and colleagues (1993) studied 95 women who had a pregnancy loss at 13 to 24 weeks and found that almost 40 percent had a preterm delivery in their next pregnancy, 5 percent had a stillbirth, and 6 percent had a neonatal death.

In a national Swedish database study of more than 410,000 deliveries, Surkan and co-workers (2004) found that delivery of a living, growth-restricted term infant was associated with a twofold increased risk of stillbirth in the next pregnancy. For those who had a live growth-restricted preterm infant, the risk was increased to fivefold.

Prenatal Evaluation. Knowledge of the cause of fetal death results in a more precise calculation of individual recurrence risk and in many cases allows a management plan to be made. For example, a cord accident would not be expected to recur. In contrast, aneuploidy generally has a 1-percent recurrence risk, and familial DiGeorge syndrome has a 50-percent recurrence. The latter two could be detected in subsequent pregnancies by chorionic villous sampling or amniocentesis. With proper treatment, infectious causes also would be unlikely to recur.

Maternal medical disorders associated with prior stillbirth are often easily identified. In some cases, intervention either preconceptionally or early in pregnancy improves outcome in subsequent pregnancies (see [Chap. 7](#), p. 193). For example, placental abruption often is associated with chronic hypertension. Although Pritchard and colleagues (1991) demonstrated an abruption recurrence rate of 10 percent, this could possibly be reduced with more stringent blood pressure control or early delivery. Similarly, a significant portion of perinatal mortality is attributable to congenital anomalies occurring in diabetic pregnancies with poor early blood glucose control. Intensive glycemic control in the periconceptional period reduces the incidence of malformations and generally improves outcome (see [Chap. 52](#), p. 1177). Lack of planning can lead to an unexplained pregnancy loss of the type that still accounts for half of stillborns of diabetic mothers (Hanson and Persson, 1993).

There is some evidence that recurrent fetal loss due to antiphospholipid antibodies can be decreased with treatment (see [Chap. 54](#), p. 1218). Testing for antiphospholipid antibodies in women who have an unexplained fetal loss in the second trimester is often helpful, but it is not recommended for the woman with a normally grown, unexplained third-trimester stillborn.

Management. Few studies address management of the woman who has suffered a prior fetal death. At the University of California at Irvine, Freeman and colleagues (1985) evaluated fetal heart rate testing in women with a variety of risk factors, including prior stillbirth. Women with a history of stillbirth were more likely to have a positive contraction stress test than women tested for other indications. The positive tests were mainly in women with hypertension (12 percent) or fetal growth restriction (17 percent). Although there were no recurrent stillbirths, the offspring of women with prior stillborns had an increased incidence of respiratory distress syndrome compared with those of women tested for other reasons. The investigators suggested that early delivery had been performed empirically in women with a previous loss.

A subsequent study by the Irvine group evaluated fetal heart rate testing in women whose only indication was prior stillbirth (Weeks and colleagues, 1995). There was only one recurrent stillbirth and only three fetuses with abnormal testing before 32 weeks among 300 study patients. The investigators found no relationship between the gestational age of the previous stillborn and the incidence or timing of abnormal tests or fetal jeopardy in the subsequent pregnancy. They concluded that antepartum surveillance should begin at 32 weeks or later in the otherwise healthy woman with a history of stillbirth. This is in agreement with recommendations of the American College of Obstetricians and Gynecologists (1999a).

INJURIES OF THE FETUS AND NEWBORN

Considered here are several varieties of birth injuries. Other injuries are described elsewhere in connection with the specific obstetrical complications that lead to or contribute to the injury.

SPONTANEOUS INTRACRANIAL HEMORRHAGE. Fetal or neonatal intracranial hemorrhage can occur at any of several sites ([Table 29-12](#)). Isolated intraventricular hemorrhage into the germinal matrix, without associated subarachnoid or subdural bleeding, is the most common type of intracranial hemorrhage. It usually occurs spontaneously as the result of immaturity, and generally does not result from traumatic delivery or obstetrical factors (Hayden and colleagues, 1985). Infants weighing less than 1500 grams are most susceptible. Thorp and colleagues (2001) prospectively studied 12,578 neonates from 23 to 35 weeks and found the incidence of grade III and IV intraventricular hemorrhage was 7.1 percent. The most significant associated factors were early gestational age, antenatal exposure to indomethacin, surfactant use, and need for neonatal transport. The likelihood of severe hemorrhage increased as gestational age at delivery decreased. Antenatal steroid use did not have a significant effect on the development of hemorrhage.

Spontaneous intracranial hemorrhage also has been documented in healthy term neonates (Huang and Robertson, 2004). In a prospective study, Whitby and colleagues (2004) used MRI in such infants and found that 6 percent of those delivered spontaneously, and 28 percent of those delivered by forceps, had a subdural hemorrhage. None of these infants had clinical findings, and hematomas resolved in all by 4 weeks.

The fetal head has considerable plasticity and may undergo appreciable molding during passage through the birth canal. The dimensions of the head actually change during the second stage, with lengthening of the occipitofrontal diameter of the skull. Rarely, severe molding and marked overlap of the parietal bones can result in tearing of the bridging veins from the cerebral cortex to the sagittal sinus, or rupture of the internal cerebral veins, the vein of Galen at its junctions with the straight sinus, or the tentorium itself. Compression of the skull can stretch the tentorium cerebelli and can tear the vein of Galen or its tributaries. As a result, intracranial hemorrhage may occur even after an apparently uneventful vaginal delivery.

INTRAVENTRICULAR HEMORRHAGE FROM MECHANICAL INJURY. Birth trauma is no longer a common cause of intracranial hemorrhage. The elimination of difficult forceps operations and appropriate management of breech delivery have contributed significantly to a reduction in the incidence of all birth injuries, including intracranial hemorrhage. As detailed in [Chapter 23](#) (see p. 558), appropriate use of forceps or vacuum delivery does not lead to increased intracranial hemorrhage or other neonatal injury (American College of Obstetricians and Gynecologists, 2000).

Infants suffering intracranial hemorrhage from mechanical injury, such as subdural hemorrhage from tentorial tears or massive infratentorial hemorrhage, have neurological abnormalities from the time of birth (Volpe, 1995). Severely affected infants usually those weighing more than 4000 g have stupor or coma, nuchal rigidity, and opisthotonus that worsen over minutes to hours. Some infants who are born depressed appear to improve until about 12 hours of age, but then drowsiness, apathy, feeble cry, pallor, failure to nurse, dyspnea, cyanosis, vomiting, and convulsions become evident.

Subarachnoid hemorrhage is usually minor with no symptoms, but seizures with an interictal period may manifest. In some infants, there is catastrophic deterioration. Ultrasound, CT, or MRI of the head are useful for diagnosis and also have contributed appreciably to an understanding of the etiology and frequency of some forms of intracranial hemorrhage (Perlman and Cunningham, 1993).

CEPHALOHEMATOMA. These hematomas are identified in 2.5 percent of all births. They are usually caused by injury to the periosteum of the skull during labor and delivery and rarely develop in the absence of birth trauma (Thacker and colleagues, 1987). In a recent Network study in which 37,100 cesarean delivery outcomes were examined, Alexander and associates (2005) found a 0.3 percent incidence of cephalohematoma. The hemorrhage may develop over one or both parietal bones, and palpable edges can be appreciated as the blood reaches the limits of the periosteum ([Fig. 29-15](#)). A cephalohematoma may not be apparent until hours after delivery, when bleeding sufficient to raise the periosteum has occurred. It often grows larger, disappearing only after weeks or even months. In contrast, caput succedaneum, also shown in [Figure 29-15](#), consists of a focal swelling of the scalp from edema that overlies the periosteum. Swelling from caput succedaneum is maximal at birth, rapidly grows smaller, and usually disappears within hours or a few days. Increasing size of the cephalohematoma and other evidence of extensive hemorrhage are indications for additional investigation, including radiographic studies and assessment of coagulation factors.

Figure 29-15. Difference between a large caput succedaneum (*left*) and cephalohematoma (*right*). In a caput succedaneum, the effusion overlies the periosteum and consists of edema fluid; in a cephalohematoma, it lies under the periosteum and consists of blood.

NERVE INJURIES

Spinal Injury. Overstretching of the spinal cord and associated hemorrhage may follow excessive traction during delivery, and there may be actual fracture or dislocation of the vertebrae. Menticoglou and associates (1995) described 15 neonates with this type of high cervical spinal cord injury and found that all of the injuries were associated with forceps rotations during delivery. Spinal cord injury also can occur during breech delivery.

Brachial Plexus Injury. These injuries are relatively common, complicating between 1 in 500 to 1 in 1000 term births (Boo and colleagues, 1991; Salonen and Uusitalo, 1990). Three types of brachial plexus damage have been described. Damage to the upper plexus is called *Erb* or *Duchenne paralysis*. It results from damage to C5 and C6 and occasionally C7, leading to paralysis of the deltoid and infraspinatus muscles as well as the flexor muscles of the forearm. The affected arm is held straight and internally rotated, with the elbow extended and the wrist and fingers flexed. The function of the fingers usually is retained. Because lateral head traction is frequently employed to effect delivery of the shoulders in normal vertex

presentations, Erb paralysis can occur even when the delivery did not appear to be difficult.

Damage to the lower plexus C8 and T1 results in *Klumpke's paralysis* in which the hand is flaccid. Total involvement of all brachial plexus nerve roots results in flaccidity of both arm and hand. With this kind of severe damage, there may also be *Horner syndrome* on the affected side—ptosis and pupillary miosis resulting from interruption of nerve fibers in the cervical sympathetic chain.

The propulsive efforts of normal delivery may cause brachial nerve stretching and damage (Sandmire and DeMott, 2000). In a study of 130 infants with brachial plexus injuries, Ubachs and colleagues (1995) found that cases involving C5 to C6 nerve roots were frequently associated with breech delivery. More extensive damage involving C5 to C7 or C5 to T1 often followed difficult cephalic deliveries. Increasing birthweight and breech delivery are significant risk factors. Unfortunately, and as discussed in detail in [Chapter 20](#) (see p. 513), shoulder dystocia leading to brachial plexus injury cannot be predicted reliably. Thus, it is fortunate indeed that the majority of cases involving nerve stretching or compression resolve with conservative therapy. In cases of complete nerve avulsion, however, normal function does not return.

Facial Paralysis. Pressure on the facial nerve as it emerges from the stylomastoid foramen can cause damage resulting in facial paralysis. The incidence, which has been reported to range from less than 1 to 7.5 per 1000 term births, likely is influenced by the vigor with which the diagnosis is sought (Levine and colleagues, 1984; White and associates, 1996). Facial paralysis may be apparent at delivery or may develop shortly after birth ([Fig. 29-16](#)). It can be caused by pressure exerted by the posterior blade when forceps have been placed obliquely on the fetal head, in which case the forceps marks indicate the cause of the injury ([Fig. 29-17](#)). It also can occur after spontaneous delivery. White and associates (1996) observed that only 18 percent of facial nerve palsies were associated with forceps delivery, and that the majority followed spontaneous vaginal or cesarean delivery. Levine and co-workers (1984) reported that one third of cases followed spontaneous delivery. Spontaneous recovery within a few days is the rule. An increase in injuries to the sixth cranial nerve with resultant lateral rectus ocular muscle paralysis following operative vaginal delivery also has been reported (Galbraith, 1994).

Figure 29-16. A. Paralysis of the right side of the face 15 minutes after forceps delivery. **B.** Same infant 24 hours later. Recovery was complete in another 24 hours.

Figure 29-17. Healing abrasions and lacerations from a difficult forceps delivery. Palsy of the right facial nerve has nearly cleared.

SKELETAL AND MUSCLE INJURIES

Fractures. *Clavicular fractures* are an unpredictable and unavoidable complication of normal birth. They are surprisingly common, occurring in 3.3 to 18 per 1000 live births (Roberts and associates, 1995; Turpenny and Nimmo, 1993). Chez and colleagues (1994) reported an incidence of 9 per 1000 vaginally delivered newborns and were unable to identify any specific factor that could be changed to avoid such fractures.

Humeral fractures are not common. Difficulty encountered in the delivery of the shoulders in cephalic deliveries and of extended arms in breech deliveries often produce such fractures. Up to 70 percent of cases, however, follow uneventful delivery (Turpenny and Nimmo, 1993). Humeral fractures are often of the greenstick type, although complete fracture with overriding of the bones may occur. Palpation of the clavicles and long bones should be performed on all newborns when a fracture is suspected, and any crepitation or unusual irregularity should prompt radiographic examination.

Femoral fractures are relatively rare and usually associated with breech delivery.

Skull fracture may follow forcible attempts at delivery, especially with forceps, but also can occur during spontaneous or cesarean delivery (Saunders and colleagues, 1979; Skajaa and associates, 1987). In the radiograph shown in [Figure 29-18](#), a focal but marked depressed skull fracture is apparent. Labor was characterized by vigorous contractions, full dilatation of the cervix, and arrest of descent of the head, which was tightly wedged in the pelvis. The fracture likely resulted from compression of the skull against the sacral promontory, from upward pressure from an assistant's hand in the vagina, or as the head was pushed upward out of the birth canal at cesarean delivery. Surgical decompression was successful.

Muscular Injuries. Injury to the sternocleidomastoid muscle may occur, particularly during a breech delivery. There may be a tear of the muscle or the fascial sheath, leading to a hematoma and gradual cicatricial contraction. As the neck lengthens in the process of normal growth, the head is gradually turned toward the side of the injury—a condition known as *torticollis*. This occurs because the damaged muscle is less elastic and does not elongate at the same rate as its normal contralateral counterpart. Roemer (1954) reported that 27 of 44 infants showing this deformity had been delivered by breech or internal podalic version. He postulated that lateral hyperextension sufficient to rupture the sternocleidomastoid may occur as the aftercoming head passes over the sacral promontory.

Figure 29-18. Depressed skull fracture evident immediately after cesarean delivery. Labor had progressed, and the head was deep in the pelvis. Dislodgment of the head from the birth canal was performed by an assistant using manual

pressure upward through the vagina.

CONGENITAL INJURIES

Amnionic Band Syndrome.

A free strip of amnion can form a focal ring around an extremity or digit, eventually producing enough constriction to cause damage or even amputation of the encircled structure. The genesis of such bands is debated. Streeter (1930), and others since, maintained that a localized failure of germ plasm or an inherent developmental abnormality of the involved structures is responsible for the abnormalities. Torpin (1968) and others contend that the lesions are the consequence of early rupture of the amnion. Occasionally, the amputated part may be found within the uterus.

Congenital Postural Deformities. Mechanical factors arising from chronically low volumes of amniotic fluid, or restriction of movement imposed by the small size and inappropriate shape of the uterine cavity or the presence of additional fetuses, may deform an otherwise normal fetal structure. Such mechanical deformations include talipes equivarus, or clubfoot; scoliosis; and hip dislocation (Miller and co-workers, 1981). Hypoplastic lungs also can result from oligohydramnios (see [Chap. 21](#), p. 531).

SECTION VI - THE PUERPERIUM

30. The Puerperium

INTRODUCTION

The puerperium is strictly defined as the period of confinement during and just after birth. By popular use, however, the meaning usually includes the six subsequent weeks (Hughes, 1972).

CLINICAL AND PHYSIOLOGICAL ASPECTS OF THE PUERPERIUM

UTERINE CHANGES

Uterine Vessels. Successful pregnancy requires a massive increase in uterine blood flow. To provide for this, arteries and veins within the uterus, and especially those of the placental site, enlarge remarkably, as do transport vessels to and from the uterus. Within the uterus, growth of new vessels also provides for the marked increase in blood flow. After delivery, the caliber of extrauterine vessels decreases to equal, or at least closely approximates, that of the prepregnant state. Within the puerperal uterus, larger blood vessels are obliterated by hyaline changes, gradually resorbed, and replaced by smaller ones. Minor vestiges of the larger vessels, however, may persist for years.

Cervix and Lower Uterine Segment. During labor, the outer cervical margin, which corresponds to the external os, is usually lacerated, especially laterally. The cervical opening contracts slowly, and for a few days immediately after labor readily admits two fingers. By the end of the first week, it has narrowed. As the opening narrows, the cervix thickens, and a canal reforms. At the completion of involution, however, the external os does not completely resume its pregravid appearance. It remains somewhat wider, and typically, bilateral depressions at the site of lacerations remain as permanent changes that characterize the parous cervix. Furthermore, cervical epithelium undergoes considerable remodeling as a result of childbirth. Ahdoot and colleagues (1998) found that approximately 50 percent of women with high-grade dysplasia demonstrated regression after vaginal delivery.

The markedly thinned-out lower uterine segment contracts and retracts, but not as forcefully as the body of the uterus. Over the course of a few weeks, the lower segment is converted from a clearly distinct substructure of the uterus, large enough to accommodate the fetal head, into a barely discernible uterine isthmus located between the uterine corpus above and the internal cervical os below.

Involution of the Uterine Corpus. Immediately after placental expulsion, the fundus of the contracted uterus is slightly below the umbilicus. The uterine body then consists mostly of myometrium covered by serosa and lined by basal decidua. The anterior and posterior walls, in close apposition, each measure 4 to 5 cm in thickness (Buhimschi and colleagues, 2003). Because its vessels are compressed by the contracted myometrium, the puerperal uterus on section appears ischemic when compared with the reddish-purple hyperemic pregnant organ. Two days after delivery, the uterus begins to shrink, and within 2 weeks it has descended into the cavity of the true pelvis. It regains its previous nonpregnant size about 4 weeks after delivery. Immediately postpartum, the uterus weighs approximately 1000 g. As the consequence of *involution*, 1 week later it weighs about 500 g, decreasing at the end of the second week to about 300 g, and soon thereafter to 100 g or less. The total number of muscle cells does not decrease appreciably, but instead, the individual cells decrease markedly in size. The involution of the connective tissue framework occurs equally rapidly.

Because separation of the placenta and membranes involves the spongy layer, the decidua basalis is not sloughed. The decidua that remains has striking variations in thickness, has an irregular jagged appearance, and is infiltrated with blood, especially at the placental site ([Fig. 30-1](#)).

AFTERPAINS. In primiparas, the puerperal uterus tends to remain tonically contracted, whereas in multiparas, the uterus often contracts vigorously at intervals, giving rise to *afterpains*. They are more pronounced as parity increases (Holdcroft and colleagues, 2003). They worsen when the infant suckles, likely because of oxytocin release. Usually, they decrease in intensity and become mild by the third day.

LOCHIA. Early in the puerperium, sloughing of decidual tissue results in a vaginal discharge of variable quantity; this is termed *lochia*. It consists of erythrocytes, shredded decidua, epithelial cells, and bacteria. For the first few days after delivery, there is blood sufficient to color it red ☞— *lochia rubra*. After 3 or 4 days, lochia becomes progressively pale in color ☞— *lochia serosa*. After about the 10th day, because of an admixture of leukocytes and reduced fluid content, lochia assumes a white or yellowish-white color ☞— *lochia alba*.

Lochia persists for up to 4 weeks and may stop and resume up to 8 weeks after delivery (Oppenheimer and colleagues, 1986; Visness and co-workers, 1997). Maternal age, parity, infant weight, and breast feeding do not influence the duration of lochia. Moreover, routine administration of oxytocic agents beyond the immediate postpartum period neither diminishes blood loss nor hastens uterine involution (Newton and Bradford, 1961).

Endometrial Regeneration. Within 2 or 3 days after delivery, the remaining decidua becomes differentiated into two layers. The superficial layer becomes necrotic, and it is sloughed in the lochia. The basal layer adjacent to the myometrium remains intact and is the source of new endometrium. The endometrium arises from proliferation of the endometrial glandular remnants and the stroma of the interglandular connective tissue.

Endometrial regeneration is rapid, except at the placental site. Within a week or so, the free surface becomes covered by epithelium, and the entire endometrium is restored during the third week. Sharman (1953) identified fully restored endometrium in all biopsy specimens obtained from the 16th postpartum day onward. Histological endometritis is part of the normal reparative process. Similarly, in almost half of postpartum women, fallopian tubes, between 5 and 15 days,

demonstrate microscopical inflammatory changes characteristic of acute salpingitis. These changes, however, do not reflect infection, but rather are part of the normal involutional process (Andrews, 1951).

SUBINVOLUTION. This term describes an arrest or retardation of involution. It is accompanied by prolongation of lochial discharge and irregular or excessive uterine bleeding, which sometimes may be profuse. On bimanual examination, the uterus is larger and softer than would be expected. Some causes of subinvolution are retention of placental fragments and pelvic infection. Because most cases of subinvolution result from local causes, they are usually amenable to early diagnosis and treatment. Ergonovine (Ergotrate) or methylergonovine (Methergine), 0.2 mg every 3 to 4 hours for 24 to 48 hours, is recommended by some clinicians, but its efficacy is questionable. On the other hand, metritis responds to oral antimicrobial therapy. Wager and colleagues (1980) reported that almost a third of cases of late postpartum uterine infection are caused by *Chlamydia trachomatis*; thus, azithromycin or doxycycline therapy may be appropriate.

Andrew and colleagues (1989) described 25 cases of hemorrhage between 7 and 40 days postpartum associated with noninvolved uteroplacental arteries. These abnormal arteries were filled with thrombi and lacked an endothelial lining. Perivascular trophoblasts were also present in the walls of these vessels, and the authors postulated that subinvolution, at least with regard to the placental vessels, may represent an aberrant interaction between uterine cells and trophoblast.

Placental Site Involution. Complete extrusion of the placental site takes up to 6 weeks (Williams, 1931). This process is of great clinical importance, for when it is defective, late-onset puerperal hemorrhage may ensue. Immediately after delivery, the placental site is about the size of the palm of the hand, but it rapidly decreases thereafter. By the end of the second week, it is 3 to 4 cm in diameter. Within hours of delivery, the placental site normally consists of many thrombosed vessels that ultimately undergo organization (see [Fig. 30-1](#)).

Williams (1931) described placental site involution as involving a process of exfoliation, which is in great part brought about by the undermining of the implantation site by growth of endometrial tissue. Thus, involution is not brought about by absorption in situ. Exfoliation consists of both extension and "downgrowth" of endometrium from the margins of the placental site and the development of endometrial tissue from the glands and stroma that are left deep in the decidua basalis after placental separation. Anderson and Davis (1968) concluded that placental site exfoliation is brought about as the consequence of sloughing of infarcted and necrotic superficial tissues followed by a reparative process.

Late Postpartum Hemorrhage. Serious uterine hemorrhage occasionally develops 1 to 2 weeks into the puerperium. This hemorrhage most often is the result of abnormal involution of the placental site. It may also be caused by retention of a portion of the placenta. Usually the retained piece of placenta undergoes necrosis with deposition of fibrin and may eventually form a so-called *placental polyp*. As the eschar of the polyp detaches from the myometrium, hemorrhage may be brisk.

In a study by Lee and associates (1981) of 3822 women delivered during a 1-year period at Henry Ford Hospital, 27 women (0.7 percent) had significant uterine bleeding after the first postpartum day. In 20 of these women, the uterus was judged to be empty by ultrasonographic evaluation, and importantly, only one woman had retained placental tissue.

It has generally been accepted that prompt curettage is necessary for treatment of late postpartum hemorrhage. However, because curettage for late puerperal hemorrhage usually does not remove identifiable placental tissue, it may actually worsen the hemorrhage by traumatizing the implantation site and inciting more bleeding. Thus, initial treatment may be best directed to medical control of the bleeding with intravenous oxytocin, ergonovine, methylergonovine, or prostaglandins (Adrinopoulos and Mendenhall, 1983). In general, curettage is carried out only if appreciable bleeding persists or recurs after medical management.

Figure 30-1. Cross sections of uteri made at the level of the involuting placental site at varying times after delivery. p.p. = postpartum. (Redrawn from Williams, 1931.)

URINARY TRACT CHANGES. Normal pregnancy is associated with an appreciable increase in extracellular water, and the diuresis that occurs postpartum is a physiological reversal of this process. This regularly occurs between the second and fifth days and corresponds with loss of residual pregnancy hypervolemia. In preeclampsia, both retention of fluid antepartum and diuresis postpartum may be greatly increased (see [Chap. 34](#), p. 774).

The puerperal bladder has an increased capacity and a relative insensitivity to intravesical fluid pressure. Overdistention, incomplete emptying, and excessive residual urine are common. The paralyzing effect of analgesics, especially epidural and spinal blocks, is often contributory. The dilated ureters and renal pelves return to their prepregnant state over the course of 2 to 8 weeks after delivery (see [Chap. 5](#), p. 138). Urinary tract infection is thus a concern because residual urine and bacteriuria in a traumatized bladder, coupled with the dilated renal pelves and ureters, create optimal conditions for development of infection. Kerr-Wilson and colleagues (1984) studied the effect of labor on postpartum bladder function using urodynamic techniques. They concluded that if labor was not prolonged, and **if catheterization was done promptly for bladder distention, bladder hypotonia did not occur.** Yip and colleagues (1997) demonstrated a positive correlation between duration of the first and second stage of labor and postvoid residual bladder volume as assessed by ultrasound on the first postpartum day. Carley and colleagues (2002) reported that overt postpartum urinary retention complicated 1 in every 200 vaginal deliveries in their institution and that most cases resolved before hospital dismissal. In their study, instrument-assisted delivery and regional analgesia were independently correlated with the risk of urinary retention.

Incontinence. Increasing attention has been focused on the potential for the development of urinary incontinence subsequent to pregnancy. Although the literature is difficult to interpret due to the multiplicity of study designs and definitions of incontinence, 3 to 26 percent of women report daily episodes of incontinence in the 3 to 6 months after delivery (Farrell and colleagues, 2001; Wijma and co-workers, 2003; Wilson and associates, 1996). In one study, Viktrup and Lose (1993) followed 305 nulliparous women during pregnancy and postpartum. Seven percent reported the development of stress incontinence after delivery, which correlated with obstetrical factors such as length of second-stage labor, infant head circumference, birthweight, and episiotomy. Impaired muscle function in or around the urethra as a result of vaginal delivery was proposed as

the pathophysiology underlying puerperal incontinence. At one-year follow-up, stress incontinence persisted in fewer than half.

Rortveit and colleagues (2003) performed a retrospective cohort study and found that women whose deliveries had all been vaginal had a 70-percent higher risk of incontinence than women whose deliveries had all been by cesarean. They cautioned, however, that for an individual woman, a decision to deliver all her infants by cesarean would decrease her risk of moderate or severe incontinence from 10 percent to only 5 percent, and that there was no evidence that this effect would persist past 50 years of age.

VAGINAL OUTLET RELAXATION AND UTERINE PROLAPSE. Early in the puerperium, the vagina and its outlet form a capacious, smooth-walled passage that gradually diminishes in size but rarely returns to nulliparous dimensions. Rugae reappear by the third week. The hymen is represented by several small tags of tissue, which during cicatrization are converted into the *myrtiform caruncles*.

Extensive lacerations of the perineum during delivery are followed by relaxation of the vaginal outlet. Even when external lacerations are not visible, stretching may lead to marked relaxation. Moreover, changes in pelvic support during parturition predispose to uterine prolapse and to urinary stress incontinence. In general, operative correction is postponed until childbearing is ended, unless serious disability, notably urinary stress incontinence, results in symptoms sufficient to require intervention.

PERITONEUM AND ABDOMINAL WALL. The broad and round ligaments require considerable time to recover from the stretching and loosening that occurred during pregnancy. As a result of the rupture of elastic fibers in the skin and the prolonged distention caused by the pregnant uterus, the abdominal wall remains soft and flaccid. Several weeks are required for these structures to return to normal. Recovery is aided by exercise. Except for silvery striae, the abdominal wall usually resumes its prepregnancy appearance. When muscles remain atonic, however, the abdominal wall also remains lax. There may be a marked separation of the rectus muscles or *diastasis recti*. In this condition, the midline abdominal wall is formed only by peritoneum, attenuated fascia, subcutaneous fat, and skin.

BLOOD AND FLUID CHANGES. Rather marked leukocytosis and thrombocytosis occur during and after labor. The leukocyte count sometimes reaches 30,000/ μ L, with the increase predominantly from granulocytes. There is also a relative lymphopenia and an absolute eosinopenia. Normally, during the first few postpartum days, hemoglobin concentration and hematocrit fluctuate moderately. If they fall much below the levels present just prior to labor, a considerable amount of blood has been lost (see [Chap. 35](#), p. 839). By 1 week after delivery, the blood volume has returned nearly to its nonpregnant level. Robson and colleagues (1987) showed that cardiac output remains elevated for at least 48 hours postpartum. Most likely this is due to increased stroke volume from venous return, because the heart rate falls at the same time. By 2 weeks, these changes have returned to normal nonpregnant values.

Pregnancy-induced changes in blood coagulation factors persist for variable periods during the puerperium. Elevation of plasma fibrinogen is maintained at least through the first week, and hence, so is the sedimentation rate.

Weight Loss. In addition to the loss of about 5 to 6 kg due to uterine evacuation and normal blood loss, there is usually a further decrease of 2 to 3 kg through diuresis. Chesley and co-workers (1959) demonstrated a decrease in sodium space of about 2 L during the first week postpartum. According to Schauburger and co-investigators (1992), most women approach their self-reported prepregnancy weight 6 months after delivery but still retain an average surplus of 1.4 kg (3 lb). Smith and colleagues (1994) reported on a cohort of women who were followed over a 5-year period. Women who had a single pregnancy and were at least 12 months postpartum had gained an average of 2 to 3 kg more weight and had greater increases in their waist-to-hip ratio (a measure of adiposity) than those who had remained nulliparous. Indigent women are more likely to retain weight gained during pregnancy (Olson and associates, 2003). Deleterious effects of weight gain are discussed in [Chapter 43](#) (see p. 1009).

MAMMARY GLANDS

BREAST ANATOMY. Each mature mammary gland is composed of 15 to 25 lobes. The lobes are arranged radially and are separated from one another by varying amounts of fat. Each lobe consists of several lobules, which in turn are made up of large numbers of alveoli ([Fig. 30-2](#)). Every alveolus is provided with a small duct that joins others to form a single larger duct for each lobe. These lactiferous ducts open separately on the nipple, where they may be distinguished as minute but distinct orifices. The alveolar secretory epithelium synthesizes the various milk constituents.

Figure 30-2. Graphic demonstration of the alveolar and ductal system. Note the myoepithelial fibers (M) that surround the outside of the uppermost alveolus. The secretions from the glandular elements are extruded into the lumen of the alveoli (A) and ejected by the myoepithelial cells into the ductal system (D), which empties through the nipple. Arterial blood supply to the alveolus is identified by the upper right arrow and venous drainage by the arrow beneath. (Courtesy of Dr. John C. Porter.)

BREAST FEEDING. After delivery, the breasts begin to secrete colostrum, which is a deep lemon-yellow-colored liquid. It usually can be expressed from the nipples by the second day.

Colostrum and Milk

COLOSTRUM. Compared with mature milk, colostrum contains more minerals and protein, much of which is globulin, but less

sugar and fat. Colostrum secretion persists for about 5 days, with gradual conversion to mature milk during the ensuing 4 weeks. Antibodies are demonstrable in colostrum, and its content of immunoglobulin A (IgA) may offer protection for the newborn against enteric pathogens. Other host resistance factors that are found in colostrum and milk include complement, macrophages, lymphocytes, lactoferrin, lactoperoxidase, and lysozymes.

MILK. Human milk is a suspension of fat and protein in a carbohydrate-mineral solution. Gestational weight gain has little, if any, impact on the subsequent milk quantity or quality (Institute of Medicine, 1990). A nursing mother easily makes 600 mL of milk per day. Milk is isotonic with plasma, with lactose accounting for half of the osmotic pressure. Major proteins, including α -lactalbumin, β -lactoglobulin, and casein, are also present. Essential amino acids are derived from blood, and nonessential amino acids are derived in part from blood or synthesized in the mammary gland. Most milk proteins are unique and not found elsewhere.

Whey is milk serum and has been shown to contain large amounts of interleukin-6 (IL-6) (Saito and co-workers, 1991). Peak levels were found in colostrum, and there was a positive correlation between its concentration and the number of mononuclear cells in human milk. In addition, IL-6 was associated closely with local IgA production by the breast. *Prolactin* appears to be actively secreted into breast milk (Yuen, 1988). *Epidermal growth factor (EGF)* has also been identified in human milk (Koldovsky and associates, 1991; McCleary, 1991). Because EGF is not destroyed by gastric proteolytic enzymes, it may be absorbed orally and promote growth and maturation of intestinal mucosa.

There are major changes in milk composition by 30 to 40 hours postpartum, including a sudden increase of lactose concentration. Some lactose enters the maternal circulation and is excreted by the kidney. This may be misinterpreted as glucosuria unless specific glucose oxidase is used in testing. Fatty acids are synthesized in the alveoli from glucose and are secreted by an apocrine-like process.

All vitamins except K are found in human milk, but in variable amounts, and maternal dietary supplementation increases the secretion of most of these (American Academy of Pediatrics, 1981). Vitamin K administration to the infant soon after delivery is required to prevent hemorrhagic disease of the newborn (see [Chap. 29](#), p. 676).

Endocrinology of Lactation. The precise humoral and neural mechanisms involved in lactation are complex. Progesterone, estrogen, and placental lactogen, as well as prolactin, cortisol, and insulin, appear to act in concert to stimulate the growth and development of the milk-secreting apparatus of the mammary gland (Porter, 1974). With delivery, there is an abrupt and profound decrease in the levels of progesterone and estrogen, which removes the inhibitory influence of progesterone on the production of α -lactalbumin by the rough endoplasmic reticulum. The increased α -lactalbumin serves to stimulate lactose synthase and ultimately to increase milk lactose. Progesterone withdrawal also allows prolactin to act unopposed in its stimulation of α -lactalbumin production.

The intensity and duration of subsequent lactation are controlled, in large part, by the repetitive stimulus of nursing. Prolactin is essential for lactation; for example, women with extensive pituitary necrosis, or *Sheehan syndrome*, do not lactate (see [Chap. 53](#), p. 1203). Although plasma prolactin falls after delivery to levels lower than during pregnancy, each act of suckling triggers a rise in levels (McNeilly and associates, 1983). Presumably a stimulus from the breast curtails the release of prolactin-inhibiting factor from the hypothalamus, and this, in turn, transiently induces increased prolactin secretion.

The neurohypophysis secretes oxytocin in pulsatile fashion. This stimulates milk expression from a lactating breast by causing contraction of myoepithelial cells in the alveoli and small milk ducts. Milk ejection, or *letting down*, is a reflex initiated especially by suckling, which stimulates the neurohypophysis to liberate oxytocin (McNeilly and associates, 1983). Milk let-down may be provoked even by the cry of the infant and can be inhibited by fright or stress.

In women who become pregnant but who continue to breast feed, milk composition undergoes progressive alterations suggesting gradual loss of metabolic and secretory breast activity (Hartmann and Prosser, 1984).

Immunological Consequences of Breast Feeding. Antibodies are present in human colostrum and milk but are poorly absorbed, if at all, by infants. For example, no serum antibodies have been detected in infants fed milk containing a high titer of anti-D antibodies. This does not lessen the importance of some of the antibodies in breast milk. The predominant immunoglobulin in milk is secretory IgA. This macromolecule is secreted across mucous membranes and has important antimicrobial functions. For example, human milk contains secretory IgA antibodies against *Escherichia coli*, and breast-fed infants are less prone to enteric infections than bottle-fed infants (Cravioto and associates, 1991). It has been suggested that IgA exerts its action by preventing bacterial adherence to epithelial cell surfaces, thus preventing tissue invasion (Samra and associates, 1991). Moreover, human milk also provides protection against rotavirus infections, which cause up to 50 percent of cases of gastroenteritis among infants in the United States (Newburg and associates, 1998).

Much attention has been directed to an elucidation of the role of maternal breast milk lymphocytes in the immunological processes of the newborn. Milk contains both T and B lymphocytes, but the T lymphocytes appear to differ from those found in blood. Specifically, milk T lymphocytes are almost exclusively composed of cells that exhibit specific membrane antigens, including the LFA-1 high-memory T-cell phenotype. These memory T cells appear to be another mechanism by which the neonate benefits from maternal immunological experience (Bertotto and associates, 1990). Lymphocytes in colostrum undergo blastoid transformation in vitro following exposure to specific antigens. In experimental animals, Beer and Billingham (1976) observed a transmission of viable lymphocytes from mother to infant through breast milk. As mentioned earlier, IL-6 is present in colostrum and appears to stimulate an increase in mononuclear cells in breast milk (Saito and co-workers, 1991).

Nursing. Between 1930 and the late 1960s, there was a dramatic decline in the percentage of American mothers who breast fed (Yaffe, 1994). In 1930, 80 percent of children were breast fed compared with only 20 percent in 1972. The picture has improved since then. Currently in the United States, more than 60 percent of infants are breast fed, and the number is increasing (American College of Obstetricians and Gynecologists, 2000).

Human milk is ideal food for neonates. It provides species- and age-specific nutrients for the infant. In addition to the proper balance of nutrients, immunological factors, and antibacterial properties, human milk contains factors that act as biological signals for promoting cellular growth and differentiation (American College of Obstetricians and Gynecologists, 2000). With limited sun exposure, however, infants who are breast fed exclusively may become vitamin D deficient. Thus supplementation

with 200 IU of vitamin D per day for the first two months for such infants is recommended by the American Academy of Pediatrics (Gartner and Greer, 2003).

In 1997, the American Academy of Pediatrics published the policy statement on the infant benefits of nursing shown in [Table 30-1](#). For both mother and infant, the benefits of breast feeding are likely long-term. For example, women who breast feed have a lower risk of breast cancer, and their children have increased adult intelligence independent of a wide range of possible confounding factors (Collaborative Group on Hormonal Factors in Breast Cancer, 2002; Mortensen and associates, 2002). A goal of the United States Public Health Service for year 2010 is to increase the proportion of mothers who breast feed to 75 percent. Educational initiatives can be effective. Kramer and colleagues (2001) demonstrated that the systematic promotion of breast feeding leads to higher rates and longer durations of breast feeding.

In most instances, even though the supply of milk at first appears insufficient, it becomes adequate if suckling is continued. An exception is that 65 percent of women who have undergone augmentation mammoplasty have lactation insufficiency (Hurst, 1996). This problem is more likely if the implant incision was periareolar (Chez and Friedman, 2000). Aerobic exercise performed four or five times per week beginning 6 to 8 weeks postpartum had no adverse effect on amounts or immunological contents of milk (Dewey and co-workers, 1994; Lovelady and associates, 2003). Weight loss of approximately 0.5 kg per week in the first 3 months postpartum does not affect infant growth of exclusively breast feeding, overweight women (Lovelady and co-workers, 2000).

According to Chez and Friedman (2000), a number of Internet resources are available for breast feeding mothers. These include the American Academy of Pediatrics (www.aap.org) and La Leche League International (www.lalecheleague.org).

LACTATION INHIBITION. Approximately 40 percent of American women currently elect not to breast feed, and many experience considerable breast pain and engorgement. Milk leakage, engorgement, and breast pain peak at 3 to 5 days postpartum (Spitz and associates, 1998). As many as 10 percent report severe pain up to 14 days postpartum, and 25 to 50 percent of all women use analgesia for breast pain relief. In 1989, an advisory committee of the Food and Drug Administration, taking the view that there is no need for pharmacological therapy for lactation suppression, recommended that medications should no longer be used for lactation suppression. In part, this decision was because *bromocriptine*, a commonly used drug for lactation inhibition, had been associated with strokes, myocardial infarctions, seizures, and psychiatric disturbances. Evidence to support these associations, however, is tenuous at best (Morgans, 1995). Nevertheless, the manufacturer voluntarily removed lactation suppression as an indication for bromocriptine (Food and Drug Administration, 1994).

The woman who does not desire to breast feed should be reassured that stopping milk production is not a major problem. During the stage of engorgement, the breasts become painful and should be supported with a well-fitting brassiere. Ice packs and oral analgesics for 12 to 24 hours may be required to relieve discomfort. Breast binders are used at Parkland Hospital for these women, and patient-supplied "sports bras" are used at the University of Alabama Hospital.

CONTRACEPTION FOR BREAST FEEDING WOMEN. Three weeks after delivery, ovulation may resume, even in lactating women. Its resumption depends on individual biological variation as well as the intensity of breast feeding. Progestin-only contraceptives—mini-pills and depot medroxyprogesterone—do not affect the quality or decrease milk volume. They are considered the hormonal contraceptives of choice for breast feeding women by the American College of Obstetricians and Gynecologists (2000). Although estrogen-progestin contraceptives have been shown to reduce the quantity and quality of breast milk, under the proper circumstances they can be used by breast feeding women. These methods are summarized in [Table 30-2](#).

CONTRAINDICATIONS TO BREAST FEEDING. Nursing is contraindicated in women who take street drugs or do not control their alcohol use; have an infant with galactosemia; have human immunodeficiency virus (HIV) infection; have active, untreated tuberculosis; take certain medications; or are undergoing treatment for breast cancer (American College of Obstetricians and Gynecologists, 2000). Breast feeding has been recognized for some time as a mode of HIV transmission (Ziegler and colleagues, 1985). Nduati and colleagues (2000) randomly assigned 401 HIV-seropositive mother-infant pairs in Kenya to formula or breast feeding. At 2 years of age, the rate of viral infection in children who were breast fed was 37 percent—significantly higher than in children who were formula fed, in whom the rate was 21 percent.

Other viral infections do not contraindicate breast feeding. For example, maternal cytomegalovirus infection is not a contraindication, because virus and antibodies are present in breast milk. Likewise, although hepatitis B virus is excreted in milk, breast feeding is not contraindicated if hepatitis B immune globulin is given to infants of seropositive mothers (American College of Obstetricians and Gynecologists, 2000). Maternal hepatitis C infection is also not a contraindication to breast feeding, and the 4-percent risk of infant transmission is the same for breast- and bottle-fed infants (Centers for Disease Control and Prevention, 1998). Women with active herpes simplex virus may suckle their infants if there are no breast lesions and if particular care is directed to hand washing before nursing.

CARE. The nipples require little attention in the puerperium other than cleanliness and attention to fissures. Because dried milk is likely to accumulate and irritate the nipples, cleaning of the areola with water and mild soap is helpful before and after nursing. When the nipples are irritated, it may be necessary to use a nipple shield for 24 hours or longer. Although inverted or retracted nipples may be troublesome, these can usually be teased out by gently pulling with the finger and thumb. This is best begun during pregnancy to prepare the nipples for subsequent nursing. Proper technique for positioning the mother and infant during nursing has been reviewed by the American College of Obstetricians and Gynecologists (2000). This includes proper techniques for *latch-on* of the infant during suckling.

DRUGS SECRETED IN MILK. Most drugs given to the mother are secreted in breast milk. Many factors influence their excretion, including the concentration of drugs in plasma, degree of protein binding, plasma and milk pH, degree of ionization, lipid solubility, and molecular weight. The amount of drug ingested by the infant typically is small. The ratio of drug concentrations in breast milk to those in maternal plasma is the *milk-to-plasma drug-concentration ratio*. Most drugs have a milk-to-plasma ratio of 1 or less, about 25 percent have a ratio of more than 1, and about 15 percent have a ratio greater than 2 (Ito, 2000).

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) agree that cytotoxic drugs may interfere with the cellular metabolism of the infant and potentially cause immune suppression or neutropenia, affect

growth, or, at least theoretically, increase the risk of cancer. These include cyclophosphamide; cyclosporine; doxorubicin, which is concentrated in breast milk; and methotrexate. Other drugs that have been associated with significant effects on some nursing infants and therefore should be used with caution are shown in [Table 30-3](#). If a medication presents a concern, then it should be ascertained whether the drug therapy is necessary, whether a safer alternative is available, and whether neonatal exposure can be minimized by having the mother take the medication immediately after breast feeding (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002).

Radioactive isotopes of copper, gallium, indium, iodine, sodium, and technetium rapidly appear in breast milk. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2002) recommend consultation with a nuclear medicine physician before performing a diagnostic study using these isotopes. The goal is to use a radionuclide with the shortest excretion time in breast milk. The mother should pump her breasts before the study and store enough milk in a freezer for feeding the infant. After the study, she should pump her breasts to maintain milk production but discard all milk produced during the time that radioactivity is present. This ranges from 15 hours up to 2 weeks, depending on the isotope used.

Breast Fever. For the first 24 hours after commencement of lactation, it is not unusual for the breasts to become distended, firm, and nodular. These findings may be accompanied by a transient elevation of temperature. Puerperal fever from breast engorgement is common. Almeida and Kitay (1986) reported that 13 percent of all postpartum women had fever that ranged from 37.8 to 39^oC from this cause. Fever seldom persisted for longer than 4 to 16 hours. The incidence and severity of breast engorgement, and fever associated with it, were lower if treatment was given for lactation suppression. **Other causes of fever, especially those due to infection, must be excluded.** Treatment consists of supporting the breasts with a binder or brassiere, applying an ice bag, and an analgesic. Pumping of the breast or manual expression of milk may be necessary at first, but in a few days the condition is usually alleviated and the infant is able to nurse normally (see p. 699).

Mastitis. Parenchymatous infection of the mammary glands is a rare complication antepartum but is occasionally observed during the puerperium and lactation. It is estimated to occur in anywhere from 2 to 33 percent of breast feeding women (Barbosa-Cesnik and associates, 2003). Symptoms of suppurative mastitis seldom appear before the end of the first week postpartum and, as a rule, not until the third or fourth week. Infection almost invariably is unilateral, and marked engorgement usually precedes the inflammation. The first sign of inflammation is chills or actual rigor, soon followed by fever and tachycardia. The breast becomes hard and reddened, and the woman complains of severe pain. About 10 percent of women with mastitis develop an abscess. Constitutional symptoms attending a mammary abscess are generally severe, but in some cases the first indication of the true diagnosis often is afforded by the detection of fluctuation. Ultrasonography may be helpful to detect an abscess.

ETIOLOGY. The most commonly isolated organism is *Staphylococcus aureus*. Matheson and colleagues (1988) cultured it from 40 percent of women with mastitis. Other commonly isolated organisms are coagulase-negative staphylococci and viridans streptococci. The immediate source of organisms that cause mastitis is almost always the infant's nose and throat. With nursing, bacteria enter the breast through the nipple at the site of a fissure or abrasion, which may be quite small. In cases of true mastitis, the infecting organism can usually be cultured from milk. Toxic shock syndrome secondary to mastitis caused by *S aureus* has been reported (Demey and associates, 1989; Fujiwara and Endo, 2001).

Suppurative mastitis among nursing mothers has at times reached epidemic levels. Such outbreaks most often coincide with the appearance of a new strain of antibiotic-resistant *Staphylococcus*, an example being methicillin-resistant *S aureus* (MRSA). Typically, the infant becomes infected after contact with nursery personnel who are colonized. Attendants' hands are the major source of contamination of the newborn. The colonization of staphylococci in the infant may be totally asymptomatic or may locally involve the umbilicus or the skin. Occasionally the organisms cause a life-threatening systemic infection.

TREATMENT. Abscess formation is more common with *S aureus* infection (Matheson and associates, 1988). Provided that appropriate therapy is started before suppuration begins, the infection usually resolves within 48 hours. Before initiating antimicrobial therapy, some clinicians recommend that milk be expressed from the affected breast onto a swab and cultured. By so doing, the organism can be identified and its antimicrobial sensitivities ascertained. Results of such cultures also provide information mandatory for a successful program for surveillance of nosocomial infections.

The initial choice of antimicrobial is undoubtedly influenced to a considerable degree by the current experience with staphylococcal infections at the institution. That said, most are community-acquired organisms, and even staphylococcal infections are usually sensitive to penicillin or a cephalosporin (American College of Obstetricians and Gynecologists, 2000). Dicloxacillin, 500 mg orally four times daily, may be started empirically (Hindle, 1994). Erythromycin is given to women who are penicillin sensitive. If the infection is caused by resistant, penicillinase-producing staphylococci, or if resistant organisms are suspected while awaiting the results of culture, an antimicrobial such as vancomycin, which is effective against MRSA, should be given. Even though clinical response may be prompt and striking, treatment should be continued for 10 to 14 days.

Marshall and colleagues (1975) demonstrated the importance of continued breast feeding. They reported that the only three abscesses that developed in 65 women with mastitis were in 15 women who chose to wean their infants. Thomsen and co-workers (1984) observed that vigorous milk expression was sufficient treatment alone in half of women with mastitis. Early therapy and continued lactation was successful in avoiding abscess formation in all 20 women described by Niebyl and co-investigators (1978). If the infected breast is too tender to allow suckling, gently pumping until nursing can be resumed is recommended. Sometimes the infant will not nurse on the inflamed breast. This probably is not related to any changes in the taste of the milk but is secondary to engorgement and edema, which can make the areola harder to grip. Pumping can alleviate this. When nursing bilaterally, it is best to begin suckling on the uninvolved breast. This allows let-down to commence before moving to the tender breast.

Breast Abscess. Clinical suspicion for abscess development is either from failure of defervescence within 48 to 72 hours or development of a palpable mass. Traditional therapy is surgical drainage, which usually requires general anesthesia. The incision should be made corresponding to skin lines for a good cosmetic result (Stehman, 1990). In early cases, a single incision over the most dependent portion of the area of fluctuation is usually sufficient, but multiple abscesses require several incisions, and a finger should be inserted to break up the walls of the locules. The resulting cavity is loosely packed with gauze, which should be replaced at the end of 24 hours by a smaller pack. A less invasive alternative is ultrasonographic-guided needle aspiration using local anesthesia, which has success rates of 80 to 90 percent (Karstrup, 1993; O'Hara, 1996; Schwarz,

2001, and all their associates).

Galactocele. Exceptionally, as the result of the clogging of a duct by inspissated secretion, milk may accumulate in one or more lobes of the breast. The amount is ordinarily limited, but an excess may form a fluctuant mass that may give rise to pressure symptoms. They may resolve spontaneously or require aspiration.

Supernumerary Breasts. One in every few hundred women has one or more accessory breasts (*polymastia*). The supernumerary breasts may be so small as to be mistaken for pigmented moles, or when without a nipple, for a lipoma. They rarely attain considerable size. They are likely to be situated in pairs on either side of the midline of the thoracic or abdominal walls, usually below the main breasts. They are also found in the axillae, and more rarely on other portions of the body, such as the shoulder, flank, groin, or thigh. When arranged symmetrically, two or four are most common, although 10 have been described. Polymastia has no obstetrical significance, although occasionally the enlargement of supernumerary breasts in the axillae may result in considerable discomfort.

Abnormalities of the Nipples. In some women, the lactiferous ducts open directly into a depression at the center of the areola. In marked cases of depressed nipple, nursing is not possible. When the depression is not very deep, the breast may occasionally be made available by use of a breast pump. More frequently, the nipple, although not depressed, is greatly inverted. In such a case, daily attempts should be made during the last few months of pregnancy to draw the nipple out, using traction with fingers.

Nipples that are normal in shape and size may become fissured. In such cases, the fissures almost invariably render nursing painful, sometimes with a deleterious influence on the secretory function. Moreover, such lesions provide a convenient portal of entry for pyogenic bacteria. For these reasons, every effort should be made to heal such fissures, particularly by protecting them from further injury with a nipple shield and topical medication. If such measures are of no avail, the infant should not be permitted to nurse on the affected side. Instead, the breast should be emptied regularly with a suitable pump until the lesions are completely healed.

Abnormalities of Secretion. There are marked individual variations in the amount of milk secreted, many of which are dependent not on the general health and appearance of the woman but on the development of the glandular portions of the breasts. Rarely, there is complete lack of mammary secretion (*agalactia*). Occasionally, the mammary secretion is excessive (*polygalactia*).

CARE OF THE MOTHER DURING THE PUERPERIUM

HOSPITAL CARE. For the first hour after delivery, blood pressure and pulse should be taken every 15 minutes, or more frequently if indicated. The amount of vaginal bleeding is monitored, and the fundus should be palpated to ensure that it is well contracted. If relaxation is detected, the uterus should be massaged through the abdominal wall until it remains contracted. Blood may accumulate within the uterus without external bleeding. This may be detected early by identifying uterine enlargement with serial and frequent fundal palpation during the first few hours. Because the likelihood of significant hemorrhage is greatest immediately postpartum, even in normal cases, a trained attendant should remain with the mother for at least 1 hour after delivery. Identification and management of postpartum hemorrhage is discussed in [Chapter 35](#).

If regional analgesia or general anesthesia is used, the mother should be observed in an appropriately equipped and staffed recovery area.

Early Ambulation. Early ambulation is an accepted puerperal practice. Women are out of bed within a few hours after delivery. The many confirmed advantages of early ambulation include less frequent bladder complications and constipation. As discussed in [Chapter 47](#) (see p. 1074), early ambulation has reduced the frequency of puerperal venous thrombosis and pulmonary embolism (Toglia and Weg, 1996). For at least the first ambulation, an attendant should be present in case the woman should become syncopal.

Care of the Vulva. The patient should be instructed to cleanse the vulva from anterior to posterior (vulva toward anus). An ice bag applied to the perineum may help reduce edema and discomfort during the first several hours after episiotomy repair. Beginning about 24 hours after delivery, moist heat as provided with warm sitz baths can be used to reduce local discomfort. Tub bathing after uncomplicated delivery is allowed.

Bladder Function. Bladder filling after delivery may be quite variable. In most hospitals, intravenous fluids are infused during labor and for an hour after delivery. Oxytocin, in doses that have an antidiuretic effect, is commonly infused after placental delivery. As a consequence of infused fluid and the sudden withdrawal of the antidiuretic effect of oxytocin, rapid bladder filling is common. Moreover, both bladder sensation and capability to empty spontaneously may be diminished by anesthesia, especially conduction analgesia, as well as by episiotomy, lacerations, or hematomas. It is not surprising, therefore, that urinary retention with bladder overdistention is a common complication of the early puerperium. In a prospective observational study, Ching-Chung and colleagues (2002) reported this complication in 4 percent of term women delivered vaginally. On long-term follow-up, only 3 of 114 women had persistent urinary symptoms.

Prevention of bladder overdistention demands observation after delivery to ensure that the bladder does not overfill and that with each voiding it empties adequately. The bladder may be palpated as a cystic mass suprapubically, or the enlarged bladder may be evident abdominally only indirectly, as a consequence of its elevating the uterine fundus above the umbilicus.

If the woman has not voided within 4 hours after delivery, it is likely that she cannot. The woman who has trouble voiding initially is likely to have further trouble. In such women, the likelihood of hematomas of the genital tract must be considered. Whenever the bladder becomes overdistended, an indwelling catheter should be left in place until the factors causing the retention have abated. Even without a demonstrable cause, it usually is best to leave the catheter in place for at least 24 hours, so as to empty the bladder completely. This prevents recurrence as well as allows recovery of normal bladder tone and sensation. When the catheter is removed, it is necessary subsequently to demonstrate ability to void appropriately. If the woman cannot void after 4 hours, she should be catheterized and urine volume measured. If there is more than 200 mL of urine, it is apparent that the bladder is not functioning appropriately. The catheter should be left in place and the bladder

drained for another day. If less than 200 mL of urine is obtained, the catheter can be removed and the bladder rechecked subsequently as described. Harris and colleagues (1977) reported that 40 percent of such women develop bacteriuria; and thus, a short course of antimicrobial therapy seems reasonable after the catheter is removed.

Subsequent Discomfort. The discomfort from cesarean delivery, its causes, and its management are considered in [Chapter 25](#) (see p. 589). During the first few days after vaginal delivery, the mother may be uncomfortable for a variety of reasons, including afterpains, episiotomy and lacerations, breast engorgement, and at times, postspinal puncture headache. It is helpful to provide codeine, 60 mg; aspirin, 600 mg; or acetaminophen, 500 mg, preferably in combinations, at intervals as frequent as every 3 hours during the first few days after delivery. Uterine contractions are commonly accentuated during nursing, giving rise at times to troublesome afterpains.

An episiotomy or lacerations may be uncomfortable, as discussed in [Chapter 17](#) (see p. 434). Early application of an ice bag may minimize swelling and discomfort. Most women also appear to obtain a measure of relief from the periodic application of a local anesthetic spray. Severe discomfort usually indicates a problem such as a hematoma within the first day or so and infection after the third or fourth day. For these reasons, severe pain warrants careful examination. The episiotomy incision normally is firmly healed and nearly asymptomatic by the third week.

Depression. It is fairly common for a mother to exhibit some degree of depressed mood a few days after delivery. This situation is termed *postpartum blues*, and it likely is the consequence of a number of factors:

1. The emotional letdown that follows the excitement and fears that most women experience during pregnancy and delivery.
2. The discomforts of the early puerperium.
3. Fatigue from loss of sleep during labor and postpartum.
4. Anxiety over her capabilities for caring for her infant after leaving the hospital.
5. Fears that she has become less attractive.

In the great majority of cases, effective treatment need be nothing more than anticipation, recognition, and reassurance. This mild disorder is self-limited and usually remits after 2 to 3 days, although it sometimes persists for up to 10 days. Should postpartum blues persist or worsen, a careful search should begin for symptoms of major depression, which can occur in almost 20 percent of puerperal women (Josefsson and associates, 2001). If severe, prompt consultation is carried out as discussed in [Chapter 55](#) (see p. 1243). Similarly, suicidal or infanticidal ideation is dealt with emergently. Postpartum depression is likely to recur and warrants pharmacological prophylaxis beginning late in future pregnancies.

Abdominal Wall Relaxation. If the abdomen is unusually flabby or pendulous, an ordinary girdle is often satisfactory. An abdominal binder does not help restore the figure. Exercises to restore abdominal wall tone may be started any time after vaginal delivery and as soon as abdominal soreness diminishes after cesarean delivery.

Diet. There are no dietary restrictions for women who have been delivered vaginally. Two hours after a normal vaginal delivery, if there are no complications likely to necessitate an anesthetic, the woman should be allowed to eat if she desires. The diet of lactating women, compared with that consumed during pregnancy, should be increased in calories and protein, as recommended by the Food and Nutrition Board of the National Research Council (see [Chap. 8](#), p. 215). If the mother does not breast feed, dietary requirements are the same as for a nonpregnant woman.

It is standard practice in our hospitals to continue iron supplementation for at least 3 months after delivery and to check the hematocrit at the first postpartum visit.

Thromboembolic Disease. Perhaps half of thromboembolic events associated with pregnancy develop in the puerperium (see [Chap. 47](#), p. 1074). The frequency of deep venous thrombosis and pulmonary embolism complicating pregnancy and the puerperium has decreased in recent years.

Obstetrical Neuropathies. Pressure on branches of the lumbosacral nerve plexus during labor may be manifest by complaints of intense neuralgia or cramplike pains extending down one or both legs as soon as the head begins to descend into the pelvis. If the nerve is injured, pain continues after delivery and may be accompanied by variable degrees of sensory loss or muscle paralysis supplied by the damaged nerve.

In a recent investigation from Northwestern University, Wong and colleagues (2003) carefully evaluated 6048 consecutively delivered women and found that 56 (approximately 1 percent) had a confirmed new nerve injury. Lateral femoral cutaneous neuropathies were the most common (24), followed by femoral neuropathies (14). A motor deficit was present in a third of injuries. Nulliparity and prolonged second-stage of labor were independent risk factors for nerve injury. In addition, women with injuries pushed longer in the semi-Fowler position than those without. The median duration of symptoms was 2 months, with a range of 2 weeks to 18 months.

Pelvic Joint Separation. Separation of the symphysis pubis or one of the sacroiliac synchondroses during labor may be followed by pain and marked interference with locomotion ([Fig. 30-3](#)). Estimates of their frequency vary widely from 1 in 600 to 1 in 30,000 deliveries (Reis and colleagues, 1932; Taylor and Sonson, 1986). In our experience, it is rare and likely closer to the latter incidence. When symptomatic, the onset of pain is acute at delivery. Treatment is generally conservative, with rest in a lateral decubitus position and an appropriately fitted pelvic binder. Occasionally, surgery may be necessary when symphyseal separation is more than 4 cm (Kharrazi and colleagues, 1997). Recurrence is more than 50 percent in subsequent pregnancy, and Culligan and associates (2002) recommend that cesarean delivery be considered.

Immunizations. The D-negative woman who is not isoimmunized and whose infant is D-positive is given 300 µg of anti-D immune globulin shortly after delivery (see [Chap. 29](#), p. 671). Women who are not already immune to rubella or rubeola measles are excellent candidates for combined measles-mumps-rubella vaccination before discharge (see [Chap. 8](#), p. 221). Unless contraindicated, a diphtheria-tetanus toxoid booster injection is also given to postpartum women prior to discharge at

Parkland Hospital.

Time of Discharge. Following vaginal delivery, if there are *no complications*, hospitalization is seldom warranted for more than 48 hours. Before discharge, the woman should receive instructions concerning the anticipated normal physiological changes of the puerperium, including lochia patterns, weight loss from diuresis, and when to expect milk let-down. She also should receive instructions concerning what to do if she becomes febrile, has excessive vaginal bleeding, or develops leg pain, swelling, or tenderness. Any shortness of breath or chest pain warrants immediate concern.

EARLY DISCHARGE. As discussed in [Chapter 1](#) (see p. 6), the issue of third-party payers dictating inappropriately short lengths of hospital stays following labor and delivery is now regulated by Federal law. In 2003, the norms are hospital stays of up to 48 hours following uncomplicated vaginal delivery and up to 96 hours following uncomplicated cesarean delivery (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2002). In 1980, the average stay for a woman following vaginal delivery was 3.2 days. This had decreased to 1.7 days by 1995 but had increased to 2.1 days by 1997 (Neergaard, 1999). Despite this, in 1997, 25 percent of new mothers (951,000) had a hospital stay of 1 day or less. This seems acceptable if this was indeed their choice.

Contraception. During the hospital stay, a concerted effort should be made to provide family planning education. Steroidal contraception and its effects on lactation are discussed on page 701. Other forms of contraception are discussed in [Chapter 32](#) and sterilization procedures in [Chapter 33](#).

If the woman does not nurse her child, menses usually return within 6 to 8 weeks. At times, however, it is difficult clinically to assign a specific date to the first menstrual period after delivery. A minority of women bleed small to moderate amounts intermittently, starting soon after delivery. Using histological dating of the endometrium, Sharman (1966) identified ovulation as early as 42 days after delivery. In another study, Perez and associates (1972) did so as early as 36 days. **The necessity for instituting contraceptive techniques for sexually active women is obvious.**

Ovulation is much less frequent in women who breast feed compared with those who do not. In fact, menses may not appear if the infant is nursed, but great variations are observed. In lactating women, the first period may occur as early as the second or as late as the 18th month after delivery. Campbell and Gray (1993) analyzed daily urine specimens to determine ovulation in 92 women. The results of this detailed description of the return of ovarian activity in breast feeding and non-breast feeding women are shown in [Figure 30-4](#). Clearly, there is delayed resumption of ovulation with breast feeding, although as already emphasized, early ovulation is not precluded by persistent lactation. Other findings included the following:

1. Resumption of ovulation was frequently marked by return of normal menstrual bleeding.
2. Breast feeding episodes lasting 15 minutes seven times each day delayed resumption of ovulation.
3. Ovulation can occur without bleeding.
4. Bleeding can be anovulatory.
5. The risk of pregnancy in breast feeding women was approximately 4 percent per year.

Figure 30-3. Radiograph demonstrating a 5-cm diastasis of the symphysis pubis immediately after vaginal delivery. The woman was treated conservatively with analgesics and ambulation as tolerated. Pain diminished over several weeks, and 6 months later, a repeat radiograph showed a 1-cm symphyseal gap. (From Chang and Markman, 2002, with permission.)

Figure 30-4. Cumulative proportion of breast feeding and non-breast feeding women who ovulated during the first 60 weeks following delivery. (From Campbell and Gray, 1993, with permission.)

HOME CARE

Coitus. There is no definite time after delivery when coitus should be resumed. Resumption of intercourse *too soon* may prove to be unpleasant, if not frankly painful, due to incomplete healing of the episiotomy or lacerations. Glazener (1997) surveyed resumption of sexual activity in 1075 British women and found that 70 percent had intercourse within 8 weeks of delivery. The median interval between delivery and intercourse was 5 weeks, but the range was 1 to 12 weeks. Difficulties frequently cited for not resuming intercourse included concern about perineal pain, bleeding, and fatigue. In another survey, Barrett and colleagues (2000) reported that almost 90 percent of 484 primiparous women had resumed sexual activity by 6 months. Although 65 percent of these reported problems, only 15 percent discussed these with a professional.

The best rule to follow is one of common sense. After 2 weeks, coitus may be resumed *based on the patient's desire and comfort*. The women should be advised that breast feeding causes a prolonged period of suppressed estrogen production with a resulting vaginal atrophy and dryness. Such a physiological state results in decreased vaginal lubrication during sexual arousal.

Infant Follow-up. Arrangements must be made to ensure that the neonate receives appropriate follow-up care. Any neonate discharged early should be term, normal, and have stable vital signs. All laboratory studies should be normal, including direct Coombs test, bilirubin, hemoglobin and hematocrit, and blood glucose. Abnormal maternal serological tests (e.g., syphilis and hepatitis B surface antigen) should be addressed. Initial hepatitis B vaccine should be administered, and all screening tests

required by law should be performed. These always include testing for hypothyroidism and phenylketonuria (PKU). If subsequent PKU retesting is required after the neonate has consumed milk, the mother must be so instructed. Finally, the importance of subsequent neonatal and well-baby care should be stressed and an emphasis placed on infant immunizations.

Late Maternal Morbidity. MacArthur and colleagues (1991), while studying the possible sequelae of labor epidural analgesia, uncovered a vast reservoir of previously unreported morbidity of considerable duration in puerperal women. Following this report, Glazener and co-workers (1995) surveyed health problems in 1249 British mothers after discharge and up to 18 months. Of these, only 3 percent required readmission to the hospital within 8 weeks of delivery. Importantly, 87 percent had milder health problems during the first 8 weeks and 76 percent continued to have a variety of problems for up to 18 months ([Table 30-4](#)). Although these self-perceived health problems declined with time, indicating return of health, they did so more slowly than generally assumed.

More recently, Lydon-Rochelle and colleagues (2001) and Thompson and colleagues (2002) reported similar findings. Clearly, maternal morbidity following delivery is extensive and heretofore underrecognized. Glazener and co-authors (1995) called for a greater awareness of the needs of puerperal women as they convalesce from birthing. As an example of how these needs can be met, Chiarelli and Cockburn (2002) designed a randomized trial of a multifaceted intervention, which included pelvic floor exercises. They reported that this intervention was effective in reducing the prevalence and severity of postpartum urinary incontinence.

Follow-up Care. By the time of discharge, women who had a normal delivery and puerperium can resume most activities, including bathing, driving, and household functions. Jimenez and Newton (1979) tabulated cross-cultural information on 202 societies from different international geographic regions. Postnatally, most societies did not restrict maternal work activity, and about half expected a return to full duties within 2 weeks. Tulman and Fawcett (1988) reported, however, that only half of women regained their usual level of energy by 6 weeks postpartum. Women who delivered vaginally were twice as likely to have normal energy levels at this time compared with those with a cesarean delivery. Ideally, the care and nurturing of the neonate should be provided by the mother with ample help from the father. For the mother to provide this care, her presence at home with the infant precludes her early return to full-time work or school.

Women discharged after delivery at Parkland Hospital are given an appointment for follow-up examination during the third postpartum week. This has proven quite satisfactory to identify any abnormalities of the later puerperium as well as to initiate contraceptive practices. Lu and Prentice (2002) have shown that women who did not receive prenatal care are three to four times more likely to miss postpartum appointments than other women.

Estrogen plus progestin oral contraceptives started at this time have proven to be effective without increased morbidity. Moreover, the frequencies of uterine perforation, expulsions, and pregnancies when intrauterine devices were inserted during the third week postpartum were no greater than when the devices were inserted 3 months or more postpartum. Family planning techniques, sterilization, and follow-up care are further discussed in [Chapters 32](#) and [33](#).

31. Puerperal Infection

INTRODUCTION

Puerperal infection is a general term used to describe any bacterial infection of the genital tract after delivery. The earliest reference to puerperal infection is found in the works of Hippocrates from the 5th century bc. In his discussion of women, *De Muliebrum Morbis*, he described the condition and attributed it to retention of bowel contents. The history of puerperal infection is discussed in greater detail in previous editions of *Williams Obstetrics*.

Along with preeclampsia and obstetrical hemorrhage, puerperal infection formed the lethal triad of causes of maternal deaths for many decades of the 20th century. Fortunately, because of effective antimicrobials, maternal deaths from infection have become uncommon. Berg and associates (2003) reported results from the Pregnancy Mortality Surveillance System, which contained 3201 maternal deaths in the United States from 1991 through 1997. Infection made up 13 percent of pregnancy-related deaths and was the fifth leading cause of death.

PUERPERAL FEVER

Puerperal morbidity is defined as follows: a *temperature of 38.0^oC (100.4^oF) or higher, which occurs on any 2 of the first 10 days postpartum, exclusive of the first 24 hours, and which is taken orally by a standard technique at least four times daily.* This definition developed from one proposed by the Joint Committee on Maternal Welfare, which was originally convened in 1919 (Mussey and colleagues, 1935).

Differential Diagnosis. A number of factors can cause fever in the puerperium. **Most persistent fevers after childbirth are caused by genital tract infection.** Filker and Monif (1979) reported that only about 20 percent of women febrile within the first 24 hours after giving birth vaginally were subsequently diagnosed with pelvic infection. This was in contrast to 70 percent of those undergoing cesarean delivery. It must be emphasized that a high-spiking fever (39^oC or higher) developing within the first 24 hours after giving birth may be associated with virulent pelvic infection caused by either group A or group B streptococcus. Other causes of puerperal fever that should be considered include breast engorgement; respiratory complications such as atelectasis, aspiration pneumonia, and bacterial pneumonia; acute pyelonephritis; and thrombophlebitis. About 15 percent of all women develop postpartum fever from breast engorgement. This rarely exceeds 39^oC in the first few postpartum days and usually lasts no longer than 24 hours.

Atelectasis or alveolar collapse is caused by hypoventilation and is best prevented by patients coughing and deep breathing on a fixed schedule following surgery. Fever associated with atelectasis is thought to be due to infection by normal flora that proliferate distal to obstructing mucous plugs. Following aspiration, women most often develop a high-spiking fever, varying degrees of wheezing, and in most instances, obvious signs of hypoxemia (Marik, 2001).

Acute pyelonephritis has a variable clinical picture, and in puerperal women, the first sign of renal infection may be a temperature elevation, followed later by costovertebral angle tenderness, nausea, and vomiting. Minor temperature elevations in puerperal women may also occasionally be caused by superficial or deep venous thrombosis of the legs.

UTERINE INFECTION

Postpartum uterine infection has been called variously *endometritis*, *endomyometritis*, and *endoparametritis*. Because infection actually involves not only the decidua but also the myometrium and parametrial tissues, the preferred term is *metritis with pelvic cellulitis*.

PREDISPOSING FACTORS. The route of delivery is the single most significant risk factor for the development of uterine infection (Burrows and associates, 2004; Koroukian, 2004).

Vaginal Delivery. Compared with cesarean delivery, metritis following vaginal delivery is relatively uncommon. A 6-month survey during 1987 of nearly 5000 women whose infants were delivered vaginally at Parkland Hospital showed that only 1.3 percent received treatment for metritis. When data from women at high risk—defined by prolonged membrane rupture and labor, multiple cervical examinations, and internal fetal monitoring—were analyzed separately, the incidence of metritis after vaginal delivery was nearly 6 percent. If there is intrapartum chorioamnionitis, the risk of infection increases to 13 percent (Maberry and colleagues, 1991). Other risk factors for metritis following vaginal delivery include any adverse perinatal outcomes, such as stillbirth, low birthweight, preterm delivery, and serious neonatal morbidity (Libombo and colleagues, 1994).

Cesarean Delivery. The incidence of metritis following surgical delivery varies with socioeconomic factors, and over the years this has been altered substantively by almost universal use of perioperative antimicrobials. For all women at high risk for pelvic infection following cesarean delivery, the American College of Obstetricians and Gynecologists (2003) recommends single-dose perioperative antimicrobial prophylaxis. This is discussed in [Chapter 25](#) (see p. 603). **The use of single-dose perioperative antimicrobial prophylaxis has done more to decrease the incidence and severity of postcesarean delivery pelvic infections than any other innovation in the past 25 years.**

Prior to use of antimicrobial prophylaxis, Sweet and Ledger (1973) reported an overall incidence of uterine infection of 13 percent among affluent women who underwent cesarean delivery at the University of Michigan Hospital. In indigent women who underwent cesarean delivery at Wayne County Hospital, however, they reported the incidence to be 27 percent. Cunningham and associates (1978) found an overall incidence of about 50 percent in women who had cesarean delivery at Parkland Hospital. Important risk factors for infection included long duration of labor and membrane rupture, multiple cervical examinations, and internal fetal monitoring.

Women with all of these factors, whose infants were delivered for cephalopelvic disproportion, and who were not given

perioperative prophylaxis had an incidence of serious pelvic infection that was nearly 90 percent (DePalma and colleagues, 1982; Gilstrap and Cunningham, 1979). Women readmitted to the hospital with postpartum metritis or wound infections are more likely to have undergone cesarean delivery (Lydon-Rochelle and colleagues, 2000).

Other Risk Factors. It is generally accepted that pelvic infection is more common in women of lower socioeconomic status compared with middle- or upper-class patients. Goldenberg and associates (1996) have shown significant racial differences in vaginal colonization with potential pathogens during pregnancy, although the precise reasons for these differences are unclear.

The evidence that *anemia* increases the likelihood of infection is not conclusive (Cook and Lynch, 1986). The results obtained from both animal and in vitro experiments are consistent with the view that iron-deficiency anemia does not predispose to infection, and some believe it may actually prevent infection. The role of *nutrition* in the genesis of infection is also unclear, although cell-mediated immunity is impaired in malnourished laboratory animals.

Bacterial colonization of the lower genital tract with certain microorganisms— for example, group B streptococcus, *Chlamydia trachomatis*, *Mycoplasma hominis*, and *Gardnerella vaginalis*— has been associated with an increased risk of postpartum infection. Watts and associates (1990) and Jacobsson and colleagues (2002) reported an increased risk of puerperal metritis in women with bacterial vaginosis. Andrews and colleagues (1995) reported that colonization of intact membranes with *Ureaplasma urealyticum* significantly increased the risk for infection following cesarean delivery.

Other factors that are associated with an increased risk of infection include cesarean delivery for *multifetal gestation* (Suonio and Huttunen, 1994), *young maternal age and nulliparity* (Magee and associates, 1994), *prolonged labor induction* (Tran and colleagues, 2000), *obesity* (Myles and co-workers, 2002), and *meconium-stained amniotic fluid* (Jazayeri and colleagues, 2002).

BACTERIOLOGY. Most female pelvic infections are caused by bacteria indigenous to the female genital tract. Over the past decade, there have been reports of group A β -hemolytic streptococcus causing toxic shock-like syndrome and life-threatening infection (Nathan and Leveno, 1994; Stefonek and colleagues, 2001). Anteby and associates (1999) reported experiences with 47 women who had group A streptococcal infections and found that a prominent risk factor was prematurely ruptured membranes. In two reviews of group A infections by Crum (2002) and Udagawa (1999) and their colleagues, women in whom infection was manifested before, during, or within 12 hours of delivery had a mortality of almost 90 percent, and associated fetal mortality was more than 50 percent.

Common Pathogens. Bacteria commonly responsible for female genital tract infections are listed in [Table 31-1](#). Usually multiple species of bacteria are isolated. Although they are typically considered to be of relatively low virulence, they may become pathogenic within hematomas and devitalized tissue.

Although the cervix routinely harbors such bacteria, the uterine cavity is usually sterile before rupture of the amniotic sac. As the consequence of labor and delivery and associated manipulations, the amniotic fluid and perhaps the uterus commonly become contaminated with anaerobic and aerobic bacteria ([Fig. 31-1](#)). Gilstrap and Cunningham (1979) cultured amniotic fluid obtained at cesarean delivery in women in labor with membranes ruptured more than 6 hours. They identified anaerobic and aerobic organisms in 63 percent of cultured samples, anaerobes alone in 30 percent, and aerobes alone in 7 percent. Predominant anaerobic organisms were *Peptostreptococcus* and *Peptococcus* species in 45 percent, *Bacteroides* species in 9 percent, and *Clostridium* species in 3 percent. Gram-positive aerobic cocci also were common; *Enterococcus* was isolated in 14 percent, and group B streptococcus in 8 percent. *Escherichia coli* comprised 9 percent of isolates. An average of 2.5 organisms was identified from each specimen. Sherman and co-workers (1999) showed that bacterial isolates at cesarean delivery correlated with those taken at 3 days postpartum when metritis had developed.

The role of other organisms such as chlamydia, mycoplasma, and ureaplasma in the etiology of these infections is unclear. Chlamydial infections have been implicated in late-onset, indolent metritis (Ismail and associates, 1985). In addition, Jacobsson and colleagues (2002) reported that the risk of puerperal infection was tripled in a group of Swedish women with bacterial vaginosis in early pregnancy.

Bacterial Cultures. Routine pretreatment genital tract cultures are of little clinical utility, and they add significantly to hospitalization costs. Similarly, the utility of routine blood cultures is questionable. In two earlier studies, blood cultures were positive in only 13 percent of women at Parkland Hospital and 24 percent at Los Angeles County Hospital who had postcesarean pelvic infections (Cunningham and colleagues, 1978; DiZerega and co-workers, 1979). From Finland, Kankuri and associates (2003) described culture-proven bacteremia in 5 percent of almost 800 women with suspected puerperal sepsis.

Figure 31-1. Pathogenesis of metritis following cesarean delivery. (Data from Gilstrap and Cunningham, 1979.)

PATHOGENESIS. Puerperal infection following vaginal delivery primarily involves the placental implantation site and the decidua and adjacent myometrium. The pathogenesis of uterine infection following cesarean delivery is that of an infected surgical incision (see [Fig. 31-1](#)). Bacteria that colonize the cervix and vagina gain access to amniotic fluid during labor, and postpartum they invade devitalized uterine tissue. Parametrial cellulitis next follows with infection of the pelvic retroperitoneal fibroareolar connective tissue. The process is usually limited to the paravaginal tissue and rarely extends deeply into the pelvis.

CLINICAL COURSE. Fever is believed proportional to the extent of infection and sepsis syndrome (see [Chap. 42](#), p. 993). **Fever is the most important criterion for the diagnosis of postpartum metritis.** Temperature commonly exceeds 38 to 39st°C. Chills may accompany fever and suggest bacteremia, which is documented in 10 to 20 percent of women with pelvic infection following cesarean delivery. Women usually complain of abdominal pain, and parametrial tenderness is elicited on abdominal and bimanual examination. Although an offensive odor may develop, many women have foul-smelling lochia without evidence for infection. Other infections, notably those due to group A β -hemolytic streptococci, are frequently associated with scanty, odorless lochia. Leukocytosis may range from 15,000 to 30,000 cells/ μ L. The average increase in the leukocyte count postpartum following cesarean delivery is 22 percent (Hartmann and co-workers, 2000).

TREATMENT

Management. If mild metritis develops after the woman has been sent home following vaginal delivery, treatment with an oral antimicrobial agent is usually sufficient. For moderate to severe infections, however, including those following cesarean delivery, intravenous therapy with a broad-spectrum antimicrobial regimen is indicated. Improvement follows in 48 to 72 hours in nearly 90 percent of women treated with one of several regimens. Persistence of fever after this interval mandates a careful search for causes of refractory pelvic infection. Complications of metritis that cause persistent fever despite appropriate therapy include a parametrial phlegmon or an area of intense cellulitis, a surgical incisional or pelvic abscess, an infected hematoma, and septic pelvic thrombophlebitis. In our experience, persistent fever is seldom due to antimicrobial-resistant bacteria or to drug side effects.

Typically, a patient is discharged after she has been afebrile for at least 24 hours. Further oral antimicrobial therapy is not needed (Dinsmoor and colleagues, 1991; French and Smaill, 2002).

Specific Antimicrobial Treatment. Although therapy is empirical, initial treatment following cesarean delivery is directed against most of the mixed flora that typically cause puerperal infections (see [Table 31-1](#)). Such broad-spectrum antimicrobial coverage is often not necessary to treat infection following vaginal delivery, and as many as 90 percent of these infections respond to regimens such as ampicillin plus gentamicin. In contrast, anaerobic coverage must be included for infections following cesarean delivery ([Table 31-2](#)).

In 1979, DiZerega and colleagues compared the effectiveness of clindamycin plus gentamicin with penicillin G plus gentamicin for treatment of pelvic infections following cesarean delivery. Women given the *clindamycin-gentamicin* regimen had a 95-percent rate of infection resolution, and this regimen now is considered by most to be the standard by which others are measured (French and Smaill, 2002). Because enterococcal infections may persist despite this standard therapy, many add ampicillin to the clindamycin-gentamicin regimen, either initially or if there is no response by 48 to 72 hours (Walmer and colleagues, 1988). Over the past decade, vancomycin-resistant enterococcal infections have been problematic in nonobstetrical units (Murray, 2000).

Brumfield and colleagues (2000) at the University of Alabama at Birmingham reaffirmed the efficacy of this standard regimen given to 322 women with postcesarean pelvic infections. Many authorities recommend that serum gentamicin levels be periodically monitored. Liu and associates (1999) compared multiple-dosing versus once-daily dosing with gentamicin and found that both provided adequate serum levels. Fortunately, once-daily dosing avoids the need for routine measurement. In a randomized clinical trial, Livingston and colleagues (2003) reported that once-daily dosing with both clindamycin and gentamicin had a similar cure rate as every eight-hour dosing with the two drugs. Because of the potential for nephrotoxicity and ototoxicity with gentamicin in the event of diminished glomerular filtration, some clinicians have recommended a combination of clindamycin and a second-generation cephalosporin to treat such women. Others have recommended a combination of clindamycin and aztreonam, a monobactam compound with activity similar to the aminoglycosides.

The spectra of β -lactam antimicrobials include activity against many anaerobic pathogens. Some examples include cephalosporins such as cefoxitin, cefotetan, cefotaxime, as well as extended-spectrum penicillins such as piperacillin, ticarcillin, and mezlocillin. Beta-lactam antimicrobials are inherently safe, and except for allergic reactions, are free of major toxicity. The β -lactamase inhibitors, clavulanic acid, sulbactam, and tazobactam, have been combined with ampicillin, amoxicillin, ticarcillin, and piperacillin to extend their spectra.

Metronidazole has superior in vitro activity against most anaerobes. This agent given with ampicillin and an aminoglycoside provides coverage against most organisms encountered in serious pelvic infections.

Imipenem is a carbapenem that has broad-spectrum coverage against the majority of organisms associated with metritis. It is used in combination with *cilastatin*, which inhibits renal metabolism of imipenem. Although this combination is effective in most cases of metritis, it seems reasonable from both a medical and an economical standpoint to reserve it for more serious infections.

PREVENTION OF INFECTION

The use of perioperative antimicrobial prophylaxis has remarkably reduced the rate of postoperative infection after cesarean delivery. For example, prophylactic antimicrobials reduce the rate of puerperal endometritis by 70 to 80 percent (Chelmw and colleagues, 2001; Smaill and Hofmeyr, 2003). The observed benefit applies to both elective and nonelective cesarean delivery and also includes a reduction in abdominal incisional infections. Single agents such as ampicillin and first-generation cephalosporins are ideal prophylactic antimicrobials (American College of Obstetricians and Gynecologists, 2003). Using broad-spectrum agents or a multiple-dose regimen gives no apparent benefit (Hopkins and Smaill, 2003).

A number of locally applied antimicrobials have been studied to assess their efficacy in preventing puerperal infection. Vaginal irrigation with *chlorhexidine* intrapartum did reduce the incidence of postpartum infection (Rouse and colleagues, 1997; Sweeten and associates, 1997). Conversely, *povidone-iodine* irrigation before cesarean delivery had no effect on the incidence of fever, metritis, or abdominal incisional infection (Reid and associates, 2001). In a blinded, placebo-controlled trial, Pitt and colleagues (2001) applied 5 grams of *metronidazole gel* preoperatively as an adjunct to perioperative antimicrobial prophylaxis. They reported reduction in the rate of metritis from 17 to 7 percent with the gel but no effect on febrile morbidity

or abdominal incisional infections.

Mercer and associates (1997) for the Maternal-Fetal Medicine Network reported no change in the incidence of pelvic infections in women with preterm prematurely ruptured membranes who were given antimicrobials. These patients received either placebo or intravenous ampicillin plus erythromycin for 48 hours followed by oral amoxicillin plus erythromycin for 5 days. A secondary analysis of the Network study was done by Andrews and associates (2003b) to evaluate the effectiveness of antimicrobial treatment to prevent preterm delivery in fetal fibronectin-positive women. They reported that metronidazole plus erythromycin decreased postpartum metritis in these women from 5.2 percent to 2.1 percent.

Antepartum treatment of asymptomatic women with vaginal infections has not been shown to prevent postpartum metritis. In another Network study, Carey and associates (2000) reported that antepartum treatment of asymptomatic bacterial vaginosis had no effect on puerperal infection rates. Similarly, Klebanoff and colleagues (2001) found that metritis rates in women treated for second-trimester asymptomatic *Trichomonas vaginalis* infection were no different from those in placebo-treated women.

Limited data hinder the assessment of surgical techniques to decrease puerperal infections. Lifting the uterus out of the abdomen to close the uterine incision did not appreciably affect the infection rate in two small studies (Enkin and Wilkinson, 2002). In another small study, changing of gloves by the surgical team after placental delivery reduced postcesarean wound infections (Ventolini and associates, 2004). No differences in postoperative infection rates were found between single- versus two-layer uterine closure at cesarean delivery (Hauth and colleagues, 1992). Similarly, uterine or abdominal incisional infection rates were not affected by peritoneal closure or nonclosure at cesarean delivery (Tulandi and Al-Jaroudi, 1993; Wilkinson and Enkin, 1999b). Finally, although closure of the subcutaneous tissue in obese women decreased separation, it had no effect on rates of hematoma formation or infection (Chelmow, 2004; Magann, 2002; Naumann, 1995, each with their colleagues).

COMPLICATIONS OF PELVIC INFECTIONS

In more than 90 percent of women, metritis responds to treatment within 48 to 72 hours. In the other women, several complications may arise.

WOUND INFECTIONS. The incidence of abdominal incisional infections following cesarean delivery ranges from 3 to 15 percent, with an average of about 6 percent (Chaim and associates, 2000; Owen and Andrews, 1994). When prophylactic antimicrobials are given, however, the incidence is less than 2 percent (Andrews and colleagues, 2003a). According to Soper and co-workers (1992), wound infection is the most common cause of antimicrobial failure in women treated for metritis. Risk factors for wound infections include obesity, diabetes, corticosteroid therapy, immunosuppression, anemia, and poor hemostasis with hematoma formation.

Abdominal incisional abscesses that develop following cesarean delivery usually cause fever on about the fourth postoperative day. In many cases, these are preceded by uterine infection, and fever persists from the first or second postoperative day or later. Wound erythema and drainage may also be present. Organisms causing these infections are usually the same as those isolated from amniotic fluid at cesarean delivery, but hospital-acquired pathogens may also be the cause (Emmons and colleagues, 1988; Owen and Andrews, 1994). Treatment includes antimicrobials and surgical drainage, with careful inspection to ensure that the abdominal fascia is intact.

Wound Dehiscence. Disruption or dehiscence refers to separation of the fascial layer. McNeeley and colleagues (1998) studied 8590 women undergoing cesarean delivery at Hutzel Hospital in Detroit. They reported fascial dehiscence in about 1 in 300 operations. Most disruptions manifest on about the fifth postoperative day with serosanguineous discharge. Two thirds of 27 fascial dehiscences identified by McNeeley and associates (1998) were associated with concurrent fascial infection and tissue necrosis.

Fascial dehiscence is a serious complication. Treatment includes secondary closure of the incision in the operating room with adequate anesthesia.

Necrotizing Fasciitis. Fortunately, this most serious of wound infections is rare, but it is associated with high mortality. These infections may involve abdominal incisions following cesarean delivery, or may complicate episiotomy or perineal lacerations. As the name implies, there is significant tissue necrosis. Of the risk factors for fasciitis summarized by Owen and Andrews (1994), three of these — *diabetes*, *obesity*, and *hypertension* — are relatively common in pregnant women. Infections may be caused by a single virulent bacterial species such as group A β -hemolytic streptococcus, but more commonly they are polymicrobial. Synnestvedt and colleagues (2003) have described a woman with streptococcal puerperal sepsis who developed a recurrent genital infection with group A organisms. Occasionally, necrotizing infections are caused by rarely encountered pathogens (Barber and Swygert, 2000; Swartz, 2004).

At the University of Alabama, Goepfert and colleagues (1997) reviewed their experiences from 1987 through 1994. There were nine cases of necrotizing fasciitis in 5048 cesarean deliveries — a rate of 1.8 per 1000 cesarean deliveries. In two women, the infection was fatal. In a report from Brigham and Women's and Massachusetts General Hospitals, Schorge and colleagues (1998) described five women with fasciitis following cesarean delivery. None of these women had predisposing risk factors, and none died.

Zimbelman and co-workers (1999) reported preliminary observations that clindamycin given with a β -lactam antimicrobial may be the most effective regimen. Adjunctive treatment includes promptly debriding wide margins of the fascial incision. With extensive resection, synthetic mesh may be required to close the fascial incision (Gallup and Meguiar, 2004; McNeeley and associates, 1998).

PERITONITIS. Occasionally, this condition is encountered following cesarean delivery complicated by metritis with uterine incisional necrosis and dehiscence. It also is sometimes seen in women with a prior cesarean delivery who then give birth vaginally. Likewise, a parametrial or adnexal abscess may rupture and produce generalized peritonitis.

With puerperal peritonitis, abdominal rigidity may not be prominent because of abdominal wall laxity from pregnancy. Pain may be severe. Frequently, the first symptoms of peritonitis are those of *adynamic ileus*, which usually is absent or mild following uncomplicated cesarean delivery. Thus, there may be marked bowel distention. If the infection begins in an intact uterus and extends into the peritoneum, antimicrobial treatment alone usually suffices. Conversely, peritonitis caused by uterine incisional necrosis or by a bowel lesion is treated surgically along with antimicrobial therapy.

ADNEXAL INFECTIONS. An *ovarian abscess* rarely develops from puerperal infection, presumably from bacterial invasion through a rent in the ovarian capsule (Wetchler and Dunn, 1985). The abscess is usually unilateral, and women typically present 1 to 2 weeks after delivery.

PARAMETRIAL PHLEGMON. In some women in whom metritis develops following cesarean delivery, parametrial cellulitis is intensive and forms an area of induration, termed a *phlegmon*, within the leaves of the broad ligament (Fig. 31-2). These infections should be considered when fever persists longer than 72 hours despite intravenous antimicrobial therapy (DePalma and colleagues, 1982). Kindig and colleagues (1998) described such an infection with uterine dehiscence occurring 6 weeks postpartum.

Areas of parametrial cellulitis are more often unilateral, and they frequently may remain limited to the base of the broad ligament. If, however, the inflammatory reaction is more intense, cellulitis extends along natural lines of cleavage. The most common form of extension is laterally, along the base of the broad ligament, with a tendency to extend to the lateral pelvic wall. Posterior extension may involve the rectovaginal septum, producing a firm mass posterior to the cervix.

Severe cellulitis of the uterine incision may cause necrosis and separation. Extrusion of purulent material commonly leads to peritonitis. Because puerperal metritis with cellulitis is typically a retroperitoneal infection, evidence of peritonitis suggests the possibility of uterine incisional necrosis, or less commonly a bowel injury or other lesion.

In most women with a phlegmon, clinical improvement follows continued treatment with a broad-spectrum antimicrobial regimen. These women usually remain febrile for 5 to 7 days, and in some cases even longer. Absorption of the induration may take several days to weeks. Surgery is reserved for women in whom uterine incisional necrosis is suspected. Hysterectomy and surgical debridement are usually difficult, and there is often appreciable blood loss. In rare cases, uterine debridement and resuturing of the incision are feasible (Rivlin and colleagues, 2004). Frequently, the cervix and lower uterine segment are involved with an intensive inflammatory process that extends to the pelvic sidewall to encompass one or both ureters. The adnexa are seldom involved, and one or both ovaries usually may be conserved.

Imaging Studies. Brown and colleagues (1991) described the use of computed tomography (CT) in 74 women to assess pelvic infections refractory to standard antimicrobial therapy. They found at least one abnormal radiological finding in 75 percent of these women. Twickler and associates (1997) found that CT with contrast and magnetic resonance imaging (MRI) effectively image ovarian vein thrombosis. Using MRI, Maldjian and associates (1999) studied 50 women with persistent low-grade fever following cesarean delivery. Bladder flap hematomas were found in two thirds, three women had parametrial edema, and two had a pelvic hematoma.

Sometimes evidence of uterine incisional dehiscence can be detected using CT scanning (Figs. 31-3 and 31-4). These radiological findings must be interpreted within the clinical context, because apparent uterine incisional defects can be visualized after cesarean delivery with no other evidence of infection or other complications (Twickler and colleagues, 1991).

Figure 31-2. Parametrial phlegmon. Cellulitis in the right parametrium begins adjacent to the cesarean incision and extends to the pelvic sidewall. On pelvic examination, the phlegmon is palpable as a firm, three-dimensional mass.

Figure 31-3. Pelvic computed tomography scan of dehiscence caused by infection of a vertical cesarean incision. Endometrial fluid (*small black arrows*) communicates with parametrial fluid (*curved white arrows*) through the uterine dehiscence (*black arrow*). A dilated bowel loop (b) is adjacent to the uterus on the left. (Courtesy of Dr. Diane Twickler.)

Figure 31-4. Pelvic computed tomography scan showing necrosis of the uterus with gas in the myometrium (*arrows*) and a large right-sided parametrial abscess (a). (Courtesy of Dr. Diane Twickler.)

PELVIC ABSCESS. Rarely, a parametrial phlegmon suppurates, forming a fluctuant broad ligament mass that may point above the Poupart ligament. These abscesses may dissect anteriorly and be amenable to needle drainage directed by CT imaging (see Fig. 31-4). Occasionally they dissect posteriorly to the rectovaginal septum, where surgical drainage is easily affected by colpotomy incision. *Psoas abscess* may rarely follow delivery. Its management includes antimicrobial therapy, and percutaneous drainage may be required (Shahabi and colleagues, 2002).

Sometimes following cesarean delivery, collections of blood develop under the bladder flap (Maldjian and associates, 1999). Hematomas may also form in the broad ligament near the uterine incision. These may become infected and require drainage.

SEPTIC PELVIC THROMBOPHLEBITIS. The pathogenesis of suppurative pelvic thrombophlebitis was described by Collins and colleagues (1951) in 70 women cared for from 1937 through 1946 at Charity Hospital in New Orleans. Septic embolization was common in these women and caused a third of maternal deaths during that period. With the advent of antimicrobial therapy, the mortality and need for surgical therapy for these infections diminished.

Pathogenesis. Puerperal infection may extend along venous routes and cause thrombosis (Fig. 31-5). Lymphangitis often coexists. The ovarian veins may then become involved because they drain the upper uterus, which most often includes veins draining the placental site. The experiences of Witlin and Sibai (1995) and Brown and colleagues (1999) suggested that puerperal septic thrombophlebitis is likely to involve one or both ovarian venous plexuses (Fig. 31-6). In a fourth of women, the clot extends into the inferior vena cava, and occasionally extends to the renal vein.

Incidence. During a five-year survey of 45,000 women who gave birth at Parkland Hospital, Brown and associates (1999) found an incidence of septic pelvic thrombophlebitis of 1:9000 with vaginal and 1:800 with cesarean delivery. The overall incidence of 1:3000 deliveries was similar to the 1:2000 reported by Dunnihoo and colleagues (1991).

Clinical Findings. Women with septic pelvic thrombophlebitis usually display some clinical improvement of their pelvic infection following antimicrobial treatment. However, they continue to have fever. They may be asymptomatic except for chills. In some women, the cardinal symptom of ovarian vein thrombophlebitis is pain typically manifested on the second or third postpartum day (Munsick and Gillanders, 1981). In some cases, a tender mass is palpable lateral to the uterine cornu on either side.

Diagnosis is usually by either pelvic CT or MRI (Sheffield and Cunningham, 2001; Twickler and associates, 1997). Using both imaging techniques, Brown and co-workers (1999) found that 20 percent of 69 women with metritis who had fever despite 5 days of appropriate therapy had was confirmed septic pelvic phlebitis. Before imaging methods were available to confirm venous involvement, the *heparin challenge test* was advocated. Supposedly after intravenous heparin was given, if the temperature decreased, this was taken as diagnostic of pelvic phlebitis and heparin treatment was continued (Josey and Stagers, 1974). This was subsequently disproved by Brown and colleagues (1986), who showed that despite withholding heparin from 6 of 11 women with CT-proven pelvic thrombophlebitis, continued antimicrobial therapy resulted in clinical resolution. Conversely, in the five women given heparin along with antimicrobial drugs, the prolonged febrile course was not appreciably abbreviated. Witlin and Sibai (1995) reported similar observations in 11 women with ovarian vein thrombophlebitis. In a follow-up randomized study of 14 women by Brown and associates (1999), the addition of heparin to antimicrobial therapy for septic pelvic thrombophlebitis did not hasten recovery or improve outcome.

Figure 31-5. Routes of extension of septic pelvic thrombophlebitis. Any pelvic vessels and the inferior vena cava may be involved: (1) inferior vena cava; (2) right ovarian vein; (3) left ovarian vein; (4) clot in right common iliac vein which extends from the uterine and internal iliac veins and into the inferior vena cava; (5) left uterine vein; and (6) right ureter.

Figure 31-6. Pelvic computed tomography scan with intravenous and oral contrast shows enlargement of right ovarian vein, low density of lumen, and vessel-wall enhancement consistent with thrombosis (arrow). Associated low-density area surrounding vein represents perivascular edema. (From Brown and colleagues, 1999, with permission.)

INFECTIONS OF THE PERINEUM, VAGINA, AND CERVIX

Episiotomy infections are not often encountered because the operation is performed much less frequently now than in the past (see Chap. 17, p. 435). For example, Owen and Hauth (1990) described only 10 episiotomy infections among 20,000 deliveries at the University of Alabama at Birmingham. With infection, dehiscence is a concern. Ramin and colleagues (1992) reported that 0.5 percent of episiotomy wounds developed dehiscence at Parkland Hospital, and 80 percent of these were due to infection. No data suggest that dehiscence is related to faulty repair.

Serious infection is more likely in women who sustain a fourth-degree laceration. Goldaber and colleagues (1993) described 390 such women of whom 5.4 percent had morbidity; 2.8 percent had infection and dehiscence, 1.8 percent had only dehiscence, and 0.8 percent had only infection. Although life-threatening septic shock is rare, it may still occur as a result of an infected episiotomy (Soltesz and colleagues, 1999).

PATHOGENESIS AND CLINICAL COURSE. Episiotomy dehiscence is most commonly associated with infection. Other factors include coagulation disorders, smoking, and human papillomavirus infection (Ramin and Gilstrap, 1994). Local pain and dysuria, with or without urinary retention, are common symptoms. Ramin and colleagues (1992), evaluating a series of 34 women with episiotomy dehiscence, reported that the most common findings were pain (65 percent), purulent discharge (65 percent), and fever (44 percent). In extreme cases, the entire vulva may become edematous, ulcerated, and covered with exudate.

Vaginal lacerations may become infected directly or by extension from the perineum. The mucosa becomes red and swollen and may then become necrotic and slough. Parametrial extension may result in lymphangitis.

Cervical lacerations are common, and the cervix normally harbors potentially pathogenic organisms. When infected, deep lacerations often extend directly into the tissue at the base of the broad ligament, and infections may cause lymphangitis, parametritis, and bacteremia.

TREATMENT. Infected episiotomies, like other infected surgical wounds, should be treated by establishing drainage. In most cases, sutures are removed and the infected wound opened. In some women with obvious cellulitis but no purulence, broad-spectrum antimicrobial therapy with close observation is appropriate. Hauth and colleagues (1986) were the first to advocate early repair after evidence of infection subsided. Subsequently, other studies have attested to the efficacy of such practice. Hankins and co-workers (1990) described early repair of episiotomy dehiscence in 31 women. The average duration from dehiscence to episiotomy repair was 6 days. All but two women had a successful repair, and both of them developed a pinpoint rectovaginal fistula treated successfully with a small rectal flap. Ramin and colleagues (1992) reported successful early repair of episiotomy dehiscence associated with infection in 32 of 34 women (94 percent).

Technique for Early Repair. A preoperative protocol for early repair is summarized in [Table 31-3](#). **Prior to attempting early repair of episiotomy dehiscence, the surgical wound must be properly cleaned and free of infection.** As shown in [Figure 31-7](#), once the surface of the episiotomy wound is free of infection and exudate and covered by pink granulation tissue, secondary repair can be accomplished. Good tissue mobility must be accomplished, including identification and mobilization of the anal sphincter muscle. Secondary closure of the episiotomy is accomplished in layers as described for primary episiotomy closure (see [Chap. 17](#), p. 436). Postoperative care includes local wound care, low-residue diet, stool softeners that avoid diarrhea, and nothing per vagina or rectum until healed.

Figure 31-7. Dehiscence of fourth-degree episiotomy. Secondary repair is done when the wound surface is free of exudate and covered by pink granulation tissue. (From Ramin and Gilstrap, 1994, with permission.)

NECROTIZING FASCIITIS. A rare but frequently fatal complication of perineal and vaginal wound infections is deep soft tissue infection involving muscle and fascia. These may also complicate vulvar infections in diabetic and immunocompromised women but may develop in otherwise healthy women. The microbiology of these serious perineal infections appears to be similar to those that cause other pelvic infections, as well as necrotizing fasciitis of the abdominal incision described previously. Although uncommon today, Shy and Eschenbach (1979) reported that episiotomy necrotizing fasciitis was responsible for 20 percent of 15 maternal deaths in King County, Washington, in the 1970s.

Necrotizing fasciitis of the episiotomy site may involve any of the several superficial or deep perineal fascial layers, and thus it may extend to the thighs, buttocks, and abdominal wall ([Fig. 31-8](#)). Although some virulent infections, for example, from group A β -hemolytic streptococci, may develop early after delivery, these infections usually do not cause symptoms until 3 to 5 days afterward. Clinical findings vary, and it is frequently difficult to differentiate superficial perineal infections from deep fascial ones. A high index of suspicion, with surgical exploration if the diagnosis is uncertain, may be lifesaving. We aggressively pursue early exploration. Certainly, if myofasciitis progresses, the woman may become very ill from septicemia, profound hemoconcentration from capillary leakage with circulatory failure commonly occurs, and death may soon follow. Early diagnosis, surgical debridement, antimicrobials, and intensive care are of paramount importance in the successful treatment of necrotizing soft tissue infections (Gallup and Meguiar, 2004; Urschel, 1999).

Aggressive surgical treatment is indicated and includes extensive debridement of all infected tissue, leaving wide margins of healthy tissue. This may include extensive vulvar debridement with unroofing and excision of abdominal, thigh, or buttock fascia (see [Fig. 31-8](#)). **Mortality is virtually universal without surgical treatment, and it approaches 50 percent even if extensive debridement is performed.**

Figure 31-8. Necrotizing fasciitis complicating episiotomy infection. Three days postpartum this woman had severe perineal pain and edema of the episiotomy site. Prompt extensive debridement was carried out. Bacteria cultured from the infected episiotomy included *Escherichia coli*, *Streptococcus viridans*, group D streptococcus, *Corynebacterium* species, *Bacteroides fragilis*, and *Clostridium* species. Blood cultures were positive for *Bacteroides fragilis*.

TOXIC SHOCK SYNDROME

This acute febrile illness with severe multisystem derangement has a case-fatality rate of 10 to 15 percent. The illness is usually characterized by fever, headache, mental confusion, diffuse macular erythematous rash, subcutaneous edema, nausea, vomiting, watery diarrhea, and marked hemoconcentration. Renal failure followed by hepatic failure, disseminated intravascular coagulation, and circulatory collapse may follow in rapid sequence. During recovery, the rash-covered areas undergo desquamation. *Staphylococcus aureus* has been recovered from almost all afflicted persons, and a staphylococcal exotoxin, termed *toxic shock syndrome toxin-1*, causes the syndrome by provoking profound endothelial injury.

In many cases, infection is not documented, and colonization of a mucosal surface is the only finding. Nearly 10 percent of pregnant women have vaginal colonization with *S aureus*, and thus it is not surprising that the disease develops in postpartum women (Guerinot and co-workers, 1982). McGregor and colleagues (1988) have described almost identical findings in women with infection complicated by *Clostridium sordellii* colonization.

More recently, as discussed on page 713, there have been reports of *streptococcal toxic shock syndrome* associated with group A β -hemolytic streptococcal infection. Preliminary data implicate serotypes M1 and M3 as particularly virulent (Beres and

associates, 2004; Okumura and collaborators, 2004). A delay in diagnosis described by Schummer and Schummer (2002) resulted in a maternal death. Crum and colleagues (2002) reported an antepartum infection at 34 weeks' gestation causing fetal distress and neonatal death.

Principal therapy for toxic shock is supportive, while allowing reversal of capillary endothelial injury (see [Chap. 42](#), p. 994). The toxins are potent, and the mortality rate correspondingly high (Hotchkiss and Karl, 2003). In severe cases, treatment requires massive fluid replacement, mechanical ventilation with positive end-expiratory pressure (Catanzarite and associates, 2001), and renal dialysis. Antimicrobial therapy with antistaphylococcal drugs is given. With evidence for uterine infection, antimicrobial therapy must include agents used for all puerperal infections. Cases of streptococcal toxic shock syndrome often require hysterectomy.

32. Contraception

INTRODUCTION

The approach to reproductive health in the United States has often been manipulated and constrained by forces from outside the medical community. Social, religious, and political groups have been particularly intrusive and coercive in the area of family planning, although at any given time, the majority of fertile American women would prefer to avoid pregnancy. Such intrusion and coercion is almost certainly counterproductive. At least 10 states and the U.S. Congress have considered legislation requiring parental notification for prescribed contraceptives. Reddy and colleagues (2002) surveyed adolescents and found that 60 percent would stop using all sexual health care services if their parents had to be informed that they were seeking contraception. The adolescents also indicated that they would also delay testing or treatment for human immunodeficiency virus (HIV) infection and other sexually transmitted diseases if parental consent were required. Even in the United States, women are denied access to family planning services. Only in the last few years have some insurance carriers begun to cover the cost of contraceptives. In the United States, access for indigent women to reproductive services is frequently a political decision, and not a medical or even a financial one.

Fortunately, a wide variety of effective methods of regulating fertility is currently available. None is completely without side effects or categorically without danger—for example, latex condoms can initiate anaphylactic reactions. That said, **contraception poses less risk than does pregnancy** (Table 32-1). In fact, for the vast majority of women, it is safer to use contraception than it is to drive an automobile (Hatcher and colleagues, 1998).

NEED FOR CONTRACEPTION

Pregnancy rates for sexually active fertile women who do not use contraception approach 90 percent at 1 year. Because ovulation often precedes menarche, young women who do not want to be pregnant should be advised to use contraception whenever they begin sexual activity. Contraceptive advice for the woman nearing menopause is more difficult to provide because it is not easy to predict when fertility has ended. Results of a study by Metcalf (1979) indicate that *when menstruation remained regular, there was evidence of ovulation in almost every cycle*. Oligomenorrhea or increasing cycle length was associated with a diminished frequency of ovulation, but even the presence of hot flashes, amenorrhea, and elevated gonadotropin levels did not absolutely guarantee that ovulation would not occur.

CONTRACEPTIVE METHODS

Methods of variable effectiveness currently used in the United States include:

1. Oral steroidal contraceptives
2. Injected steroidal contraceptives
3. Intrauterine devices (IUDs)
4. Transdermal and transvaginal steroidal contraceptives
5. Physical, chemical, or barrier techniques
6. Preejaculatory withdrawal
7. Sexual abstinence around the time of ovulation
8. Breast feeding
9. Permanent sterilization

The most recent nationally representative data concerning contraceptive use were collected in 1995 (Fig. 32-1). Estimates of the failure rate *during the first year of use* are given in Table 32-2. Effective education, as well as motivation, can appreciably reduce the cited failure rates (Vessey and co-workers, 1982). **Elective abortion is not a contraceptive technique.** It serves, at times, as a less than ideal remedy for contraceptive failure or neglect (see Chap. 9, p. 241).

Figure 32-1. Contraceptive use in the United States circa 1995 for users aged 15 to 44. Data from Piccinino and Mosher (1998). (IUD = intrauterine device.) (From the Association of Professors of Gynecology and Obstetrics, 1999, with permission.)

HORMONAL CONTRACEPTIVES

These contraceptives are currently available in a wide variety of oral, injectable, transdermal (patch), and transvaginal (ring) forms. Oral contraceptives are a combination of estrogen and progestin (*the pill*) or progestin only (*mini-pill*). The other forms contain progestins alone or a combination of estrogen and progestin. Unfortunately, no reliable reversible male hormonal contraceptives have been developed (Kamischke and Nieschlag, 2004).

ESTROGEN PLUS PROGESTIN CONTRACEPTIVES. Oral contraceptives are the most frequently used method of hormonal contraception, and an almost bewildering variety are marketed (Table 32-3). Generic

formulations have become more popular. In 1990, generic oral contraceptives accounted for only 3.6 percent of prescriptions, and by 2001, this value had increased to 18 percent (Keith and associates, 2001). Oral contraceptives typically consist of a combination of an estrogen and a progestational agent taken daily for 3 weeks and then omitted for 1 week, during which time there is withdrawal uterine bleeding. Longer durations of active hormone administration, designed to minimize the number of menses, have been investigated (Miller and Hughes, 2003). One such extended-cycle product is Seasonale— is now available in the United States.

Mechanisms of Action. The contraceptive actions of combination oral contraceptives are multiple, but the most important effect is to prevent ovulation by suppression of hypothalamic gonadotropin-releasing factors, which in turn prevents pituitary secretion of follicle-stimulating and luteinizing hormones. Progestin prevents ovulation by suppressing luteinizing hormone. Progestins also thicken cervical mucus, thereby retarding sperm passage. In addition, they render the endometrium unfavorable to implantation. Estrogen prevents ovulation by suppressing the release of follicle-stimulating hormone. A second effect is to stabilize the endometrium, which prevents breakthrough bleeding.

The net effect of estrogen and progestin is extremely effective ovulation suppression, inhibition of sperm migration through cervical mucus, and creation of an unfavorable endometrium for implantation. Thus, estrogen plus progestin containing combined oral contraceptives provide virtually absolute protection against conception *when taken daily for 3 out of every 4 weeks*.

Pharmacology. In the United States, the only *estrogens* available are *ethinyl estradiol* and much less commonly, its 3-methyl ether, *mestranol*. The exact conversion factor for potency of ethinyl estradiol to mestranol is not definitely known but probably is 1.2 to 1.5.

Almost all currently available *progestins* are 19-nortestosterone derivatives, and one is an aldosterone derivative. Although individual progestins are initially chosen because of their progestational potencies, they are often compared and prescribed based on their presumed estrogenic, antiestrogenic, and especially their androgenic effects. However, a scientific basis for such selective prescribing is lacking (Wallach and Grimes, 2000). All progestins reduce serum free testosterone, and they inhibit 5 α -reductase and the conversion of testosterone to its active metabolite, dihydrotestosterone. Thus, all progestins are expected to have salutary effects on androgen-related conditions such as acne (Wallach and Grimes, 2000).

Dosage. Since oral contraceptives have come into use, their estrogen and progestin contents have been reduced remarkably. This is important, because most adverse effects are dose related. The lowest acceptable dose is governed by the ability to prevent unacceptable breakthrough bleeding. Although daily estrogen content varies from 20 to 50 μ g of ethinyl estradiol, the vast majority contain 35 μ g or less (see [Table 32-3](#)). The amount of progestin varies in two ways:

1. Among older, well-evaluated formulations, the progestin dose remains constant during the cycle (*monophasic*).
2. In some newer preparations, the progestin (and in some, the estrogen) dose varies during the cycle (*biphasic and triphasic*).

Ideally, women should begin taking combination oral contraceptives on the first day of a menstrual cycle, in which case a back-up contraceptive method is unnecessary. The more traditional "Sunday start" during the first week of a menstrual cycle necessitates use of a back-up method for 1 week to ensure that conception does not occur.

To obtain maximum effectiveness and promote regular use, most suppliers offer dispensers that provide 21 sequentially and individually wrapped, color-coded tablets containing hormones, followed by seven inert tablets of another color. It is important for maximum contraceptive efficiency and for peace of mind that each woman adopt an effective scheme for ensuring daily (or nightly) self-administration. One technique is to keep a pill supply and toothbrush close to each other and to swallow a pill at tooth brushing time, either in the morning or in the evening. If one dose is missed, contraception is likely not minimized if higher-dose monophasic estrogen and progestin pills are used. It may be desirable to double the next dose to minimize breakthrough bleeding and to stay on schedule. If several doses are missed, or lower-dose pills are used, an effective barrier technique should be used. The pill may be restarted after withdrawal bleeding. Alternatively, a new pack can be started with a barrier method as back-up for a week. If withdrawal bleeding does not occur, the woman should continue to take the pills but seek medical attention to rule out pregnancy.

PHASIC PILLS. These preparations were developed in an effort to reduce the amount of total progestin per cycle without sacrificing contraceptive efficacy or cycle control. The reduction is achieved by beginning with a low dose of progestin and increasing it later in the contraceptive cycle. Theoretically, the lower total dose should result in fewer progestin-attributable metabolic changes and adverse side effects. Similarly, the estrogen dose may be kept constant or increased later in the cycle. In all phasic preparations, estrogen doses are between 20 and 40 μ g of ethinyl estradiol (see [Table 32-3](#)).

Despite the advantages, both theoretical and actual, there are distinct disadvantages to triphasic formulations. These include confusion due to multicolored pills and breakthrough bleeding or spotting, which likely is increased compared with that of monophasic pills (Hatcher and colleagues, 1990; Woods and associates, 1992).

Drug Interactions. Oral contraceptives interfere with the actions of some drugs ([Table 32-4](#)). Conversely, some drugs decrease the contraceptive effectiveness of combination oral contraceptives ([Table 32-5](#)). Phenytoin and rifampin are believed to increase breakthrough bleeding and reduce contraceptive effectiveness of pills containing less than 50 μ g of ethinyl estradiol (Hatcher and colleagues, 1998). Although package inserts for some broad-spectrum antimicrobials such as ampicillin and tetracycline warn that they may reduce the efficacy of oral contraceptives, this likely is not true. Because vitamin C competes for active sulfate in the intestinal wall and increases the bioavailability of ethinyl estradiol, erratic use of vitamin C can result in breakthrough bleeding (Kubba and Guillebaud, 1993).

Safety. In general, oral contraceptives have proven to be safe for most women (see [Table 32-1](#)). The possibility of adverse effects from "the pill" has received so much attention for so long that the major negative health consequence among users may be the anxiety created by unbalanced media coverage! Unfortunately, physicians as well as the public are frequently confused by the many and often conflicting reports.

Beneficial Effects. When used reliably, there is no more effective rapidly reversible form of contraception than the combined

estrogen plus progestin pill (see [Table 32-2](#)). Some of the associated noncontraceptive benefits include the following:

1. Increased bone density.
2. Reduced menstrual blood loss and anemia.
3. Decreased risk of ectopic pregnancy.
4. Improved dysmenorrhea from endometriosis.
5. Fewer premenstrual complaints.
6. Decreased risk of endometrial and ovarian cancer.
7. Reduction in various benign breast diseases.
8. Inhibition of hirsutism progression.
9. Improvement of acne.
10. Prevention of atherogenesis.
11. Decreased incidence and severity of acute salpingitis.
12. Improvement in rheumatoid arthritis.

Possible Adverse Effects. A number of metabolic changes, often qualitatively similar to those of pregnancy, have been identified in women taking oral contraceptives. For example, total plasma thyroxine and thyroid-binding proteins are elevated. Plasma cortisol concentration increases with a nearly comparable increase in transcortin. Therefore, it is extremely important that these pregnancy-like effects be considered when evaluating laboratory tests in women using oral contraceptives.

LIPOPROTEINS AND LIPIDS. In general, the combination oral contraceptives increase triglycerides and total cholesterol. Estrogen decreases the concentration of low-density lipoprotein cholesterol and increases high-density lipoprotein cholesterol. Some progestins cause the reverse (Stadel, 1981). Despite this, the clinical consequences of these perturbations have almost certainly been overstated (Hoppe, 1990). Oral contraceptives are not atherogenic, and their impact on lipids, irrespective of individual formulation, is inconsequential for the vast majority of women (Wallach and Grimes, 2000).

CARBOHYDRATE METABOLISM. With older, higher-dose oral contraceptive formulations, deterioration in glucose tolerance, mediated principally by the progestin component, was a legitimate clinical concern. With current formulations, such concern is no longer warranted (Speroff and Darney, 2001). In healthy women, large prospective studies with long-term follow-up have demonstrated that oral contraceptives do not increase the risk of diabetes (Hannaford and Kay, 1989; Rimm and associates, 1992). Moreover, oral contraceptives do not increase the risk that women with a history of gestational diabetes will progress to adult-onset diabetes (Kjos and colleagues, 1998).

PROTEIN METABOLISM. Estrogens increase hepatic production of a variety of *globulins*. Increased *angiotensinogen* production appears to be dose related, and its conversion by renin to angiotensin I has been suspected to be associated with so-called "pill-induced hypertension" (see p. 733). Fibrinogen, and likely factors II, VII, IX, X, XII, and XIII, are increased in direct proportion to estrogen dose (Comp, 1996; Kaunitz, 1999b). The relationship of these increased clotting factors to venous and arterial thrombosis is discussed on page 732. The incidence of both forms of thrombosis appears to be estrogen-dose related (Mann, 1982).

LIVER DISEASE. Cholestasis and *cholestatic jaundice* are uncommon complications in users of oral contraceptives. If they develop, signs and symptoms clear when the medication is stopped. It appears that oral contraceptives may accelerate the development of gallbladder disease in women who are susceptible, but there is no overall increased long-term risk (Royal College of General Practitioners, 1982; Strom and colleagues, 1986). There is no reason to withhold oral contraceptives from women who have recovered from viral hepatitis.

NEOPLASIA. A stimulatory effect on some cancers is always a concern with female sex steroids. However, a number of studies indicate that it is unlikely that hormonal contraception causes cancer (Cancer and Steroid Hormone Study, 1986, 1987a, 1987b; Prentice and Thomas, 1987; Schlesselman and colleagues, 1988). In fact, a protective effect against ovarian and endometrial cancer has been shown in these studies. However, there are conflicting reports concerning the risks of premalignant and malignant changes of the liver, cervix, and breast.

In the past, use of estrogen plus progestin contraceptives has been linked circumstantially with the development of *hepatic focal nodular hyperplasia* and benign hepatic *adenoma*. These associations were observed in women using high-dose estrogen-containing formulations for prolonged periods. Reassuringly, large studies conducted in women taking contemporary low-dose oral contraceptives do not support an association with hepatic adenoma (Hannaford and associates, 1997; Heinemann and colleagues, 1998). Finally, an association between prolonged oral contraceptive use and *hepatocellular carcinoma* in women younger than 50 years of age was reported (Neuberger and associates, 1986). In contrast, conclusions derived from a multicenter World Health Organization study (1989) support the view that there is no increased risk.

There is a correlation between the risk of *cervical dysplasia* and oral contraceptive use, and the risk of invasive cancer increases after 5 years of use (Thomas and Ray, 1996; Vessey and associates, 1983b; Zondervan and co-workers, 1996). It is unclear if these associations have a causal basis. For example, oral contraceptive users are not protected from exposure to human papillomavirus, and they are more frequently screened cytologically for cervical cancer. Thus, they may be more likely to be diagnosed with dysplasia (Butterworth and associates, 1992).

In addition, it is unclear whether oral contraceptives contribute to the development of *breast cancer*. In the largest study,

there was no increased risk for breast cancer among oral contraceptive users (Cancer and Steroid Hormone Study, 1986). Moreover, risk did not vary according to preparation or duration of use. The Collaborative Group on Hormonal Factors in Breast Cancer (1996) reanalyzed data from 54 studies that included more than 53,000 women with breast cancer and more than 100,000 without the disease. The study found a small but significantly increased relative risk of breast cancer in women who were taking combined oral contraceptives or who had stopped within 10 years. The relative risk was 1.24 for current users, 1.16 for those 1 to 4 years after stopping, and 1.07 for those 5 to 9 years after stopping. The risk was not influenced by age at first use, duration of use, family history of breast cancer, first use prior to pregnancy, or the dose or type of hormone used. The lack of correlation with these factors calls into question the causal nature of the association. In this study, tumors associated with oral contraceptive use tended to be less aggressive and to be detected at an earlier stage, a finding consistent with the possibility that the increased risk of breast cancer was due to greater surveillance among users. In a recent case-control study (4575 cases and 4682 controls), there was no relationship between either current or past oral contraceptive use and breast cancer (Marchbanks and colleagues, 2002).

NUTRITION. Aberrations in the levels of several *nutrients*, similar to changes induced by normal pregnancy, have been described for women who use oral contraceptives. Lower plasma levels in users compared with those in nonusers have been described by some investigators for ascorbic acid, folic acid, vitamin B₆ (pyridoxine), vitamin B₁₂, niacin, riboflavin, and zinc. An adequate diet, however, is sufficient prophylaxis against any detrimental deficiency (Mooij and co-workers, 1991).

CARDIOVASCULAR EFFECTS. A number of infrequent but significant cardiovascular risks are associated with hormonal contraceptive use.

The risk of *deep vein thrombosis* and *pulmonary embolism* is increased in women who use oral contraceptives (Realini and Goldzieher, 1985; Stadel, 1981). These risks clearly are estrogen-dose related and are decreased with the use of formulations containing 20 to 35 µg of ethinyl estradiol (Westhoff, 1998). Mishell (2000) performed a scholarly evidence-based review of the risks of venous thromboembolism in oral contraceptive users. After analyzing six epidemiologically sound studies, he estimated that the risk is increased three- to fourfold in users but not in former users. Importantly, the baseline risk is low—about 1 per 10,000 woman-years—and thus the incidence with oral contraceptives of 3.0 to 4.0 per 10,000 woman-years is still quite low. Once again, the risk is clearly lower than the incidence of 5.7 per 10,000 woman-years estimated for pregnancy.

The enhanced risk of thromboembolism appears to decrease rapidly once the contraceptive is stopped. Women who develop thromboembolism while taking estrogen-containing contraceptives, however, also appear to be at increased risk during pregnancy and the early puerperium. Those most at risk for venous thrombosis and embolism include women with protein C or S deficiencies (Comp, 1996). Other clinical factors that increase the risk of venous thrombosis and embolism are hypertension, obesity, diabetes, smoking, and a sedentary lifestyle (Hatcher and associates, 1998). Contraceptive use during the month before a major operative procedure appears to increase the risk of postoperative thromboembolism significantly.

According to the World Health Organization Collaborative Study (1998), *ischemic and hemorrhagic strokes* are uncommon in nonsmoking women younger than 35 years of age. Their incidence is 10 and 24 events per 1 million woman years, respectively. The earlier reports by Lidegaard and colleagues (1993, 1998) that the risk of cerebral thromboembolism was increased in women using low-dose estrogen contraceptives stimulated a number of focused studies. At least five subsequent studies concluded that the use of such compounds by healthy, nonsmoking women is not associated with an increased risk of thrombotic or hemorrhagic strokes (Mishell, 2000; Petitti and co-workers, 1996; Schwartz and associates, 1998; World Health Organization Collaborative Study, 1996). Conversely, women who have hypertension, smoke, or have migraine headaches and use oral contraceptives have an increased risk of strokes (Mishell, 2000; Schwartz and colleagues, 1998).

An association between oral contraceptives and *hypertension* was apparent by the late 1960s. Several reports appeared of the occasional woman who, while using an estrogen-progestin oral contraceptive, became overtly hypertensive. Usually blood pressure returned to normal when the medication was stopped. Oral contraceptives, presumably the estrogen component, were shown to increase plasma angiotensinogen (renin substrate) to levels near those found in normal pregnancy. Although the great majority of women using oral contraceptives demonstrate these changes, most do not become hypertensive. Current low-dose oral contraceptive formulations rarely, if ever, cause clinically significant hypertension (Blumenstein, 1980; Chasan-Taber and colleagues, 1996; Kovacs, 1986; Nichols, 1993, and their co-workers). Most certainly, the development of hypertension during pregnancy does not preclude subsequent use of oral contraceptives.

Oral contraceptives containing low-dose estrogen and low-androgenic progestins are not associated with an increased risk of *myocardial infarction* in nonsmokers (Lewis, 1996; Mishell, 2000; Petitti, 1998; Sidney, 1996, 1998; World Health Organization Collaborative Study, 1997, and all their colleagues). In fact, the American College of Obstetricians and Gynecologists (2000b) states there is no contraindication to oral contraceptives in nonsmoking women older than 35 years of age. Finally, the Food and Drug Administration (FDA) revised their labeling of oral contraceptives to remove restrictions for nonsmoking women older than 40 years of age. It is important to recognize that smoking is an independent risk factor for myocardial infarction, and that smoking and oral contraceptives act synergistically to increase this risk, especially beyond 35 years of age (Craft and Hannaford, 1989).

Oral contraceptives have no predictable effect on the frequency or severity of *migraine headaches*. They may, however, add to the already increased risk of stroke faced by women with migraine headaches and neurological symptoms or aura (Chang and associates, 1999). Therefore, most clinicians prefer to avoid combined oral contraceptives in such women, although in certain women, the risks of pregnancy may warrant their use. For other women with migraine headaches, a progestin-only pill may be more appropriate, because it does not increase the risk of stroke (Speroff and Darney, 2001).

Effects on Reproduction. *Postpill amenorrhea* after combination contraception discontinuation is likely reflective of a preexisting problem (Wallach and Grimes, 2000). At least 90 percent of women who previously ovulated regularly begin to do so within 3 months after discontinuance of oral contraceptives.

There is no evidence that estrogen-progestin preparations are teratogenic. Rothman and Louik (1978) and Savolainen and associates (1981) found no increase in major malformations in infants whose mothers had used oral contraceptives during conception. Similarly, Lammer and Cordero (1986) found no association between major malformations and contraceptive exposure in early pregnancy (see [Chap. 14](#), p. 361).

LACTATION. Data concerning the interaction of combination oral contraceptives and lactation are limited. Very small quantities of the hormones are excreted in breast milk, but no adverse effects on infants have been noted. There is concern that these agents reduce the volume of breast milk, although a recent review confirms the ambiguity of these data (Truitt and colleagues, 2003). Because progestin-only oral contraceptives have little effect on lactation and provide excellent contraception, they are preferred for up to 6 months in women who are breast feeding their infants exclusively (see p. 746). A woman who is breast feeding only intermittently should use effective contraception beginning as soon as 3 weeks postpartum (Kaunitz, 1997).

Other Effects. *Cervical mucorrhea*, likely due to cervical ectopy, is fairly common in response to the estrogen component (Critchlow and colleagues, 1995). The mucus at times may be irritating to the vagina and vulva. *Vaginitis* or *vulvovaginitis*, especially that caused by *Candida*, also may develop.

Hyperpigmentation of the face and forehead (also known as *chloasma*) is more likely in women who demonstrated such a change during pregnancy (see [Chap. 56](#), p. 1250). This is seen much less commonly with the transition to low-dose estrogen formulations. As discussed, low-dose oral contraceptives may improve acne.

Uterine *myomas* do not increase in size with oral contraceptive use (Wise and colleagues, 2004). Although *weight gain* is reported as a side effect by some women, low-dose oral contraceptives do not promote an appreciable weight increase (Gallo and associates, 2004). Low-dose estrogen formulations are not associated with *depression*, and indeed, may cause it to improve (Goldzeiher and Zamah, 1995; Vessey and associates, 1985).

Multiple studies have been conducted to evaluate the relationship between the use of oral and injectable contraceptives and the risk of *HIV infection*. Although most of these have methodological limitations, on balance they do not suggest increased risk (Stephenson, 1998). On the other hand, hormonal contraception does not *prevent* the transmission of HIV infection or any other viral infection.

Risk of Death. Mortality associated with oral contraceptives is very low if the woman is younger than 35 years of age, has no systemic illness, and does not smoke (see [Table 32-1](#)). Porter and associates (1987) reported only one death attributed to oral contraceptive use in nearly 55,000 woman-years from the Group Health Cooperative of Puget Sound.

Postpartum Use. Women who do not breast feed, especially those who have undergone an abortion, may ovulate before 6 weeks after pregnancy (see [Chap. 30](#), p. 701). There is an advantage, therefore, to starting oral contraceptives before the traditional "6-week postpartum check." On the other hand, increased risks of adverse effects, especially venous thromboembolism, might be anticipated from use of estrogen-progestin contraceptives earlier in the puerperium. The use of 35 μg or smaller estrogen doses has reduced this risk greatly. Thus far, in our now extensive experience in which oral contraceptives have been started during the third week postpartum, there has been no evidence of increased morbidity or mortality.

Contraindications. It could be argued that because pregnancy is usually more dangerous than oral contraception, then no contraindication to oral contraceptives should be considered absolute. Pragmatically, considering the multiplicity of alternative contraceptive methods, if a contraindication listed in [Table 32-6](#) is present, combined oral contraceptive pills should probably not be prescribed or used.

Transdermal Administration. The recently approved patch (Evra) is applied to the buttocks, upper outer arm, lower abdomen, or upper torso but avoiding the breasts ([Fig. 32-2](#)). It delivers 150 μg of the progestin norelgestromin and 20 μg of ethinyl estradiol daily. A new patch is applied weekly for 3 weeks, followed by a patch-free week to allow for withdrawal bleeding.

Audet and co-workers (2001) found that the patch was slightly more effective than a low-dose oral contraceptive in preventing pregnancy—1.2 versus 2.2 pregnancies per 100 woman-years. Although the patch was well tolerated and safe overall, dysmenorrhea, breast tenderness, and breakthrough bleeding in the first two cycles were more frequent in the women who received the patch. Almost 5 percent of the patches required replacement for either complete (1.8 percent) or partial (2.8 percent) detachment. In about 3 percent of women, the patch caused an application site reaction severe enough to limit usage.

Data suggest that woman who weigh 90 kg or more who use the patch are at increased risk for contraceptive failure. Of 15 failures reported, five women met this threshold, even though they constituted less than 3 percent of the study population (Zieman and associates, 2002). This translates to a relative risk of failure of 16 or more. This may also reflect a phenomenon general to hormone contraceptives as Holt and colleagues (2002) reported that obesity increases the chance of failure.

Therefore, the patch seems to provide an effective alternative hormonal contraceptive method for women who prefer weekly application rather than daily dosing, find the transdermal method of delivery acceptable, and weigh less than 90 kg. Its metabolic and physiological effects should be substantively the same as with low-dose oral contraceptives, although the accumulated experience with the patch is small compared with that of combination oral contraceptives.

Transvaginal Administration. In 2001, the FDA approved for use an intravaginal hormonal contraceptive ring (NuvaRing). This flexible polymer ring has an outer diameter of 54 mm and an inner diameter of 50 mm ([Fig. 32-3](#)). The core of this ring contains ethinyl estradiol and the progestin etonogestrel, which are released at rates of 15 μg and 120 μg per day, respectively. Although this release results in systemic hormone levels lower than comparable low-dose oral contraceptive formulations, ovulation inhibition is complete (Mulders and Dieben, 2001). The ring is highly effective, and in one study, the failure rate was 0.65 per 100 woman-years (Roumen and colleagues, 2001).

The ring is placed within 5 days of the onset of menses and is removed after 3 weeks of use for 1 week to allow withdrawal bleeding. Breakthrough bleeding is uncommon. Almost 20 percent of women and 35 percent of men reported being able to feel the ring during intercourse. If this is bothersome, the ring may be removed for intercourse but should be replaced within 3 hours. Before dispensing, the rings are refrigerated, and once dispensed, their shelf life is 4 months (Burkman, 2002).

PROGESTATIONAL CONTRACEPTIVES

Oral Progestins. So-called *mini-pills* are oral progestin-only contraceptives that are taken daily. Unlike combined oral contraceptives, they do not reliably inhibit ovulation. Rather, their effectiveness depends more on alterations in cervical mucus and effects on the endometrium. Because the mucus changes do not last longer than 24 hours, mini-pills should be taken at the same time every day to be maximally effective. These contraceptives have not achieved widespread popularity because of a much higher incidence of irregular bleeding and a somewhat higher pregnancy rate than combined contraceptives (see [Table 32-2](#)). Improved effectiveness has been reported for married and, in a progressive fashion, older women (Guillebaud, 1985).

BENEFITS. Progestin-only pills have minimal if any effect on carbohydrate metabolism or coagulation, and they do not cause or exacerbate hypertension. They may be ideal for some women who are at increased risk of cardiovascular complications. This includes women with a history of thrombosis, hypertension, or migraine headaches, or who are older than 35 years of age and who smoke. The mini-pill is often an excellent choice for lactating women. In combination with breast feeding, it is virtually 100 percent effective for up to 6 months and does not impair milk production (Betrabet and colleagues, 1987; Shikary and associates, 1987).

DISADVANTAGES. The major drawback of progestin-only pills is contraceptive failure. With these failures, there is a relative increase in the proportion of ectopic pregnancies (Sivin, 1991). Irregular uterine bleeding is another distinct disadvantage and may manifest as amenorrhea, spotting, breakthrough bleeding, or prolonged periods of amenorrhea or menorrhagia. Functional ovarian cysts develop with a greater frequency in women using these agents, although they do not usually necessitate intervention.

A distinct disadvantage is that these contraceptives must be taken at the same or nearly the same time daily (Guillebaud, 1985). **If a progestin-only pill is taken even 4 hours late, a back-up form of contraception must be used for the next 48 hours.** Also, their effectiveness is decreased by the medications shown in [Table 32-7](#). Women taking any of these medications should not use this form of contraception. Finally, unlike combined oral contraceptives, the mini-pill does not improve acne and may even worsen it in some women.

CONTRAINDICATIONS. Progestin-only pills are contraindicated in women with unexplained uterine bleeding, especially in older women.

Injectable Progestin Contraceptives. Depot medroxyprogesterone acetate (Depo-Provera) and norethindrone ethanolate (Norgest) have been used effectively worldwide for many years. Depo-Provera was approved for contraceptive use in the United States in 1992. Norgest is not yet available. The mechanisms of action of both drugs are multiple and similar to those for oral administration. They include ovulation inhibition, increased viscosity of cervical mucus, and stimulation of an endometrium unfavorable for ovum implantation (Mishell, 1996).

Depot medroxyprogesterone is injected deeply into the upper outer quadrant of the buttock without massage to ensure that the drug is released slowly. The usual dose is 150 mg every 90 days. An additional contraceptive method should be used for at least 2 weeks after the initial injection.

BENEFITS AND DISADVANTAGES. Injected progestins have contraceptive effectiveness comparable with or better than combined oral contraceptives, a long duration of action, and minimal to no impairment of lactation (American College of Obstetricians and Gynecologists, 2000a). Iron-deficiency anemia is less likely in long-term users, probably as a result of amenorrhea which develops after 5 years in 80 percent of women (Gardner and Mishell, 1970).

The principal disadvantages of depot progestins include irregular menstrual bleeding and prolonged anovulation after discontinuation, resulting in delayed fertility resumption. Cromer and associates (1994) reported that one fourth of women discontinued its use in the first year because of irregular bleeding. After the injections are stopped, one fourth of women do not resume regular menses for up to 1 year (Gardner and Mishell, 1970).

The reported risks of breast cancer are conflicting. Skegg and colleagues (1995) pooled the results of the New Zealand and World Health Organization case-control studies. These studies included almost 1800 women with breast cancer and 14,000 controls. Within the first 5 years of use, the contraceptive was associated with a twofold risk of cancer, but overall the risk was not increased. Cervical and hepatic malignancy does not appear to be increased, and the risk of ovarian and endometrial cancers is decreased (Earl and David, 1994; Kaunitz, 1996). The risk of cervical carcinoma in situ may be increased (Thomas and colleagues, 1995).

Although weight gain is often attributed to Depo-Provera, conclusive evidence is lacking (Mainwaring, 1995; Moore, 1995; Taneepanichskul, 1998, and their associates). Breast tenderness is reported by some users, as is depression, although a causal link for the latter has not been demonstrated.

In long-term users of depot medroxyprogesterone, loss of bone mineral density is a potential problem (Scholes and colleagues, 1999). This concern is probably most relevant for teenagers because bone density increases most rapidly from 10 to 30 years of age (Cromer and colleagues, 1996; Sulak and Kaunitz, 1999). Reassuringly, bone loss appears to be reversible after discontinuation of therapy (Cundy and colleagues, 1994).

Progestin Implants (Norplant System). This system provides levonorgestrel in six silastic containers that are implanted subdermally. Its contraceptive effectiveness persists for 60 months, at which point the system should be removed (Hatcher and colleagues, 1998). Despite the effectiveness, safety, and patient satisfaction with this excellent contraceptive, its use waned dramatically in the United States after becoming the target of personal injury lawyers. Based on spurious allegations such as "illness" related to the silicone in the rods, a climate of litigation developed around this system, and currently, it is no longer available. A fund has been established by the manufacturer to ensure medical access for removal.

INJECTABLE MEDROXYPROGESTERONE ACETATE/ESTRADIOL CYPIONATE. This agent, marketed under the trade name Lunelle, contains 25 mg of medroxyprogesterone acetate plus 5 mg of estradiol cypionate (Kaunitz, 1999a). One injection is given monthly. Oettinger and associates (2005) described preliminary good results with subcutaneously implanted estradiol pellets (25 mg) in various numbers and norethindrone-induced withdrawal bleeding.

Mechanism of Action. The drug inhibits ovulation and suppresses endometrial proliferation (Aedo and co-workers, 1985). Estradiol values reach a peak level by 3 to 4 days postinjection and then decline, leading to withdrawal bleeding 20 to 25 days after injection (Garceau and colleagues, 2000).

Effectiveness. Only six method failures in 70,000 woman-years of use have been reported (Hall and co-workers, 1994). This is an effectiveness similar to that seen following female sterilization procedures.

Advantages and Disadvantages. Return to fertility after discontinuation is more rapid compared with depot progestins. Almost 85 percent of women who attempt pregnancy conceive within 12 months of discontinuation (Kaunitz, 1999a). Breakthrough bleeding occurs less often, but amenorrhea is more frequent than with oral contraceptives (Garceau and colleagues, 2000). After 3 months, bleeding irregularities appear to be less common than with depot progesterone injections (Kaunitz, 1999a).

Monthly injections are a drawback for some women. The interval between injections should not exceed 33 days. Other effects are similar to those for depot medroxyprogesterone injections (Cuong and My Huong, 1996; Sang and colleagues, 1995; World Health Organization, 1988, 1993). Because of its estrogen component, Lunelle is likely to decrease lactation, and depot progestin may be a better choice for the woman who is breast feeding. Injectable estrogen-progestin contraception may promote weight gain. In one comparative trial, combination oral contraceptives were associated with no weight gain at one year, compared with 2 to 8 lb with Lunelle (Kaunitz and colleagues, 1999).

Metabolic Effects. Perturbations in the coagulation system with Lunelle are minimal and likely of no clinical consequence. There have been no reports of stroke, thromboembolic events, anaphylaxis, or myocardial infarction (Kaunitz, 1999a). Although slight variations in lipid values have been reported, they have not been clinically important (Nelson, 2000). No studies of bone density have as yet been reported.

Contraindications. These are similar to those for combined oral contraceptives as shown in [Table 32-6](#). Although still FDA-approved, this method has not been available in the United States since late 2002 because of manufacturing problems.

MECHANICAL METHODS OF CONTRACEPTION

INTRAUTERINE DEVICES. At one time in the United States, approximately 7 percent of sexually active women used an intrauterine device (IUD) for contraception. The two devices currently approved for use in this country are shown in [Figure 32-4](#). Unwanted pregnancies during the first year of perfect use are 0.6 percent for the copper-containing ParaGard T 380A and 0.1 percent for the levonorgestrel-containing Mirena. Respective typical failure rates are 0.8 percent and 0.1 percent.

With new information on safety, the IUD is once again gaining in popularity for several reasons:

1. Both ParaGard and Mirena are "use and forget" effective reversible contraceptive methods that do not have to be replaced for 10 and 5 years, respectively.
2. It is now better established that the major actions of IUDs are contraceptive, not abortifacient.
3. The risk of pelvic infections is markedly reduced with the currently used monofilament string and with techniques to ensure safer insertion.
4. The risk of an associated ectopic pregnancy has been clarified. Specifically, the contraceptive effect decreases the absolute number of ectopic pregnancies by about 50 percent compared with that of women not using contraception (World Health Organization, 1985, 1987). With failure, however, pregnancy is more likely to be ectopic (Furlong, 2002).
5. Legal liability appears to be less because the FDA currently classifies available IUDs as drugs (Mishell and Sulak, 1997). As such, the manufacturers must provide product information to be read by women prior to insertion. Signed consent forms that include a reasonable list of risks and benefits are also required.

Types of Intrauterine Devices. IUDs that are *chemically inert* are composed of a nonabsorbable material, most often polyethylene, and impregnated with barium sulfate for radiopacity. IUDs that are *chemically active* have continuous elution of

copper or a progestational agent. At the present time, only chemically active IUDs are available.

LEVONORGESTREL DEVICE (MIRENA). This device releases levonorgestrel into the uterus at a relatively constant rate of 20 µg/day, which reduces the systemic effects of the progestin. It is a T-shaped polyethylene structure that has its stem wrapped with a cylinder of polydimethylsiloxane/levonorgestrel mixture (see [Fig. 32-4](#)). A permeable membrane surrounds the mixture to regulate the rate of hormone release.

COPPER DEVICE (PARAGARD T 380A). This device is composed of polyethylene and barium sulfate. The stem is wound with 314 mm² of fine copper wire, and the arms each have 33-mm² copper bracelets, thus totaling 380 mm² of copper. Two strings extend from the base of the stem (see [Fig. 32-4](#)). Originally blue, the strings are now off-white.

Mechanisms of Action. These mechanisms have not been defined precisely and are the subject of ongoing controversy. Interference with successful implantation of the fertilized ovum, which at one time was believed to be the main mode of action, is less important than prevention of fertilization (Mishell and Sulak, 1997; Stanford and Mikolajczyk, 2002). The intense local inflammatory response induced in the uterus, especially by copper-containing devices, leads to lysosomal activation and other inflammatory actions that are spermicidal (Alvarez and associates, 1988; Ortiz and Croxatto, 1987). In the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst. Finally, the endometrium is transformed into a hostile site for implantation.

In long-time users of progestin devices, the endometrium becomes atrophic. There may be a major effect in preventing fertilization by spermicidal action, speeding ovum transport through the fallopian tube, or both (Alvarez and co-workers, 1988; Ortiz and Croxatto, 1987). The progestin may interfere with sperm penetration through thickened cervical mucus, and it inhibits ovulation, but not consistently (Nilsson and colleagues, 1984).

Effectiveness. IUDs have 1-year continuation rates equal to those of oral contraceptives. This almost certainly is due to the effectiveness of IUDs and a once-only approach to contraception. Their effectiveness is similar overall to that of tubal sterilization (American College of Obstetricians and Gynecologists, 2003a). Importantly, the unintended pregnancy rate decreases progressively after the first year of use (Vessey and associates, 1983a). The levonorgestrel-containing Mirena has a typical-user failure rate of 0.1 percent, which is lower than that of the copper-containing ParaGard (Rowe, 1992).

Other Beneficial Effects. The Mirena device reduces menstrual blood loss and can even be used to treat menorrhagia. Moreover, reduced blood loss is often associated with a reduction in dysmenorrhea. Overall, despite the higher up-front costs of IUDs, extended use makes their long-term cost-effectiveness competitive with other forms of contraception. Women with contraindications to combination oral contraceptives can often use these devices. The device is also reported to reduce the incidence of pelvic infections and to be useful for women with uterine fibroids (Toivonen and associates, 1991; van den Hurk and O'Brien, 1999).

Adverse Effects. Numerous complications have been described with use of various IUDs. For the most part, however, common side effects have not been serious, and serious side effects have not been common. Moreover, with extended use and advancing user age, unintended pregnancy, expulsion, and bleeding complications decrease in frequency.

UTERINE PERFORATION AND ABORTION. The earliest adverse effects are those associated with insertion. They include clinically apparent or silent *uterine perforation*, which occurs while sounding the uterus or during insertion. Another adverse effect is *abortion of an unsuspected pregnancy*. The frequency of these complications depends on operator skill and the precautions taken to detect pregnancy. Perforations occur at a rate of approximately 1 per 1000 insertions (World Health Organization, 1987). Although devices may migrate spontaneously into and through the uterine wall, most perforations occur, or at least begin, at the time of insertion.

UTERINE CRAMPING AND BLEEDING. *Cramping* and some *bleeding* are common soon after insertion. These persist for variable periods. Cramping can be minimized by administering a nonsteroidal anti-inflammatory agent approximately 1 hour prior to insertion. The occasional increase in cramping with menses is controlled in a similar manner.

MENORRHAGIA. *Menstrual blood loss* is commonly doubled with use of the ParaGard device, and this may cause iron-deficiency anemia. Most providers measure hemoglobin concentration or hematocrit annually. Menorrhagia is a troubling side effect, and approximately 10 to 15 percent of women using the copper device have it removed because of this problem (Hatcher and associates, 1998). In contrast, the Mirena device is associated with progressive amenorrhea, which is reported by 30 percent of women after 2 years and by 60 percent after 12 years (Ronnerdag and Odland, 1999).

INFECTION. A variety of *pelvic infections*, in some cases fatal, have been described with IUDs. These include *septic abortion*, which mandates immediate curettage. *Tubo-ovarian abscesses*—sometimes unilateral—have been described. With suspected infection, the IUD should be removed, and the woman treated with effective antimicrobials. Because of the risk of severe pelvic infections and sterility, IUD use has historically been discouraged for women younger than 25 years of age or those of low parity. According to Vessey and associates (1983a), prolonged impairment of fertility is not observed after removing the device from parous women. Long-term use by nulliparous women, however, has been associated with some degree of subfertility (Doll and co-workers, 2001). Even so, nulliparous women in mutually monogamous relationships may safely use the IUD (Speroff and Darney, 2001). That said, Lee and Rubin (1988) reported that married women and those with only one sexual partner had no higher risk of developing pelvic infection than controls *after* the first 4 months of use.

The major risk of infection is at the time of insertion and does not increase with long-term use. There is a small increased risk of pelvic infection for up to the first 20 days following insertion (Farley and associates, 1992). There currently is no consensus whether antimicrobial administration at the time of insertion reduces the incidence of infection (Sinei, 1990; Walsh, 1998, and their associates). Because of this, the American College of Obstetricians and Gynecologists (2001a) does not recommend prophylaxis with insertion. Long-term use of current IUDs is associated with pelvic infection rates comparable with those associated with oral contraceptives. Any infection after 45 to 60 days should be considered sexually transmitted and appropriately treated.

Actinomyces-like structures identified in Papanicolaou smears and the prolonged use of IUDs have been linked. Fiorino (1996) cited an incidence of 7 percent of *Actinomyces* seen on cytology smears from users of IUDs compared with less than 1 percent

in nonusers. The clinical importance of this finding is not clear. In most studies, an increased prevalence of *Actinomyces israelii* or similar organisms was apparent only after several years. Women who developed a pelvic abscess caused by this organism had used the device for a mean of 8 years before symptoms developed.

In the absence of symptoms, the incidental finding of actinomyces by cytology is problematic. Because antimicrobial therapy is not effective with the IUD in place, some clinicians choose to remove the device, although there is no evidence that this prevents infection (Fiorino, 1996). Most clinicians agree, however, that if signs or symptoms of infection develop in women who harbor actinomyces, the device should be removed and antimicrobial therapy instituted.

Pregnancy with a Device In Utero. It is important to identify all pregnant women who might be using an IUD. For up to about 14 weeks, the tail of the device may be visible through the cervix, and if it can be seen, it should be removed. This action reduces subsequent complications such as late abortion, sepsis, and preterm birth. Tatum and co-workers (1976) reported the abortion rate to be 54 percent with the device left in place compared with one of 25 percent if it was promptly removed. Moreover, if the device remained, the frequency of low birthweight, chiefly from preterm delivery, was 20 percent, compared with that of about 5 percent if removed. Vessey and associates (1979) confirmed these observations. If the tail of the device is not visible, attempts to locate and remove the device may result in abortion, although some practitioners have successfully used ultrasonography to assist in the removal of devices without visible strings. After fetal viability has been reached, it is unclear whether it is better to remove an IUD in which the string is visible or leave it in place; both pro and con arguments can be made. Fetal malformations have not been reported to be increased with a device in place.

Second-trimester abortion with an IUD in place is more likely to be septic than one without an IUD (Lewit, 1970; Vessey and associates, 1974). Sepsis may be fulminant and is often fatal. Because of these risks, the woman should be offered the option of pregnancy termination. Women pregnant with a device in utero who demonstrate any evidence of uterine infection are treated with intensive antimicrobial therapy and prompt uterine evacuation. In women who give birth with a device in place, appropriate steps should be taken at delivery to identify it and ensure its removal.

Ectopic Pregnancies. Although the IUD prevents most intrauterine pregnancies, the device provides less protection against extrauterine nidation (Furlong, 2002).

Contraindications. Manufacturers' contraindications to the use of the IUD are listed in [Table 32-8](#). Because the progestin released by the Mirena device may inhibit tubal mobility, a previous ectopic pregnancy or predisposing risk factors are considered contraindications.

Procedures for Insertion. The FDA requires that before an IUD is inserted, the woman must be given a brochure detailing the side effects and apparent risks associated with its use. Most devices have a special inserter, usually a sterile graduated plastic tube into which the device is drawn just before insertion ([Fig. 32-5](#)). Timing of insertion influences the ease of placement as well as the pregnancy and expulsion rates. Insertion near the end of normal menstruation, when the cervix is usually softer and the canal somewhat more dilated, may facilitate insertion and at the same time exclude early pregnancy. Insertion, however, need not be limited to this time. For the woman who is sure she is not pregnant and does not want to be pregnant, insertion may be carried out at any time.

Insertion immediately or very soon after delivery is followed by an unsatisfactorily high expulsion rate. The recommendation has been made, therefore, to withhold insertion for at least 8 weeks to reduce expulsion as well as to minimize the risk of perforation. In our extensive experiences, however, earlier insertion has not led to perforation or expulsion rates significantly higher than for insertion more remote from pregnancy. In the absence of infection, the device may be inserted immediately after early abortion.

A satisfactory technique for insertion of the ParaGard device is as follows:

1. Determine whether there are contraindications, counsel the woman regarding various problems associated with device use, and obtain written consent.
2. Administer a nonsteroidal anti-inflammatory agent with or without codeine to allay cramps.
3. Perform a pelvic examination to identify the position and size of the uterus and adnexa. If abnormalities are found, they should be evaluated, because the IUD may be contraindicated. Mucopurulent discharge and significant vaginitis should be appropriately treated and resolved before insertion.
4. **Make sure that the device is not loaded into its inserter tube more than 5 minutes before insertion.** The malleable arms tend to retain the "memory" of the inserter.
5. Wipe the cervix and the vaginal walls with an antiseptic solution. Then grasp the cervix with a vertically oriented single-tooth tenaculum — one tooth in the canal and one atop the cervix. Use sterile instruments and a sterile device. The cervical canal and uterine cavity are first straightened by applying gentle traction on the tenaculum, and the uterus is sounded to identify the direction and depth of the uterine cavity.
6. Adjust the movable flange on the barrel of the inserter to the sounded depth, from external cervical os to fundus. As shown in [Figure 32-5](#), the inserter, with the IUD contained within its most distal portion, is then gently inserted to the fundus. After rotating the inserter so that the device is positioned high in the transverse plane of the uterus, the inserter is removed while the device is held in the fundus by the plastic rod within the inserter. **Thus, the device is not pushed out of the tube, but rather it is held in place by the rod while the inserter tube is withdrawn.**
7. Cut the marker tail 2 cm from the external os, remove the tenaculum, observe for bleeding from the tenaculum puncture sites, and if there is no bleeding, remove the speculum.
8. Advise the woman to report any apparent adverse effects promptly.

The Mirena device requires some modifications to this technique, which are described in detail in its package insert.

Specifically, the arms of the device are released in the uterus *prior* to advancing the device 1.5 to 2 cm to the fundus. This is accomplished by setting the flange to the sounded uterine depth, and using it to gauge, based on its 1.5 to 2 cm distance from the external os, when to release the arms.

Expulsion. Loss of the IUD from the uterus is most common during the first month. The woman should be instructed to palpate the strings protruding from the cervix by either sitting on the edge of a chair or squatting down and then advancing the middle finger into the vagina until the cervix is reached. The woman should be examined again in about a month, usually after menses, for appropriate placement by identifying the tail protruding from the cervix. Barrier contraception may be desirable during this time, especially if a device has been expelled previously.

Lost Device. When the tail of an IUD cannot be visualized, the device may have been expelled, or it may have perforated the uterus. In either event, pregnancy is possible. Conversely, the tail simply may be in the uterine cavity along with a normally positioned device. Often, gentle probing of the uterine cavity with a Randall stone clamp or a rod with a terminal hook retrieves the string. **Never assume that the device has been expelled unless it was seen.**

When the tail is not visible and the device is not felt by gentle probing of the uterine cavity, sonography can be used to ascertain if the device is within the uterine cavity. If these findings are negative or inconclusive, then a radiograph of the abdomen and pelvis is taken with a sound inserted into the uterine cavity. Instillation of radiocontrast for hystero-graphy may be done. Hysteroscopy is yet another alternative. Obviously none of these maneuvers except sonography should be performed during early pregnancy.

An open device of inert material, such as the Lippes Loop, located outside the uterus may or may not do harm. Perforations of large and small bowel and bowel fistulas, with attendant morbidity, have been reported remote from insertion. An extrauterine copper-bearing device induces an intense local inflammatory reaction and adhesions. Chemically inert devices usually are removed easily from the peritoneal cavity by laparoscopy or colpotomy. Copper-bearing devices are more firmly adherent, and laparotomy may be necessary.

A device may penetrate the uterine wall to varying degrees. Part of the device may extend into the peritoneal cavity, or part may remain firmly fixed in the myometrium. A device also may penetrate into the cervix and actually protrude into the vagina.

Replacement. The ParaGard device is approved for 10 years of continuous use and the Mirena device for 5 years.

BARRIER METHODS. For many years, condoms, vaginal spermicidal agents, and vaginal diaphragms have been used for contraception with variable success (see [Table 32-2](#)).

Male Condom. These products provide effective contraception, and their failure rate with strongly motivated couples has been as low as 3 or 4 per 100 couple-years of exposure (Vessey and co-workers, 1982). Generally, and during the first year of use especially, the failure rate is much higher (see [Table 32-2](#)). Women older than 30 years of age have had fewer unintended pregnancies than those younger than 25 years of age (Trussell and colleagues, 1990).

When used properly, condoms provide considerable but not absolute protection against a broad range of sexually transmitted diseases, including HIV, gonorrhea, syphilis, herpes, chlamydia, and trichomoniasis. They also may prevent and ameliorate premalignant cervical changes, probably by blocking transmission of human papillomavirus (Population Reports, 1982). Because the Centers for Disease Control and Prevention recommend condoms for couples at risk for HIV infection, including those with multiple sex partners, their use has escalated exponentially since the mid-1980s.

The contraceptive effectiveness of the male condom is enhanced appreciably by a reservoir tip and, theoretically, by the addition of spermicidal lubricant to the condom. The contraceptive effectiveness is further improved by the addition of an intravaginal spermicidal agent. Such agents, as well as those used for lubrication, should be water-based, because oil-based products destroy latex condoms and diaphragms (Waldron, 1989).

Speroff and Darney (2001) emphasize the following key steps to ensure maximal condom effectiveness:

1. They must be used with every coital act.
2. Placement should occur before contact of the penis with the vagina.
3. Withdrawal must occur with the penis still erect.
4. The base of the condom must be held during withdrawal.
5. Either an intravaginal spermicide or a condom lubricated with spermicide should be used.

LATEX SENSITIVITY. Some individuals are sensitive to latex. Condoms made from lamb intestines are effective, but they do not provide protection against infection. Fortunately, a nonallergenic condom was developed using synthetic thermoplastic elastomer, similar to that used in surgical gloves (Mason, 1992). Polyurethane condoms are effective against sexually transmitted diseases but have a significantly higher breakage and slippage rate than latex condoms (Frezieres and colleagues, 1998; Waldron, 1991). In a randomized trial of 901 couples, Steiner and colleagues (2003) documented breakage and slippage at 8.4 percent with polyurethane condoms compared with that of 3.2 percent with latex condoms. Respective 6-month typical pregnancy probabilities were 9.0 compared with that of 5.4 percent.

Female Condom (Vaginal Pouch). Before approval for marketing, a vaginal pouch must be proven to prevent pregnancy and sexually transmitted diseases. The only female condom available is marketed as the FC Female Condom. It is a polyurethane sheath with one flexible polyurethane ring at each end. The open ring remains outside the vagina, and the closed internal ring is fitted under the symphysis like a diaphragm (Fig. 32-6). In vitro tests have shown the condom to be impermeable to HIV, cytomegalovirus, and hepatitis B virus. It has a 0.6 percent breakage rate. The slippage and displacement rate is about 3 percent compared with that of 3 to 8 percent for male condoms. It has an acceptability rate of about 60 percent for women and 80 percent for men. The pregnancy rate is higher than with the male condom (see Table 32-2).

Spermicides. These contraceptives are marketed variously as creams, jellies, suppositories, films, and foam in aerosol containers. They are used widely in the United States, especially by women who find other methods unacceptable. They are useful especially for women who need temporary protection, for example, during the first week after starting oral contraceptives or while nursing. Most agents can be purchased without a prescription.

Typically, spermicides function by providing a physical barrier to sperm penetration as well as a chemical spermicidal action. The active ingredient is nonoxynol-9 or octoxynol-9. Raymond and colleagues (2004) showed that products with 100 mg of nonoxynol-9 were most effective. **Spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse.** Their duration of maximal effectiveness is usually no more than 1 hour. Thereafter they must be reinserted before repeat intercourse. Douching should be avoided for at least 6 hours after intercourse.

High pregnancy rates are primarily attributable to inconsistent use rather than to method failure. Even if inserted regularly and correctly, however, foam preparations probably result in 5 to 12 pregnancies per 100 woman-years of use (Trussell and associates, 1990). Spermicides in current use may provide partial protection against some sexually transmitted diseases such as gonorrhea (Feldblum and Fortney, 1988). They are not teratogenic (Briggs and colleagues, 2002).

Diaphragm Plus Spermicide. The diaphragm consists of a circular rubber dome of various diameters supported by a circumferentially placed metal spring. It can be very effective when used in combination with spermicidal jelly or cream. The spermicide is applied to the superior surface both along the rim and centrally. The device is then placed in the vagina so that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. At the same time, the centrally placed spermicidal agent is held against the cervix by the diaphragm. When appropriately positioned, the rim is lodged superiorly deep in the posterior vaginal fornix, and inferiorly the rim lies in close proximity to the inner surface of the symphysis immediately below the urethra (Fig. 32-7). If the diaphragm is too small, it does not remain in place. If it is too large, it is uncomfortable when it is forced into position. Cystocele or uterine prolapse is very likely to result in instability and therefore expulsion. Because the variables of size and spring flexibility must be specified, the diaphragm is available only by prescription (Allen, 2004).

The diaphragm and spermicidal agent can be inserted hours before intercourse, but if more than 6 hours elapse, additional spermicide should be placed in the upper vagina for maximum protection and be reapplied before each coital episode. The diaphragm should not be removed for at least 6 hours after intercourse. Because *toxic shock syndrome* has been described following its use, it may be worthwhile to remove the diaphragm at 6 hours, or at least the next morning, to minimize this uncommon event (Alcid and associates, 1982).

The diaphragm requires a high level of motivation for proper use. Vessey and colleagues (1982) reported a pregnancy rate of only 1.9 to 2.4 per 100 woman-years for motivated users. Bounds and associates (1995), in a small study, reported a much higher failure rate of 12.3 per 100 woman-years. The unintended pregnancy rate is lower in women older than 35 years of age than in those younger than 30 years of age. Diaphragm use results in a lower incidence of sexually transmitted diseases compared with that of condom use (Rosenberg and colleagues, 1992). Conversely, diaphragm use is associated with a slight increase in the rate of urinary infections (Hatcher and associates, 1998).

Contraceptive Sponge. After being off the market in the United States for 8 years, the Today contraceptive sponge is again available. It is sold over-the-counter. It consists of a nonoxynol-9-impregnated polyurethane disc that can be inserted for up to 24 hours prior to intercourse. After moistening, it is placed directly against the cervix. While in place, it provides contraception regardless of the frequency of coitus. It should remain in place for 6 hours after intercourse. Although the sponge is perhaps more convenient than the diaphragm or condom, it is less effective (see Table 32-2).

Cervical Cap. The Prentif cavity-rim cervical cap was approved for use by the FDA in 1988. The flexible, cup-like device is made of natural rubber and is fitted around the base of the cervix. It can be self-inserted and allowed to remain in place for up to 48 hours. It should be used with a spermicide applied once at insertion. If properly fitted and used correctly, the cap is comparable in effectiveness to the diaphragm (Bernstein and associates, 1982; Richwald and colleagues, 1989). However, it is relatively costly, and overall, incorrect fitting and/or improper placement make the cap less effective than the diaphragm plus spermicide (see Table 32-2).

Figure 32-6. FC Female Condom insertion and positioning. **A.** Inner ring is squeezed for insertion. **B.** Sheath is inserted similarly to a diaphragm. **C.** Inner ring is pushed up as far as it can go with index finger. **D.** Vaginal pouch is in place. (Courtesy of Wisconsin Pharmacal Company, Jackson, WI.)

Figure 32-7. A diaphragm in place creates a physical barrier between the vagina and cervix and, importantly, provides for intimate contact between the contraceptive jelly or cream and the cervix.

PERIODIC (RHYTHMIC) ABSTINENCE. Because the human ovum is probably susceptible to successful fertilization for only about 12 to 24 hours after ovulation, periodic abstinence has intuitive appeal as a means of birth control. Pregnancy rates, however, with various methods of periodic abstinence—rhythm, natural family planning, or fertility awareness—have been estimated from 5 to 40 per 100 woman-years (Population Reports, 1981). In other words, the unwanted pregnancy rate during the first year of use is approximately 20 percent (see [Table 32-2](#)).

Calendar Rhythm Method. Ovulation most often occurs about 14 days before the onset of the next menstrual period. Unfortunately, this is not necessarily 14 days *after* the onset of the last menstrual period. Therefore, the *calendar rhythm method* is not reliable. The International Planned Parenthood Federation (1982) concluded that "couples electing to use periodic abstinence should, however, be clearly informed that the method is not considered an effective method of family planning."

Temperature Rhythm Method. The temperature rhythm method relies on *slight* changes—sustained 0.4 degree Fahrenheit increases—in the morning basal body temperature that usually occur just before ovulation. This method is much more likely to be successful if, during each menstrual cycle, intercourse is avoided until well after the ovulatory temperature rise. For this method to be most effective, the woman must abstain from intercourse from the first day of menses through the third day after the increase in temperature. For obvious reasons, this is not a popular method! With excellent compliance, however, the unwanted pregnancy is about 2 percent the first year.

Cervical Mucus Rhythm Method. The so-called *Billings method* depends on awareness of vaginal "dryness" and "wetness." These are the consequence of changes in the amount and quality of cervical mucus at different times in the menstrual cycle. Abstinence is required from the beginning of menses until 4 days after slippery mucus is identified. Although this method has not achieved popularity, when it is used accurately, the first-year failure rate is approximately 3 percent.

Symptothermal Method. This method combines the use of changes in cervical mucus (onset of fertile period), changes in basal body temperature (end of fertile period), and calculations to estimate the time of ovulation. Although this method is more complex to learn and apply, it does not appreciably improve reliability. The use of home kits to detect luteal hormone increases in the urine on the day prior to ovulation may improve the accuracy of periodic abstinence methods (Hatcher and associates, 1998).

Natural Family Planning Methods. For the interested reader, the December 1991 supplement to the *American Journal of Obstetrics and Gynecology* was devoted to the subject of natural family planning. Clearly, proper instruction is critical for natural family planning methods to be successful. Complex charting is involved, and these charts, as well as detailed advice, are available online from the National Fertility Awareness and Natural Family Planning Service for the United Kingdom (<http://www.fertilityuk.org>) and The Natural Family Site, BYG Publishing (<http://www.bygpub.com/natural>).

SPECIAL CONSIDERATIONS IN CONTRACEPTION

A number of unique circumstances present special challenges for assuming contraceptive efficacy while minimizing undesirable effects.

CONTRACEPTION IN ADOLESCENTS. A discussion of the biological antecedents of teenage pregnancy was presented in [Chapter 3](#) (see p. 40). Briefly stated, menarche has decreased from approximately 17 years of age in the mid-1800s to near 12 years of age in 2001. Unfortunately, this means that reproductive function is established sooner than the psychological understanding of the consequences of sexual activity. This far too often results in intermittent spontaneous sexual encounters and a naive perception of the risks of pregnancy and sexually transmitted diseases (Cromer and associates, 1996; Sulak and Haney, 1993).

Contraception is most often sought more than a year after sexual activity has begun (Mosher and McNally, 1991). Concerns over confidentiality and lack of money deter adolescents from seeking and obtaining contraception (American College of Obstetricians and Gynecologists, 2003b). Both barriers are surmountable and in most cases should not impede access to contraception. Indeed, in the majority of states, minors have explicit legal authority to consent to contraceptive services, and in many areas, publicly funded clinics provide free contraception to adolescents (Alan Guttmacher Institute, 2002).

Combination Oral Contraceptives. As a method, these agents are the best choice for adolescents because they provide effective contraception, increase bone density, and can be used to improve acne and regulate irregular menses. The obvious disadvantage is the daily requirement of taking a pill.

Long-Acting Methods. Injectable depot *medroxyprogesterone* is an effective contraceptive that also may be considered a "use and forget" method for 3 months. The disadvantages include the need for injection every 3 months, menstrual irregularities, and loss of bone mass (Sulak and Kaunitz, 1999).

Barrier Methods. Despite their obvious advantage of providing some protection against sexually transmitted diseases, barrier methods are not good choices for adolescents because they require preplanning and motivation for proper use. Such methods, especially vaginal spermicides and male condoms, should be considered primarily as back-up contraceptives and protective methods for sexually transmitted diseases.

CONTRACEPTIVE CHOICES FOR WOMEN OLDER THAN 35 YEARS OF AGE.

Although fertility decreases beginning at 35 to 40 years of age, these women are still at risk for unwanted pregnancy and sexually transmitted diseases. Henshaw (1998) reported that half of all pregnancies in women in their 40s are unintended, and that 65 percent of these are terminated.

Combination Oral Contraceptives. These agents, especially the newer low-dose estrogen compounds, when used by nonsmokers without systemic disease, are highly effective, are well tolerated, provide many health benefits, and are associated with minimal risk (Beck, 1995; Speroff and Sulak, 1995). According to the American College of Obstetricians and Gynecologists (2000b), healthy, nonsmoking women may use combination oral contraceptives containing less than 50 µg of estrogen until menopause.

Injectable Depot Medroxyprogesterone. This is a highly effective hormonal contraceptive. It can also be used by some women who cannot for medical reasons take combination oral contraceptives (Speroff and Sulak, 1995).

Intrauterine Devices. IUDs are a logical choice for an older woman who has completed her family and is in a monogamous relationship.

Barrier Techniques and Spermicidal Agents. These methods can be used as either primary or back-up contraception. Their effectiveness improves with advancing age after 40, likely because of diminished fertility.

CONTRACEPTION IN WOMEN WITH MEDICAL CONDITIONS.

Pregnancies in women with medical complications often result in dangers that far exceed those seen with most forms of contraception (American College of Obstetricians and Gynecologists, 2000b). The choice of the most effective and safest method of contraception, however, is dependent on the basic pathophysiology of the disease and how pregnancy affects it. Only with such knowledge can the appropriate contraceptive be prescribed or a recommendation for sterilization be made. For these reasons, contraceptive and sterilization recommendations are made throughout this book when individual diseases are discussed.

EMERGENCY CONTRACEPTION.

Many women present for contraceptive care following consensual but unprotected sexual intercourse and in some cases aggravated sexual assault. In these situations, a number of methods substantially decrease the likelihood of an unwanted pregnancy when used correctly.

Hormonal Emergency Contraception (morning-after pill or Yuzpe method). The high unintended pregnancy rate in the United States has become the focus of public health attention. To address this problem, there have been some recent rapid changes in the availability of hormonal emergency contraception. Three hormonal methods are currently available: the Yuzpe method, which consists of commonly available combination oral contraceptives; and two products designed specifically for this purpose, one consisting of an estrogen and progestin combination and the other a progestin-only product.

YUZPE AND ESTROGEN-PROGESTIN COMBINATIONS. In 1997, the FDA approved a number of combined oral contraceptive regimens for use as emergency contraception ([Table 32-9](#)), and in 1998, the FDA approved the Preven Emergency Contraceptive Kit. It contains a pregnancy test and four oral contraceptive tablets each containing 50 µg of ethinyl estradiol and 0.25 mg of levonorgestrel. Two tablets are taken within 72 hours of intercourse, followed 12 hours later by the second dose. The regimen is more effective the sooner it is taken after unprotected intercourse. All oral hormone regimens shown in [Table 32-9](#) follow the same dosage schedule.

PROGESTIN-ONLY PREPARATION. Plan B is a progestin-only regimen that consists of two tablets each containing 0.75 mg levonorgestrel. The first dose is taken within 72 hours of unprotected coitus and the second dose 12 hours later (see [Table 32-9](#)). This regimen resulted in a crude pregnancy rate of 1.1 compared with that of 3.2 percent in a similar group of women treated with the Yuzpe regimen. The manufacturer of Plan B applied to the FDA to request the product to be sold over the counter. Wai and colleagues (2005) showed that a 24-hour interval between the doses was also effective.

According to the Task Force on Postovulatory Methods of Fertility Regulation (1998), mini-pill progestins are more effective than combination estrogen-progestin pills. The Ovrette method consists of 20 pills taken as one dose within 72 hours of unprotected intercourse followed in 12 hours by a second dose of 20 pills (see [Table 32-9](#)). Each dose of 20 pills contains 1.5 mg of norgestrel. This method has proven to be effective and is less likely to cause nausea and vomiting. Jackson and colleagues (2003) reported that *advanced* provision of emergency contraception increased its use without adversely affecting the use of routine contraception.

Access to emergency contraception has not been universal. Trussell and colleagues (2000) found that only 75 percent of attempts to access care through the Emergency Contraception Hotline were successful. Physicians can register to be included as a resource, and patients can obtain referrals on the Hotline at 1-888-NOT-2-LATE (888-668-2528) or the Emergency Contraception Website (<http://www.not-2late.com>).

In spite of sound published evidence, compelling arguments such as those by Grimes (2002), and a 23 to 4 affirming vote by its two advisory committees, the FDA in 2004 decided to deny over-the-counter status to levonorgestrel emergency contraception. This decision has been widely decried as politically motivated (Drazen and colleagues, 2004; Grimes, 2004).

MECHANISM OF ACTION. The major mechanism is inhibition or delay of ovulation (Food and Drug Administration, 1997). Other mechanisms include alteration of the endometrium, sperm penetration, and tubal motility. **Established pregnancies are not harmed.**

Emergency hormone contraceptive regimens are highly effective and decrease the risk of pregnancy by 75 percent (Trussell and associates, 1996, 1998b). Thus, if 100 women had unprotected intercourse during the second to third week of their menstrual cycle, eight would be expected to conceive. With appropriate use of one of the regimens shown in [Table 32-9](#), only two would actually conceive.

Nausea and vomiting are major problems due to the estrogen in these regimens. Trussell and associates (1998a) reported nausea in 50 percent of women and vomiting in 20 percent. For this reason, we routinely prescribe an oral antiemetic at least 1 hour before each dose. Raymond and colleagues (2000) conducted a randomized trial and found that 1-hour pretreatment with 50-mg meclizine given orally decreased nausea substantially. Ragan and associates (2003) found that 10 mg of oral metoclopramide decreased both nausea and cramping compared with that of placebo. If vomiting occurs within 2 hours of a dose, the dose must be repeated.

Copper-Containing Intrauterine Devices. Fasoli and co-workers (1989) summarized nine studies that included results from 879 women who accepted some type of copper-containing IUD as a sole method of postcoital contraception. The only pregnancy reported aborted spontaneously. Trussell and Stewart (1998) reported that when the IUD was inserted up to 5 days after unprotected intercourse, the failure rate was 1 percent. A secondary advantage is that this method also puts in place an effective 5- to 10-year method of contraception.

Mifepristone (RU 486) and Epostane. These medications are discussed in [Chapter 9](#) (see p. 245). They should be ideal for postcoital contraception, because they either block progesterone production (epostane) or interfere with its action (mifepristone). Implantation prevented by either mechanism results in so-called *menstrual induction*.

Ashok and colleagues (2002) reported that a single 100-mg dose of mifepristone was more effective than the Yuzpe regimen, with crude pregnancy rates of 0.6 versus 3.6 percent, respectively. There were also fewer side effects with mifepristone. Although hormonal regimens must be used within 72 hours of unprotected intercourse, mifepristone is effective up to 17 days after intercourse (Weiss, 1993). Grimes and Cook (1992) propose that that wider availability of mifepristone for postcoital contraception would result in a lowering of the induced abortion rate.

Failure of Emergency Contraception. Any postcoital contraceptive method is associated with failures, which likely can be reduced by employing a barrier technique until the next menses to prevent fertilization after use of the postcoital method. If menstruation is delayed for more than 3 weeks past its expected onset, pregnancy is likely.

LACTATION

Breast feeding is important to infant health and to child-spacing. For mothers who are nursing, ovulation during the first 10 weeks after delivery is unlikely (Perez, 1981). Nursing, however, is not a reliable method of family planning for women whose infants are on a daytime-only feeding schedule. **Waiting for first menses involves a risk of pregnancy, because ovulation usually antedates menstruation.** Certainly, after the first menses, contraception is essential unless the woman desires pregnancy. Estrogen-progestin contraceptives may reduce both the rate and the duration of milk production. The benefits from prevention of pregnancy by the use of combined oral contraceptives would appear to outweigh the risks in selected patients. According to the American College of Obstetricians and Gynecologists (2000a), progestin-only oral contraceptives are the preferred choice in most cases (see p. 733). IUDs have been recommended for the lactating sexually active woman. The rate of uterine perforation is very slightly increased in lactating women with IUDs, perhaps as a consequence of vigorous myometrial contractions from the release of oxytocin in response to suckling (Heartwell and Schlesselman, 1983).

33. Sterilization

INTRODUCTION

Surgical sterilization has become the most popular form of contraception. The volume of sterilization procedures cannot be tracked accurately in the United States because most interval tubal sterilizations and vasectomies are performed in ambulatory centers. Westhoff and Davis (2000), however, citing data from the National Survey of Family Growth, estimate that about 700,000 tubal sterilizations are performed annually. Unfortunately, there are still excessive federal rules and regulations that discourage voluntary sterilization among financially underprivileged women. Several important multicenter studies of voluntary sterilization have been performed by investigators of the U.S. Collaborative Review of Sterilization (CREST) and the Centers for Disease Control and Prevention. Many of their observations are subsequently described.

FEMALE STERILIZATION

Female sterilization is the contraceptive method of choice for 28 percent of couples in the United States (American College of Obstetricians and Gynecologists, 2003). It is usually accomplished by occlusion or division of the fallopian tubes. This can be performed at any time, but at least half of tubal sterilization procedures are performed in conjunction with cesarean or vaginal delivery (MacKay and associates, 2001). Nonpuerperal tubal sterilization is usually accomplished via laparoscopy in an outpatient surgical center.

PUERPERAL TUBAL STERILIZATION. The oviducts are accessible at the umbilicus directly beneath the abdominal wall for several days after delivery. Thus, puerperal tubal sterilization is technically simple, and hospitalization need not be prolonged. Some practitioners prefer to perform sterilization immediately following delivery (Bucklin and Smith, 1999), although others wait for 12 to 24 hours. At Parkland and the University of Alabama Hospitals, puerperal tubal ligation is performed in the obstetrical surgical suite the morning after delivery. This minimizes the hospital stay but allows the likelihood of postpartum hemorrhage to diminish. In addition, the status of the newborn can be better ascertained.

The first tubal sterilization reported in the United States, performed 120 years ago, consisted of a silk ligature placed around the tubes about 1 inch from their uterine attachment after a cesarean delivery (Lungren, 1881). It soon was apparent that ligation without tubal resection had an unacceptably high failure rate, and a variety of techniques are now used to disrupt tubal patency.

Irving Procedure. This procedure is the most difficult to perform but the least likely to fail. The cut oviduct is separated from the mesosalpinx sufficiently to free a medial segment of tube (Fig. 33-1A). The freed distal stump of the proximal tubal segment is buried within a tunnel created in the myometrium posteriorly, and the proximal end of the distal tubal segment is buried within the mesosalpinx.

Pomeroy Procedure. This is the simplest method of dividing the tube (Fig. 33-1B). Plain catgut is used to ligate the knuckle of tube to ensure prompt absorption of the ligature and subsequent separation of the severed tubal ends. Even so, ectopic pregnancy in the distal segment can occur (Berker and colleagues, 2002).

Parkland Procedure. This procedure, shown in Figure 33-2, was developed in the 1960s. It was designed to avoid the initial intimate approximation of the cut ends of the oviduct inherent with the Pomeroy procedure.

SURGICAL TECHNIQUE. A small infraumbilical incision is made. The oviduct is identified by grasping its midportion with a Babcock clamp, and the distal fimbria is identified. This prevents confusing the round ligament with the midportion of the oviduct. **Whenever the oviduct is inadvertently dropped, it is mandatory to repeat this identification procedure.** An avascular site in the mesosalpinx adjacent to the oviduct is then perforated with a small hemostat, and the jaws are opened to separate the oviduct from the adjacent mesosalpinx for about 2.5 cm (see Fig. 33-2). The freed oviduct is ligated proximally and distally with 0-chromic suture, and the intervening segment of about 2 cm is excised and inspected for hemostasis. Both segments are submitted for histological confirmation. During four decades, the failure rate has been less than 1 in 400 procedures.

Other Procedures. The *Madlener technique* and the *Kroener fimbriectomy* for tubal sterilization are rarely used today because of high failure rates (Pati and Cullins, 2000). In most cases, failures are due to recanalization of the proximal portion of the tube.

Failure Rates. Puerperal sterilization fails for two major reasons.

1. Surgical errors, which include transection of the round ligament instead of the oviduct or partial transection of the oviduct.
2. Formation of a fistulous tract between the severed tubal stumps or spontaneous reanastomosis.

In their first report, investigators from the CREST study described follow-up of 10,863 women who had undergone tubal sterilization from 1978 through 1986. The failure rates for various procedures are summarized in Figure 33-3. It is readily apparent that puerperal sterilization is highly effective, with a short- and long-term failure rate that is better than most interval procedures. Some clinicians have reported an increased failure rate for sterilization at the time of cesarean delivery; however, we have identified no such differences with the technique of tubal sterilization used at Parkland Hospital (see Fig. 33-2).

Figure 33-1. Techniques for tubal sterilization. **A. Irving procedure:** the medial cut end of the oviduct is buried in the myometrium posteriorly, and the distal cut end is buried in the mesosalpinx. **B. Pomeroy procedure:** a loop of oviduct is

ligated, and the knuckle of tube above the ligature is excised.

Figure 33-2. Parkland tubal ligation: The avascular mesosalpinx is opened by blunt dissection. A 2-cm midsegment of tube is ligated with 0-chromic suture and divided between the sutures.

Figure 33-3. Data from the U.S. Collaborative Review of Sterilization (CREST) shows the cumulative probability of pregnancy per 1000 procedures for five methods of tubal sterilization. (Data from Peterson and colleagues, 1996.)

NONPUERPERAL (INTERVAL) TUBAL STERILIZATION. Techniques for nonpuerperal tubal sterilization, including modifications, basically consist of:

1. Ligation and resection at laparotomy, as described earlier for puerperal sterilization.
2. The application of a variety of permanent rings or clips to the fallopian tubes, usually by laparoscopy.
3. Electrocoagulation of a segment of the tubes, again usually through a laparoscope.

Surgical Approaches. A number of approaches and techniques may be used to perform nonpuerperal tubal sterilization. In developed countries, laparoscopic techniques are most often used. In the United States, laparoscopic tubal ligation is the leading method of female sterilization (American College of Obstetricians and Gynecologists, 2003). The procedure is frequently performed in an ambulatory surgical setting under general anesthesia with tracheal intubation. In almost all cases, the woman can be discharged several hours later. The actual disruption of tubal continuity is accomplished using loops, clips, and electrocauterization with or without transection of the tube. Because electrocauterization destroys a large segment of tube, surgical reversal is usually difficult and often not possible.

"Minilaparotomy" using a 3-cm suprapubic incision is also popular, especially in resource-poor countries (Kulier and colleagues, 2002). The peritoneal cavity can also be entered through the posterior vaginal fornix — *colpotomy* or *culdotomy* — to perform tubal interruption. This approach is not commonly used today.

Major morbidity is rare with either minilaparotomy or laparoscopy. In the study by Kulier and associates (2002), minor morbidity was twice as common in women who had minilaparotomies.

Laparoscopic Methods of Tubal Interruption. A number of techniques or devices can be used to accomplish tubal sterilization via laparoscopy. Details of these have been provided by a number of reviews (Gilstrap and associates, 2002; Pati and Cullins, 2000).

Electrocoagulation is used for destruction of a segment of tube and can be accomplished with either unipolar or bipolar electrical current. Although unipolar electrocoagulation has the lowest long-term failure rate (see Fig. 33-3), it also has the highest serious complication rate. For this reason, bipolar coagulation is favored by most clinicians (American College of Obstetricians and Gynecologists, 2003).

Mechanical methods of tubal occlusion can be accomplished with a silicone rubber band such as the Falope Ring and the Tubal Ring; the spring-loaded Hulka-Clemens Clip (also known as the Wolf Clip); or the silicone-lined titanium Filshie Clip. Sokal and co-workers (2000) compared the Tubal Ring and Filshie Clip in a randomized trial of 2746 women. They reported similar rates of safety and a 1-year pregnancy rate of 1.7 per 1000 women. All these methods have favorable long-term success rates (see Fig. 33-3). When done via laparoscopy, these procedures are technically more difficult, and they have significantly higher failure rates before experience is gained (Peterson and colleagues, 2001).

Operative Complications. Principal hazards are anesthetic complications, inadvertent injury of adjacent structures, the rare occurrence of pulmonary embolism, and sterilization failure with subsequent intrauterine or ectopic pregnancy (see Chap. 10). Because of improved safety with anesthetic and laparoscopic techniques, the case-fatality rates for tubal sterilization have diminished appreciably over the past 2 decades. For example, from 1977 to 1981, Peterson and co-workers (1983) estimated the case-fatality frequency to be 8 per 100,000 procedures. Fifteen years later, Hatcher and colleagues (1998) reported mortality rates of approximately 1.5 per 100,000 for laparoscopic sterilizations. Using the CREST database, Jamieson and co-workers (2000) reported an overall complication rate of 0.9 to 1.6 per 100 laparoscopic interval sterilization procedures. Unintended laparotomy was done in about 1 per 100 procedures.

Failure Rates. The reasons for interval tubal failures are not always apparent, but some are:

1. Surgical errors likely account for 30 to 50 percent of cases.
2. An occlusion method failure may be due to fistula formation, especially with electrocautery procedures. Faulty clips may not be occlusive enough, or the fallopian tube may spontaneously undergo reanastomosis.
3. Equipment failure, such as a defective electrical current for the electrocautery, may be a causative factor.

4. The woman was already pregnant at the time of surgery — a so-called *luteal phase pregnancy*.

As shown in [Figure 33-3](#), some sterilization methods have lower failure rates than others. Even with the same procedure, there are variations in failure rate. For example, when fewer than three tubal sites are coagulated, the five-year cumulative probability of pregnancy is about 12 per 1000 procedures. This compares with only 3 per 1000 if three or more sites are coagulated (Peterson and associates, 1999).

The lifetime increased cumulative failure rates over time are supportive that failures after 1 year are not likely due to technical errors. Soderstrom (1985) found that most sterilization failures were not preventable. The American College of Obstetricians and Gynecologists (1996) concluded that "pregnancies after sterilization may occur without any technical errors."

Long-Term Complications. In addition to the 15-year cumulative pregnancy rates shown in [Figure 33-3](#), there are other long-term adverse effects.

ECTOPIC PREGNANCY. Approximately half of the pregnancies that follow a failed electrocoagulation procedure were ectopic, compared with only 10 percent following failure of a ring, clip, or tubal resection method (Hatcher and colleagues, 1990; Hendrix and associates, 1999). **Any symptoms of pregnancy in a woman after tubal sterilization must be investigated, and an ectopic pregnancy must be excluded.** Diagnosis and management are discussed in detail in [Chapter 10](#).

POSTTUBAL LIGATION SYNDROME. In 1951, Williams and colleagues described their 22-year experiences with long-term follow-up in women who had undergone tubal ligation. They reported an excessive incidence of menorrhagia and intermenstrual bleeding, a condition that later became known as *posttubal ligation syndrome*. Subsequently, a similar incidence of menstrual dysfunction was reported in women whose husbands had undergone vasectomy (DeStefano and colleagues, 1985; Shy and associates, 1992). Thus, debate over the very existence of a unique syndrome has persisted.

Observations from the CREST study are very informative concerning these issues. Peterson and colleagues (2000) compared long-term outcomes of 9514 women who had undergone tubal sterilization with a cohort of 573 women whose partners had undergone vasectomy. They found that both groups had similar risks for menorrhagia, intermenstrual bleeding, and dysmenorrhea. In fact, they found that women who had undergone sterilization had *decreased* duration and volume of menstrual flow as well as *less* dysmenorrhea. There was, however, an increased incidence of cycle irregularity in the sterilized women. The cause of these findings remains an enigma, although Harlow and co-workers (2002) reported no significant change in serum levels of follicle-stimulating hormone, luteinizing hormone, and estradiol. Timonen and co-workers (2002) reported a transient increase in follicular phase serum estradiol levels that normalized by 12 months.

OTHER EFFECTS. Whether the incidence of *subsequent hysterectomy* is increased in women who have undergone tubal sterilization is controversial (Mall and colleagues, 2002; Pati and Cullins, 2000). In a CREST follow-up study, Hillis and associates (1997) reported that 17 percent of women undergoing tubal sterilization also underwent hysterectomy in the subsequent 14 years. Although the investigators did not compare this incidence with a cohort control, the indications were similar to those for nonsterilized women undergoing hysterectomy.

Westhoff and Davis (2000) concluded that tubal sterilization likely protects against *ovarian cancer*. They found no differences in the incidence of *breast cancer*.

According to Holt and colleagues (2003), the incidence of *functional ovarian cysts* is increased almost twofold following tubal sterilization. Levгур and Duvivier (2000) reported that women who had undergone tubal sterilization were highly unlikely to have subsequent *salpingitis*.

Less objective but important psychological sequelae of sterilization have also been evaluated. In the CREST study, Costello and colleagues (2002) found that tubal ligation did not change *sexual interest or pleasure* in 80 percent of women. In the majority of the 20 percent of women who did report a change, *positive effects* were 10 to 15 times more likely to occur. Invariably, a number of women express *regrets about sterilization*. In the CREST study, Jamieson and co-workers (2002) reported that by 5 years, 7 percent of women who had undergone tubal ligation had regrets. This is not limited to their own sterilization, because 6.1 percent of women whose husbands had undergone vasectomy had similar regrets.

REVERSAL OF TUBAL STERILIZATION. No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed by either surgery or assisted reproductive techniques. These latter procedures are technically difficult, expensive, and not always successful. Success rates vary greatly depending on the age of the woman, the amount of tube remaining, and the technology used. Van Voorhis (2000) reviewed a number of reports and found that pregnancy rates varied from 45 to 90 percent with surgical reversals. For example, pregnancy rates as high as 80 percent have been reported for tubal reanastomosis (Cha and associates, 2001). When neosalpingostomy is done for fimbriectomy reversal, however, successful pregnancies occur in only 30 percent of women (Tourgeman and co-workers, 2001). **Almost 10 percent of women who undergo reversal of tubal sterilization have an ectopic pregnancy.**

Reversal procedures can be done by laparoscopy or laparotomy, and pregnancy rates are similar with either method (Cha and colleagues, 2001). In a cost-effectiveness study from Canada, Hawkins and associates (2002) found laparoscopy to have lower costs than laparotomy.

HYSTERECTOMY. For the woman who desires no more children, hysterectomy has many theoretical advantages. In the absence of uterine or other pelvic disease, however, hysterectomy solely for sterilization at the time of cesarean delivery, early in the puerperium, or even remote from pregnancy is difficult to justify.

TRANSCERVICAL STERILIZATION. Sterilization has been performed by using hysteroscopy to visualize the tubal ostia and obliterating them with a variety of compounds or devices.

INTRATUBAL CHEMICAL METHODS. Several compounds are being investigated as useful in tubal sterilization (Ballagh, 2003). Liquid silicone is injected transcervically into the tubes, where it hardens, forming *silicone plugs*. Repeat procedures are necessary in 20 percent of women, however, and continued tubal patency is common. Tubal injections with the adhesive *methylcyanoacrylate* cause inflammation, necrosis, and fibrosis. Insertion of *quinacrine pellets* in more than 100,000 women in other countries has also been used to achieve tubal occlusion. Few well-done studies concerning its efficacy are available, but advantages include minimal complications and low cost. Randic and colleagues (2001) reported cumulative pregnancy rates by 8 years of more than 6 per 100. Because of concerns about carcinogenesis based on a study of 30,000 Vietnamese women, the World Health Organization recommended halting usage of quinacrine (Lippes, 2002). In addition, *erythromycin* placed tubally to incite inflammation has been investigated, but it has an unacceptably high one-year failure rate of 36 percent (Bairagy and Mullick, 2004).

INTRATUBAL DEVICES. Tubes can be occluded by hysteroscopic insertion of some type of mechanical device into the proximal tube. Several of these devices have been evaluated. One of these, Essure, was approved by the Food and Drug Administration in November, 2002. This device is a microinsert that has a stainless steel inner coil enclosed in polyester fibers and an expandable outer coil of Nitinol—a nickel and titanium alloy used in coronary artery stents. The outer coil expands after placement allowing the fiber to also expand, and as tissue grows within the fiber, tubal occlusion results.

Preliminary results with this device and others have been encouraging (Association of Reproductive Health Professionals, 2002). In one study, Cooper and co-workers (2003) used intravenous sedation or paracervical block to insert Essure hysteroscopically. These investigators succeeded in proper insertion in 464 of 507 women (92 percent). None of these women had pregnancies by 9620 woman-months. In a similar study, Kerin and colleagues (2001) reported that 97 percent of women with the device in place after 2 years expressed a satisfaction level of very good to excellent.

Essure use has two major drawbacks: the high cost of the device itself (almost \$1000) and the necessity of hysterosalpingography at 3 months to ensure tubal blockage.

MALE STERILIZATION

Nearly a half million men in the United States undergo vasectomy each year (Magnani and colleagues, 1999). Through a small incision in the scrotum, the lumen of the vas deferens is disrupted to block the passage of sperm from the testes (Fig. 33-4). With local analgesia, the procedure is usually performed within 20 minutes.

In a review, Hendrix and colleagues (1999) found that, compared with vasectomy, female tubal sterilization has a 20-fold increased complication rate, a 10- to 37-fold failure rate, and a 3-fold increased cost. Similarly, in Dallas in 2003, total charges for a vasectomy were \$800 compared with almost \$6000 for an outpatient laparoscopic tubal ligation.

A disadvantage of vasectomy is that sterility is not immediate. Complete expulsion of sperm stored in the reproductive tract beyond the interrupted vas deferens takes about 3 months or 20 ejaculations (American College of Obstetricians and Gynecologists, 1996). Although most protocols dictate that semen should be analyzed until two consecutive sperm counts are zero, Bradshaw and colleagues (2001) reported that only one azoospermic semen analysis is sufficient evidence of sterility. During the period before azoospermia is documented, another form of contraception must be used.

The failure rate for vasectomy during the first year is 9.4 per 1000 procedures but only 11.4 per 1000 at 2, 3, and 5 years (Jamieson and colleagues, 2004). Failures result from unprotected intercourse too soon after ligation, incomplete occlusion of the vas deferens, or recanalization. A phenomenon termed *transient sperm reappearance* usually is not associated with pregnancy. Haldar and co-workers (2000) described temporary low sperm counts in 20 of 2250 men who had been documented to have azoospermia following vasectomy. Of the 20, the count was less than 10,000/mL, and in the 14 retested one month later, azoospermia was again confirmed. They concluded that spermatozoa present in the distal vas deferens are slowly released, or that microchannels form with sperm granulomas.

Figure 33-4. Anatomy of male reproductive system, showing procedure for vasectomy.

RESTORATION OF FERTILITY. Success after vasectomy reversal depends on several factors. Fibrosis increases with time (Raleigh and colleagues, 2004). A review of several reports suggests that odds for success are about 50 percent, with somewhat higher rates following microsurgical reanastomosis.

LONG-TERM EFFECTS. Other than regrets, long-term consequences are rare (Amundsen and Ramakrishnan, 2004). After vasectomy, antibodies directed at spermatozoa can frequently be identified. Concern was raised about the possibility that the immune response might cause harmful systemic changes. Despite this, studies have not identified an increase in cardiovascular disease, circulating immune complexes, or damage to retinal blood vessels (Giovannucci and colleagues, 1992; Goldacre and co-workers, 1983). Subsequently, Manson and associates (1999) provided data on 1159 physicians from the U.S. Physicians' Health Study. In a 15-year follow-up, there was no difference in the incidence of myocardial infarction or stroke in men with or without vasectomy. On the basis of their review, Schwingl and Guess (2000) also concluded that vasectomy is not followed by accelerated atherogenesis.

There is no convincing evidence of an increased incidence of *testicular cancer* following vasectomy (Giovannucci and colleagues, 1992). Earlier studies found no evidence to associate development of *prostatic carcinoma* after vasectomy (Giovannucci and associates, 1993a, 1993b; Hayes and co-workers, 1993). This changed, however, when Lesko and

SECTION VII - OBSTETRICAL COMPLICATIONS

34. Hypertensive Disorders in Pregnancy

INTRODUCTION

Hypertensive disorders complicating pregnancy are common and form one of the deadly triad, along with hemorrhage and infection, that contribute greatly to maternal morbidity and mortality. In 2001, according to the National Center for Health Statistics, gestational hypertension was identified in 150,000 women, or 3.7 percent of pregnancies (Martin and colleagues, 2002). Importantly, Berg and colleagues (2003) reported that almost 16 percent of 3201 pregnancy-related deaths in the United States from 1991 to 1997 were from complications of pregnancy-related hypertension. These investigators also found that black women in this country are 3.1 times as likely to die from preeclampsia as white women.

How pregnancy incites or aggravates hypertension remains unsolved despite decades of intensive research. Indeed, hypertensive disorders remain among the most significant and intriguing unsolved problems in obstetrics. To elucidate these, ongoing research is sponsored by the National Institutes of Child Health and Human Development (NICHD) and its Maternal-Fetal Medicine Units Network. Another important stimulus for research is the International Society for the Study of Hypertension in Pregnancy. The National Heart, Lung, and Blood Institute promotes research and coordination through the National High Blood Pressure Education Program (NHBPEP) and its Working Group for High Blood Pressure in Pregnancy.

TERMINOLOGY AND CLASSIFICATION

The term *gestational hypertension* is used now to describe any form of new-onset pregnancy-related hypertension. It was adopted by the Working Group of the NHBPEP (2000), which proposed a classification system based on clinical simplicity to guide management. The term was chosen to emphasize the cause-and-effect connection between pregnancy and its unique form of hypertension—preeclampsia and eclampsia. It is also meant to be a working term that is purposefully vague, but it should convey that the development of hypertension in a previously normotensive pregnant woman should and must be considered potentially dangerous to both herself and her fetus. In the past several editions of *Williams Obstetrics*, the term *pregnancy-induced hypertension* was used. It was popularized by Dr. Jack Pritchard to convey the same principles, and it still is used by some interchangeably with gestational hypertension.

The classification of hypertensive disorders complicating pregnancy by the Working Group of the NHBPEP (2000) is shown in [Table 34-1](#). There are five types of hypertensive disease:

1. Gestational hypertension (formerly pregnancy-induced hypertension that included transient hypertension).
2. Preeclampsia.
3. Eclampsia.
4. Preeclampsia superimposed on chronic hypertension.
5. Chronic hypertension.

An important consideration in this classification is differentiating hypertensive disorders that precede pregnancy from preeclampsia and eclampsia, which are potentially more ominous.

DIAGNOSIS

Hypertension is diagnosed when the resting blood pressure is 140/90 mm Hg or greater; Korotkoff phase V is used to define diastolic pressure. In the past, it had been recommended that an incremental increase of 30 mm Hg systolic or 15 mm Hg diastolic pressure be used as diagnostic criteria, even when absolute values were below 140/90 mm Hg. These criteria are no longer recommended because evidence shows that these women are not likely to suffer increased adverse pregnancy outcomes (Levine and co-workers, 2000; North and colleagues, 1999). That said, women who have a rise of 30 mm Hg systolic or 15 mm Hg diastolic warrant close observation. Edema has been abandoned as a diagnostic criterion because it occurs in too many normal pregnant women to be discriminant.

GESTATIONAL HYPERTENSION. As shown in [Table 34-1](#), the diagnosis of gestational hypertension is made in women whose blood pressure reaches 140/90 mm Hg or greater for the first time during pregnancy but in whom *proteinuria is not identified*. Gestational hypertension is also called *transient hypertension* if preeclampsia does not develop and the blood pressure has returned to normal by 12 weeks' postpartum. In this classification, the final diagnosis that the woman *does not* have gestational hypertension is not made until several weeks after delivery. Thus, gestational hypertension is a diagnosis of exclusion. Importantly, some women with gestational hypertension may later develop other findings of preeclampsia, for example, symptoms such as headaches or epigastric pain, proteinuria, or thrombocytopenia, all of which influence management.

When blood pressure rises appreciably during the latter half of pregnancy, it is dangerous, especially to the fetus, not to act simply because proteinuria has not yet developed. As Chesley (1985) emphasized, 10 percent of eclamptic seizures develop before overt proteinuria is identified. Thus, it is clear that when blood pressure begins to rise, both mother and fetus are at increased risk. Proteinuria is a sign of worsening hypertensive disease, specifically preeclampsia. Overt and persistent proteinuria further increases maternal and fetal risks.

PREECLAMPSIA. This condition is best described as a *pregnancy-specific syndrome* of reduced organ perfusion secondary to vasospasm and endothelial activation. *Proteinuria* is an important sign of preeclampsia, and Chesley (1985) rightfully concluded that the diagnosis is questionable in its absence. Significant proteinuria is defined by 24-hour urinary protein exceeding 300 mg per 24 hours, or persistent 30 mg/dL (1+ dipstick) in random urine samples. The degree of proteinuria may fluctuate widely over any 24-hour period, even in severe cases. Therefore, a single random sample may fail to demonstrate significant proteinuria.

In their extensive study of renal biopsy specimens obtained from hypertensive pregnant women, McCartney and co-workers (1971) invariably found proteinuria when the glomerular lesion considered to be characteristic of preeclampsia was evident. Importantly, both proteinuria and alterations of glomerular histology develop late in the course. It is apparent that preeclampsia becomes evident clinically only near the end of a covert pathophysiological process that may begin as early as implantation.

Thus, the minimum criteria for the diagnosis of preeclampsia are hypertension plus minimal proteinuria. The more severe the hypertension or proteinuria, the more certain is the diagnosis of preeclampsia (see [Table 34-1](#)). Similarly, abnormal laboratory findings in tests of renal, hepatic, and hematological function increase the certainty of preeclampsia. In addition, persistent premonitory symptoms of eclampsia, such as headache and epigastric pain, also increase the certainty.

The combination of proteinuria and hypertension during pregnancy markedly increases the risk of perinatal mortality and morbidity (Ferrazzani and associates, 1990). A widely quoted study by Friedman and Neff (1976) of more than 38,000 pregnancies was completed over three decades ago. It showed that diastolic hypertension of 95 mm Hg or greater was associated with a threefold increase in the fetal death rate. Worsening hypertension, especially if accompanied by proteinuria, was more ominous, but proteinuria without hypertension was rather benign. In a recent study, however, Newman and co-workers (2003) reported that worsening proteinuria resulted in increasing preterm delivery, but that neonatal survival was not significantly altered. In contrast, following their analysis of more than 9000 nulliparous women ascertained from the Collaborative Perinatal Project, a large cohort study conducted between 1959 and 1965, Zhang and co-workers (2001) concluded that neither blood pressure severity nor proteinuria were sensitive predictors of adverse outcome.

Epigastric or right upper quadrant pain is thought to result from hepatocellular necrosis, ischemia, and edema that stretches the Glisson capsule. This characteristic pain is frequently accompanied by elevated serum hepatic transaminase levels and usually is a sign to terminate the pregnancy. The pain presages hepatic infarction and hemorrhage or catastrophic rupture of a subcapsular hematoma. Fortunately, hepatic rupture is rare.

Thrombocytopenia is characteristic of worsening preeclampsia, and it probably is caused by platelet activation and aggregation as well as microangiopathic hemolysis induced by severe vasospasm. Evidence of gross hemolysis such as hemoglobinemia, hemoglobinuria, or hyperbilirubinemia is indicative of severe disease.

Other factors indicative of severe hypertension include cardiac dysfunction with pulmonary edema as well as obvious fetal growth restriction.

Severity of Preeclampsia. The severity of preeclampsia is assessed by the frequency and intensity of the abnormalities listed in [Table 34-2](#). The more profound these aberrations, the more likely is the need for pregnancy termination. **The differentiation between mild and severe preeclampsia can be misleading because apparently mild disease may progress rapidly to severe disease.**

Although hypertension is a requisite to diagnosing preeclampsia, absolute blood pressure alone is not always a dependable indicator of its severity. For example, young adolescent women may have 3+ proteinuria and convulsions with a blood pressure of 135/85 mm Hg, whereas most women with blood pressures as high as 180/120 mm Hg do not have seizures. A rapid increase in blood pressure followed by convulsions is usually preceded by an unrelenting severe headache or visual disturbances. For this reason, these symptoms are considered ominous.

ECLAMPSIA. The onset of convulsions in a woman with preeclampsia that cannot be attributed to other causes is termed eclampsia. The seizures are generalized and may appear before, during, or after labor. In older studies, in about 10 percent of eclamptic women, especially nulliparas, seizures did not develop until after 48 hours postpartum (Brown and colleagues, 1987; Lubarsky and associates, 1994). As prenatal care improved, many antepartum and intrapartum cases are now prevented, and a more recent study reported that a fourth of eclamptic seizures developed beyond 48 hours postpartum (Chames and co-workers, 2002).

PREECLAMPSIA SUPERIMPOSED ON CHRONIC HYPERTENSION. All *chronic hypertensive disorders*, regardless of their cause, predispose to development of superimposed preeclampsia and eclampsia. These disorders can create difficult problems with diagnosis and management in women who are not seen until after midpregnancy. The diagnosis of chronic underlying hypertension is made when:

1. Hypertension (140/90 mm Hg or greater) is documented antecedent to pregnancy.
2. Hypertension (140/90 mm Hg or greater) is detected before 20 weeks, unless there is gestational trophoblastic disease.
3. Hypertension persists long after delivery (see [Table 34-1](#)).

Additional historical factors that help support the diagnosis are multiparity and hypertension complicating a previous pregnancy other than the first. There frequently is also a family history of essential hypertension.

The diagnosis of chronic hypertension may be difficult to make if the woman is not seen until the latter half of pregnancy, because blood pressure decreases during the second and early third trimesters in both normotensive and chronically hypertensive women (see [Chap. 45](#), p. 1045). Thus, a woman with chronic vascular disease, who is seen for the first time at 20 weeks, frequently has blood pressure within the normal accepted range. During the third trimester, however, if blood

pressure returns to its former hypertensive level, it presents a diagnostic problem as to whether the hypertension is chronic or induced by pregnancy. In these situations, a search for evidence of end-organ damage from chronic hypertension may help elucidate the underlying cause of hypertension. Examples include left ventricular hypertrophy or retinal changes such as arteriolar narrowing, exudates, or cotton-wool spots.

Some of the many causes of underlying hypertension that are encountered during pregnancy are listed in [Table 34-3](#). Essential or familial hypertension is the cause of underlying vascular disease in more than 90 percent of pregnant women. Obesity and diabetes are other common causes. In some women, hypertension develops as a consequence of underlying renal parenchymal disease. Although earlier studies of renal biopsies identified abnormalities, especially in multiparas, Fisher and co-workers (1969) did not confirm a high prevalence of chronic glomerulonephritis.

Depending on its duration, chronic hypertension can lead to ventricular hypertrophy and cardiac decompensation, cerebrovascular accidents, or renal damage. These complications are more likely during pregnancy if there is superimposed preeclampsia, which develops in up to 25 percent of these women (Sibai and colleagues, 1998). The risk of placental abruption is also increased substantively if there is superimposed preeclampsia (see [Chap. 35](#), p. 813). Moreover, the fetuses of women with chronic hypertension are at appreciable risks for growth restriction, preterm delivery, and death.

In some women with chronic hypertension, blood pressure increases to abnormal levels, typically after 24 weeks. If accompanied by proteinuria, then superimposed preeclampsia is diagnosed. Often, superimposed preeclampsia develops earlier in pregnancy than "pure" preeclampsia, and it tends to be more severe and often accompanied by fetal growth restriction. Indicators of severity shown in [Table 34-2](#) are also used to further characterize superimposed preeclampsia.

INCIDENCE AND RISK FACTORS. Gestational hypertension more often affects nulliparous women. Because of the increasing incidence of chronic hypertension with advancing age, older women are at greater risk for superimposed preeclampsia. Thus, women at either end of reproductive age are considered to be more susceptible (see [Chap. 7](#), p. 194).

The incidence of preeclampsia is commonly cited to be about 5 percent, although rather wide variations are reported. The incidence is markedly influenced by parity; it is related to race and ethnicity and thus to genetic predisposition, and environmental factors likely also play a role. For example, Palmer and associates (1999) reported that living at high altitude in Colorado increased the incidence of preeclampsia. Some investigators have concluded that socioeconomically advantaged women have a lesser incidence of preeclampsia, however, Lawlor and colleagues (2005) did not observe this in an Aberdeen cohort of 3485 women.

The incidence of hypertensive disorders in healthy nulliparous women was carefully studied in a trial of dietary calcium supplementation (Hauth and colleagues, 2000). Of 4302 nulliparous women delivered at or beyond 20 weeks, a fourth developed a pregnancy-related hypertensive disorder. When all nulliparas were considered, preeclampsia was diagnosed in 7.6 percent and severe disease developed in 3.3 percent. By contrast, Vatten and Skj(2004) reported an incidence of preeclampsia of 2.6 percent in more than 1.6 million Norwegian nulliparas.

Other risk factors associated with preeclampsia include chronic hypertension as discussed, multifetal gestation, maternal age over 35 years, obesity, and African-American ethnicity (Conde-Agudelo and Belizan, 2000; Sibai and colleagues, 1997; Walker, 2000). The relationship between maternal weight and the risk of preeclampsia is progressive. It increases from 4.3 percent for women with a body mass index less than 19.8 kg/m² to 13.3 percent in those with a body mass index greater than 35 kg/m². In women with twin gestations compared with those with singletons, the incidence of gestational hypertension (13 versus 6 percent) and the incidence of preeclampsia (13 versus 5 percent) are both significantly increased (Sibai and co-workers, 2000). The incidence is unrelated to zygosity (Maxwell and associates, 2001). Although smoking during pregnancy causes a variety of adverse pregnancy outcomes, ironically, smoking has consistently been associated with a *reduced risk* of hypertension during pregnancy (Bainbridge and associates, 2005; Zhang and colleagues, 1999). Placenta previa has also been reported to reduce the risk of hypertensive disorders in pregnancy (Ananth and colleagues, 1997).

Eclampsia. This condition is somewhat preventable, and its incidence has decreased in the United States because most women now receive adequate prenatal care. For example, in the 15th edition of *Williams Obstetrics* (1976), for the prior 25-year period, the incidence of eclampsia at Parkland Hospital was 1 in 700 deliveries. For the 4-year period from 1983 to 1986, it decreased to 1 in 1150 deliveries, and for the 3-year period ending in 1999, it was approximately 1 in 1750 deliveries (Alexander and associates, 2004). In the National Vital Statistics Report, Ventura and colleagues (2000) estimated that the incidence of eclampsia in the United States in 1998 was about 1 in 3250. In the United Kingdom in 1992, Douglas and Redman (1994) reported that the incidence of eclampsia was 1 in 2000.

ETIOLOGY

Any satisfactory theory concerning the etiology and pathophysiology of preeclampsia must account for the observation that hypertensive disorders due to pregnancy are very much more likely to develop in women who:

1. Are exposed to chorionic villi for the first time.
2. Are exposed to a superabundance of chorionic villi, as with twins or hydatidiform mole.
3. Have preexisting vascular disease.
4. Are genetically predisposed to hypertension developing during pregnancy.

Although chorionic villi are essential, they need not be located within the uterus. A fetus is not a requisite for preeclampsia. Regardless of precipitating etiology, the cascade of events that leads to the preeclampsia syndrome is characterized by a host of abnormalities that result in vascular endothelial damage with vasospasm, transudation of plasma, and ischemic and thrombotic sequelae.

Writings describing eclampsia have been traced as far back as 2200 b.c. (Lindheimer and colleagues, 1999). It is thus not surprising that a number of mechanisms have been proposed to explain its cause. Many of the absurd, and especially the dangerous, thankfully have been discarded. According to Sibai (2003), currently plausible potential causes include the following:

1. Abnormal trophoblastic invasion of uterine vessels.
2. Immunological intolerance between maternal and fetoplacental tissues.
3. Maternal maladaptation to cardiovascular or inflammatory changes of normal pregnancy.
4. Dietary deficiencies.
5. Genetic influences.

ABNORMAL TROPHOBLASTIC INVASION. In normal implantation, the uterine spiral arteries undergo extensive remodeling as they are invaded by endovascular trophoblasts (Fig. 34-1). In preeclampsia, however, there is *incomplete trophoblastic invasion*. In this case, decidual vessels, but not myometrial vessels, become lined with endovascular trophoblasts. Meekins and co-workers (1994) described a continuum in the number of spiral arteries with endovascular trophoblasts in placentas of normal women and in those with preeclampsia. Madazli and colleagues (2000) showed that the magnitude of defective trophoblastic invasion of the spiral arteries correlated with the severity of the hypertensive disorder.

Using electron microscopy, De Wolf and co-workers (1980) examined arteries taken from the uteroplacental implantation site. They observed that early preeclamptic changes included endothelial damage, insudation of plasma constituents into vessel walls, proliferation of myointimal cells, and medial necrosis. They found that lipid accumulates first in myointimal cells and then in macrophages. Shown in Figure 34-2, such lipid-laden cells and associated findings have been termed *atherosis* (Hertig, 1945). Typically, the vessels affected by atherosclerosis develop aneurysmal dilatation and are frequently found in association with spiral arterioles that have failed to undergo normal adaptation (Khong, 1991). Obstruction of the spiral arteriolar lumen by atherosclerosis may impair placental blood flow. It is thought that these changes cause placental perfusion to be pathologically diminished, which eventually leads to the preeclampsia syndrome (Lain and Roberts, 2002; Redman and Sargent, 2003).

Figure 34-1. Normal placental implantation shows proliferation of extravillous trophoblasts, forming a cell column beneath the anchoring villus. The extravillous trophoblasts invade the decidua and extend down the inside of the spiral arteriole. This results in replacement of the endothelium and muscular wall of the vessel and in subsequent enlargement of the blood vessel. (From Rogers and colleagues, 1999, with permission.)

Figure 34-2. Atherosclerosis is demonstrated in this blood vessel from the placental bed (left, photomicrograph; right schematic diagram of vessel). Disruption of the endothelium results in a narrowed lumen because of accumulation of plasma proteins and foamy macrophages beneath the endothelium. Some of the foamy macrophages are shown by *curved arrows* in the left photograph and *straight arrows* highlight areas of endothelial disruption. (Modified from Rogers and colleagues, 1999, with permission.)

IMMUNOLOGICAL FACTORS. There is circumstantial evidence to support the theory that preeclampsia is immune mediated. Certainly the microscopic changes at the maternal-placental interface are suggestive of acute graft rejection (Labarrere, 1988). There are also inferential data. For example, the risk of preeclampsia is appreciably enhanced in circumstances where formation of blocking antibodies to placental antigenic sites *might* be impaired. This may arise in situations in which effective immunization by a previous pregnancy is lacking, as in first pregnancies; or in which the number of antigenic sites provided by the placenta is unusually great compared with the amount of antibody, as with multiple fetuses (Beer, 1978). "Immunization" from a prior abortion does not seem to occur. Strickland and associates (1986) analyzed outcomes of over 29,000 pregnancies at Parkland Hospital and reported that hypertensive disorders were decreased only slightly (22 versus 25 percent) in women who previously had miscarried (thus who were previously "immunized") and were now having their first advanced pregnancy. The immunization concept was supported by their observations that preeclampsia developed less often in multiparas who had a prior term pregnancy. Other studies have shown that multiparous women impregnated by a new consort have an increased risk of preeclampsia (Mostello and co-workers, 2002; Trupin and colleagues, 1996).

Dekker and Sibai (1998) have reviewed the possible role of immune maladaptation in the pathophysiology of preeclampsia. Beginning in the early second trimester, women destined to develop preeclampsia have a significantly lower proportion of helper T cells (Th_1) compared with that of women who remain normotensive (Bardeguet and associates, 1991). This Th_1/Th_2 imbalance, with Th_2 dominance, may be mediated by adenosine, which is found in higher serum levels in preeclamptic compared with normotensive women (Yoneyama and co-workers, 2002). These helper T lymphocytes secrete specific cytokines that promote implantation, and their dysfunction may favor preeclampsia (Hayashi and associates, 2004; Whitecar and colleagues, 2001).

In women with anticardiolipin antibodies, placental abnormalities and preeclampsia develop more commonly (see [Chap. 54](#), p. 1217). This, however, was recently challenged by Branch and associates (2001). According to Katano and colleagues (1996), antibodies associated with β_2 -glycoprotein I appear most relevant. Immune complexes and anti-endothelial cell antibodies may also be involved (Taylor and Roberts, 1999).

THE VASCULOPATHY AND THE INFLAMMATORY CHANGES. In many ways, inflammatory changes are a continuation of the placental cause(s) discussed above. In response to placental factors released by ischemic changes, or any other inciting cause, a cascade of events is set in motion (Redman and Sargent, 2003). The decidua also contains an abundance of cells that, when activated, can release noxious agents (Staff and colleagues, 1999). These then serve as mediators to provoke endothelial cell injury.

Redman and colleagues (1999) have proposed that the endothelial cell dysfunction associated with preeclampsia can result from a "generalized perturbation of the normal, generalized maternal intravascular inflammatory adaptation to pregnancy" ([Fig. 34-3](#)). In this hypothesis, preeclampsia is considered a disease due to an extreme state of activated leukocytes in the maternal circulation (Faas and colleagues, 2000; Gervasi and co-workers, 2001). Briefly, cytokines such as tumor necrosis factor- α (TNF- α) and the interleukins may contribute to the oxidative stress associated with preeclampsia. Oxidative stress is characterized by reactive oxygen species and free radicals that lead to formation of self-propagating lipid peroxides (Manten and associates, 2005). These in turn generate highly toxic radicals that injure endothelial cells, modify their nitric oxide production, and interfere with prostaglandin balance.

Not all investigators have confirmed these findings. Diedrich and colleagues (2001) did not detect any lipid hydroperoxides in 38 preeclamptic women, 10 of whom had HELLP syndrome (hemolysis, elevated liver enzymes, low platelets). They did, however, find other evidence of oxidative stress. Other consequences of oxidative stress include production of the lipid-laden macrophage foam cells seen in atherosclerosis (see [Fig. 34-2](#)); activation of microvascular coagulation, seen in thrombocytopenia; and increased capillary permeability, seen in edema and proteinuria.

These observations on the effects of oxidative stress in preeclampsia have given rise to increased interest in the potential benefit of antioxidants to prevent preeclampsia (Chappell and colleagues, 1999; Zhang and co-workers, 2002). Antioxidants are a diverse family of compounds that function to prevent overproduction of and damage caused by noxious free radicals. Examples of antioxidants include vitamin E or α -tocopherol, vitamin C (ascorbic acid), and β -carotene. Dietary supplementation with these antioxidants is discussed on page 780.

Figure 34-3. Pathophysiological considerations in the development of hypertensive disorders due to pregnancy. (Adapted from Friedman and Lindheimer, 1999, with permission.)

NUTRITIONAL FACTORS. A number of dietary deficiencies or excesses over the centuries have been blamed as the cause of eclampsia. Dietary taboos that have included meat, protein, purines, fat, dairy products, salt, and other elements have been advocated at times. Observations and theories led to studies of dietary deprivation of various sorts that many times were models of absurdity. In more recent times, sanity and a scientific approach have prevailed. For example, blood pressure in nonpregnant individuals is affected by a number of dietary influences, including minerals and vitamins. Some studies have shown a relationship between dietary deficiencies and the incidence of preeclampsia. This was followed by studies of supplementation with various elements such as zinc, calcium, and magnesium to prevent preeclampsia. Other studies, such as the one by John and co-workers (2002), showed that in the general population a diet high in fruits and vegetables that have antioxidant activity is associated with decreased blood pressure. This is related to the case-control study by Zhang and associates (2002) cited above, in which the incidence of preeclampsia was doubled in women whose daily intake of ascorbic acid was less than 85 mg.

As previously discussed, obesity is a potent risk factor for preeclampsia (see also [Chap. 43](#), p. 1012). Evidence has accrued that obesity in nonpregnant individuals causes endothelial activation and a systemic inflammatory response associated with atherosclerosis (Ross, 1999). In the study of pregnant women by Wolf and colleagues (2001), C-reactive protein, an inflammatory marker, was shown to be increased in obesity, which in turn was associated with preeclampsia.

GENETIC FACTORS. The predisposition to hereditary hypertension undoubtedly is linked to preeclampsia (Ness and colleagues, 2003), and the tendency for preeclampsia-eclampsia is inherited. Chesley and Cooper (1986) studied sisters, daughters, granddaughters, and daughters-in-law of eclamptic women and concluded that preeclampsia-eclampsia is highly heritable. The single-gene model, with a frequency of 0.25, best explained their observations. Other investigators cite possibilities of polygenic inheritance (Trogstad and co-workers, 2004). A Swedish study by Nilsson and co-workers (2004) that included almost 1.2 million births reported a genetic component for gestational hypertension as well as preeclampsia. They reported 60-percent concordance in monozygotic female twin pairs, which was much higher than that found by Treloar and co-workers (2001).

Kilpatrick and associates (1989), but not Hayward and co-workers (1992), reported an association between the histocompatibility antigen HLA-DR4 and proteinuric hypertension. Hoff and associates (1992) concluded that a maternal humoral response directed against fetal anti-HLA-DR immunoglobulin antibody might influence the development of gestational hypertension. A number of single-gene mutations have been studied in women with preeclampsia. For example, Ward (1993) and Zhang (2003) and their associates reported that women heterozygous for the angiotensinogen gene variant T235 had a higher incidence preeclampsia and fetal growth restriction. Morgan and colleagues (1995, 1999) did not confirm this, but they did find that women homozygous for this mutation had abnormal trophoblastic invasion. Some of the inherited thrombophilias

predispose some women to preeclampsia (see [Table 47-4](#), p. 1079). Polymorphisms of the genes for TNF, lymphotoxin- α , and interleukin-1 β have been studied with varying results (Hefler, 2001; Lachmeijer, 2001; Livingston, 2001b, and all their colleagues).

PATHOGENESIS

VASOSPASM. The concept of vasospasm was advanced by Volhard (1918) based on direct observations of small blood vessels in the nail beds, ocular fundi, and bulbar conjunctivae. It was also surmised from histological changes seen in various affected organs (Hinselmann, 1924; Landesman and co-workers, 1954). Vascular constriction causes resistance and subsequent hypertension. At the same time, endothelial cell damage causes interstitial leakage through which blood constituents, including platelets and fibrinogen, are deposited subendothelially. Wang and colleagues (2002) have also demonstrated disruption of endothelial junctional proteins. Suzuki and co-workers (2003) demonstrated ultrastructural changes in the subendothelial region of resistance arteries in preeclamptic women. With diminished blood flow because of maldistribution, ischemia of the surrounding tissues would lead to necrosis, hemorrhage, and other end-organ disturbances characteristic of the syndrome. Ironically, vasospasm may be worse in women with preeclampsia than in those with the HELLP syndrome (Fischer and colleagues, 2000).

ENDOTHELIAL CELL ACTIVATION. Over the past two decades, endothelial cell activation has become the centerpiece in the contemporary understanding of the pathogenesis of preeclampsia (see [Fig. 34-3](#)). In this scheme, unknown factor(s), likely from the placenta, are secreted into the maternal circulation and provoke activation and dysfunction of the vascular endothelium. The clinical syndrome of preeclampsia is thought to result from these widespread endothelial cell changes (Hayman and associates, 2000; Roberts, 2000; Walker, 2000).

Intact endothelium has anticoagulant properties, and it also blunts the response of vascular smooth muscle to agonists by releasing nitric oxide. Damaged or activated endothelial cells secrete substances that promote coagulation and increase the sensitivity to vasopressors. Further evidence of endothelial activation includes the characteristic changes in glomerular capillary endothelial morphology, increased capillary permeability, and elevated blood concentrations of substances associated with such activation. These latter substances are transferrable, and serum from women with preeclampsia stimulates cultured endothelial cells to produce greater amounts of prostacyclin than serum from normal pregnant women.

Increased Pressor Responses. Normally, pregnant women develop refractoriness to infused vasopressors (Abdul-Karim and Assali, 1961). Women with early preeclampsia, however, have increased vascular reactivity to infused norepinephrine and angiotensin II (Raab and co-workers, 1956; Talledo and associates, 1968). Moreover, increased sensitivity to angiotensin II clearly precedes the onset of gestational hypertension ([Fig. 34-4](#)). Normotensive nulliparas remained refractory to infused angiotensin II, but those who subsequently became hypertensive lost this refractoriness several weeks before the onset of hypertension. Women with underlying chronic hypertension have almost identical responses (Gant and colleagues, 1977).

PROSTAGLANDINS. A number of prostanoids are central to the pathophysiology of the preeclampsia syndrome. Specifically, the blunted pressor response seen in normal pregnancy is at least partially due to decreased vascular responsiveness mediated by vascular endothelial prostaglandin synthesis. For example, when compared with normal pregnancy, endothelial prostacyclin (PGI₂) production is decreased in preeclampsia. This action appears to be mediated by phospholipase A₂ (Taylor and Roberts, 1999). At the same time, thromboxane A₂ secretion by platelets is increased, and the prostacyclin:thromboxane A₂ ratio decreases. The net result favors increased sensitivity to infused angiotensin II, and ultimately, vasoconstriction. Chavarria and co-workers (2003b) have provided evidence that these changes are apparent as early as 22 weeks in women who later develop preeclampsia.

NITRIC OXIDE. This potent vasodilator is synthesized from L-arginine by endothelial cells. Withdrawal of nitric oxide results in a clinical picture similar to preeclampsia in a pregnant animal model (Conrad and Vernier, 1989; Weiner and associates, 1989). In other animal studies, inhibition of nitric oxide synthesis increases mean arterial pressure, decreases heart rate, and reverses the pregnancy-induced refractoriness to vasopressors. In humans, nitric oxide likely is the compound that maintains the normal low-pressure vasodilated state characteristic of fetoplacental perfusion (Myatt and co-workers, 1992; Weiner and associates, 1992). It also is produced by fetal endothelium and is increased in response to preeclampsia, diabetes, and infection (Parra and associates, 2001; von Mandach and co-workers, 2003).

Preeclampsia is associated with decreased endothelial nitric oxide synthase expression, which increases cell permeability (Wang and colleagues, 2004). There is not decreased nitric oxide release or production prior to the onset of hypertension (Anumba and colleagues, 1999). Its production is increased in severe preeclampsia possibly as a compensatory mechanism for the increased synthesis and release of vasoconstrictors and platelet-aggregating agents (Benedetto and associates, 2000). Thus, increased serum concentrations of nitric oxide in women with preeclampsia are likely the result of hypertension, not the cause (Morris and colleagues, 1996).

ENDOTHELINS. These 21-amino acid peptides are potent vasoconstrictors, and endothelin-1 (ET-1) is the primary isoform produced by human endothelium (Mastrogiannis and co-workers, 1991). Plasma ET-1 is increased in normotensive pregnant women, but women with preeclampsia have even higher levels (Ajne, 2003; Clark, 1992; Nova, 1991, and their associates). According to Taylor and Roberts (1999), the placenta is not the source of increased ET-1 and it likely arises from systemic endothelial activation. Interestingly, treatment of preeclamptic women with magnesium sulfate lowers ET-1 concentrations (Sagsoz and Kucukozkan, 2003).

ANGIOGENIC FACTORS. Several glycosylated glycoproteins are selectively mitogenic for endothelial cells and are thought to be important in mediating the preeclampsia syndrome. Two of these are *vascular endothelial growth factor (VEGF)* and *placental growth factor (PlGF)*. Their secretion increases across normal pregnancy, and they promote angiogenesis and induce nitric oxide and vasodilatory prostaglandins, discussed above. Placental VEGF is important in vasculogenesis and control of microvascular permeability.

Paradoxically, VEGF is increased in serum from women with preeclampsia but its bioavailability is decreased (Baker and

associates, 1995; Simmons and co-workers, 2000). In preeclampsia, the gene for *soluble fms-like tyrosine kinase 1 (sFlt1)* is upregulated, and serum levels are increased for up to 48 hours after delivery (Maynard and associates, 2003). Because sFlt1 antagonizes VEGF and PlGF by binding them and decreasing their unbound serum levels, their effects are lost and there is endothelial dysfunction (Luttun and Carmeliet, 2003).

Figure 34-4. Comparison of the mean angiotensin II infusion doses required to evoke a pressor response in 120 nulliparous women who remained normotensive (solid circles) and 72 who subsequently developed pregnancy-induced hypertension (open circles). (From Gant and co-workers, 1973, with permission.)

PATHOPHYSIOLOGY

By strict definition, preeclampsia-eclampsia fits the definition of a syndrome: *A group of symptoms or pathological signs which consistently occur together, especially with an (originally) unknown cause* (Oxford English Dictionary, 1993). Although the cause of preeclampsia remains unknown, evidence for it begins to manifest early in pregnancy with covert pathophysiological changes that gain momentum across gestation. Unless delivery supervenes, these changes ultimately result in multiorgan involvement with a clinical spectrum ranging from barely noticeable to one of cataclysmic pathophysiological deterioration that can be life threatening for both mother and fetus. These adverse maternal and fetal effects develop simultaneously. As discussed, these presumably are a consequence of vasospasm, endothelial dysfunction, and ischemia. The myriad of maternal consequences of the preeclampsia syndrome are described in terms of organ systems, but they frequently overlap. It is enigmatic that there are such wide variations of involvement of these systems in individual pregnancies.

CARDIOVASCULAR SYSTEM. Severe disturbances of normal cardiovascular function are common with preeclampsia or eclampsia. These are related to (1) increased cardiac afterload caused by hypertension; (2) cardiac preload, which is substantively affected by pathologically diminished hypervolemia of pregnancy or is iatrogenically increased by intravenous crystalloid or oncotic solutions; and (3) endothelial activation with extravasation into the extracellular space, especially the lung (see [Chap. 42](#), p. 991). In addition, left ventricular mass is increased relative to normal pregnancy (Borghi and colleagues, 2000).

Hemodynamic Changes. The cardiovascular aberrations of hypertensive disorders of pregnancy vary depending on a number of factors. Some of these include severity of hypertension, presence of underlying chronic disease, whether preeclampsia is present, and at what point in the clinical course they are studied. For example, some of these changes precede the onset of hypertension. Bosio and colleagues (1999) used noninvasive Doppler hemodynamic monitoring in a longitudinal study of 400 nulliparous women commencing early in pregnancy. Gestational hypertension developed in 24 women, and 20 others had preeclampsia. Compared with normotensive women, the women who developed preeclampsia had significantly elevated cardiac outputs before hypertension developed. This substantiates earlier observations of Easterling and co-workers (1990), except that the latter group reported increased peripheral resistance during this preclinical phase. With clinical onset of preeclampsia, there was a marked reduction in cardiac output and increased peripheral resistance. By contrast, the women with gestational hypertension maintained their significantly elevated cardiac outputs with development of hypertension.

Much of the data based on invasive hemodynamic studies ([Table 34-4](#)) are confounded because of these factors as well as interventions that also may significantly alter these measurements. Thus, variables that define cardiovascular status in women with hypertensive disorders range from high cardiac output with low vascular resistance to low cardiac output with high resistance. Similarly, left ventricular filling pressures, estimated by pulmonary capillary wedge pressure determination, range from low to pathologically high. The studies listed in [Table 34-4](#) are separated into three groups based on clinical management prior to when the initial hemodynamic studies were done:

1. No therapy.
2. Magnesium sulfate and hydralazine without large volumes of intravenous fluid.
3. Magnesium sulfate and hydralazine plus intravenous volume loading.

Ventricular function studies from the investigations in [Table 34-4](#) are plotted in [Figure 34-5](#). Although cardiac function was hyperdynamic in all women, filling pressures varied markedly. Data obtained prior to treatment of preeclampsia identified normal left ventricular filling pressures, high systemic vascular resistances, and hyperdynamic ventricular function. Benedetti (1980) and Hankins (1984) and their associates reported similar findings in women with severe preeclampsia or eclampsia who were being treated with magnesium sulfate and hydralazine, and with intravenous crystalloid restricted to 75 to 100 mL/hour. Cardiac function was normal, and decreased vascular resistance was most likely due to hydralazine treatment.

Women similarly treated with magnesium sulfate and hydralazine plus aggressive intravenous therapy or volume expansion had the lowest systemic vascular resistances and highest cardiac outputs. Volume restriction with aggressive hydration results in hyperdynamic ventricular function in most women in both groups, however, there were two responses with respect to left ventricular stroke work index and pulmonary capillary wedge pressure ([Fig. 34-6](#)). Women in the fluid restriction group had pulmonary wedge pressures less than 10 mm Hg, and most were less than 5 mm Hg. Thus, hyperdynamic ventricular function was largely a result of low wedge pressures and not a result of augmented myocardial contractility measured as left ventricular stroke work index. By comparison, women given appreciably larger volumes of fluid commonly had filling pressures that exceeded normal, but their ventricular function remained hyperdynamic because of increased cardiac output.

From these studies, it is reasonable to conclude that aggressive fluid administration given to women with severe preeclampsia causes normal left-sided filling pressures to become substantively elevated, while increasing an already normal cardiac output to supranormal levels.

Blood Volume. It has been known for over 75 years that *hemoconcentration* is a hallmark of eclampsia. Zeeman and colleagues (2004b) expanded the previous observations of Pritchard and co-workers (1984) that in eclamptic women the normally expected hypervolemia was severely curtailed or even absent (Fig. 34-7). Women of average size should have a blood volume of nearly 5000 mL during the last several weeks of a normal pregnancy, compared with about 3500 mL when they are not pregnant. With eclampsia, however, much or all of the anticipated excess 1500 mL of blood normally present is absent. Such hemoconcentration is likely the consequence of generalized vasoconstriction and endothelial dysfunction with vascular permeability. In women with preeclampsia, and depending on severity, hemoconcentration is usually not as marked, whereas women with gestational hypertension usually have a normal blood volume (Silver and colleagues, 1998; Silver and Seebeck, 1996).

For women with severe hemoconcentration, it was once taught that an acute fall in hematocrit suggested resolution of preeclampsia. However, this usually is the consequence of blood loss, even of normal amounts, at delivery. It may also be partially the result of intense erythrocyte destruction as subsequently described.

In the absence of hemorrhage, the intravascular compartment in eclamptic women is usually not underfilled. Vasospasm and endothelial leakage of plasma has contracted the space to be filled. These changes persist until a variable amount of time after delivery when the vascular endothelium repairs. Vasodilation then occurs, and as the blood volume increases, the hematocrit usually falls. Thus, women with eclampsia:

1. Are unduly sensitive to vigorous fluid therapy administered in an attempt to expand the contracted blood volume to normal pregnancy levels.
2. Are quite sensitive to even normal blood loss at delivery. (Management in these circumstances is considered in [Chapter 35.](#))

Figure 34-5. Ventricular function in severe preeclampsia-eclampsia. Data plotted represent mean values obtained in five of six studies cited in Table 34-4. Left ventricular stroke work index (LVSWI) and pulmonary artery capillary wedge pressure (PCWP) are plotted on a standard ventricular function curve. Points falling within the two solid lines represent normal function, whereas those below represent depressed function. Points above the solid lines represent hyperdynamic ventricular function. Each letter adjacent to the data points is the first initial of the last name of the investigator who reported this value. (From Hauth and Cunningham, 1999, with permission.)

Figure 34-6. Ventricular function in women with severe preeclampsia-eclampsia. Left ventricular stroke work index (LVSWI) and pulmonary capillary wedge pressure (PCWP) are plotted. **A.** Restricted intravenous fluids. **B.** Aggressive fluid therapy. (From Hankins and colleagues, 1984, with permission.)

Figure 34-7. Bar graph comparing nonpregnant mean blood volumes with those obtained at the time of delivery in a group of women with normal pregnancy, eclampsia in their first pregnancy, and subsequent normal pregnancy in some of the women who had eclampsia. Extensions above bars represent one standard deviation. Comparison between values with identical lowercase letters (namely, a-a, b-b, c-c, d-d) are significant ($P < .001$). (Data from Zeeman and Cunningham, 2002.)

BLOOD AND COAGULATION. Hematological abnormalities develop in some women with preeclampsia.

Among these are thrombocytopenia, which at times may become so severe as to be life threatening. In addition, the levels of some plasma clotting factors may be decreased, and erythrocytes may display bizarre shapes and undergo rapid hemolysis.

Platelets. Because thrombocytopenia can be induced acutely by preeclampsia-eclampsia, the platelet count is routinely measured in hypertensive pregnant women. The frequency and intensity of maternal thrombocytopenia varies and likely is dependent on the intensity of the disease process, duration of preeclampsia, and the frequency with which platelet counts are performed. Overt thrombocytopenia, defined by a platelet count less than $100,000/\mu\text{L}$, indicates severe disease (see [Table 34-2](#)). In most cases, delivery is indicated because the platelet count continues to decrease. After delivery, the platelet count increases progressively to reach a normal level within 3 to 5 days.

Thrombocytopenia results from platelet activation, aggregation, and consumption that is accompanied by increased mean platelet volume and decreased life span (Harlow and colleagues, 2002). Levels of platelet-activating factor are increased (Rowland and co-workers, 2000). Platelet production is increased, and *thrombopoietin*, a cytokine that promotes platelet proliferation from megakaryocytes, is increased in preeclampsia with thrombocytopenia (Frolich and associates, 1998). Paradoxically, in most studies, platelet aggregation is decreased compared with the normal increase seen in pregnancy (Baker and Cunningham, 1999). This likely is due to platelet "exhaustion" following in vivo activation. Although the cause(s) is unknown, immunological processes or simply platelet deposition at sites of endothelial damage may be implicated (Pritchard and colleagues, 1976). Platelet-bound and circulating platelet-bindable immunoglobulins are increased, which suggest platelet surface alterations (Samuels and colleagues, 1987).

HELLP SYNDROME. The clinical significance of thrombocytopenia, in addition to any impairment in coagulation, is that it reflects the severity of the pathological process. In general, the lower the platelet count, the higher the maternal and fetal

morbidity and mortality (Leduc and co-workers, 1992). In 1954, Pritchard and colleagues called attention to thrombocytopenia accompanied by elevated serum liver transaminase levels in women with eclampsia. Weinstein (1982) later referred to this combination of events as the *HELLP syndrome*— hemolysis (H), elevated liver enzymes (EL), and low platelets (LP)— and this moniker now is used worldwide.

NEONATAL THROMBOCYTOPENIA. Thiagarajah and co-workers (1984) and Weinstein (1985) reported thrombocytopenia in neonates whose mothers had preeclampsia. Conversely, Pritchard and colleagues (1987), in a large clinical study, did *not* observe severe thrombocytopenia in the fetus or infant at or very soon after delivery. In fact, no cases of fetal thrombocytopenia were identified, despite severe maternal thrombocytopenia. **Maternal thrombocytopenia in hypertensive women is not a fetal indication for cesarean delivery.**

Coagulation. Subtle changes consistent with intravascular coagulation, and less often erythrocyte destruction, commonly are found with preeclampsia and especially eclampsia (Baker and Cunningham, 1999). Since the early description by Pritchard and co-workers (1954) of coagulation abnormalities in women with eclampsia, there is little evidence that these abnormalities are clinically significant (Pritchard and colleagues, 1984). Except for thrombocytopenia, discussed above, laboratory aberrations generally are mild. Unless there is associated placental abruption, plasma fibrinogen levels do not differ remarkably from levels found in normal pregnancy, and fibrin degradation products are elevated only occasionally. Barron and colleagues (1999) found routine laboratory assessment of coagulation, including prothrombin time, activated partial thromboplastin time, and plasma fibrinogen level, to be unnecessary in the management of pregnancy-associated hypertensive disorders. The *thrombin time* is somewhat prolonged in a third of the cases of eclampsia even when elevated levels of fibrin degradation products are not identified. The reason for this elevation is not known, but it has been attributed to hepatic derangements discussed subsequently (Leduc and associates, 1992).

OTHER CLOTTING FACTORS. Clinically concerning deficiency of any of the soluble coagulation factors is very uncommon in preeclampsia-eclampsia unless another event coexists that predisposes to consumptive coagulopathy. Examples include placental abruption or profound hemorrhage due to hepatic infarction.

The *thrombophilias* are clotting factor deficiencies that lead to hypercoagulability. They may be associated with early-onset preeclampsia (see [Table 47-4](#), p. 1079). *Antithrombin* has been reported to be lower in women with preeclampsia compared with normally pregnant women and women with chronic hypertension (Chang and co-workers, 1992). Theories that antithrombin levels might be used to predict development of preeclampsia have not been confirmed (Sen and colleagues, 1994).

Fibronectin, a glycoprotein associated with vascular endothelial cell basement membrane, is elevated in women with preeclampsia (Brubaker and colleagues, 1992). This observation is consistent with the view that preeclampsia causes vascular endothelial injury with subsequent hematological aberrations.

Fragmentation Hemolysis. Severe preeclampsia is frequently accompanied by evidence of hemolysis indicated by elevated serum lactate dehydrogenase levels. Other evidence is from peripheral blood changes that include schizocytosis, spherocytosis, and reticulocytosis (Cunningham and associates, 1985; Pritchard and colleagues, 1954, 1976). These derangements result in part from microangiopathic hemolysis caused by endothelial disruption with platelet adherence and fibrin deposition. Sanchez-Ramos and colleagues (1994) described increased erythrocyte membrane fluidity with HELLP syndrome and postulated that these changes predispose to hemolysis. Erythrocytic membrane changes, increased adhesiveness, and aggregation may also facilitate a hypercoagulable state (Gamzu and co-workers, 2001; Grisaru and associates, 1997).

VOLUME HOMEOSTASIS

Endocrine Changes. Plasma levels of *renin*, *angiotensin II*, and *aldosterone* are increased during normal pregnancy. With preeclampsia, these values decrease toward the normal nonpregnant range (Weir and colleagues, 1973). With sodium retention, hypertension, or both, renin secretion by the juxtaglomerular apparatus decreases. Renin catalyzes the conversion of angiotensinogen to angiotensin I, which is then transformed into angiotensin II by angiotensin-converting enzyme (ACE). Thus, with preeclampsia, angiotensin II levels decline, resulting in a decrease in aldosterone secretion. Despite this, women with preeclampsia avidly retain infused sodium (Brown and colleagues, 1988b).

Deoxycorticosterone (DOC) is another potent mineralocorticoid that is increased remarkably in third-trimester plasma (see [Chap. 5](#), p. 143). This results from conversion from plasma progesterone rather than increased maternal adrenal secretion. Because of this, DOC is not reduced by sodium retention or hypertension, and it may serve to explain why women with preeclampsia retain sodium.

Vasopressin levels are normal in women with preeclampsia despite decreased plasma osmolality (Durr and Lindheimer, 1999). During normal pregnancy, serum concentrations of *atrial natriuretic peptide* are maintained in the nonpregnant range despite the increased plasma volume. The peptide is released on atrial wall stretching from blood volume expansion. It is vasoactive and promotes sodium and water excretion, probably by inhibiting aldosterone, renin activity, angiotensin II, and vasopressin. Secretion of atrial natriuretic peptide is increased in women with preeclampsia (Borghesi and colleagues, 2000; Gallery and Lindheimer, 1999). Increases in atrial natriuretic peptide following volume expansion result in comparable increases in cardiac output and decreases in peripheral vascular resistance in both normotensive and preeclamptic women (Nisell and associates, 1992). This observation may in part explain observations of a fall in peripheral vascular resistance following volume expansion in preeclamptic women.

Fluid and Electrolyte Changes. The volume of *extracellular fluid*, manifest as edema, in women with severe preeclampsia is usually expanded beyond that of normal pregnant women. The mechanism responsible for pathological fluid retention is thought to be endothelial injury. In addition to generalized edema and proteinuria, these women have reduced plasma oncotic pressure, which creates a filtration imbalance, further displacing intravascular fluid into the surrounding interstitium.

Electrolyte concentrations do not differ appreciably in women with preeclampsia compared with normal pregnant women unless there has been vigorous diuretic therapy, sodium restriction, or administration of free water with sufficient oxytocin to produce antidiuresis.

Following an eclamptic convulsion, the serum pH and *bicarbonate* concentration are lowered due to lactic acidosis and compensatory respiratory loss of carbon dioxide. The intensity of acidosis relates to the amount of lactic acid produced and its metabolic rate, as well as the rate at which carbon dioxide is exhaled.

KIDNEY. During normal pregnancy, renal blood flow and glomerular filtration rate are increased appreciably (see [Chap. 5](#), p. 137). With development of preeclampsia, a number of reversible anatomical and pathophysiological changes may occur. For example, renal perfusion and glomerular filtration are reduced. Levels that are much less than normal nonpregnant values are the consequence of severe disease. Plasma uric acid concentration is typically elevated, especially in women with severe disease. The elevation exceeds the reduction in glomerular filtration rate and creatinine clearance that accompanies preeclampsia (Chesley and Williams, 1945). Taufield and associates (1987) reported that preeclampsia is associated with diminished urinary excretion of calcium because of increased tubular reabsorption.

Mild to moderately diminished glomerular filtration may result from a reduced plasma volume resulting in plasma creatinine values up to twice those expected for normal pregnancy (from about 0.5 mg/dL to 1.0 mg/dL). In some cases of severe preeclampsia, however, severe intrarenal vasospasm is profound, and plasma creatinine may be elevated several times the nonpregnant normal value—up to 2 to 3 mg/dL (Pritchard and colleagues, 1984). In severe preeclampsia, oliguria develops despite normal ventricular filling pressures (Lee and associates, 1987). In most women, urine sodium concentration is elevated. Urine osmolality, urine:plasma creatinine ratio, and fractional excretion of sodium are also indicative that a prerenal mechanism is involved. Kirshon and co-workers (1988) infused dopamine intravenously into oliguric women with preeclampsia, and this renal vasodilator stimulated increased urine output, fractional sodium excretion, and free water clearance. *Intensive intravenous fluid therapy is not indicated for these women with oliguria.*

Proteinuria. There should be some degree of proteinuria to establish the diagnosis of preeclampsia-eclampsia. Because proteinuria develops late, however, some women may be delivered before it appears. Meyer and colleagues (1994) reported that proteinuria quantification by dipstick was not accurate and recommended 24-hour measurements. Adelberg and co-workers (2001) found that urine protein quantification in 8- and 12-hour samples correlated when there was mild to moderate proteinuria. Use of random urinary protein:creatinine ratio to predict significant proteinuria is controversial. Neithardt and colleagues (2002) and Rodriguez-Thompson and Lieberman (2001) found these determinations to be suitable to predict 24-hour results. Conversely, Durnwald and Mercer (2003) reported that determination of this ratio was not accurate.

Albuminuria is an incorrect term to describe proteinuria of preeclampsia. As with any other glomerulopathy, there is increased permeability to most large-molecular-weight proteins; thus, abnormal albumin excretion is accompanied by other proteins, such as hemoglobin, globulins, and transferrin. Normally, these large protein molecules are not filtered by the glomerulus, and their appearance in urine signifies a glomerulopathic process. Some of the smaller proteins that usually are filtered but reabsorbed are also detected in urine.

Anatomical Changes. Changes identifiable by light and electron microscopy are commonly found in the kidney. Sheehan (1950) observed that the glomeruli were enlarged by about 20 percent. The capillary loops variably are dilated and contracted. The endothelial cells are swollen, and deposited within and beneath them are fibrils that have been mistaken for thickening of the basement membrane.

Most electron microscopy studies of renal biopsies are consistent with glomerular capillary endothelial swelling. These changes, accompanied by subendothelial deposits of protein material, were called *glomerular capillary endotheliosis* by Spargo and associates (1959). The endothelial cells are often so swollen that they block or partially block the capillary lumens. Homogeneous deposits of an electron-dense substance are found between basal lamina and endothelial cells and within the cells themselves. Recently, Strevens and co-workers (2003) questioned whether endotheliosis is pathognomonic of preeclampsia. They identified this lesion on renal biopsies in all 28 women with preeclampsia, in all 8 with gestational hypertension without proteinuria, and in 5 of 12 normotensive controls. The degree of endotheliosis increased with severity of preeclampsia and electron-dense deposits and pronounced endotheliosis were identified only in women with hypertension.

On the basis of immunofluorescent staining, Lichtig and co-workers (1975) identified deposited fibrinogen or its derivatives in 13 of 30 renal biopsy specimens from women with preeclampsia. Kincaid-Smith (1991) found that these deposits disappear progressively in the first week postpartum. Strevens and colleagues (2003) found occasional scarce deposits of immunoglobulin M (IgM), IgA, and C₃ in 32 biopsy specimens.

Renal tubular lesions are common in women with eclampsia, but what has been interpreted as degenerative changes may represent only an accumulation within cells of protein reabsorbed from the glomerular filtrate. The collecting tubules may appear obstructed by casts from derivatives of protein, including, at times, hemoglobin.

Acute renal failure from *acute tubular necrosis* may develop. Such kidney failure is characterized by oliguria or anuria and rapidly developing azotemia (approximately 1 mg/dL increase in serum creatinine per day). Although this is more common in neglected cases, it is invariably induced by hypovolemic shock, usually associated with hemorrhage at delivery, for which adequate blood replacement is not given (see [Chap. 48](#), p. 1106). Drakeley and co-workers (2002) described 72 women with preeclampsia and renal failure, half of whom had HELLP syndrome and a third of whom had placental abruption. Looked at another way, Haddad and colleagues (2000) reported that 5 percent of 183 women with HELLP syndrome developed acute renal failure. Half of these also had a placental abruption, and most had postpartum hemorrhage. Rarely, irreversible *renal cortical necrosis* developed.

LIVER. Hepatic changes in women with fatal eclampsia were described in 1856 by Virchow. The characteristic lesions commonly found were regions of periportal hemorrhage in the liver periphery. In elegant autopsy studies, Sheehan and Lynch (1973) described that infarction accompanied hemorrhage in almost 50 percent of cases. Reports of elevated serum hepatic transaminase levels began with the observations by Pritchard and colleagues (1954), who described these findings in women with eclampsia, hemolysis, and thrombocytopenia. It became appreciated that these changes were also seen in women with severe preeclampsia. As described above, this involvement was later termed *HELLP syndrome* by Weinstein (1985) to call attention to its seriousness.

Anatomical changes with extensive lesions as shown in [Figure 34-8](#) are seldom identified with liver biopsy in nonfatal cases (Barton and colleagues, 1992). Bleeding from these lesions may cause *hepatic rupture*, or they may extend beneath the hepatic capsule and form a *subcapsular hematoma* ([Fig. 34-9](#)). These hemorrhages without rupture are probably more common than previously suspected (Manas and colleagues, 1985; Rosen and co-workers, 2003). As subsequently discussed, they are more likely in women with HELLP syndrome.

Most clinicians prefer observation and conservative treatment of hematomas unless hemorrhage is ongoing. That said, in some cases, prompt surgical intervention may be lifesaving. Merchant and associates (2004) reported successful use of recombinant factor VIIa to help control hepatic hemorrhage. Rinehart and co-workers (1999) reviewed 121 cases of spontaneous hepatic rupture associated with preeclampsia, and the mortality rate was 30 percent. One woman cared for at Parkland Hospital survived hepatic rupture after receiving blood and blood products from more than 200 donors along with several laparotomies. Hunter and co-workers (1995) as well as Wicke and colleagues (2004) each described similar women in whom liver transplant was considered lifesaving.

HELLP Syndrome. Because there is no strict definition of the HELLP syndrome, the incidence of the syndrome varies by investigator. In one large study, it was identified in almost 20 percent of women with severe preeclampsia or eclampsia (Sibai and co-workers, 1993b). Earlier reports of severe morbidity and mortality were confirmed by later studies. For example, in a multicenter study, Haddad and colleagues (2000) described 183 women with the syndrome. Adverse outcomes occurred in almost 40 percent of cases, and two women died. Other complications included eclampsia (6 percent), placental abruption (10 percent), acute renal failure (5 percent), pulmonary edema (10 percent), and subcapsular liver hematoma (1.6 percent). Citing autopsy data, Isler and associates (1999) identified factors contributing to the death of 54 women with HELLP syndrome. These included stroke, coagulopathy, acute respiratory distress syndrome, renal failure, and sepsis.

Some clinicians have advocated corticosteroid therapy for amelioration of HELLP syndrome. Martin and colleagues (2003) reviewed outcomes of almost 500 women cared for at the University of Mississippi. Outcomes of women from 1994 to 2000 (90 percent treated) were considered more favorable than the cohort from 1985 to 1991 (16 percent treated). Unfortunately, there was no untreated control group (Isler and associates, 2001). In a Cochrane Database review, Matchaba and Moodley (2004) concluded that there is insufficient evidence to conclude that adjunctive steroid use is beneficial.

Figure 34-8. Gross liver specimen from a woman with preeclampsia who died from severe acidosis and liver failure. Periportal hemorrhagic necrosis was seen microscopically. (From Cunningham, 1993.)

Figure 34-9. Computed tomographic scan of liver showing a subcapsular hematoma with a peripheral hyperdense rim corresponding to more recent hemorrhage. (From Wicke and colleagues, 2004, with permission.)

BRAIN. Headaches and visual symptoms are common with severe eclampsia, and associated convulsions define eclampsia. The earliest anatomical descriptions of brain involvement came from autopsy specimens, but imaging and Doppler studies have added new insight into cerebrovascular involvement.

Anatomical Pathology. There are two distinct but related types of cerebral pathology. The first is gross hemorrhage due to ruptured arteries caused by severe hypertension. These can be seen in any woman with gestational hypertension, and preeclampsia is not necessary for their development. These complications are more common in women with underlying chronic hypertension (see [Chap. 45](#), p. 1045). In an older series, Govan (1961) reported that cerebral hemorrhage was the cause of death in 39 of 110 fatal cases of eclampsia.

The second type of cerebral lesion is variably demonstrated with preeclampsia but probably is universal with eclampsia. These are more widespread, focal, and seldom fatal. The principal postmortem lesions are edema, hyperemia, ischemias, thrombosis, and hemorrhage. Sheehan (1950) found hemorrhages, ranging from petechiae to gross bleeding, in 56 percent of the brains of 48 women with eclampsia he examined very soon after death. In addition, he reported that if the brains were examined within an hour after death, they most often displayed normal firmness without obvious edema. This correlates with our clinical and neuroimaging studies in which only 5 percent of 175 eclamptic women had evidence of widespread cerebral edema (Cunningham and Twickler, 2000).

Neuroimaging Studies. With improved computed tomography (CT) and magnetic resonance imaging (MRI) capabilities, Zeeman and colleagues (2004a) reported that nearly all women with eclampsia have abnormal brain findings. Those most commonly seen with CT are hypodense areas in the cortex and correspond to the petechial hemorrhages and infarctions described by Sheehan and Lynch (1973). Several investigators have also described remarkable changes in the area of distribution of the posterior cerebral artery as shown in [Figure 34-10](#) (Brown and colleagues, 1988a; Morris and associates, 1997). The extent and location of these ischemic and petechial lesions likely influence the severity of the clinical picture. For example, worrisome neurological complications, such as blindness or coma, sometimes occur. It appears that these symptoms represent a continuum of involvement.

Because of clinical resolution in most cases, it was assumed that these findings primarily were areas of edema. This is not the case, however, and recent studies reported that 25 percent of women with eclampsia have areas of cerebral infarction (Loureiro and co-workers, 2003). In another study, Zeeman and colleagues (2004a) evaluated 27 nulliparous women with eclampsia, and all but two had reversible vasogenic edema. In 25 percent, there also were areas of infarction that persisted at

follow-up (Fig. 34-11).

Cerebral Blood Flow. Until recently, noninvasive determination of cerebral blood flow was limited to transcranial Doppler ultrasonography. This technology measures blood flow, and *cerebral perfusion pressure* is calculated. Belfort and associates (1999) found that preeclampsia was associated with increased cerebral perfusion pressure counterbalanced by increased cerebrovascular resistance with no net change in cerebral blood flow. In eclampsia, presumably due to loss of autoregulation of cerebral blood flow, there was hyperperfusion similar to that seen in hypertensive encephalopathy unrelated to pregnancy. Women with headaches frequently had increased cerebral perfusion. The investigators' conclusion that eclampsia is caused by a transient loss of cerebrovascular autoregulation is supported by evidence of widespread low-density areas confirmed by CT and MRI studies (Apollon and co-workers, 2000; Cunningham and Twickler, 2000). Importantly, most studies have not identified appreciable cerebral vasospasm (Morriss, 1997; Rutherford, 2003; Zeeman, 2004b, and all their associates).

MRI techniques have now been developed that allow for accurate measurement of cerebral blood flow, and these correlate with invasive procedures. Zeeman and colleagues (2003b) found in normal pregnancy that blood flow decreases beginning early in pregnancy and is 20 percent less than nonpregnant values by late pregnancy. Subsequently, these investigators showed that with preeclampsia, there is hyperperfusion, which at least contributes to vasogenic edema that they identified using MRI.

Blindness. Although visual disturbances are common with severe preeclampsia, blindness is rare with preeclampsia alone. It follows eclamptic convulsions in up to 10 percent of women. Blindness has been reported to develop up to a week or more following delivery (Chambers and Cain, 2004). This condition is also called *amaurosis* (from the Greek *dimming*), and affected women have evidence of extensive occipital lobe vasogenic edema on CT and MRI (see Fig. 34-10). During a 14-year period, 15 such women cared for at Parkland Hospital were described by Cunningham and associates (1995). Blindness lasted from 4 hours to 8 days, but it resolved completely in all cases.

Rarely, permanent visual defects, including blindness, complicate preeclampsia-eclampsia. This can be caused either by cerebral infarction or by retinal artery ischemia and infarction (Lara-Torre and associates, 2002; Moseman and Shelton, 2002).

Retinal detachment may also cause altered vision, although it is usually one-sided and seldom causes total visual loss. Occasionally it coexists with cortical edema and visual defects. Detachment is obvious by examination. Surgical treatment is seldom indicated, the prognosis generally is good, and vision usually returns to normal within a week.

Cerebral Edema. Clinical manifestations suggesting more widespread cerebral edema are worrisome. During a 13-year period, we identified 10 of 175 women with eclampsia at Parkland Hospital who had symptomatic cerebral edema (Cunningham and Twickler, 2000). Symptoms ranged from lethargy, confusion, and blurred vision to obtundation and coma. In some cases, symptoms waxed and waned. Mental status changes generally correlated with the degree of involvement seen with CT and MRI studies. Three women with generalized edema were comatose and had imaging findings of impending transtentorial herniation, and one of these died from herniation.

Clinically, these women are very susceptible to sudden and severe blood pressure elevations, which acutely worsen the widespread vasogenic edema. Thus, careful blood pressure control is essential. Consideration is given for treatment with mannitol or dexamethasone.

Electroencephalography. Sibai and colleagues (1985a) reported that 75 percent of 65 women with eclampsia had nonspecific *electroencephalographic abnormalities* within 48 hours of seizures. Half of the abnormalities persisted longer than 1 week, but most resolved within 3 months.

Figure 34-10. Magnetic resonance imaging in a 22-year-old woman with eclampsia who had cortical blindness for 96 hours. A high-signal lesion (*arrow*) is apparent in the left occipital lobe. (From Cunningham and associates, 1995, with permission.)

Figure 34-11. Follow-up MRIs performed 6 weeks after delivery complicated by eclampsia and in a woman with no residual neurological findings. **A.** There is T2 hyperintensity on FLAIR image in previous areas of vasogenic edema and subcortical infarction. **B.** Corresponding low signal intensity on T1-weighted image (*arrows*) indicates evolution to gliosis or cerebral scarring. (From Zeeman and colleagues, 2004a, with permission.)

UTEROPLACENTAL PERFUSION. Compromised uteroplacental perfusion from vasospasm is almost certainly a major culprit in the genesis of increased perinatal morbidity and mortality associated with preeclampsia. Brosens and associates (1972) reported that the mean diameter of myometrial spiral arterioles of 50 normal pregnant women was 500 μm . The same measurement in 36 women with preeclampsia was 200 μm . Attempts to assess human maternal and placental blood flow have been hampered by several obstacles, including inaccessibility of the placenta, the complexity of its venous effluent, and the unsuitability of certain investigative techniques for humans.

Indirect Measurement. The clearance rate of dehydroisoandrosterone sulfate through placental conversion to 17 β -estradiol was reported to be an accurate reflection of human placental perfusion (Everett and colleagues, 1980). The placental clearance rate increases with advancing pregnancy, but it decreases before the onset of overt hypertension (Worley and associates, 1975). Subsequently, Fritz and colleagues (1985) reported this method paralleled uteroplacental perfusion in primates.

DOPPLER VELOCIMETRY. Measurement of blood flow velocity through uterine arteries has been used to estimate resistance to uteroplacental blood flow. As described in [Chapter 16](#) (see p. 400), vascular resistance is estimated by comparing arterial systolic and diastolic velocity waveforms. Earlier studies were done to assess this by measuring these ratios from uterine and umbilical arteries in preeclamptic pregnancies. The findings indicated that in some cases, but certainly not all, there was increased resistance (Ducey, 1987; Fleischer, 1986; Hanretty, 1988; Trudinger, 1990, and all their colleagues). Thus, compromised uteroplacental circulation is present in only a few women with preeclampsia. Except for one woman with a previable fetus, all others with abnormal Doppler velocimetry required cesarean delivery for fetal indications. In 50 women with HELLP syndrome, Bush and colleagues (2001) reported that 18 to 36 percent of fetuses had abnormal waveforms.

Matijevic and Johnson (1999) used color pulsed Doppler velocimetry to measure resistance in *uterine spiral arteries*. Impedance was higher in peripheral than in central vessels. This has been termed a "ring-like" distribution. Mean resistance was higher in all women with preeclampsia compared with normotensive controls.

PREDICTION AND PREVENTION

PREDICTION. Measurement in early pregnancy of a variety of biological, biochemical, and biophysical markers implicated in the pathophysiology of preeclampsia has been proposed to predict its development. Investigators have attempted to identify early markers of faulty placentation, reduced placental perfusion, endothelial cell activation and dysfunction, and activation of coagulation. Attempts thus far have resulted in testing strategies with poor sensitivity and with poor positive predictive value for preeclampsia (Conde-Agudelo and colleagues, 2004; Friedman and Lindheimer, 1999; Sibai, 2003; Stamilio and colleagues, 2000). Currently, there are no screening tests for preeclampsia that are reliable, valid, and economical. One goal of the Maternal-Fetal Medicine Units Network is to identify such factors. Selected tests are now discussed.

Roll-Over Test. A hypertensive response induced by having women at 28 to 32 weeks assume the supine position after lying laterally recumbent predicted gestational hypertension (Gant and colleagues, 1974). Women who demonstrated a positive "roll-over" test were also found to be abnormally sensitive to infused angiotensin II (see p. 135). With preeclampsia, rather than gestational hypertension, as the end point, the positive predictive value (true positive) was only 33 percent (Dekker and colleagues, 1990; Friedman and Lindheimer, 1999).

Uric Acid. Elevated serum uric acid levels due to decreased renal urate excretion are frequently found in women with preeclampsia. Jacobson and colleagues (1990) found that plasma uric acid values exceeding 5.9 mg/dL at 24 weeks had a positive predictive value for preeclampsia of 33 percent. Chappell and associates (2002) found it predictive in a small case-control study of high-risk women. In contrast, Weerasekera and Peiris (2003) found that serum uric acid levels did not vary significantly before the detection of hypertension. Because uric acid levels have not even proven useful in differentiating gestational hypertension from preeclampsia, they are not widely used (Lim and co-workers, 1998).

Fibronectin. Endothelial cell activation likely is the cause of elevated serum cellular fibronectin levels in some women with preeclampsia (Brubaker and associates, 1992; Halligan and colleagues, 1994). In a clinical study to predict preeclampsia, Paarlberg and colleagues (1998) found low sensitivity (69 percent) and positive predictive values (12 percent). Chavarria and co-workers (2003a) did four-week sampling beginning at 16 weeks in 378 low-risk nulliparas. The women who subsequently developed preeclampsia had significantly higher levels by 12 weeks but the positive predictive value was only 29 percent, however, the negative predictive value was 98 percent.

Coagulation Activation. Thrombocytopenia and platelet dysfunction are integral features of preeclampsia, as discussed on page 773. Increased destruction causes platelet volumes to increase because of relatively younger, and therefore larger, platelets. Ahmed and associates (1993) found high platelet volumes to be a marker of impending preeclampsia. However, there was substantive overlap with normotensive women. Fibrinolytic activity is normally decreased in pregnancy due to increased plasminogen activator inhibitors (PAI) 1 and 2. In preeclampsia, PAI-1 is increased relative to PAI-2 because of endothelial cell dysfunction (Caron and colleagues, 1991). In the case-control study mentioned above, Chappell and associates (2002) found the PAI-1:PAI-2 ratio to be predictive of preeclampsia in high-risk women.

Oxidative Stress. Increased levels of lipid peroxides, coupled with decreased activity of antioxidants in women with preeclampsia, have raised the possibility that markers of oxidative stress might predict preeclampsia (Walsh, 1994). For example, malondialdehyde is a marker of lipid peroxidation. Other markers are a variety of pro-oxidants or potentiators of pro-oxidants, including iron, transferrin, and ferritin; blood lipids, including triglycerides, free fatty acids, and lipoproteins; and antioxidants, including ascorbic acid and vitamin E (Bainbridge and associates, 2005; Hubel, 1989, 1996; Mikhail, 1994; Powers, 2000, and all their colleagues). Some of these have been studied clinically.

Hyperhomocysteinemia is an independent risk factor for atherosclerosis in women who are not pregnant. According to Rogers and colleagues (1999), this is very similar to implantation site atherosclerosis. Cotter and colleagues (2001, 2003) reported that women with elevated serum homocysteine levels around midpregnancy had a three- to fourfold risk of preeclampsia. Although clinical studies substantiate this association, they have not shown elevated serum homocysteine levels to be a useful predictor (D'Anna, 2004; Hietala, 2001; Zeeman, 2003a, and all their colleagues). Homocysteine levels are influenced by folic acid supplementation (Powers and associates, 2003).

Cytokines. These protein messengers are released by vascular endothelium and leukocytes as well as by macrophages and lymphocytes at the trophoblast-decidua interface. There are over 50 cytokines, and a number of these are elevated in preeclampsia. These include some interleukins and TNF- α . The response to cytokines is the inflammatory process discussed on page 767. A cascade of markers (e.g., C-reactive protein) arise from these reactions, and elevations of their levels have been suggested as possibly predictive of preeclampsia. A number of these have been evaluated in clinical trials but none have yet proved sufficiently predictive (Savvidou and colleagues, 2002; Takacs and associates, 2003).

Placental Peptides. As discussed on page 767, as a result of the inflammatory cascade, a number of peptides are produced by the placenta, and some may prove to be markers for prediction of preeclampsia. Those studied include corticotropin-releasing hormone, chorionic gonadotropin, activin A, and inhibin A (Aquilina, 1999; Ashour, 1997; Cuckle, 1998; Muttukrishna, 1997; Petraglia, 1996, and all their colleagues). The problems with these are similar to those with other markers

—namely, they are variably elevated depending on the duration and severity of preeclampsia. Moreover, there usually is substantive overlap with normal pregnant women. For example, Keelan and colleagues (2002) reported that activin A and inhibin A were increased markedly in women who developed preeclampsia. Conversely, other investigators have reported significant overlap of activin A and inhibin A levels in normotensive and preeclamptic pregnancies (Blackburn and associates, 2003; Grobman and Wang, 2000; Zeeman and co-workers, 2002).

As described earlier, the two placentally derived angiogenic factors, VEGF and PlGF, regulate placental development. Both are antagonized by another placental protein, sFlt1, whose function is upregulated in women with preeclampsia. Excessively elevated serum levels of sFlt1 have been reported in women with preeclampsia (Levine and associates, 2004b; Maynard and colleagues, 2003).

Thadhani and co-authors (2004) found that first-trimester serum levels of PlGF and sFlt1 could be used to identify women at high risk for preeclampsia. By contrast, Livingston and colleagues (2001a) reported that PlGF levels in early pregnancy were not predictive. Levine and colleagues (2003) and Robinson and Johnson (2003) reported that levels of these two factors correlated with severity and onset of clinical disease. Ecker and colleagues (2003) found that combined first-trimester serum levels of PlGF and sFlt1 were highly predictive of subsequent preeclampsia.

Fetal DNA. Identification of fetal DNA in maternal serum may be predictive of preeclampsia. At the same time that endothelial activation and inflammation occur, fetal cells and cellular material are released into the maternal circulation (Zhong and colleagues, 2001). In a nested, case-control study, Levine and co-workers (2004a) reported that maternal serum levels of cell-free fetal DNA were elevated at two stages. They suggested that screening for fetal DNA in earlier pregnancy may be predictive of subsequent preeclampsia, but that elevations after 28 weeks indicate impending disease.

Uterine Artery Doppler Velocimetry. Measurement of uteroplacental vascular resistance during Doppler ultrasound evaluation of uterine artery impedance in the second trimester has been used as an early screening test for preeclampsia (Bewley and colleagues, 1991; Chappell and Bewley, 1998) (see [Chap. 16](#), p. 400). The rationale for this is based on the presumption that the pathophysiology of preeclampsia includes impaired trophoblastic invasion of the spiral arteries leading to reduction in uteroplacental blood flow. Bower and colleagues (1993) used a two-step screening test beginning at 18 to 22 weeks and its sensitivity for prediction of preeclampsia was 78 percent, but the positive predictive value was only 28 percent. Irion and associates (1998) found uterine artery velocimetry to be an unreliable screening test in low-risk pregnancies. Florio and associates (2003) combined inhibin A and activin A measurements in women with abnormal Doppler findings and reported that the probability of preeclampsia was 86 percent if both hormone markers were elevated and 17 percent if they were both unaltered. Audibert and co-workers (2005) combined second-trimester maternal serum screening for hCG and AFP with uterine artery notching and found sensitivities that ranged from 2 to 40 percent.

PREVENTION. A variety of strategies used to prevent or modify the severity of preeclampsia have been evaluated. In general, none of these have been found to be clinically efficacious (Sibai, 2003).

Dietary Manipulation. One of the earliest research efforts to prevent preeclampsia was salt restriction (De Snoo, 1937). After years of inappropriate salt restriction, followed by years of more inappropriate diuretic therapy, those practices were discarded. Ironically, it was not until relatively recently that the first randomized trial was done by Knuist and colleagues (1998), who showed that a sodium-restricted diet was ineffective in preventing preeclampsia in 361 women.

Early studies performed outside the United States showed that women with low dietary calcium were at significantly increased risk for gestational hypertension (Belizan and Villar, 1980; Lopez-Jaramillo and associates, 1989; Marya and colleagues, 1987). At least 14 randomized trials and a meta-analysis done subsequently showed that prenatal calcium supplementation resulted in a significant reduction in blood pressure and incidence of preeclampsia (Bucher and colleagues, 1996). These were countered, however, by the randomized double-masked NICHD trial. Almost 4600 nulliparous women were given either supplemental calcium or placebo and the incidence of gestational hypertension or preeclampsia was similar in each group (Levine and co-workers, 1997).

Fish oil capsules were given as a supplement in an effort to modify the abnormal prostaglandin balance implicated in the pathophysiology of preeclampsia. The supplement was ineffective in a study of 1474 pregnancies conducted at 19 European hospitals (Olsen and colleagues, 2000).

Low-Dose Aspirin. Early successes of 60-mg aspirin to reduce the incidence of preeclampsia were attributed to selective thromboxane suppression with resultant dominance of endothelial prostacyclin (Hauth and co-workers, 1998; Wallenburg and colleagues, 1986). Subsequent multicenter randomized trials in both low-risk and high-risk women have consistently shown that low-dose aspirin was ineffective in preventing preeclampsia (Caritis, 1998; CLASP Collaborative Group, 1994; Hauth, 1993, 1998; Rotchell, 1998; Sibai, 1993a, and all their colleagues).

Antioxidants. Sera of normal pregnant women contain antioxidant mechanisms that control lipid peroxidation, which has been implicated in endothelial cell dysfunction. Davidge and associates (1992) observed that sera of women with preeclampsia have markedly reduced antioxidant activity. Schiff and colleagues (1996) reported that vitamin E consumption was unrelated to preeclampsia. They found high plasma vitamin E levels in women with preeclampsia and speculated that these were a response to oxidative stress. Chappell and associates (1999) randomly assigned 283 high-risk women at 18 to 22 weeks to treatment with the antioxidants vitamin C or E versus placebo. Therapy significantly reduced endothelial cell activation and led to a significant reduction in preeclampsia compared with that of the control group (17 versus 11 percent). Because of these promising findings, the Maternal-Fetal Medicine Units Network is currently conducting a larger randomized trial.

MANAGEMENT

Basic management objectives for any pregnancy complicated by preeclampsia are:

1. Termination of pregnancy with the least possible trauma to mother and fetus.
2. Birth of an infant who subsequently thrives.

3. Complete restoration of health to the mother.

In certain women with preeclampsia, especially those at or near term, all three objectives are served equally well by induction of labor. **Therefore, the most important information that the obstetrician has for successful management of pregnancy, and especially a pregnancy that becomes complicated by hypertension, is precise knowledge of the age of the fetus.**

EARLY PRENATAL DETECTION. Traditionally, the frequency of prenatal visits is increased during the third trimester to facilitate early detection of preeclampsia. Women with overt hypertension (140/90 mm Hg or greater) are frequently admitted to the hospital for 2 to 3 days to evaluate the severity of new-onset hypertension. Women with persistent severe disease are observed closely, and many are delivered. Conversely, women with mild disease are often managed as outpatients.

Management of women without overt hypertension, but in whom early preeclampsia is suspected during routine prenatal visits, consists primarily of increased surveillance. The protocol used successfully for many years at Parkland Hospital in women with new-onset diastolic blood pressure readings between 81 and 89 mm Hg or sudden abnormal weight gain (more than 2 pounds per week during the third trimester) includes return visits at 3- to 4-day intervals. Such outpatient surveillance is continued unless overt hypertension, proteinuria, visual disturbances, or epigastric discomfort supervene.

ANTEPARTUM HOSPITAL MANAGEMENT. Hospitalization is considered at least initially for women with new-onset hypertension, especially if there is persistent or worsening hypertension or development of proteinuria. A systematic evaluation is instituted to include the following:

1. Detailed examination followed by daily scrutiny for clinical findings such as headache, visual disturbances, epigastric pain, and rapid weight gain.
2. Weight on admittance and every day thereafter.
3. Analysis for proteinuria on admittance and at least every 2 days thereafter.
4. Blood pressure readings in the sitting position with an appropriate-size cuff every 4 hours, except between midnight and morning.
5. Measurements of plasma or serum creatinine, hematocrit, platelets, and serum liver enzymes, the frequency to be determined by the severity of hypertension.
6. Frequent evaluation of fetal size and amniotic fluid volume either clinically or with sonography.

If these observations lead to a diagnosis of severe preeclampsia (see [Table 34-2](#)), further management is the same as described subsequently for eclampsia.

Reduced physical activity throughout much of the day is beneficial. Absolute bed rest is not necessary, and sedatives and tranquilizers are not prescribed. Ample, but not excessive, protein and calories should be included in the diet. Sodium and fluid intakes should not be limited or forced. Further management depends on:

1. Severity of preeclampsia, determined by presence or absence of conditions cited.
2. Duration of gestation.
3. Condition of the cervix.

Fortunately, many cases prove to be sufficiently mild and near enough to term that they can be managed conservatively until labor commences spontaneously or until the cervix becomes favorable for labor induction. Complete abatement of all signs and symptoms, however, is uncommon until after delivery. *Almost certainly, the underlying disease persists until after delivery!*

TERMINATION OF PREGNANCY. Delivery is the cure for preeclampsia. Headache, visual disturbances, or epigastric pain are indicative that convulsions may be imminent, and oliguria is another ominous sign. Severe preeclampsia demands anticonvulsant and usually antihypertensive therapy followed by delivery. Treatment is identical to that described subsequently for eclampsia. The prime objectives are to forestall convulsions, to prevent intracranial hemorrhage and serious damage to other vital organs, and to deliver a healthy infant.

When the fetus is known or suspected to be preterm, however, the tendency is to temporize in the hope that a few more weeks in utero will reduce the risk of neonatal death or serious morbidity. As discussed, such a policy certainly is justified in milder cases. Assessments of fetal well-being and placental function have been attempted, especially when there is hesitation to deliver the fetus because of prematurity. Most investigators recommend frequent performance of various tests currently used to assess fetal well-being as described by the American College of Obstetricians and Gynecologists (1999). These include the *nonstress test* or the *biophysical profile*, which are discussed in [Chapter 15](#) (see p. 377 and p. 381). Measurement of the lecithin-sphingomyelin ratio in amniotic fluid may provide evidence of lung maturity. Even when this ratio is less than 2.0, however, respiratory distress may not develop (see [Chap. 29](#), p. 650).

With moderate or severe preeclampsia that does not improve after hospitalization, delivery is usually advisable for the welfare of both mother and fetus. Labor should be induced by intravenous oxytocin. Many clinicians favor preinduction cervical ripening with a prostaglandin or osmotic dilator (see [Chap. 22](#), p. 537). Whenever it appears that labor induction almost certainly will not succeed, or attempts at induction have failed, cesarean delivery is indicated for more severe cases.

For a woman near term, with a soft, partially effaced cervix, even milder degrees of preeclampsia probably carry more risk to the mother and her fetus-infant than does induction of labor by carefully monitored oxytocin infusion. This is not likely to be the case, however, if the preeclampsia is mild but the cervix is firm and closed. The hazards of cesarean delivery may be greater than that of allowing the pregnancy to continue *under close observation* until the cervix is more suitable for induction.

Elective Cesarean Delivery. Once severe preeclampsia is diagnosed, the obstetrical propensity is for prompt delivery. Labor induction to effect vaginal delivery has traditionally been considered to be in the best interest of the mother. Several concerns, including an unfavorable cervix precluding successful induction of labor, a perceived sense of urgency because of the severity of preeclampsia, and the need to coordinate neonatal intensive care, have led some practitioners to advocate cesarean delivery. Alexander and colleagues (1999) reviewed 278 singleton liveborn infants weighing 750 to 1500 g delivered of women with severe preeclampsia at Parkland Hospital. Half of the women had labor induced and the remainder underwent cesarean delivery without labor. Induction was not successful in 35 percent of the women in the induced group, but it was not harmful to their very low-birthweight infants. Similar results were reported by Nassar and colleagues (1998).

ANTIHYPERTENSIVE DRUG THERAPY. The use of antihypertensive drugs in attempts to prolong pregnancy or modify perinatal outcomes in pregnancies complicated by various types and severities of hypertensive disorders has been of considerable interest. Unfortunately, drug treatment for early mild preeclampsia has been disappointing ([Table 34-5](#)). Sibai and associates (1987a) performed a well-designed randomized study to evaluate the effectiveness of labetalol and hospitalization compared with hospitalization alone. They evaluated 200 nulliparous women with preeclampsia diagnosed between 26 and 35 weeks. Although women given labetalol had significantly lower mean blood pressures, there were no differences between the groups in terms of mean pregnancy prolongation, gestational age at delivery, or birthweight. The cesarean delivery rates were similar, as were the number of infants admitted to special-care nurseries. **Growth-restricted infants were twice as frequent in women given labetalol compared with those treated by hospitalization alone (19 versus 9 percent).**

At least three other studies have been done to compare either the β -blocking agent, labetalol, or calcium-channel blockers, nifedipine and isradipine, with placebo. As shown in [Table 34-5](#), in none of these studies were any benefits of antihypertensive treatment shown. Von Dadelszen and associates (2000) performed a meta-analysis that included the aforementioned trials for the purpose of determining the relation between fetal growth and antihypertensive therapy. These investigators concluded that treatment-induced decreases in maternal blood pressure may adversely affect fetal growth.

In a somewhat unusual study, Easterling and colleagues (1999) identified 58 women at risk for preeclampsia because they had a high cardiac output at 24 weeks. Cardiac output was measured by Doppler technique and the women were randomly assigned to receive either prophylactic atenolol or placebo. The incidence of preeclampsia was 18 percent in the control group, which was significant compared with 4 percent in the atenolol group.

The use of angiotensin-converting enzyme (ACE) inhibitors during the second and third trimesters should be avoided (see [Chap. 14](#), p. 349). Reported complications include oligohydramnios, fetal growth restriction, bony malformations, limb contractures, persistent patent ductus arteriosus, pulmonary hypoplasia, respiratory distress syndrome, prolonged neonatal hypotension, and neonatal death (Nightingale, 1992). Lip and colleagues (1997) reported that ACE inhibitors taken during early pregnancy do not carry an adverse outlook as long as these drugs are discontinued as soon as possible.

DELAYED DELIVERY WITH SEVERE PREECLAMPSIA. Women with severe preeclampsia are usually delivered without delay. In recent years, a different approach in the treatment of women with severe preeclampsia remote from term has been advocated by several investigators worldwide (Many and colleagues, 1999). This approach advocates conservative or "expectant" management in a selected group of women with the aim of improving infant outcome without compromising the safety of the mother. Aspects of such conservative management always include careful daily, and more frequent, monitoring of the pregnancy in the hospital with or without use of drugs to control hypertension.

Theoretically, antihypertensive therapy has potential usefulness when preeclampsia severe enough to warrant termination of pregnancy develops before neonatal survival is likely. Such management is controversial, and it may be catastrophic. Sibai and colleagues (1985b) attempted to prolong pregnancy because of fetal immaturity in 60 women with severe preeclampsia diagnosed between 18 and 27 weeks. **The total perinatal mortality rate was 87 percent, and although no mothers died, thirteen suffered placental abruption, ten eclampsia, five consumptive coagulopathy, three renal failure, two hypertensive encephalopathy, one intracerebral hemorrhage, and one a ruptured hepatic hematoma.**

Sibai and associates (1994) subsequently performed a randomized controlled trial of expectant versus aggressive management of severe preeclampsia in 95 women at more advanced gestations of 28 to 32 weeks. Women with HELLP syndrome were specifically excluded from this trial. Aggressive management included glucocorticoid administration for fetal lung maturation followed by delivery in 48 hours. Expectantly managed women were treated with bed rest and either labetalol or nifedipine given orally. Pregnancy was prolonged for a mean of 15.4 days in the expectant management group with an improvement in neonatal outcome. Importantly, 4 percent in each group sustained placental abruption.

In a follow-up nonrandomized study, Abramovici and colleagues (1999) compared infant outcomes for deliveries between 24 and 36 weeks between 133 women with HELLP syndrome and 136 women with severe preeclampsia. Women with HELLP syndrome were subdivided into those with hemolysis plus elevated liver enzymes plus low platelets and those with partial HELLP syndrome, defined as either one or two, but not three, of these laboratory findings. It was concluded that women with partial HELLP syndrome, as well as those with severe preeclampsia, could be managed expectantly. They also concluded that infant outcomes were related to gestational age rather than the hypertensive disorder per se. As shown in [Table 34-6](#), these women were indeed severely hypertensive and had mean diastolic blood pressures of 110 mm Hg. The distinguishing feature between those with HELLP syndrome appears to be the platelet count— the mean value was 52,000/ μ L in women with complete HELLP syndrome compared with 113,000/ μ L in those with partial HELLP syndrome. Gestational age was about 2 weeks more advanced in women with severe preeclampsia alone compared with those with some degree of HELLP syndrome. Accordingly, neonatal outcomes, in terms of need for mechanical ventilation and neonatal death, were better in women with severe preeclampsia. Fetal growth restriction was not related to the severity of maternal disease and was prevalent in all three groups. Maternal morbidity was not described.

Witlin and associates (2000) later reported that growth restriction adversely affected survival in infants from that institution. Most importantly, the median elapsed time from admission to delivery was 0, 1, and 2 days for women with HELLP syndrome, partial HELLP syndrome, or severe preeclampsia, respectively.

Taken in toto, these three studies require comment about repeated claims that expectant management of severe preeclampsia and partial HELLP syndrome is beneficial. First, with expectant management, the interval from admission to delivery is very short, particularly in pregnancies managed subsequent to their report claiming efficacy and safety. Second, it seems possible, even likely, that the gestational age difference between severe preeclampsia and HELLP syndrome is related to the timing of onset of the disease itself. That is, HELLP syndrome may develop earlier in pregnancy than severe preeclampsia. Third, fetal growth restriction is prevalent in women with severe disease and it adversely affects infant survival. Lastly, and most importantly, the authors overlook that the overriding reason to terminate pregnancies with severe preeclampsia is maternal safety. The results shown in [Table 34-6](#) clearly confirm that severe preeclampsia is deleterious for fetal outcome. However, the table provides no data suggesting that expectant management is beneficial for the mother.

In a more recent study from Panama, Vigil-De Gracia and colleagues (2003) described the outcomes of 129 women at 24 to 34 weeks with either severe or superimposed preeclampsia in whom efforts were made to delay delivery. Treatment consisted of bed rest, magnesium sulfate for 48 hours, bolus doses of antihypertensive medications to control blood pressures exceeding 160/110 mm Hg, volume expansion, and dexamethasone to promote fetal maturation. Indications for delivery included uncontrollable blood pressure, fetal distress, placental abruption, renal function deterioration, HELLP syndrome, persistent severe symptoms, or attainment of 34 weeks' gestation. The average pregnancy prolongation was 8 days. Although there were no maternal deaths, there were six stillbirths, 11 placental abruptions, and 28 infants diagnosed with growth restriction. Similar results have been described by Visser and Wallenburg (1995). The observations of Chammas and co-workers (2000) provide further data that delay in delivery of the growth-restricted fetus may not be advisable.

Hall and colleagues (2000b) managed 360 women and Haddad and associates (2004), 239 women with severe preeclampsia before 34 weeks. In the first study, the women gained a mean duration of 11 days, but a fourth had major complications: 20 percent had placental abruption, 2 percent had pulmonary edema, and 1.2 percent had eclampsia. In the second study, a median of 5 days was gained with 6 percent having an abruption and 4 percent developing pulmonary edema. Reports such as these serve to emphasize that it is prudent for clinicians to be concerned about maternal as well as fetal safety in women with preterm fetuses. We are reluctant to advise clinicians that it is safe to expectantly manage women with persistent severe hypertension or significant hematological, cerebral, or liver abnormalities due to preeclampsia.

GLUCOCORTICOIDS. In attempts to enhance fetal lung maturation, glucocorticoids have been administered to women with severe hypertension who are remote from term. Treatment does not seem to worsen maternal hypertension, and a decrease in the incidence of respiratory distress and improved fetal survival have been cited (see [Chap. 29](#), p. 650). As discussed on page 776, there are insufficient data to conclude that corticosteroids are beneficial to ameliorate the severity of HELLP syndrome (Matchaba and Moodley, 2004).

There has been only one randomized clinical trial of corticosteroids given to hypertensive women for fetal lung maturation (Amorim and associates, 1999). This trial included 218 women with severe preeclampsia between 26 and 34 weeks who were randomly assigned to be given betamethasone or placebo. Neonatal complications, including respiratory distress, intraventricular hemorrhage, and death, were decreased significantly when betamethasone was given compared with placebo. **But two maternal deaths and 18 stillbirths occurred.** We interpret this report to be an indictment of a strategy in which delivery is delayed in women with severe preeclampsia to allow the administration of glucocorticoids (Bloom and Leveno, 2003).

Thiagarajah and co-authors (1984) were the first to suggest that glucocorticoids might also play a role in treatment of the laboratory abnormalities associated with the HELLP syndrome. O'Brien and associates (2002) and Tompkins and Thiagarajah (1999) later reported that glucocorticoids produced significant but transient improvement in the hematological abnormalities associated with the HELLP syndrome. In the latter study of 52 women between 24 and 34 weeks, platelet counts increased by an average of 23,000/ μ L. This salutary effect, however, was short-lived, and platelets decreased by an average of 46,000/ μ L within 48 hours after completion of treatment. Importantly, few of the women studied had platelet counts less than 100,000/ μ L before therapy, and hence, the efficacy of glucocorticoids in women with more severe hematological abnormalities was not extensively tested.

HIGH-RISK PREGNANCY UNIT. An inpatient antepartum unit was established in 1973 by Dr. Peggy Whalley at Parkland Hospital in large part to provide care for women with hypertensive disorders. Initial results from this High-Risk Pregnancy Unit were reported by Hauth (1976) and Gilstrap (1978) and their colleagues. The majority of women hospitalized have a beneficial response characterized by disappearance or improvement of hypertension. **These women are not "cured," because nearly 90 percent have recurrent hypertension before or during labor.** By the end of 2000, almost 8000 nulliparous women with mild to moderate early-onset hypertension during pregnancy had been managed successfully in this unit. Provider costs (*not* charges) for the relatively simple physical facility, modest nursing care, no drugs other than iron and folate supplements, and the very few laboratory tests that are essential are slight compared with the cost of neonatal intensive care for a preterm infant.

HOME HEALTH CARE. Many clinicians believe that further hospitalization is not warranted if hypertension abates within a few days, and this has legitimized third-party payors to refuse hospital reimbursement. Consequently, most women with mild to moderate hypertension, without proteinuria, are managed at home. Such management may continue as long as the disease does not worsen and if fetal jeopardy is not suspected. Sedentary activity throughout the greater part of the day is recommended. These women should be instructed in detail about reporting symptoms. Home blood pressure and urine protein monitoring or frequent evaluations by a visiting nurse may be necessary. Lo and collaborators (2002) cautioned about the use of certain automated home blood pressure monitors that may fail to detect severe hypertension.

Barton and colleagues (1994) used such a home care scheme to manage 592 predominately nulliparous women with mild hypertension. They were 24 to 36 weeks at enrollment. A fourth had proteinuria. Gestation was prolonged for a mean of 4 weeks and 60 percent were delivered after 37 weeks. Importantly, 50 percent developed severe hypertension, and 10 percent

had fetal jeopardy. These investigators concluded that in highly motivated women, such management produced results similar to inpatient care. Helewa and associates (1993) reached similar conclusions.

In a study from Parkland Hospital, Horsager and associates (1995) randomly assigned 72 nulliparas with new-onset hypertension from 27 to 37 weeks to continued hospitalization or outpatient care. In all of these women, proteinuria had receded to less than 500 mg per day when randomized. Outpatient management included daily blood pressure monitoring by the patient or her family and weight and spot urine protein were determined three times weekly. A home health nurse visited twice weekly and the women were seen weekly in the clinic. Although perinatal outcomes were similar, development of severe preeclampsia was more common in the home-treated women than in hospitalized women (42 versus 25 percent).

Day-care is another approach that has become common in European countries. It has been evaluated only on a limited basis. Tuffnell and colleagues (1992) randomly assigned 54 women with gestational hypertension after 26 weeks to either day-care or routine management by their individual physicians. Hospitalizations, the development of preeclampsia, and labor inductions were significantly increased in the routine management group. More recently, Turnbull and colleagues (2004) from Australia reported a randomized study of 395 women assigned to either day-care or inpatient management. Almost 95 percent had mild to moderate hypertension; 288 had no proteinuria and 86 had at least 1+ proteinuria at baseline. Perinatal outcomes were good and there were no cases of eclampsia, HELLP syndrome, or neonatal deaths. Routes of delivery and neonatal complications were similar. Surprisingly, costs for either scheme were not significantly different. General satisfaction among the patients favored day-care.

ECLAMPSIA. Preeclampsia complicated by generalized tonic-clonic convulsions is termed eclampsia. Fatal coma without convulsions has also been called eclampsia. However, it is better to limit the diagnosis to women with convulsions and to regard deaths in nonconvulsive cases as due to severe preeclampsia. Once eclampsia has ensued, the risk to both mother and fetus is appreciable. For example, Mattar and Sibai (2000) described the hazards in 399 consecutive women with eclampsia delivered between 1977 and 1998 at their center in Memphis. Major complications included placental abruption (10 percent), neurological deficits (7 percent), aspiration pneumonia (7 percent), pulmonary edema (5 percent), cardiopulmonary arrest (4 percent), acute renal failure (4 percent), and maternal death (1 percent).

Almost without exception, preeclampsia precedes the onset of eclamptic convulsions. Depending on whether convulsions appear before, during, or after labor, eclampsia is designated as antepartum, intrapartum, or postpartum. Eclampsia is most common in the last trimester and becomes increasingly more frequent as term approaches. As discussed on page 764, in more recent years, there has been an increasing shift in the incidence of eclampsia toward the postpartum period. This is presumably related to improved access to prenatal care, earlier detection of preeclampsia, and prophylactic use of magnesium sulfate (Chames and co-workers, 2002). Importantly, other diagnoses including those listed on page 787 should be considered in women with the onset of convulsions more than 48 hours postpartum.

Regardless of the time of onset, the convulsive movements usually begin about the mouth in the form of facial twitchings. After a few seconds, the entire body becomes rigid in a generalized muscular contraction. This phase may persist for 15 to 20 seconds. Suddenly the jaws begin to open and close violently, and soon after, the eyelids as well. The other facial muscles and then all muscles alternately contract and relax in rapid succession. So forceful are the muscular movements that the woman may throw herself out of her bed, and if not protected, her tongue is bitten by the violent action of the jaws (Fig. 34-12). This phase, in which the muscles alternately contract and relax, may last about a minute. Gradually, the muscular movements become smaller and less frequent, and finally the woman lies motionless.

Throughout the seizure the diaphragm has been fixed, with respiration halted. For a few seconds the woman appears to be dying from respiratory arrest, but then she takes a long, deep, stertorous inhalation, and breathing is resumed. Unless treated, the first convulsion is usually the forerunner of others, which may vary in number from one or two in mild cases to even continuous convulsions—status epilepticus—in untreated severe cases. After a seizure, coma then ensues. The woman does not remember the convulsion(s) or, in all probability, events immediately before and afterward. Over time, these memories return.

The duration of coma after a convulsion is variable. When the convulsions are infrequent, the woman usually recovers some degree of consciousness after each attack. As the woman arouses, a semiconscious combative state may ensue. In very severe cases, the coma persists from one convulsion to another, and death may result before she awakens. In rare instances, a single convulsion may be followed by coma from which the woman may never emerge, although, as a rule, death does not occur until after frequent convulsions.

Respirations after an eclamptic convulsion are usually increased in rate and may reach 50 or more per minute, in response presumably to hypercarbia from lactic acidemia, as well as to varying intensities of hypoxia. Cyanosis may be observed in severe cases. High fever is a very grave sign, because it is probably the consequence of a central nervous system hemorrhage.

Proteinuria is almost always present and frequently pronounced. Urine output is likely diminished appreciably, and occasionally anuria develops. Hemoglobinuria is common, but hemoglobinemia is observed only rarely. Often, as shown in Figure 34-13, the edema is pronounced— at times, massive—but it may also be absent.

As with severe preeclampsia, after delivery an increase in urinary output is usually an early sign of improvement. Proteinuria and edema ordinarily disappear within a week (see Fig. 34-13). In most cases, blood pressure returns to normal within a few days to 2 weeks after delivery. The longer hypertension persists postpartum, the more likely that it is the consequence of chronic vascular disease (see Table 34-1).

In antepartum eclampsia, labor may begin spontaneously shortly after convulsions ensue and progress rapidly, sometimes before the attendants are aware that the unconscious or stuporous woman is having effective uterine contractions. If the convulsion occurs during labor, contractions may increase in frequency and intensity, and the duration of labor may be shortened. Because of maternal hypoxemia and lactic acidemia caused by convulsions, it is not unusual for fetal bradycardia to follow a seizure (Fig. 34-14). This usually recovers within 3 to 5 minutes; if it persists more than about 10 minutes, another cause, such as placental abruption or imminent delivery, must be considered.

Pulmonary edema may follow eclamptic convulsions. This may be caused by aspiration pneumonitis from inhalation of gastric contents if simultaneous vomiting accompanies convulsions. Alternatively, it may be caused by cardiac failure as the result of a combination of severe hypertension and vigorous intravenous fluid administration.

In some women with eclampsia, sudden death occurs synchronously with a convulsion or follows shortly thereafter, as the result of a massive cerebral hemorrhage (Fig. 34-15). Hemiplegia may result from sublethal hemorrhage. Cerebral hemorrhages are more likely in older women with underlying chronic hypertension. Rarely they may be due to a ruptured berry aneurysm or arteriovenous malformation (Witlin and co-workers, 1997a).

In about 10 percent of women, some degree of blindness follows a seizure. Blindness seldom develops spontaneously with preeclampsia. Two causes of blindness or impaired vision are varying degrees of retinal detachment or occipital lobe ischemia and edema. These are discussed in detail on page 777. In both instances, the prognosis for return to normal is good and is usually complete within a week (Cunningham and associates, 1995). About 5 percent of women have substantively altered consciousness, including persistent coma, following a seizure. This is due to extensive cerebral edema, and transtentorial uncal herniation may cause death as discussed on page 778 (Cunningham and Twickler, 2000).

Rarely, eclampsia is followed by psychosis, and the woman becomes violent. This usually lasts for several days to 2 weeks, but the prognosis for return to normal is good, provided there was no preexisting mental illness. Antipsychotic medications in carefully titrated doses have proved effective in the few cases of post eclampsia psychosis treated at Parkland Hospital.

Differential Diagnosis. Generally, eclampsia is more likely to be diagnosed too frequently rather than overlooked, because epilepsy, encephalitis, meningitis, cerebral tumor, cysticercosis, and ruptured cerebral aneurysm during late pregnancy and the puerperium may simulate eclampsia. **Until other such causes are excluded, however, all pregnant women with convulsions should be considered to have eclampsia.**

Prognosis. The prognosis for eclampsia is always serious; it is one of the most dangerous conditions in pregnancy. Fortunately, maternal mortality due to eclampsia has decreased from four decades ago when the rate was between 10 and 15 percent (Eastman and Hellman, 1961). Between 1991 and 1997, approximately 6 percent of maternal deaths in the United States were related to eclampsia; it accounted for at least 207 deaths (Berg and co-workers, 2003). When all hypertensive disorders of pregnancy are considered, the percent of maternal deaths during this same time period was nearly 16 percent (Berg and co-workers, 2003). These facts clearly indicate that eclampsia, as well as severe preeclampsia, should be considered overt threats to maternal life.

Treatment. In 1955, Pritchard initiated a standardized treatment regimen for eclampsia at Parkland Hospital, and this successful approach is still in use today. The results of this regimen employed in 245 women with eclampsia were reported by Pritchard and associates (1984). Most eclampsia regimens used in the United States adhere to a similar philosophy, the tenets of which include:

1. Control of convulsions using an intravenously administered loading dose of magnesium sulfate. This is followed either by a continuous infusion of magnesium sulfate or by an intramuscular loading dose and periodic intramuscular injections.
2. Intermittent intravenous or oral administration of an antihypertensive medication to lower blood pressure whenever the diastolic pressure is considered dangerously high. Some clinicians treat at 100 mm Hg, some at 105 mm Hg, and some at 110 mm Hg.
3. Avoidance of diuretics and limitation of intravenous fluid administration unless fluid loss is excessive. Hyperosmotic agents are avoided.
4. Delivery.

MAGNESIUM SULFATE TO CONTROL CONVULSIONS. In more severe cases of preeclampsia, as well as eclampsia, magnesium sulfate administered parenterally is an effective anticonvulsant agent without producing central nervous system depression in either the mother or the infant. It may be given intravenously by continuous infusion or intramuscularly by intermittent injection (Table 34-7). The dosage schedule for severe preeclampsia is the same as for eclampsia. Because labor and delivery is a more likely time for convulsions to develop, women with preeclampsia-eclampsia usually are given magnesium sulfate during labor and for 24 hours postpartum. **Magnesium sulfate is not given to treat hypertension.**

Based on a number of studies cited subsequently, as well as extensive clinical observations, magnesium most likely exerts a specific anticonvulsant action on the cerebral cortex. Typically, the mother stops convulsing after the initial administration of magnesium sulfate and, within an hour or two, regains consciousness sufficiently to be oriented as to place and time.

The magnesium sulfate dosage schedules presented in Table 34-7 usually result in plasma magnesium levels illustrated in Figures 34-16 and 34-17. When magnesium sulfate is given to arrest and prevent recurrent eclamptic seizures, about 10 to 15 percent of women have a subsequent convulsion. An additional 2-g dose of magnesium sulfate in a 20-percent solution is administered slowly intravenously. In a small woman, an additional 2-g dose may be used once, and twice if needed in a larger woman. In only 5 of 245 women with eclampsia at Parkland Hospital was it necessary to use supplementary medication to control convulsions (Pritchard and associates, 1984). Sodium amobarbital is given slowly intravenously in doses up to 250 mg in women who are excessively agitated in the postconvulsion phase. Thiopental is suitable also. Maintenance magnesium sulfate therapy for eclampsia is continued for 24 hours after delivery. For eclampsia that develops postpartum, magnesium sulfate is administered for 24 hours after the onset of convulsions.

PHARMACOLOGY AND TOXICOLOGY OF MAGNESIUM SULFATE. Magnesium sulfate USP is $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ and not MgSO_4 . Parenterally administered magnesium is cleared almost totally by renal excretion, and magnesium intoxication is avoided by ensuring that urine output is adequate, the patellar or biceps reflex is present, and there is no respiratory depression. Eclamptic convulsions are almost always prevented by plasma magnesium levels maintained at 4 to 7 mEq/L (4.8 to 8.4 mg/dL, or 2.0 to 3.5 mmol/L).

When administered as described in [Table 34-7](#), the drug practically always arrests eclamptic convulsions and prevents their recurrence. The initial intravenous infusion of 4 to 6 g is used to establish a prompt therapeutic level that is maintained by the nearly simultaneous intramuscular injection of 10 g of the compound, followed by 5 g intramuscularly every 4 hours, or by continuous infusion at 2 to 3 g per hour. With these dosage schedules, therapeutically effective plasma levels of 4 to 7 mEq/L are achieved compared with pretreatment plasma levels of less than 2.0 mEq/L.

It should be noted that although laboratories typically report *total* magnesium levels, *free* or *ionized* magnesium is the active moiety for suppressing neuronal excitability. Taber and colleagues (2002) found that there is a poor correlation between total and ionized magnesium levels. Further studies are necessary to determine whether measurement of ionized, rather than total, magnesium would provide a superior method for surveillance.

Sibai and co-workers (1984) performed a prospective study in which they compared intramuscular and continuous intravenous magnesium sulfate. There was no significant difference between mean magnesium levels observed after intramuscular magnesium sulfate and those observed following a maintenance intravenous infusion of 2 g per hour (see [Fig. 34-17](#)). In our experience, a number of women require 3 g/hr to maintain effective plasma levels of magnesium.

Patellar reflexes disappear when the plasma magnesium level reaches 10 mEq/L (about 12 mg/dL) presumably because of a curariform action. This sign serves to warn of impending magnesium toxicity, because a further increase leads to respiratory depression. When plasma levels rise above 10 mEq/L, respiratory depression develops, and at 12 mEq/L or more, respiratory paralysis and arrest follow. Somjen and co-workers (1966) induced in themselves, by intravenous infusion, marked hypermagnesemia, achieving plasma levels up to 15 mEq/L. Predictably, at such high plasma levels, respiratory depression developed that necessitated mechanical ventilation, but depression of the sensorium was not dramatic as long as hypoxia was prevented.

Treatment with calcium gluconate, 1 g intravenously, along with withholding further magnesium sulfate usually reverses mild to moderate respiratory depression. Unfortunately, the effects of intravenously administered calcium may be short-lived. For severe respiratory depression and arrest, prompt tracheal intubation and mechanical ventilation are lifesaving. Direct toxic effects on the myocardium from high levels of magnesium are uncommon. It appears that the cardiac dysfunction associated with magnesium is due to respiratory arrest and hypoxia. With appropriate ventilation, cardiac action is satisfactory even when plasma levels are exceedingly high (McCubbin and colleagues, 1981).

Because magnesium is cleared almost exclusively by renal excretion, plasma magnesium concentration, using the doses described previously, is excessive if glomerular filtration is decreased substantively. The initial standard dose of magnesium sulfate can be safely administered without knowledge of renal function. Renal function is thereafter estimated by measuring plasma creatinine, and whenever it is 1.3 mg/dL or higher, only half of the maintenance intramuscular magnesium sulfate dose outlined in [Table 34-7](#) is given. With this renal impairment dosage, plasma magnesium levels are usually within the desired range of 4 to 7 mEq/L. When magnesium sulfate is being given intravenously by continuous infusion, serum magnesium levels are used to adjust the infusion rate. **With either method, when there is renal insufficiency, plasma magnesium levels must be checked periodically.**

Acute cardiovascular effects of parenteral magnesium ion in women with severe preeclampsia have been studied by Cotton and associates (1986b), who obtained data using pulmonary and radial artery catheterization. After a 4-g intravenous dose given during 15 minutes, mean arterial blood pressure fell slightly, and this was accompanied by a 13-percent increase in cardiac index. Thus, magnesium decreased systemic vascular resistance and mean arterial pressure, and at the same time increased cardiac output, without evidence of myocardial depression. These findings were coincidental with transient nausea and flushing, and the cardiovascular effects persisted for only 15 minutes despite continued infusion of magnesium sulfate at 1.5 g per hour.

Thurnau and colleagues (1987) showed that there was a small but highly significant increase in magnesium concentration in the cerebrospinal fluid after magnesium therapy for preeclampsia. The magnitude of the increase was directly proportional to the corresponding serum concentration. This increase cannot be due to the disease itself, because magnesium levels in the cerebrospinal fluid are unchanged in untreated women with severe preeclampsia when compared with normotensive controls (Fong and associates, 1995).

Lipton and Rosenberg (1994) attribute anticonvulsant effects to blocked neuronal calcium influx through the glutamate channel. Cotton and associates (1992) induced seizure activity in the hippocampus region of rats because it is a region with a low seizure threshold and a high density of N-methyl-D-aspartate (NMDA) receptors. These receptors are linked to various models of epilepsy. Because hippocampal seizures can be blocked by magnesium, it is believed that this implicated the NMDA receptor in eclamptic convulsions (Hallak and colleagues, 1998). Importantly, results such as these suggest that magnesium has a central nervous system effect in blocking seizures.

Uterine Effects. Magnesium ions in relatively high concentration depress myometrial contractility both in vivo and in vitro. With the regimen described earlier and the plasma levels that have resulted, no evidence of myometrial depression has been observed beyond a transient decrease in activity during and immediately after the initial intravenous loading dose. Indeed, Leveno and colleagues (1998) compared labor and delivery outcomes in 480 nulliparous women given phenytoin for preeclampsia with outcomes in 425 similar women given magnesium sulfate. Magnesium sulfate did not significantly alter oxytocin stimulation of labor, admission-to-delivery intervals, or route of delivery. Similar results have been reported by others (Atkinson and associates, 1995; Szal and co-workers, 1999; Witlin and colleagues, 1997b).

The mechanisms by which magnesium might inhibit uterine contractility are not established but are generally assumed to depend on its effect on intracellular calcium (Watt-Morse and associates, 1995). The regulatory pathway leading to uterine contraction begins with an increase in the intracellular free calcium concentration, which activates myosin light chain kinase (Mizuki and associates, 1993). High concentrations of extracellular magnesium have been reported not only to inhibit calcium entry into myometrial cells but to also lead to high intracellular magnesium levels.

This latter effect has been reported to inhibit calcium entry into the cell — presumably by blocking calcium channels (Mizuki and associates, 1993). These mechanisms for inhibition of uterine contractility appear to be dose dependent, because serum magnesium levels of at least 8 to 10 mEq/L are necessary to inhibit uterine contractions (Watt-Morse and associates, 1995).

This likely explains why there is no uterine effect clinically when magnesium sulfate is given for treatment or prophylaxis of eclampsia.

Fetal Effects. Magnesium administered parenterally to the mother promptly crosses the placenta to achieve equilibrium in fetal serum and less so in amniotic fluid (Hallak and colleagues, 1993). Neonatal depression occurs only if there is severe hypermagnesemia at delivery. Neonatal compromise after therapy with magnesium sulfate has not been reported (Cunningham and Pritchard, 1984; Green and associates, 1983). Whether magnesium sulfate affects the fetal heart rate pattern, specifically beat-to-beat variability, is controversial (see [Chap. 18](#), p. 449). In a randomized investigation, Hallak and colleagues (1999b) compared an infusion of magnesium sulfate with saline and reported that magnesium was associated with a small but clinically insignificant decrease in heart rate variability.

There has been a suggestion of a possible protective effect of magnesium against cerebral palsy in very-low-birthweight infants (Nelson and Grether, 1995; Schendel and colleagues, 1996). Not all studies, however, have reproduced these findings (Grether and associates, 2000). Such uncertainty underscored the impetus for two large randomized trials designed to assess the fetal effects of magnesium sulfate exposure. In the first trial, conducted at 16 hospitals in Australia and New Zealand, 1062 women with fetuses younger than 30 weeks for whom birth was planned or expected within 24 hours were randomly assigned to receive magnesium sulfate or placebo (Crowther and colleagues, 2003). Nearly all children were evaluated at 2 years of age. Mortality and cerebral palsy were less frequent for infants exposed to magnesium, but the differences were not significant. Substantial gross motor dysfunction, however, was reduced significantly in the magnesium group. Importantly, no serious harmful effects from magnesium were observed. The second trial, with an even larger sample size, is currently being conducted by the Maternal-Fetal Medicine Units Network.

CLINICAL EFFICACY OF MAGNESIUM SULFATE THERAPY. The multinational Eclampsia Trial Collaborative Group (1995) study was funded in part by the World Health Organization and coordinated by the National Perinatal Epidemiology Unit in Oxford, England. This study involved 1687 women with eclampsia who were randomly allocated to different anticonvulsant regimens. In one study, 453 women were randomly given magnesium sulfate and compared with 452 given diazepam. Another 388 eclamptic women were randomly given magnesium sulfate and compared with 387 women given phenytoin.

As shown in [Figure 34-18](#), women allocated to magnesium sulfate therapy had a 50-percent reduction in recurrent seizures compared with that in those given diazepam. Importantly, as shown in [Table 34-8](#), maternal deaths were reduced in women given magnesium sulfate, and although these differences are clinically impressive, they are not statistically significant. Specifically, there was a 3.8-percent death rate in 453 women randomly allocated to magnesium sulfate compared with a 5.1-percent rate in 452 given diazepam. Maternal and perinatal morbidity were not different between these two groups, and there was no difference in the number of labor inductions or cesarean deliveries.

In a second comparison, also shown in [Figure 34-18](#), women randomly assigned to receive magnesium sulfate compared with phenytoin had a 67-percent reduction in recurrent convulsions. Again shown in [Table 34-8](#), maternal mortality was lower in the magnesium group compared with that in the phenytoin group (2.6 versus 5.2 percent). This clinically impressive decreased maternal mortality of 50 percent again was not significant.

In other comparisons, women allocated to magnesium sulfate therapy were less likely to be artificially ventilated, to develop pneumonia, and to be admitted to intensive care units than those given phenytoin. Neonates of women given magnesium sulfate were significantly less likely to require intubation at delivery and to be admitted to the neonatal intensive care unit compared with infants whose mothers received phenytoin.

The Collaborative Group concluded: "There is now compelling evidence in favour of magnesium sulfate, rather than diazepam or phenytoin, for the treatment of eclampsia." These results are even more impressive when it is emphasized that women in this study who received intravenous magnesium sulfate received only 1 g per hour!

PREVENTION OF ECLAMPSIA. Magnesium sulfate therapy also is superior to phenytoin in *preventing* eclamptic seizures. Lucas and colleagues (1995) reported results of a prospective study from Parkland Hospital in which women with gestational hypertension were randomly allocated to receive magnesium sulfate or phenytoin during labor. The magnesium sulfate therapy consisted of the intramuscular regimen presented in [Table 34-7](#). The phenytoin regimen consisted of a 1000-mg loading dose infused over a 1-hour period, followed by a 500-mg oral dose 10 hours later. Anticonvulsant therapy in both groups was continued for 24 hours postpartum. Ten of the 1089 women randomly assigned to the phenytoin regimen had eclamptic convulsions compared with no convulsions in 1049 women given magnesium sulfate ($P = .004$). Maternal and neonatal outcomes were similar in the two groups. Women given phenytoin who developed eclampsia did so despite "therapeutic" serum levels of 10 to 25 $\mu\text{g/mL}$.

In an even larger study, more than 10,000 women with preeclampsia in 33 countries were randomly given magnesium sulfate or placebo—the MAGnesium Sulphate for Prevention of Eclampsia, or Magpie trial (Magpie Trial Collaborative Group, 2002). Women allocated to magnesium had a 58-percent lower risk of eclampsia than those given placebo. Stated differently, the overall number of women treated to prevent one case of eclampsia was 91. For women with severe preeclampsia, this number was 63 and for those with milder disease, it was 109. Interestingly, the risk of placental abruption was also significantly lower in the magnesium sulfate group.

Belfort and associates (2003) compared magnesium sulfate and nimodipine, a calcium-channel blocker with specific cerebral vasodilator activity, for the prevention of eclampsia. In this unblinded randomized trial involving 1650 women with severe preeclampsia, the rate of eclampsia was more than threefold higher for women allocated to the nimodipine group (2.6 versus 0.8 percent).

A number of other studies have helped predict the seizure rate in women with preeclampsia who were not given seizure prophylaxis. Burrows and Burrows (1995) described 467 women not given seizure prophylaxis, and 3.9 percent developed eclampsia. Hall and colleagues (2000a) reported this to be 1.5 percent in 318 preeclamptic women. Coetzee and colleagues (1998) randomly allocated 699 South African women with severe preeclampsia to intravenous magnesium sulfate or to saline placebo. Eclampsia developed in 1 of 30 women given saline, and although the maternal and fetal outcomes were good in both groups, the study was stopped.

Despite proof of its efficacy, there is still debate about whether magnesium sulfate prophylaxis should be given routinely to all hypertensive women in labor (Nelson and Grether, 1995; Robson, 1996). The debate hinges primarily on the belief by some clinicians that a convulsion due to eclampsia does no immediate great harm to most mothers and fetuses. Presumably, those who embrace this view would reserve magnesium sulfate therapy for only those women who develop eclampsia. The unknowns are fetal effects of maternal convulsions. For example, Hallak and associates (1999a) have reported in experimental animals that maternal seizures were associated with fetal brain injury due to maternal hypoxia during the convulsion. Magnesium sulfate prevented this fetal damage.

In the United States, the debate currently centers around which women with preeclampsia should be given prophylaxis. For women with mild preeclampsia, the estimated risk of eclampsia without magnesium prophylaxis is 1 in 100 or less (Lucas and colleagues, 1995). Moreover, in a preliminary study, Livingston and associates (2003) found that magnesium sulfate does not appear to alter the progression of mild preeclampsia to severe preeclampsia.

Because of these findings, we ceased giving intravenous magnesium sulfate as seizure prophylaxis for women with mild gestational hypertension in late 1999. Alexander and co-workers (2003) presented the clinical outcomes in these women for 3-year periods before and after our protocol change. As expected, eclamptic seizures increased in the "after" 3-year period when mildly hypertensive women were not given magnesium. The rate of eclampsia in these women tripled from 2.9 to 9.3 per 1000 mildly hypertensive women. Neonatal outcomes, however, were similar.

The development of eclampsia in these women with mild hypertension and not given magnesium sulfate was not associated with severe maternal morbidity. Despite this, we emphasize two caveats:

1. Severe maternal morbidity due to eclampsia in women with mild hypertension is uncommon and the fact that we did not see such morbidity is likely due to sample size. Indeed, we are of the view that the very large sample size necessary to definitively address the issue of prophylaxis of maternal morbidity in women with mild hypertension is not feasible. Therefore, this issue will likely never be resolved.
2. The women who developed eclampsia at Parkland Hospital because they did not receive prophylaxis were in a labor-delivery unit with considerable experience in the management of eclampsia. In other settings in which eclampsia is rare, prevention of eclampsia in women with mild hypertension may be preferred as compared with treatment of the convulsing woman.

We currently do not give magnesium sulfate for seizure prophylaxis in women with mild hypertension at Parkland Hospital.

HYDRALAZINE TO CONTROL SEVERE HYPERTENSION. At Parkland Hospital, hydralazine is given intravenously whenever the diastolic blood pressure is 110 mm Hg or higher or the systolic blood pressure is more than 160 mm Hg. Some recommend treatment of diastolic pressures higher than 100 mm Hg and some use 105 mm Hg as a limit (Cunningham and Lindheimer, 1992; Sibai, 1996). Because precise data are lacking, the Working Group of the NHBPEP (2000) suggested the compromise value of persistent systolic pressure exceeding 160 mm Hg or diastolic pressure exceeding 105 mm Hg.

A number of regimens have been used. Hydralazine is administered in 5- to 10-mg doses at 15- to 20-minute intervals until a satisfactory response is achieved. A satisfactory response antepartum or intrapartum is defined as a decrease in diastolic blood pressure to 90 to 100 mm Hg, but not lower lest placental perfusion be compromised. Hydralazine so administered has proven remarkably effective in the prevention of cerebral hemorrhage. At Parkland Hospital, approximately 8 percent of all women with hypertensive disorders are given hydralazine as described, and we estimate that more than 4000 women have been treated. Seldom was another antihypertensive agent needed because of poor response to hydralazine. In many European centers, hydralazine is also favored (Redman and Roberts, 1993).

The tendency to give a larger initial dose of hydralazine when the blood pressure is higher must be avoided. The response to even 5- to 10-mg doses cannot be predicted by the level of hypertension; thus, we always give 5 mg as the initial dose. An example of very severe hypertension in a woman with chronic hypertension complicated by superimposed eclampsia that responded to repeated intravenous injections of hydralazine is shown in [Figure 34-19](#). Hydralazine was injected more frequently than recommended in the protocol, and blood pressure decreased in less than 1 hour from 240/270/130-150 mm Hg to 110/80 mm Hg. Fetal heart rate decelerations characteristic of uteroplacental insufficiency were evident when the pressure fell to 110/80 mm Hg, and persisted until maternal blood pressure increased.

LABETALOL. Intravenous labetalol, an α_1 - and nonselective β -blocker, is also used to treat acute hypertension of pregnancy.

Mabie and associates (1987) compared intravenous hydralazine with labetalol for blood pressure control in 60 peripartum women. Labetalol lowered blood pressure more rapidly, and associated tachycardia was minimal, but hydralazine lowered mean arterial pressure to safe levels more effectively. We have evaluated labetalol given intravenously for women with severe preeclampsia, and our results are very similar. Our protocol calls for 10 mg intravenously initially. If the blood pressure has not decreased to the desirable level in 10 minutes, then 20 mg is given. The next 10-minute incremental dose is 40 mg followed by another 40 mg, and then 80 mg if a salutary response is not yet achieved.

The Working Group of the NHBPEP (2000) recommends starting with a 20-mg intravenous bolus. If not effective within 10 minutes, this is followed by 40 mg, then 80 mg every 10 minutes but not to exceed a 220-mg total dose per episode treated.

OTHER ANTIHYPERTENSIVE AGENTS. The Working Group of the NHBPEP (2000) recommends *nifedipine* in a 10-mg oral dose to be repeated in 30 minutes if necessary. Scardo and colleagues (1996) gave 10 mg nifedipine orally to 10 women with preclampsic hypertensive emergencies and reported no hypotension or fetal compromise. Aali and Nejad (2002) found that when nifedipine was compared with hydralazine, fewer doses were required to achieve blood pressure control without increased adverse effects. In contrast, Mabie and colleagues (1988b) administered nifedipine sublingually to 34 women with peripartum hypertension. Its antihypertensive effects were potent and rapid, and two women developed worrisome hypotension. Similar effects in nonpregnant patients have caused cerebrovascular ischemia, myocardial infarction, conduction disturbances, and death. This led Grossman and colleagues (1996) to call for a moratorium on its use in hypertensive emergencies in nonpregnant patients. Vermillion and colleagues (1999) and Scardo and co-workers (1999) compared nifedipine with labetalol in randomized trials and found neither definitively superior to the other.

Belfort and associates (1990) administered the calcium antagonist, *verapamil*, by intravenous infusion at 5 to 10 mg per hour.

Mean arterial pressure was lowered by 20 percent. Belfort and co-workers (1996, 2003) reported that *nimodipine* given by continuous infusion as well as orally was effective to lower blood pressure in women with severe preeclampsia. Bolte and colleagues (1998, 2001) reported good results with intravenous *ketanserin*, a selective serotonin₂ receptor blocker, in preeclamptic women.

Nitroprusside is not recommended by the Working Group of the NHBPEP (2000) unless there is no response to hydralazine, labetalol, or nifedipine. A continuous infusion is begun with a dose of 0.25 µg/kg/min increased as necessary to 5 µg/kg/min. Fetal cyanide toxicity may occur after 4 hours.

PERSISTENT IMMEDIATE SEVERE POSTPARTUM HYPERTENSION. The potential problem of antihypertensive agents causing serious compromise of placental perfusion and fetal well-being is obviated by delivery. If there is a problem after delivery in controlling severe hypertension and intravenous hydralazine or another agent is being used repeatedly early in the puerperium to control persistent severe hypertension, then other regimens can be used. We have had success with intramuscular hydralazine, usually in 10- to 25-mg doses at 4- to 6-hour intervals. Once repeated blood pressure readings remain near normal, hydralazine is stopped.

If hypertension of appreciable intensity persists or recurs *in these postpartum women*, oral labetalol or a thiazide diuretic are given for as long as necessary. A variety of other antihypertensive agents have been used for this purpose, including other β-blockers and calcium-channel antagonists. The persistence or refractoriness of hypertension is likely due to at least two mechanisms:

1. Underlying chronic hypertension.
2. Mobilization of edema fluid with redistribution into the intravenous compartment.

Labetalol and a diuretic are effective treatment for both mechanisms.

PLASMA EXCHANGE. Over the years, a group at the University of Mississippi Medical Center has described an atypical syndrome in which severe preeclampsia-eclampsia persists despite delivery. Martin and associates (1995) described 18 such women over a 10-year period during which time they delivered nearly 43,000 patients. They advocate single or multiple plasma exchange for these women, and in some cases, 3 L of plasma (representing 12 to 15 donors) were exchanged three times before a response was forthcoming. Other investigators have described cases in which plasma exchange was performed in postpartum women with HELLP syndrome (Forster and colleagues, 2002; Obeidat and associates, 2002). In these cases, however, the distinction between HELLP syndrome and possible thrombotic thrombocytopenic purpura or hemolytic uremic syndrome was not clear (see [Chap. 51](#), p. 1159). In our experience with over 50,000 hypertensive women among nearly 350,000 pregnancies, we have not encountered a syndrome of persistent severe postpartum preeclampsia. In a very few women, persistent hypertension, thrombocytopenia, and renal dysfunction was found to be due to thrombotic microangiopathy (Dashe and colleagues, 1998).

DIURETICS AND HYPEROSMOTIC AGENTS. Potent diuretics further compromise placental perfusion, because their immediate effects include intravascular volume depletion, which most often is already reduced compared with that of normal pregnancy. Therefore, diuretics are not used to lower blood pressure lest they enhance the intensity of the maternal hemoconcentration and its adverse effects on the mother and the fetus (Zondervan and co-authors, 1988). Antepartum use of furosemide or similar drugs typically is limited to the rare instances in which pulmonary edema is identified or strongly suspected.

Once delivery is accomplished, there is a spontaneous diuresis that usually begins within 24 hours in almost all cases of severe preeclampsia and eclampsia. This diuresis results in the disappearance of excessive extravascular fluid over the next 3 to 4 days (see [Fig. 34-13](#)).

With infusion of hyperosmotic agents, the potential exists for an appreciable intravascular influx of fluid and, in turn, subsequent escape of intravascular fluid in the form of edema into vital organs, especially the lungs and brain. Moreover, an osmotically active agent that leaks through capillaries into lungs and brain promotes accumulation of edema at these sites. Most importantly, a sustained beneficial effect from their use has not been demonstrated.

FLUID THERAPY. Lactated Ringer solution is administered routinely at the rate of 60 mL to no more than 125 mL per hour unless unusual fluid loss from vomiting, diarrhea, or diaphoresis, or more likely, excessive blood loss at delivery has occurred. Oliguria, common in cases of severe preeclampsia and eclampsia, coupled with the knowledge that maternal blood volume is very likely constricted compared with that of normal pregnancy, makes it tempting to administer intravenous fluids more vigorously. The rationale for controlled, conservative fluid administration is that the typical woman with eclampsia already has excessive extracellular fluid that is inappropriately distributed between the intravascular and extravascular spaces. Infusion of large fluid volumes could and does enhance the maldistribution of extravascular fluid and thereby appreciably increases the risk of pulmonary and cerebral edema (Sciscione and associates, 2003; Sibai and colleagues, 1987b).

PULMONARY EDEMA. Women with severe preeclampsia-eclampsia who develop pulmonary edema most often do so postpartum (Cunningham and colleagues, 1986). Aspiration of gastric contents, the result of convulsions or perhaps from anesthesia, or oversedation, should be excluded, however, the majority of these women have cardiac failure. Some normal pregnancy changes, magnified by preeclampsia-eclampsia, predispose to pulmonary edema. Importantly, plasma oncotic pressure decreases appreciably in normal term pregnancy because of decreases in serum albumin, and oncotic pressure falls even more with preeclampsia (Sciscione and collaborators, 2003; Zinaman and associates, 1985). Moreover, Ian and colleagues (1986) described increased extravascular fluid oncotic pressure in women with preeclampsia, and this favors capillary fluid extravasation. Brown and associates (1989) verified increased capillary permeability in women with preeclampsia. Bhatia and associates (1987) found a correlation between plasma colloid osmotic pressure and fibronectin concentration; this suggested to them that vascular protein loss was the result of increased vascular permeability caused by vessel injury.

The frequent findings of hemoconcentration, as well as the identification of reduced central venous and pulmonary capillary wedge pressures in women with severe preeclampsia, have tempted some investigators to infuse various fluids, starch

polymers, or albumin concentrates, or all three, in attempts to expand blood volume and thereby somehow relieve vasospasm and reverse organ deterioration. Thus far, clear-cut evidence of benefits from this approach is lacking, however, serious complications, especially pulmonary edema, have been reported. Lopez-Llera (1982) reported that vigorous volume expansion was associated with a high incidence of pulmonary edema in more than 700 eclamptic women. Benedetti and colleagues (1985) described pulmonary edema in 7 of 10 women with severe preeclampsia who were given colloid therapy. Sibai and colleagues (1987b) cited excessive colloid and crystalloid infusions as causing most of their 37 cases of pulmonary edema associated with severe preeclampsia-eclampsia.

For these reasons, until it is understood how to contain more fluid within the intravascular compartment and, at the same time, less fluid outside the intravascular compartment, we remain convinced that, in the absence of marked fluid loss, fluids can be administered safely only in moderation. To date, no serious adverse effects have been observed from such a policy. Importantly, dialysis for renal failure was not required for any of the more than 400 cases of eclampsia so managed.

INVASIVE HEMODYNAMIC MONITORING. Much of what has been learned within the past decade about cardiovascular and hemodynamic pathophysiological alterations associated with severe preeclampsia-eclampsia has been made possible by invasive hemodynamic monitoring using a flow-directed pulmonary artery catheter. The need for clinical implementation of such technology for women with preeclampsia-eclampsia, however, has not been established. Gilbert and colleagues (2000) described a retrospective review of pulmonary artery catheterization in 17 women with eclampsia. Although they found this procedure subjectively "helpful" in clinical management, all of these women had undergone "multiple interventions," including volume expansion, prior to catheterization.

Use of pulmonary artery catheterization has been reviewed by Clark and Cotton (1988), Hankins and Cunningham (1991), Nolan and colleagues (1992), and Young and Johanson (2001). Two conditions frequently cited as indications for such monitoring are preeclampsia associated with oliguria and preeclampsia associated with pulmonary edema. Perhaps somewhat paradoxically, it is usually vigorous treatment of the oliguria that results in most cases of pulmonary edema.

Because vigorous intravenous hydration and osmotically active agents are avoided at Parkland Hospital in women with severe preeclampsia and eclampsia, hemodynamic monitoring has not been used for the vast majority of these women. Such measures are usually reserved for women with accompanying severe cardiac disease, renal disease, or both, or in cases of refractory hypertension, oliguria, and pulmonary edema. Similar indications are used by Clark and Cotton (1988), Cowles and colleagues (1994), and Easterling and co-workers (1989), as well as recommended by the American College of Obstetricians and Gynecologists (2002). The routine use of such monitoring even if pulmonary edema develops is questionable. Most of these women respond quickly to furosemide given intravenously. Afterload reduction with intermittent doses of intravenous hydralazine to lower blood pressure, as described earlier, may also be necessary, because women with chronic hypertension and severe superimposed preeclampsia are more likely to develop heart failure (Cunningham and colleagues, 1986). As discussed in [Chapter 43](#) (see p. 1011) obese women in these circumstances are even more likely to develop heart failure (Mabie and associates, 1988a).

Invasive monitoring should be considered for those women with multiple clinical factors, such as intrinsic heart disease, advanced renal disease, or both, that might cause pulmonary edema by more than one mechanism. This is particularly relevant if pulmonary edema is inexplicable or refractory to treatment. Still, in most of these cases it is not necessary to perform pulmonary artery catheterization for clinical management.

DELIVERY. To avoid maternal risks from cesarean delivery, steps to effect vaginal delivery are used initially in women with eclampsia. After an eclamptic seizure, labor often ensues spontaneously or can be induced successfully even in women remote from term. An immediate cure does not immediately follow delivery by any route, but serious morbidity is less common during the puerperium in women delivered vaginally.

BLOOD LOSS AT DELIVERY. Hemoconcentration, or lack of normal pregnancy-induced hypervolemia, is an almost predictable feature of severe preeclampsia-eclampsia. **These women, who consequently lack normal pregnancy hypervolemia, are much less tolerant of blood loss than are normotensive pregnant women.** It is of great importance to recognize that an appreciable fall in blood pressure very soon after delivery most often means excessive blood loss and not sudden dissolution of vasospasm. When oliguria follows delivery, the hematocrit should be evaluated frequently to help detect excessive blood loss that, if identified, should be treated appropriately by careful blood transfusion.

permission.)

Figure 34-15. Hypertensive hemorrhage with eclampsia.

Figure 34-16. A. Plasma magnesium levels are plotted for a woman with antepartum eclampsia in whom 4 g of magnesium sulfate intravenously and 10 g intramuscularly were administered at the outset. When she soon convulsed again, 2 g more were injected slowly followed by 5 g intramuscularly every 4 hours, as described in Table 34-7. She did not convulse again. **B.** The same woman as in **A.** Maternal magnesium levels during the first 28 hours postpartum and 4 days after magnesium sulfate was discontinued are plotted. Before and the day after delivery, the renal clearance of magnesium remained relatively constant at about 35 percent of the somewhat depressed creatinine clearance. The mother recovered fully, and the infant thrived. (From Pritchard and associates, 1984, with permission.)

Figure 34-17. Comparison of serum magnesium levels following (1) mild preeclampsia \mathcal{R} — 10-g intramuscular loading dose of magnesium sulfate and a 5-g maintenance dose every 4 hours ($\bullet\text{---}\bullet$); (2) severe preeclampsia \mathcal{R} — 4-g intravenous loading dose followed by the same regimen as in (1) ($\bullet\text{---}\bullet$); compared with (3) 4-g intravenous loading dose followed by a continuous infusion of 2 g/hr ($\blacktriangle\text{---}\blacktriangle$). (From Sibai and co-workers, 1984, with permission.)

Figure 34-18. Effects of magnesium sulfate versus diazepam and phenytoin on recurrent convulsions. (From the Eclampsia Trial Collaborative Group, 1995, with permission.)

Figure 34-19. Effects of acute blood pressure decrease on fetal status. Hydralazine was given at 5-minute intervals instead of 15-minute intervals, and mean arterial pressure decreased from 180 to 90 mm Hg within 1 hour; this change was associated with fetal bradycardia.

ANALGESIA AND ANESTHESIA. In the past, both spinal and epidural analgesia were avoided in women with severe preeclampsia and eclampsia. The primary concern centered on the hypotension induced by sympathetic blockade and, in turn, on dangers from pressor agents or large volumes of intravenous fluid used to correct iatrogenically induced hypotension. For example, rapid infusion of large volumes of crystalloid or colloid, given to counteract maternal hypovolemia caused by a variety of factors, including epidural analgesia, has been implicated as a cause of pulmonary edema (Hogg and co-workers, 1999; Sibai and colleagues, 1987b). There have also been concerns about fetal safety, because sympathetic blockade-induced hypotension can dangerously lower uteroplacental perfusion (Montan and Ingemarsson, 1989). Another concern is that attempts to restore blood pressure pharmacologically with vasopressors may be hazardous because women with preeclampsia are extremely sensitive to such agents.

As regional analgesia techniques improved during the past decade, epidural analgesia for women with severe preeclampsia was promoted by some proponents to ameliorate vasospasm and lower blood pressure (Gutsche and Cheek, 1993). Moreover, many clinicians who favored epidural blockade believed that general anesthesia was inadvisable because stimulation caused by tracheal intubation may result in sudden hypertension, which may cause pulmonary edema, cerebral edema, or intracranial hemorrhage (Lavies and colleagues, 1989). Other practitioners have also cited that tracheal intubation may be particularly hazardous in women with airway edema due to preeclampsia (Chadwick and Easterling, 1991).

These differing perspectives on the advantages, disadvantages, and safety of the anesthetic method used in the cesarean delivery of women with severe preeclampsia have evolved so that most authorities believe that epidural analgesia is the preferred method (see [Chap. 19](#), p. 487). Wallace and colleagues (1995) evaluated these important issues by conducting a randomized investigation in women with severe preeclampsia cared for at Parkland Hospital. There were 80 women with severe preeclampsia who were to be delivered by cesarean and who were randomized to general anesthesia or epidural or combined spinal-epidural analgesia. Their mean preoperative blood pressure was approximately 170/110 mm Hg, and all had proteinuria. Anesthetic and obstetrical management included antihypertensive drug therapy and limited intravenous fluids and other drug therapy. The infants, whose mean gestational age at delivery was 34.8 weeks, all were born in good condition as assessed by Apgar scores and umbilical arterial blood gas determinations. Maternal hypotension resulting from regional analgesia was managed without excessive intravenous fluid administration. Similarly, maternal blood pressure was managed

without severe hypertensive effects in women undergoing general anesthesia ([Fig. 34-20](#)). There were no serious maternal or fetal complications attributable to any of the three anesthetic methods. It was concluded that general as well as regional anesthetic methods are equally acceptable for cesarean delivery in pregnancies complicated by severe preeclampsia if steps are taken to ensure a careful approach to either method. A similar conclusion was reached by Dyer and colleagues (2003) following their randomized study of spinal versus general anesthesia in 70 patients with preeclampsia and a nonreassuring fetal heart rate tracing.

As discussed, the immense popularity and increasing availability of epidural analgesia for labor has led many anesthesiologists as well as obstetricians to develop the viewpoint that epidural analgesia is an important factor in the intrapartum *treatment* of women with preeclampsia (Chadwick and Easterling, 1991; Ramanathan, 1991). To study this issue, Lucas and associates (2001) from Parkland Hospital randomly assigned 738 laboring women at 36 weeks or more who had gestational hypertension of varying severity to epidural analgesia or patient-controlled intravenous meperidine analgesia. Maternal and infant outcomes were similar in the two study groups. As shown in [Table 34-9](#), although epidural analgesia significantly lowered the maternal blood pressure compared with meperidine, this provided no significant benefit in terms of preventing severe hypertension later in labor. It was concluded that epidural analgesia during labor was safe for women with pregnancy-associated hypertensive disorders; it should not be misconstrued to be a therapy for hypertension.

Head and co-workers (2002) from the University of Alabama at Birmingham randomly assigned 116 women with severe preeclampsia to receive either epidural or patient-controlled intravenous meperidine analgesia during labor. Although 9 percent of women who received an epidural required ephedrine for hypotension, pain relief was superior with epidural analgesia and, using a standardized protocol that limited intravenous fluids, there was not a significant increase in other maternal or neonatal complications, including pulmonary edema.

Newsome and colleagues (1986) studied the lowered mean arterial pressure that follows epidural blockade in a group of women with severe preeclampsia. Despite decreased blood pressure, the cardiac index did not fall, and intravenous fluid loading caused elevation of pulmonary capillary wedge pressures as compared with that in women in whom fluids were restricted. It is clear that aggressive volume replacement in these women increases their risk for pulmonary edema, especially in the first 72 hours postpartum (Clark and colleagues, 1985; Cotton and associates, 1986a). When pulmonary edema develops there is also concern for development of cerebral edema. Finally, Heller and co-workers (1983) demonstrated that the majority of cases of pharyngolaryngeal edema seen in women with severe preeclampsia were related to aggressive volume replacement therapy.

Figure 34-20. Blood pressure effects of general anesthesia versus epidural or spinal-epidural analgesia for cesarean delivery in 80 women with severe preeclampsia. [MAP = mean arterial pressure. Time posts (T): OR = operating room, IN = anesthesia induction, T = intubation, SKI = skin incision, D = delivery, SKO = skin closure, O = extubation.] (From Wallace and associates, 1995, with permission.)

LONG-TERM CONSEQUENCES

Women who develop hypertension during pregnancy should be evaluated during the immediate postpartum months and counseled about future pregnancies and also their cardiovascular risk later in life (Working Group of the NHBPEP, 2000). As mentioned earlier, the longer hypertension diagnosed during pregnancy persists postpartum, the greater the likelihood that the cause is underlying chronic hypertension. Indeed, the Working Group has taken the position that hypertension attributable to pregnancy must resolve within 12 weeks of delivery. Persistence of hypertension beyond this time is considered evidence of chronic hypertension (see [Chap. 45](#)).

Although hypertension during pregnancy is common, there are few reports concerning the long-term maternal consequences of hypertensive disorders during pregnancy. Most reports are focused on the risk of recurrence of hypertension during a subsequent pregnancy in women affected during a prior pregnancy.

COUNSELING FOR FUTURE PREGNANCIES. Women who have had preeclampsia are more prone to hypertensive complications in future pregnancies (Working Group of the NHBPEP, 2000). Generally, the earlier preeclampsia is diagnosed during the index pregnancy, the greater the likelihood of recurrence. For example, Sibai and colleagues (1986, 1991) found that nulliparous women diagnosed with preeclampsia before 30 weeks have a recurrence risk as high as 40 percent during a subsequent pregnancy.

Sibai and colleagues (1995) found that the recurrence rate for women with one episode of HELLP syndrome was approximately 5 percent. Sullivan and associates (1994) reported a recurrence rate of 27 percent. Our experiences are more in agreement with the lower number. Even if HELLP does not recur, with subsequent preeclampsia there is a high incidence of preterm delivery, fetal growth restriction, placental abruption, and cesarean delivery (Hnat and collaborators, 2002). Multiparous women who develop preeclampsia are at increased risk for recurrence of preeclampsia in subsequent pregnancy compared with nulliparas who develop preeclampsia (Trupin and associates, 1996). Trogstad and associates (2004), using the Medical Birth Registry of Norway, found that the recurrence risk of preeclampsia for women with a prior singleton versus twin pregnancy complicated by preeclampsia was 14 and 7 percent, respectively.

Women with early-onset severe preeclampsia may have underlying thrombophilias. These disorders, discussed in [Chapter 47](#) (see p. 1074), not only complicate subsequent pregnancies but also have an impact on overall long-term health.

LONG-TERM PROGNOSIS. There is one truly remarkable and unparalleled effort to measure long-term maternal consequences of hypertension due to pregnancy. Chesley and co-workers (1976) identified 270 women with eclampsia delivered at the Margaret Hague Maternity Hospital between 1931 and 1951 and meticulously followed these women

through 1974—entailing a follow-up period of up to 43 years in some of the women. As shown in [Table 34-10](#), the long-term cardiovascular prognosis depends on whether eclampsia occurred in nulliparous, compared with multiparous women. Chesley and co-workers (1976) also analyzed the long-term outcome in 54 nulliparous women with eclampsia in their index pregnancy and hypertension again during a subsequent pregnancy compared with that of 100 eclamptic nulliparous who were normotensive during all subsequent pregnancies. Those with recurrent pregnancy hypertension were at increased risk for chronic hypertension, whereas those who remained normotensive during subsequent pregnancies were at decreased risk. Thus, normal blood pressure during subsequent pregnancies serves to define women not at risk for future chronic hypertension. According to the Working Group of the NHBPEP (2000), women experiencing normotensive births have a reduced risk for remote hypertension. Thus, in some respects, repeated pregnancy serves as a screening test for future hypertension. Finally, and importantly, preeclampsia does not cause chronic hypertension (Fisher and colleagues, 1981).

TABLE 34-1. Diagnosis of Hypertensive Disorders Complicating Pregnancy

Gestational hypertension

- BP \geq 140/90 mm Hg for first time during pregnancy
- No proteinuria
- BP returns to normal < 12 weeks' postpartum
- Final diagnosis made only postpartum
- May have other signs or symptoms of preeclampsia, for example, epigastric discomfort or thrombocytopenia

Preeclampsia

Minimum criteria

- BP \geq 140/90 mm Hg after 20 weeks' gestation
- Proteinuria \geq 300 mg/24 hours or \geq 1 + dipstick

Increased certainty of preeclampsia

- BP \geq 160/110 mm Hg
- Proteinuria 2.0 g/24 hours or \geq 2+ dipstick
- Serum creatinine > 1.2 mg/dL unless known to be previously elevated
- Platelets < 100,000/mm³
- Microangiopathic hemolysis (increased LDH)
- Elevated ALT or AST
- Persistent headache or other cerebral or visual disturbance
- Persistent epigastric pain

Eclampsia

Seizures that cannot be attributed to other causes in a woman with preeclampsia

Superimposed Preeclampsia (on chronic hypertension)

- New-onset proteinuria \geq 300 mg/24 hours in hypertensive women but no proteinuria before 20 weeks' gestation
- A sudden increase in proteinuria or blood pressure or platelet count < 100,000/mm³ in women with hypertension and proteinuria before 20 weeks' gestation

Chronic Hypertension

BP \geq 140/90 mm Hg before pregnancy or diagnosed before 20 weeks' gestation not attributable to gestational trophoblastic disease

or

Hypertension first diagnosed after 20 weeks' gestation and persistent after 12 weeks' postpartum

ALT = alanine aminotransferase; AST = aspartate aminotransferase; BP = blood pressure; LDH = lactate dehydrogenase.

35. Obstetrical Hemorrhage

INTRODUCTION

Obstetrics is "bloody business." Even though hospitalization for delivery and the availability of blood for transfusion have dramatically reduced the maternal mortality rate, death from hemorrhage still remains a leading cause of maternal mortality. From 1991 through 1997 in the United States, hemorrhage was a direct cause of more than 18 percent of 3201 pregnancy-related maternal deaths, as ascertained from the Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention (Berg and colleagues, 2003). Similarly, in the United Kingdom, hemorrhage was the major factor in more than 150 maternal deaths between 1985 and 1996 (Bonnar, 2000). Moreover, in both countries, hemorrhage is a leading reason for admission of pregnant women to intensive care units (Gilbert, 2003; Hazelgrove, 2001; Zeeman, 2003, and all their associates). In countries with fewer resources, the contribution of hemorrhage to maternal mortality is even more striking (Jegasothy, 2002; Rahman and co-workers, 2002). Indeed, hemorrhage has been identified as the single most important cause of maternal death worldwide, accounting for almost half of all postpartum deaths in developing countries (McCormick and colleagues, 2002).

Undoubtedly, there has been great improvement in mortality from hemorrhage with modernization of American obstetrics. For example, Sachs and associates (1987) reported that maternal deaths from obstetrical hemorrhage in Massachusetts declined tenfold from the mid-1950s to the mid-1980s. Similarly, maternal mortality due to hemorrhage at Grady Memorial Hospital in Atlanta decreased from 13 percent between 1949 and 1971 to 6 percent between 1972 and 2000 (Ho and associates, 2002).

Causes of maternal death from hemorrhage are shown in [Table 35-1](#). Fatal hemorrhage is most likely in circumstances in which blood or components are not available immediately. For example, Singla and associates (2001) reported that women who are Jehovah's Witnesses are at a 44-fold increased risk of maternal death because of hemorrhage. The establishment and maintenance of facilities that allow prompt administration of blood are absolute requirements for acceptable obstetrical care. Hemorrhage may be *antepartum*, such as with placenta previa or placental abruption, or more likely *postpartum*, from uterine atony or genital tract lacerations.

Incidence and Predisposing Conditions. Because of inexact terminology, the incidence of obstetrical hemorrhage cannot be determined precisely. Combs and colleagues (1991b) defined hemorrhage by a postpartum hematocrit drop of 10 volumes percent or by need for transfusion. Using these criteria, the incidence was 3.9 percent for women delivered vaginally. In women undergoing cesarean delivery, it was 6 to 8 percent (Combs and associates, 1991a; Naef and co-workers, 1994). In a study at Beth Israel Hospital, Klapholz (1990) reviewed over 30,000 deliveries from 1976 to 1986. The incidence of transfusion decreased over the years; in 1976 it was 4.6 percent, but by 1986 it was 1.9 percent.

[Table 35-2](#) lists the many clinical circumstances in which risk of hemorrhage is appreciably increased. It is apparent that serious hemorrhage may occur at any time throughout pregnancy and the puerperium. The time of bleeding is widely used to classify obstetrical hemorrhage; the term *third-trimester* bleeding, however, is imprecise, and its use is not recommended. One factor not generally considered as "predisposing" to exsanguination is the lack of availability of obstetrical and anesthetic services. According to Bonnar (2000), the majority of deaths from hemorrhage in the United Kingdom cited earlier were associated with substandard care. Nagaya and associates (2000) reviewed 197 maternal deaths in Japan in the 2-year period spanning 1991 and 1992. Hemorrhage caused 40 percent of these deaths, and the investigators concluded that many of these were preventable because they were associated with inadequate obstetrical facilities.

ANTEPARTUM HEMORRHAGE

Slight vaginal bleeding is common during active labor. This "bloody show" is the consequence of effacement and dilatation of the cervix, with tearing of small veins. Uterine bleeding from a site above the cervix before delivery is cause for concern. The bleeding may be the consequence of some separation of a placenta implanted in the immediate vicinity of the cervical canal — *placenta previa*. It may come from separation of a placenta located elsewhere in the uterine cavity — *placental abruption*. Rarely, the bleeding may be the consequence of velamentous insertion of the umbilical cord with rupture and hemorrhage from a fetal blood vessel at the time of rupture of the membranes — *vasa previa*.

The source of uterine bleeding that originates above the level of the cervix is not always identified. In that circumstance, the bleeding typically begins with little or no other symptomatology, and then stops, and at delivery no anatomical cause is identified. Almost always the bleeding must have been the consequence of slight marginal separation of the placenta that did not expand. **The pregnancy in which such bleeding occurs remains at increased risk for a poor outcome even though the bleeding soon stops and placenta previa appears to have been excluded by sonography.** Lipitz and colleagues (1991) studied 65 consecutive women who had uterine bleeding between 14 and 26 weeks. Almost a fourth had placental abruption or previa. Total fetal loss including abortions and perinatal deaths was 32 percent. Leung and colleagues (2001) found that unexplained antepartum hemorrhage before 34 weeks was associated with a 62-percent risk of delivery within one week when associated with uterine contractions and a 13-percent risk even in the absence of contractions. In pregnancies with hemorrhage after 26 weeks not explained by placental abruption or previa, Ajayi and associates (1992) reported adverse outcomes in a third. For this reason, delivery should be considered in any woman at term with unexplained vaginal bleeding.

PLACENTAL ABRUPTION

Definition. The separation of the placenta from its site of implantation before delivery has been variously called placental abruption, abruptio placentae, and in Great Britain, accidental hemorrhage. The term *premature separation of the normally implanted placenta* is most descriptive because it differentiates the placenta that separates prematurely but that is implanted some distance beyond the cervical internal os from one that is implanted over the cervical internal os — that is, placenta previa. This is cumbersome, however, and hence the shorter term *abruptio placentae*, or *placental abruption*, has been used. The Latin *abruptio placentae*, which means "rending asunder of the placenta," denotes a sudden accident, a clinical characteristic of most cases of this complication.

Some of the bleeding of placental abruption usually insinuates itself between the membranes and uterus, and then escapes through the cervix, causing *external hemorrhage* (Fig. 35-1). Less often, the blood does not escape externally but is retained between the detached placenta and the uterus, leading to *concealed hemorrhage* (see Figs. 35-1 and 35-2). As shown in Figures 35-1, 35-2 and 35-3, placental abruption may be *total* or *partial*. Placental abruption with concealed hemorrhage carries with it much greater maternal and fetal hazards, not only because of the possibility of consumptive coagulopathy, but also because the extent of the hemorrhage is not appreciated and the diagnosis typically is made later (Chang and co-workers, 2001).

Frequency and Significance. The frequency with which placental abruption is diagnosed varies because of different criteria. The intensity of the abruption often varies depending on how quickly the woman seeks and receives care following the onset of symptoms. With delay, the likelihood of extensive separation causing death of the fetus is increased remarkably.

The reported frequency for placental abruption averages about 1 in 200 deliveries. According to U.S. birth certificate data for the year 2001, the incidence of placental abruption was 1 in 185 deliveries (Martin and co-workers, 2002). At Parkland Hospital from 1988 through 2003, the incidence of abruption in over 235,000 deliveries has been approximately 1 in 290. Both incidence and severity have decreased over time. Applying the criterion of placental separation so extensive as to kill the fetus, the incidence was 1 in 420 deliveries from 1956 through 1967 (Pritchard and Brekken, 1967). As the number of high-parity women cared for decreased, and community-wide availability of prenatal care as well as emergency transportation improved, the frequency of abruption causing fetal death dropped to about 1 in 830 deliveries from 1974 through 1989 (Pritchard and colleagues, 1991). Between 1996 and 2003, it decreased to about 1 in 1600.

PERINATAL MORBIDITY AND MORTALITY. As stillbirths from other causes have decreased appreciably, those from placental abruption have become especially prominent. For example, of all third-trimester stillbirths at Parkland Hospital between 1992 and 1994, 12 percent were the consequence of placental abruption (Cunningham and Hollier, 1997). This figure has been stable, and from 2000 through 2002, abruption accounted for 10 percent of third-trimester stillbirths among nearly 45,000 deliveries. These frequencies are similar to that described by Fretts and Usher (1997) for the Royal Victoria Hospital in Montreal between 1978 and 1995. Based on their analysis of more than 7 million singleton births delivered in the United States during 1995 and 1996, Ananth and Wilcox (2001) calculated that the perinatal mortality rate associated with placental abruption was 119 per 1000 births compared with 8.2 per 1000 for all others. The high mortality was due in part to the strong association between placental abruption and preterm delivery. Even in those infants delivered at term, however, perinatal mortality was 25-fold higher with placental abruption.

Importantly, if the infant does survive, there may be adverse sequelae. Of the 182 survivors in the study by Abdella and associates (1984), about 15 percent were identified to have significant neurological deficits within the first year of life. Similarly, of the 39 survivors delivered between 26 and 36 weeks followed by Matsuda and co-workers (2003), about 20 percent were diagnosed with cerebral palsy compared with 1 percent of gestational age-matched controls.

Etiology. The primary cause of placental abruption is unknown, but there are several associated conditions. Some of these are listed in Table 35-3. As shown in Figure 35-4, the incidence increases with *maternal age*. Although Pritchard and colleagues (1991) have also shown it to be higher in women of *great parity*, Toohey and associates (1995) did not find this in women para 5 or greater. *Race* or ethnicity appears to be important. In the almost 170,000 deliveries studied at Parkland Hospital, abruption was more common in African-American and Caucasian women (1 in 200) than in Asian (1 in 300) or Latin-American women (1 in 450).

By far the most commonly associated condition is some type of *hypertension*. This includes preeclampsia, gestational hypertension, and chronic hypertension. In the earlier Parkland Hospital study of 408 women with placental abruption so severe as to kill the fetus, maternal hypertension was apparent in about 50 percent of the women once the depleted intravascular compartment was adequately refilled (Pritchard and co-workers, 1991). Half of these women had chronic hypertension, and the remainder had gestational hypertension or preeclampsia. Morgan and colleagues (1994) found that hypertensive women were more likely to suffer a more severe abruption. According to Witlin and colleagues (1999), however, the severity of preeclampsia did not correlate with the incidence of abruption in 445 women. From the Maternal-Fetal Medicine Units Network, Sibai and co-workers (1998) reported that 1.5 percent of women with chronic hypertension suffered placental abruption. Ananth and associates (1999a) reported a threefold increased incidence of abruption with chronic hypertension and fourfold with severe preeclampsia. Interestingly, results from the Magpie Trial Collaborative Group (2002) suggests that women with preeclampsia may have a reduced risk of placental abruption when treated with magnesium sulfate (see Chap. 34, p. 792).

There is an increased incidence of abruption with *preterm prematurely ruptured membranes*. Major and colleagues (1995) described an incidence of 5 percent in 756 women with ruptured membranes between 20 and 36 weeks. Kramer and co-workers (1997) found an incidence of 3.1 percent in all patients if membranes were ruptured for longer than 24 hours. In a meta-analysis of 54 studies, Ananth and associates (1996) found a threefold risk of abruption with prematurely ruptured membranes.

In the earliest studies from the Collaborative Perinatal Project, *cigarette smoking* was linked to an increased risk for abruption (Misra and Ananth, 1999; Naeye, 1980). In a meta-analysis of 1.6 million pregnancies, Ananth and colleagues (1999a, 1999b) found a twofold risk for abruption in smokers. This was increased to five- to eightfold if smokers had chronic hypertension, severe preeclampsia, or both. Similar findings have been reported by Odendaal and associates (2001) and Mortensen and colleagues (2001).

Cocaine abuse has been associated with an alarming frequency of placental abruption. In one report of 50 women who abused cocaine during pregnancy, eight stillbirths were caused by placental abruption (Bingol and colleagues, 1987). Addis and associates (2001) systematically reviewed 15 studies of cocaine-using women, all of which showed that placental abruption was more common than in controls.

Over the past decade, a number of inherited or acquired *thrombophilias* have been described that are associated with thromboembolic disorders during pregnancy (see Chap. 47, p. 1074). These clotting disorders also are associated with placental abruption and infarction (Gherman and Goodwin, 2000). For example, Kupferminc and colleagues (1999) found a

significantly increased risk of abruption in women with a factor V Leiden or prothrombin gene mutation.

External trauma was implicated in only 3 of 207 cases of placental abruption causing fetal death at Parkland Hospital (see [Chap. 42](#), p. 998). These experiences are similar to those of Kettel (1988) and Stafford (1988) and their co-workers, who stressed that abruption caused by relatively minor trauma may cause fetal jeopardy that is not always associated with immediate evidence of placental separation. In such cases, monitoring for 2 to 6 hours is usually adequate to exclude a subclinical abruption in the absence of uterine contractions, tenderness, or bleeding (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2002).

Uterine leiomyomas, especially if located behind the placental implantation site, predispose to abruption (see [Chap. 40](#), p. 963). Rice and associates (1989) reported that 8 of 14 women with retroplacental myomas developed placental abruption; four women had stillborn infants. In contrast, abruption developed in only 2 of 79 women whose myoma was not retroplacental.

Recurrent Abruption. Pritchard and co-workers (1970) identified a recurrence rate of severe abruption in 1 in 8 pregnancies. Importantly, of the 14 recurrent placental abruptions, eight caused fetal death for a second time. Furuhashi and colleagues (2002) analyzed subsequent pregnancy outcomes from 27 women who had a prior placental abruption. Of the six (22 percent) recurrences, four were at a gestational age 1 to 3 weeks earlier than the first abruption. Management of the subsequent pregnancy is made difficult in that placental separation may suddenly occur at any time, even remote from term. In the majority of cases, moreover, fetal well-being is normal beforehand, and thus currently available methods of fetal evaluation are usually not predictive (Toivonen and colleagues, 2002). In an extreme example, Seski and Compton (1976) documented both a normal nonstress test and a normal contraction stress test performed four hours before the onset of placental abruption that promptly killed the fetus.

Pathology. Placental abruption is initiated by hemorrhage into the decidua basalis. The decidua then splits, leaving a thin layer adherent to the myometrium. Consequently, the process in its earliest stages consists of the development of a decidual hematoma that leads to separation, compression, and the ultimate destruction of the placenta adjacent to it (see [Chap. 27](#), p. 621). In its early stage, there may be no clinical symptoms. The condition is discovered only on examination of the freshly delivered organ, which has a circumscribed depression measuring a few centimeters in diameter on its maternal surface, and is covered by dark, clotted blood. Undoubtedly, it takes at least several minutes for these anatomical changes to materialize. Thus, a very recently separated placenta may appear no different from a normal placenta at delivery. According to Benirschke and Kaufmann (2000), and in our experiences, the "age" of the retroplacental clot cannot be determined exactly.

In some instances, a decidual spiral artery ruptures to cause a retroplacental hematoma, which as it expands disrupts more vessels to separate more placenta. The area of separation rapidly becomes more extensive and reaches the margin of the placenta. Because the uterus is still distended by the products of conception, it is unable to contract sufficiently to compress the torn vessels that supply the placental site. The escaping blood may dissect the membranes from the uterine wall and eventually appear externally or may be completely retained within the uterus (see [Figs. 35-1](#) and [35-2](#)).

CONCEALED HEMORRHAGE. Retained or concealed hemorrhage is likely when:

1. There is an effusion of blood behind the placenta but its margins still remain adherent.
2. The placenta is completely separated yet the membranes retain their attachment to the uterine wall.
3. Blood gains access to the amniotic cavity after breaking through the membranes.
4. The fetal head is so closely applied to the lower uterine segment that the blood cannot make its way past it.

Most often, however, the membranes are gradually dissected off the uterine wall, and blood sooner or later escapes.

CHRONIC PLACENTAL ABRUPTION. In some women, hemorrhage with retroplacental hematoma formation is somehow arrested completely without delivery. We have been able to document this phenomenon by labeling maternal red cells with ⁵¹chromium. This technique demonstrated that red blood cells concealed as a 400-mL clot within the uterus at delivery 3 weeks later contained no chromium and therefore were shed before.

FETAL-TO-MATERNAL HEMORRHAGE. Bleeding with placental abruption is almost always maternal. In nontraumatic placental abruption, evidence of fetal-to-maternal hemorrhage was found in 20 percent of 78 cases; in all instances, it was less than 10 mL (Stettler and colleagues, 1992). Significant fetal bleeding is more likely to be seen with traumatic abruption (see [Chap. 42](#), p. 998). **In this circumstance, fetal bleeding results from a tear or fracture in the placenta rather than from the placental separation itself.** Pearlman and associates (1990) found that fetal bleeding averaged 12 mL in a third of women with a traumatic abruption. Stettler and colleagues (1992) reported that there was fetal-to-maternal hemorrhage of 80 to 100 mL in 3 of 8 cases of traumatic placental abruption.

Clinical Diagnosis. It is emphasized that the signs and symptoms of placental abruption can vary considerably. For example, external bleeding can be profuse, yet placental separation may not be so extensive as to compromise the fetus directly. Rarely, there may be no external bleeding but the placenta may be completely sheared off and the fetus dead as the direct consequence. In one very unusual case, a multiparous woman near term presented to the Parkland Hospital obstetrical emergency room because of nosebleed. There was no abdominal or uterine pain or tenderness and no vaginal bleeding, but her fetus was dead. Her blood did not clot, and the plasma fibrinogen level was 25 mg/dL. Labor was induced, and at delivery a total abruption with fresh clots was found.

Hurd and co-workers (1983), in a prospective study of placental abruption, identified the frequency of a variety of pertinent signs and symptoms ([Table 35-4](#)). Bleeding and abdominal pain were the most frequent findings. **In 22 percent of cases, idiopathic preterm labor was considered to be the diagnosis until subsequent fetal death or distress developed.** Other findings included back pain, uterine tenderness, frequent uterine contractions, and persistent uterine hypertonus.

Studies consistently demonstrate that ultrasound infrequently confirms the diagnosis of abruption. For example, Sholl (1987) confirmed the clinical diagnosis sonographically in only 25 percent of women. Similarly, Glantz and Purnell (2002) calculated a

24-percent sensitivity in 149 consecutive women who underwent sonography to rule out placental abruption. **Importantly, negative findings with ultrasound examination do not exclude placental abruption.**

Shock. It was once held that the shock sometimes seen with placental abruption was out of proportion to the amount of hemorrhage. Supposedly, thromboplastin from decidua and placenta entered the maternal circulation and incited intravascular coagulation and other features of the amniotic fluid embolism syndrome (see p. 845). This sequence is rare, and the intensity of shock is seldom out of proportion to maternal blood loss. Pritchard and Brekken (1967) studied blood loss in 141 women with placental abruption so severe as to kill the fetus and found that it often amounted to at least half of the pregnant blood volume. Neither hypotension nor anemia is obligatory in cases of concealed hemorrhage, even when the acute hemorrhage has achieved considerable magnitude. Oliguria caused by inadequate renal perfusion but responsive to vigorous treatment of hypovolemia may also be observed in these circumstances.

Differential Diagnosis. With severe placental abruption, the diagnosis generally is obvious. Milder and more common forms of abruption are difficult to recognize with certainty, and the diagnosis is often made by exclusion. Unfortunately, neither laboratory tests nor diagnostic methods are available to detect lesser degrees of placental separation accurately. Therefore, with vaginal bleeding complicating a viable pregnancy, it often becomes necessary to rule out placenta previa and other causes of bleeding by clinical inspection and ultrasound evaluation. It has long been taught, perhaps with some justification, that painful uterine bleeding means placental abruption, whereas painless uterine bleeding is indicative of placenta previa. Unfortunately, the differential diagnosis is not that simple. Labor accompanying placenta previa may cause pain suggestive of placental abruption. On the other hand, abruption may mimic normal labor, or it may cause no pain at all. The latter is more likely with a posteriorly implanted placenta. At times, the cause of the vaginal bleeding remains obscure even after delivery.

Consumptive Coagulopathy. One of the most common causes of clinically significant consumptive coagulopathy in obstetrics is placental abruption. Overt *hypofibrinogenemia* (less than 150 mg/dL of plasma) along with elevated levels of fibrinogen-fibrin degradation products, d-dimers, and variable decreases in other coagulation factors are found in about 30 percent of women with placental abruption severe enough to kill the fetus. Such severe coagulation defects are seen less commonly in those cases in which the fetus survives. Our experience has been that serious coagulopathy, when it develops, is usually evident by the time the woman is symptomatic.

The major mechanism is almost certainly the induction of coagulation intravascularly and, to a lesser degree, retroplacentally. Although an appreciable amount of fibrin is commonly deposited within the uterine cavity in instances of severe placental abruption and hypofibrinogenemia, the amounts are insufficient to account for all of the fibrinogen missing from the circulation (Pritchard and Brekken, 1967). Moreover, Bonnar and co-workers (1969) have observed, and we have confirmed, that the levels of fibrin degradation products are higher in serum from peripheral blood than in serum from blood contained in the uterine cavity. The reverse would be anticipated in the absence of significant intravascular coagulation.

An important consequence of intravascular coagulation is the activation of plasminogen to plasmin, which lyses fibrin microemboli, thereby maintaining patency of the microcirculation. In every instance of placental abruption severe enough to kill the fetus, we have identified clearly pathological levels of fibrinogen-fibrin degradation products in maternal serum. At the outset, severe hypofibrinogenemia may or may not be accompanied by overt thrombocytopenia. After repeated blood transfusions, however, thrombocytopenia is common.

Renal Failure. Acute renal failure may be seen in severe forms of placental abruption. This includes those in which treatment of hypovolemia is delayed or incomplete (see [Chap. 48](#), p. 1106). Of 72 pregnant women with acute renal failure described by Drakeley and colleagues (2002), 32 percent had placental abruption. Fortunately, reversible acute tubular necrosis accounts for 75 percent of cases of renal failure (Turney and colleagues, 1989). According to Lindheimer and associates (2000), acute cortical necrosis in pregnancy is usually caused by abruptio placentae, and Grunfeld and Pertuiset (1987) reported that 7 of 19 women with this lesion had placental abruption.

Seriously impaired renal perfusion is the consequence of massive hemorrhage. Because preeclampsia frequently coexists with placental abruption, renal vasospasm is likely intensified (Hauth and Cunningham, 1999). Even when placental abruption is complicated by severe intravascular coagulation, prompt and vigorous treatment of hemorrhage with blood and crystalloid solution often prevents clinically significant renal dysfunction. For unknown reasons, even without preeclampsia, *proteinuria* is common, especially with more severe forms of placental abruption. It usually clears soon after delivery.

Couvellaire Uterus. There may be widespread extravasation of blood into the uterine musculature and beneath the uterine serosa ([Fig. 35-5](#)). This so-called *uteroplacental apoplexy*, first described by Couvellaire in the early 1900s, is now frequently called *Couvellaire uterus*. Such effusions of blood are also occasionally seen beneath the tubal serosa, in the connective tissue of the broad ligaments, and in the substance of the ovaries, as well as free in the peritoneal cavity. Its precise incidence is unknown because it can be demonstrated conclusively only at laparotomy. These myometrial hemorrhages seldom interfere with uterine contractions sufficiently to produce severe postpartum hemorrhage and are not an indication for hysterectomy.

Management. Treatment for placental abruption varies depending on gestational age and the status of the mother and fetus. With a live and mature fetus, and if vaginal delivery is not imminent, then emergency cesarean delivery is chosen by most clinicians. As discussed in the section Hypovolemic Shock on page 839, with massive external bleeding, intensive resuscitation with blood plus crystalloid and prompt delivery to control the hemorrhage are lifesaving for the mother and, it is hoped, for the fetus. If the diagnosis is uncertain and the fetus is alive but without evidence of fetal compromise, very close observation, with facilities for immediate intervention, can be practiced.

EXPECTANT MANAGEMENT IN PRETERM PREGNANCY. Delaying delivery may prove beneficial when the fetus is immature. Bond and associates (1989) expectantly managed 43 women with placental abruption before 35 weeks, and 31 of them were given tocolytic therapy. The mean time to delivery in all 43 was about 12 days and there were no stillborns. Cesarean delivery was performed in 75 percent of cases.

Women with evidence of very early abruption frequently develop oligohydramnios, either with or without premature membrane rupture. Elliott and associates (1998) described four women with an abruption at a mean gestational age of 20 weeks and who also developed oligohydramnios. They were delivered at an average of 28 weeks.

Lack of ominous decelerations does not guarantee the safety of the intrauterine environment for any period of time. The placenta may further separate at any instant and seriously compromise or kill the fetus unless delivery is performed immediately. Some of the immediate causes of fetal distress from abruptio placentae are shown in [Figure 35-6](#). It is important for the welfare of the distressed fetus that steps be initiated immediately to correct maternal hypovolemia, anemia, and hypoxia so as to restore and maintain the function of any placenta that is still implanted. Little can be done to favorably modify the other causes that contribute to fetal distress except to deliver the fetus.

TOCOLYSIS. Some clinicians have advocated tocolysis for the preterm pregnancy complicated by suspected abruption. Hurd and associates (1983) found that abruption went unrecognized for dangerously long periods if tocolysis was initiated. Conversely, Sholl (1987) as well as Combs and co-workers (1992) provided data that tocolysis improved outcome in a highly selected group of preterm pregnancies complicated by partial abruption. Towers and co-workers (1999) administered magnesium sulfate, terbutaline, or both to 95 of 131 women with placental abruption diagnosed before 36 weeks. The perinatal mortality was 5 percent and did not differ from the nontreated group. They concluded that a randomized clinical trial could be safely conducted. Until then, we are of the view that clinically evident placental abruption should be considered a contraindication to tocolytic therapy.

CESAREAN DELIVERY. Rapid delivery of the fetus who is alive but in distress practically always means cesarean delivery. Kayani and colleagues (2003) studied the relationship between the rapidity of delivery and neonatal outcome in 33 singleton pregnancies with a clinically overt placental abruption and fetal bradycardia. Of the 22 neurologically intact survivors, 15 were delivered within 20 minutes of the decision to operate. Of the 11 infants who died or developed cerebral palsy, 8 were delivered beyond 20 minutes of the decision time, suggesting that the speed of response is an important factor in neonatal outcome.

It is important to note that an electrode applied directly to the fetus may rarely provide misleading information, as in the case illustrated in [Figure 35-7](#). At first impression at least, fetal bradycardia of 80 to 90 beats/min, with a degree of beat-to-beat variability, seemed evident. The fetus, however, was dead, and the maternal pulse rate was identical to that recorded through the fetal scalp electrode. Cesarean delivery at this time would likely have proved dangerous for the mother because she was profoundly hypovolemic and had severe consumptive coagulopathy.

VAGINAL DELIVERY. If placental separation is so severe that the fetus is dead, vaginal delivery is preferred unless hemorrhage is so brisk that it cannot be successfully managed even by vigorous blood replacement, or there are other obstetrical complications that prevent vaginal delivery. Serious coagulation defects are likely to prove especially troublesome with cesarean delivery. The abdominal and uterine incisions are prone to bleed excessively when coagulation is impaired. Hemostasis at the placental implantation site depends primarily on myometrial contraction. Therefore, with vaginal delivery, stimulation of the myometrium pharmacologically and by uterine massage causes these vessels to constrict so that serious hemorrhage is avoided even though coagulation defects persist. Moreover, bleeding that does occur is shed through the vagina. In the following example, there was an indication for abdominal delivery despite documented fetal demise:

Although placental abruption was suspected, because rupture of a prior uterine incision could not be excluded, a repeat cesarean was performed for a 26-week stillborn fetus. The patient had profound hypofibrinogenemia and serious bleeding was encountered from all surgical incisions. Persistent bleeding necessitated hysterectomy followed by internal iliac artery ligation. Lactated Ringer solution was given along with 17 units of blood, 8 units of plasma, and 10 units of platelets to maintain perfusion and treat the coagulopathy.

LABOR. With extensive placental abruption, the uterus is likely to be persistently hypertonic. The baseline intra-amniotic pressure may be 50 mm Hg or higher, with rhythmic increases up to 75 to 100 mm Hg. Because of persistent hypertonus, it may be difficult at times to determine by palpation if the uterus is contracting and relaxing to any degree ([Fig. 35-8](#)).

AMNIOTOMY. Rupture of the membranes as early as possible has long been championed in the management of placental abruption. The rationale for amniotomy is that the escape of amniotic fluid might both decrease bleeding from the implantation site and reduce the entry into the maternal circulation of thromboplastin and perhaps activated coagulation factors from the retroplacental clot. There is no evidence, however, that either is accomplished by amniotomy. If the fetus is reasonably mature, rupture of the membranes may hasten delivery. If the fetus is immature, the intact sac may be more efficient in promoting cervical dilatation than is a small fetal part poorly applied to the cervix.

OXYTOCIN. Although baseline hypertonus characterizes myometrial function in most cases of severe placental abruption, if no rhythmic uterine contractions are superimposed, then oxytocin is given in standard doses. Uterine stimulation to effect vaginal delivery provides benefits that override the risks. The use of oxytocin has been challenged on the basis that it might enhance the escape of thromboplastin into the maternal circulation and thereby initiate or enhance consumptive coagulopathy or amniotic fluid embolism syndrome. There is no evidence to support this fear (Clark and colleagues, 1995; Pritchard and Brekken, 1967).

Timing of Delivery After Severe Placental Abruption. When the fetus is dead or previable, there is no evidence that establishing an arbitrary time limit for delivery is necessary. Experiences at both the University of Virginia and Parkland Hospitals indicate that maternal outcome depends on the diligence with which adequate fluid and blood replacement therapy is pursued, rather than on the interval to delivery (Brame and associates, 1968; Pritchard and Brekken, 1967). At the University of Virginia Hospital, women with severe placental abruption who were transfused for 18 hours or more before delivery experienced complications that were neither more numerous nor greater in severity than did the group in which delivery was accomplished sooner. Our observations are similar.

Figure 35-1. Hemorrhage from premature placental separation. Upper left: Extensive placental abruption but with the periphery of the placenta and the membranes still adherent, resulting in completely concealed hemorrhage. Lower: Placental abruption with the placenta detached peripherally and with the membranes between the placenta and cervical canal stripped from underlying decidua, allowing external hemorrhage. Right: Partial placenta previa with placental

separation and external hemorrhage.

Figure 35-2. Total placental abruption with concealed hemorrhage. The fetus is now dead.

Figure 35-3. Partial placental abruption with adherent clot.

Figure 35-4. Incidence of abruptio placentae and placenta previa by maternal age in 169,108 deliveries at Parkland Hospital from 1988 through 1999. (Data courtesy of Dr. Don McIntire.)

Figure 35-5. Couvelaire uterus with total placental abruption before cesarean delivery. Blood had markedly infiltrated much of the myometrium to reach the serosa. After the infant was delivered and the uterus closed, the uterus remained well contracted despite extensive extravasation of blood into the uterine wall.

Figure 35-6. Various causes of fetal distress from placental abruption and their treatment.

Figure 35-7. A recording of uterine pressures and presumed fetal heart rate in a case of placental abruption so severe as to have killed the fetus. The scalp electrode conducted the maternal ECG signal. Note the increased uterine basal tone.

Figure 35-8. Placental abruption in a woman with severe preeclampsia. Persistent uterine hypertonus is demonstrated by an elevated baseline pressure of 20 to 25 mm Hg and frequent contractions. The fetal heart rate demonstrates baseline bradycardia with repetitive late decelerations.

PLACENTA PREVIA

Definition. In placenta previa, the placenta is located over or very near the internal os. Four degrees of this abnormality have been recognized:

1. *Total placenta previa.* The internal cervical os is covered completely by placenta ([Fig. 35-9](#)).
2. *Partial placenta previa.* The internal os is partially covered by placenta (see [Fig. 35-1](#); [Fig. 35-10](#)).
3. *Marginal placenta previa.* The edge of the placenta is at the margin of the internal os.
4. *Low-lying placenta.* The placenta is implanted in the lower uterine segment such that the placenta edge actually does not reach the internal os but is in close proximity to it.

In another condition, termed *vasa previa*, the fetal vessels course through membranes and present at the cervical os. Vasa previa is an uncommon cause of antepartum hemorrhage and is associated with a high rate of fetal death. It is discussed in detail in [Chapter 27](#) (see p. 627).

The degree of placenta previa depends in large measure on the cervical dilatation at the time of examination. For example, a low-lying placenta at 2-cm dilatation may become a partial placenta previa at 8-cm dilatation because the dilating cervix has uncovered placenta. Conversely, a placenta previa that appears to be total before cervical dilatation may become partial at 4-cm dilatation because the cervix dilates beyond the edge of the placenta (see [Fig. 35-10](#)). **Digital palpation to try to**

ascertain these changing relations between the edge of the placenta and the internal os as the cervix dilates can incite severe hemorrhage!

With both total and partial placenta previa, a certain degree of spontaneous placental separation is an inevitable consequence of the formation of the lower uterine segment and cervical dilatation. Such separation is associated with hemorrhage from blood vessels so disrupted.

Incidence. According to U.S. birth certificate data for the year 2001, placenta previa complicated 1 in 305 deliveries (Martin and co-workers, 2002). In almost 93,000 deliveries in Nova Scotia, Crane and associates (1999) found the incidence to be 0.33 percent (1 in 300). At Parkland Hospital, the incidence was 0.26 percent (1 in 390) for more than 169,000 deliveries during 12 years. These statistics are remarkably similar considering the lack of precision in definition and identification for reasons already discussed. Moreover, should painless bleeding from focal separation of a placenta implanted in the lower uterine segment but away from a partially dilated cervical os be classified as placenta previa or placental abruption? This question is difficult to answer. Obviously, it is both.

PERINATAL MORBIDITY AND MORTALITY. Preterm delivery is a major cause of perinatal death even with expectant management of placenta previa. Using U.S. linked birth and infant death data sets for 1997, Salihi and associates (2003) found that the neonatal mortality rate was threefold higher in pregnancies complicated by placenta previa primarily because of increased preterm birth. In another large series, Ananth and associates (2003b) reported a comparably increased risk of neonatal death even for those fetuses delivered at term. Some of this risk appears related to fetal growth restriction and limited prenatal care. Although some investigators suggested earlier that congenital malformations are increased with a previa, Crane and co-workers (1999) were the first to confirm this. Their study controlled for maternal age. For reasons that are unclear, fetal anomalies were increased 2.5-fold.

It is also uncertain if there is associated fetal growth restriction with a previa. Brar and colleagues (1988) reported that the incidence was nearly 20 percent. Conversely, Crane and co-workers (1999) found no increased incidence after controlling for gestational age. Ananth and associates (2001a) examined the relationship between placenta previa, fetal growth restriction, and preterm delivery in a large population-based cohort of more than 500,000 singleton births. They found that most of the association between placenta previa and low birthweight is due primarily to preterm birth and, to a lesser extent, growth impairment.

Etiology. Advancing *maternal age* increases the risk of placenta previa. As shown in [Figure 35-4](#), in more than 169,000 deliveries at Parkland Hospital from 1988 through 1999, the incidence of previa increased significantly with each age group. At the extremes, it is 1 in 1500 for women 19 years of age or younger, and it is 1 in 100 for women older than 35 years of age. Frederiksen and colleagues (1999) reported that the incidence of previa increased from 0.3 percent in 1976 to 0.7 percent in 1997. They attributed this to a shift to an older obstetrical population.

Multiparity is associated with previa. In a study of 314 women who were para 5 or greater, Babinszki and collaborators (1999) reported that the 2.2 percent incidence of previa was increased significantly compared with that of women of lower parity. Using U.S. natality figures for 1989 to 1998, Ananth and associates (2003a) found that the rate of placenta previa was 40 percent higher in *multifetal gestations* compared with that of singletons.

Prior cesarean delivery increases the likelihood of placenta previa. Miller and associates (1996) cited a threefold increase of previa in women with prior cesarean delivery in over 150,000 deliveries at Los Angeles County Women's Hospital. The incidence increased with the number of previous cesarean deliveries; it was 1.9 percent with two prior cesarean deliveries and 4.1 percent with three or more. Gesteland and co-workers (2004) and Gilliam and colleagues (2002) also found that the risk of placenta previa increases progressively as parity and number of prior cesarean deliveries increase. Both groups calculated that the likelihood of placenta previa was increased more than eightfold in women with parity greater than four and more than four prior cesareans. Certainly, a prior uterine incision with a previa increases the incidence of *cesarean hysterectomy*. Frederiksen and co-workers (1999) reported a 25-percent hysterectomy rate in women undergoing repeat cesarean for a previa compared with only 6 percent in those undergoing primary cesarean for placenta previa.

Williams and colleagues (1991) found the relative risk of placenta previa to be increased twofold related to *smoking*. These findings were confirmed by Ananth (2003a) and Handler (1994) and all their associates. The Williams group (1991) theorized that carbon monoxide hypoxemia caused compensatory placental hypertrophy. Perhaps related, defective decidual vascularization, the possible result of inflammatory or atrophic changes, is implicated in the development of previa.

Clinical Findings. The most characteristic event in placenta previa is painless hemorrhage, which usually does not appear until near the end of the second trimester or after. Some abortions, however, may result from such an abnormal location of the developing placenta. Frequently, bleeding from placenta previa has its onset without warning, presenting without pain in a woman who has had an uneventful prenatal course. Fortunately, the initial bleeding is rarely so profuse as to prove fatal. Usually it ceases spontaneously, only to recur. In some women, particularly those with a placenta implanted near but not over the cervical os, bleeding does not appear until the onset of labor, when it may vary from slight to profuse hemorrhage and clinically may mimic placental abruption.

The cause of hemorrhage is reemphasized: When the placenta is located over the internal os, the formation of the lower uterine segment and the dilatation of the internal os result inevitably in tearing of placental attachments. The bleeding is augmented by the inherent inability of the myometrial fibers of the lower uterine segment to contract and thereby constrict the torn vessels.

Hemorrhage from the placental implantation site in the lower uterine segment may continue after delivery of the placenta, because the lower uterine segment contracts poorly compared with the uterine body. Bleeding may also result from lacerations in the friable cervix and lower uterine segment, especially following manual removal of a somewhat adherent placenta.

PLACENTA ACCRETA, INCRETA, AND PERCRETA. Placenta previa may be associated with *placenta accreta* or one of its more advanced forms, *placenta increta* or *percreta*. Such abnormally firm attachment of the placenta might be anticipated because of poorly developed decidua in the lower uterine segment. Almost 7 percent of 514 cases of previa reported by Frederiksen and collaborators (1999) had an associated abnormal placental attachment. Biswas and co-workers (1999)

performed placental bed biopsies at cesarean delivery in 50 women with previas and 50 control women. Although about 50 percent of specimens from previas showed myometrial spiral arterioles with trophoblastic giant-cell infiltration, only 20 percent from normally implanted placentas had these changes. Placenta accreta is discussed in detail on page 830.

COAGULATION DEFECTS. In our experience, coagulopathy is rare with placenta previa, even when extensive separation from the implantation site has occurred. Wing and colleagues (1996b) studied 87 women with antepartum bleeding from placenta previa and found no evidence of coagulopathy. Presumably thromboplastin that incites intravascular coagulation that commonly characterizes abruptio placentae readily escapes through the cervical canal rather than being forced into the maternal circulation.

Diagnosis. Placenta previa or abruption should always be suspected in women with uterine bleeding during the latter half of pregnancy. The possibility of placenta previa should not be dismissed until appropriate evaluation, including sonography, has clearly proved its absence. The diagnosis of placenta previa can seldom be established firmly by clinical examination unless a finger is passed through the cervix and the placenta is palpated. **Such examination of the cervix is never permissible unless the woman is in an operating room with all the preparations for immediate cesarean delivery, because even the gentlest examination of this sort can cause torrential hemorrhage.** Furthermore, this type of examination should not be performed unless delivery is planned, for it may cause bleeding that necessitates immediate delivery even though the fetus is immature. This "double set-up" examination is rarely necessary, because placental location can almost always be obtained by sonography.

LOCALIZATION BY SONOGRAPHY. The simplest, most precise, and safest method of placental localization is provided by *transabdominal sonography*, which is used to locate the placenta with considerable accuracy ([Figs. 35-11](#) and [35-12](#)). According to Laing (1996), the average accuracy is about 96 percent, and rates as high as 98 percent have been obtained. **False-positive results are often a result of bladder distention. Therefore, ultrasonic scans in apparently positive cases should be repeated after emptying the bladder.** An uncommon source of error has been identification of abundant placenta implanted in the uterine fundus but failure to appreciate that the placenta was large and extended downward all the way to the internal os of the cervix.

The use of *transvaginal ultrasonography* has substantively improved diagnostic accuracy of placenta previa. Although it may appear dangerous to introduce an ultrasound probe into the vagina of women with placenta previa, the technique has been shown to be safe (Timor-Tritsch and Yunis, 1993). Farine and associates (1988) were able to visualize the internal cervical os in all cases using the transvaginal technique, in contrast to only 70 percent using transabdominal equipment. In later studies comparing abdominal ultrasound with transvaginal imaging, Smith (1997) and Taipale (1998) and their colleagues also found the transvaginal technique to be superior.

Hertzberg and associates (1992) demonstrated that *transperineal sonography* allowed visualization of the internal os in all 164 cases examined because transabdominal sonography disclosed a previa or was inconclusive. Placenta previa was correctly excluded in 154 women, and in 10 in whom it was diagnosed sonographically, nine had a previa confirmed at delivery. The positive predictive value was 90 percent and the negative predictive value was 100 percent.

MAGNETIC RESONANCE IMAGING. A number of investigators have used magnetic resonance imaging (MRI) to visualize placental abnormalities, including placenta previa. Although there are many positive attributes of MRI, it is unlikely that this imaging technique will replace ultrasonic scanning for routine evaluation in the near future.

PLACENTAL "MIGRATION."

Since the report by King (1973), the apparent peripartetic nature of the placenta has been well established. Sanderson and Milton (1991) found that 12 percent of placentas were "low lying" in 4300 women at 18 to 20 weeks. Of those not covering the internal os, previa did not persist and hemorrhage was not encountered. Conversely, of those covering the os at midpregnancy, about 40 percent persisted as a previa. Thus, placentas that lie close to the internal os, but not over it, during the second trimester, or even early in the third trimester, are unlikely to persist as previas by term.

As shown in [Figure 35-13](#), the likelihood that placenta previa persists after being identified sonographically before 28 weeks is greater in women who have had a prior cesarean delivery (Dashe and colleagues, 2002). In the absence of any other abnormality, sonography need not be frequently repeated simply to follow placental position. Restriction of activity is not necessary unless a previa persists beyond 28 weeks, or becomes clinically apparent before that time.

The mechanism of apparent placental movement is not completely understood. The term *migration* is clearly a misnomer, however, because invasion of chorionic villi into the decidua on either side of the cervical os persists. The apparent movement of the low-lying placenta relative to the internal os probably results from inability to precisely define this relationship in a three-dimensional manner using two-dimensional sonography in early pregnancy. This difficulty is coupled with differential growth of lower and upper myometrial segments as pregnancy progresses. Thus, those placentas that "migrate" most likely never had actual circumferential villus invasion that reached the internal cervical os in the first place.

Management. Women with a placenta previa may be considered as follows:

1. Those in whom the fetus is preterm and there is no indication for delivery.
2. Those in whom the fetus is reasonably mature.
3. Those in labor.
4. Those in whom hemorrhage is so severe as to mandate delivery despite fetal immaturity.

Management with a preterm fetus, but with no active uterine bleeding, consists of close observation. For some women, prolonged hospitalization may be ideal, however, the woman is usually discharged after bleeding has ceased and her fetus judged to be healthy. The woman and her family must fully appreciate the problems of placenta previa and be prepared to transport her to the hospital immediately. In properly selected patients, there appears to be no benefit to inpatient versus

outpatient management of placenta previa (Mouer, 1994). In another study, Drost and Keil (1994) demonstrated a 50-percent reduction in hospitalization and maternal costs, as well as a 40-percent reduction in cost for mother-infant pairs with outpatient compared with those with inpatient management. Importantly, there were no differences in maternal or fetal morbidity. Wing and colleagues (1996a) reported preliminary results from their randomized clinical trial of inpatient versus home management of 53 women with bleeding from a previa at 24 to 36 weeks. Maternal and perinatal morbidities were similar in each group, but home management saved \$15,000 per case. Importantly, 33 (62 percent) of these 53 women had recurrent bleeding, and 28 (52 percent) required expeditious cesarean delivery.

Delivery. Cesarean delivery is necessary in practically all women with placenta previa. Most often, a transverse uterine incision is made. Because fetal bleeding may result from an incision into an anterior placenta, a vertical incision is sometimes recommended. Even when the incision extends through the placenta, however, maternal or fetal outcome is rarely compromised.

An alternative surgical technique that avoids incising the placenta has been described by Ward (2003). Following the uterine incision, a cleavage plane is developed with the forefinger between the uterus and the placenta large enough to deliver the infant. The operator undermines the placenta toward the edge closest to the uterine incision until the membranes are palpable and may be ruptured. Although this approach is intriguing, it has not yet been evaluated in controlled studies.

Because of the poorly contractile nature of the lower uterine segment, there may be uncontrollable hemorrhage following placental removal. This can occur even without histological confirmation of placenta accreta. Under these circumstances, management appropriate for placenta accreta is indicated (see p. 832). When placenta previa is complicated by degrees of accreta that render control of bleeding from the placental bed difficult by conservative means, other methods of hemostasis are necessary. Oversewing the implantation site with 0 chromic sutures may provide hemostasis. In some women, bilateral uterine or internal iliac artery ligation as described on page 828 may provide hemostasis. Cho and colleagues (1991) have described placing circular interrupted 0 chromic sutures around the lower segment, above and below the transverse incision, which controlled hemorrhage in all eight women in whom this was employed. Druzin (1989) described four cases in which the lower uterine segment was tightly packed with gauze that successfully arrested hemorrhage. The pack was removed transvaginally 12 hours later. Pelvic artery embolization as discussed on page 836 also has gained acceptance (Hansch and colleagues, 1999; Pelage and associates, 1999). If such conservative methods fail, and bleeding is brisk, then hysterectomy is necessary (see [Chap. 25](#), p. 599). **For women whose placenta previa is implanted anteriorly in the site of a prior hysterotomy incision, there is an increased likelihood of associated placenta accreta and need for hysterectomy.**

Prognosis. A marked reduction in maternal mortality from placenta previa has been achieved, a trend that began in 1927 when Bill advocated adequate transfusion and cesarean delivery. Since 1945, when Macafee and Johnson independently suggested expectant therapy for patients remote from term, a similar trend has been evident in perinatal loss. Although half of women are near term when bleeding first develops, preterm delivery still poses a formidable problem for the remainder, because not all women with placenta previa and a preterm fetus can be treated expectantly. Interestingly, Butler and co-workers (2001) found that women with placenta previa who also had maternal serum alpha-fetoprotein levels at least 2.0 multiples of the median (MOM) were at increased risk of bleeding early in the third trimester and of preterm birth.

Figure 35-9. Total placenta previa. Even with the modest cervical dilatation illustrated, copious hemorrhage would be anticipated.

Figure 35-10. Partial placenta previa seen through a cervix 3- to 4-cm dilated at 22 weeks' gestation. The arrow points to mucus dripping from the cervix. Uterine cramping was described, but earlier intermittent bleeding had stopped 1 month before. The fetus weighed 410 g when delivered vaginally the next day. Blood loss was not massive. (Photograph courtesy of Dr. Rigoberto Santos.)

Figure 35-12. Total placenta previa at 18 weeks' gestation. Placenta (PLAC) completely overlies the cervical os. (Courtesy of Dr. Rigoberto Santos.)

Figure 35-13. Percentage of women with persistent placenta previa at delivery according to gestational age at diagnosis and prior cesarean delivery. Error bars represent one direction (half-width) of the 95-percent confidence intervals. (* $P < .05$ comparing women with prior cesarean delivery with multiparous women with no

prior cesarean delivery.) (From Dashe and colleagues, 2002, with permission.)

POSTPARTUM HEMORRHAGE

Hemorrhage following delivery is from excessive bleeding from the placental implantation site, trauma to the genital tract and adjacent structures, or both (Table 35-5). Postpartum hemorrhage is a description of an event rather than a diagnosis, and when encountered, its cause must be determined.

Definition. Traditionally, postpartum hemorrhage has been defined as the loss of 500 mL of blood or more after completion of the third stage of labor. This is unreasonable, because nearly half of all women who are delivered vaginally shed that amount of blood or more when measured quantitatively. Blood loss somewhat in excess of 500 mL by accurate measurement is not necessarily unusual for vaginal delivery (Fig. 35-14). Pritchard and associates (1962) found that about 5 percent of women delivering vaginally lost more than 1000 mL of blood. **They also observed that estimated blood loss is commonly only about half the actual loss.** An estimated blood loss in excess of 500 mL in many institutions, therefore, should call attention to mothers who are bleeding excessively and warn the physician that dangerous hemorrhage is imminent.

The blood volume of a pregnant woman with normal pregnancy-induced hypervolemia usually increases by 30 to 60 percent, which amounts to 1500 to 2000 mL for an average-sized woman (Pritchard, 1965). Table 35-6 presents an equation that determines this, which we have verified as accurate. A normally pregnant woman tolerates blood loss at delivery that approaches the volume of blood she added during pregnancy without any remarkable decrease in postpartum hematocrit. Thus, if blood loss is less than the amount added by pregnancy, the hematocrit stays the same acutely and eventually increases. **Any time the postpartum hematocrit is lower than one obtained on admission for delivery, blood loss can be estimated as the sum of the calculated pregnancy hypervolemia plus 500 mL for each 3 volumes percent drop in the hematocrit.** In one study, the mean postpartum hematocrit decline ranged from 2.6 to 4.3 volumes percent, and a third of women had no decline or had an actual increase (Combs and colleagues, 1991b). Women undergoing cesarean delivery had a mean drop in hematocrit of 4.2 volume percent, but 20 percent had no decline (Combs and co-workers, 1991a).

Hemorrhage after the first 24 hours is designated *late postpartum hemorrhage* and is discussed in Chapter 30 (see p. 698).

Hemostasis at the Placental Site. Near term, it is estimated that approximately 600 mL/min of blood flows through the intervillous space. With separation of the placenta, there is also separation of the many uterine arteries and veins that carry blood to and from the placenta. Usually, hemostasis in the absence of surgical ligation depends on intrinsic vasospasm and formation of blood clot locally. At the placental implantation site, most important for achieving hemostasis are contraction and retraction of the myometrium to compress the formidable number of relatively large vessels and obliterate their lumens. Adherent pieces of placenta or large blood clots prevent effective contraction and retraction of the myometrium and thereby impair hemostasis at the implantation site. Fatal postpartum hemorrhage can occur from a hypotonic uterus, although the maternal blood coagulation mechanism is quite normal. Conversely, if the myometrium at and adjacent to the denuded implantation site contracts and retracts vigorously, fatal hemorrhage *from the placental implantation site* is unlikely even though the coagulation mechanism is severely impaired.

Clinical Characteristics. Contrary to general opinion, whether postpartum bleeding begins before or after placental delivery, or at both times, there may be no sudden massive hemorrhage but rather steady bleeding that at any given instant appears to be moderate, but persists until serious hypovolemia develops. Especially with hemorrhage after placental delivery, the constant seepage may lead to enormous blood loss.

The effects of hemorrhage depend to a considerable degree on the nonpregnant blood volume, magnitude of pregnancy-induced hypervolemia, and degree of anemia at the time of delivery. A treacherous feature of postpartum hemorrhage is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood have been lost. The normotensive woman may actually become somewhat hypertensive in response to hemorrhage, at least initially. Moreover, the already hypertensive woman may be interpreted to be normotensive although remarkably hypovolemic. Tragically, the hypovolemia may not be recognized until very late.

The woman with severe preeclampsia or eclampsia does not have normally expanded blood volume. Zeeman and Cunningham (2002) documented a mean increase of only 10 percent in 29 eclamptic women before delivery. Thus, these women are very sensitive to or even intolerant of what may be considered normal blood loss (see Chap. 34, p. 771). **Therefore, when excessive hemorrhage is even suspected in the woman with severe preeclampsia, efforts should be made immediately to identify those clinical and laboratory findings that would prompt vigorous crystalloid and blood replacement.**

In instances in which the fundus has not been adequately monitored after delivery, the blood may not escape vaginally but instead may collect within the uterus. The uterine cavity may thus become distended by 1000 mL or more of blood while an attendant fails to identify the large uterus or, having done so, erroneously massages a roll of abdominal fat. The care of the postpartum uterus, therefore, must not be left to an inexperienced person.

Diagnosis. Except possibly when intrauterine and intravaginal accumulation of blood are not recognized, or in some instances of uterine rupture with intraperitoneal bleeding, the diagnosis of postpartum hemorrhage should be obvious. The differentiation between bleeding from uterine atony and from lacerations is tentatively made on predisposing risk factors and the condition of the uterus (see Table 35-5). If bleeding persists despite a firm, well-contracted uterus, the cause of the hemorrhage most likely is from lacerations. Bright red blood also suggests lacerations. **To ascertain the role of lacerations as a cause of bleeding, careful inspection of the vagina, cervix, and uterus is essential.**

Sometimes bleeding may be caused by both atony and trauma, especially after major operative delivery. In general, inspection of the cervix and vagina should be performed after every delivery to identify hemorrhage from lacerations. Anesthesia should be adequate to prevent discomfort during such an examination. Examination of the uterine cavity, the cervix, and all of the vagina is essential after internal podalic version and breech extraction. The same is true when unusual bleeding is identified

during the second stage of labor.

Sheehan Syndrome. Severe intrapartum or early postpartum hemorrhage is on rare occasions followed by pituitary failure or Sheehan syndrome. The classical case is characterized by failure of lactation, amenorrhea, breast atrophy, loss of pubic and axillary hair, hypothyroidism, and adrenal cortical insufficiency (see [Chap. 53](#), p. 1203). The exact pathogenesis is not well understood, because such endocrine abnormalities do not develop in most women who hemorrhage severely. In some but not all instances of Sheehan syndrome, varying degrees of anterior pituitary necrosis with impaired secretion of one or more trophic hormones account for the endocrine abnormalities. The anterior pituitary of some women who develop hypopituitarism after puerperal hemorrhage does respond to various releasing hormones, which at the least implies impaired hypothalamic function. Moreover, Whitehead (1963) identified specific atrophic changes in hypothalamic nuclei histologically in some cases. Lactation after delivery usually, but not always, excludes extensive pituitary necrosis. In some women, failure to lactate may not be followed until many years later by other symptoms of pituitary insufficiency. In the series reported by Ammini and Mathur (1994), the average duration of onset of symptoms was 5 years.

The incidence of Sheehan syndrome was originally estimated to be 1 per 10,000 deliveries (Sheehan and Murdoch, 1938). It appears to be even less common today (Kovacs, 2003). Bakiri and colleagues (1991) used computed tomography to study 54 women with documented Sheehan syndrome. In all of these, the appearance of the pituitary was abnormal and the sella turcica was either totally or partially empty.

Figure 35-14. Blood loss associated with vaginal delivery, repeat cesarean delivery, and repeat cesarean delivery plus hysterectomy. (From Pritchard and associates, 1962, with permission.)

THIRD-STAGE BLEEDING. Some bleeding is inevitable during the third stage as the result of transient partial separation of the placenta. As the placenta separates, blood from the implantation site may escape into the vagina immediately (*Duncan mechanism*), or it may be concealed behind the placenta and membranes (*Schultze mechanism*) until the placenta is delivered.

In the presence of any external hemorrhage during the third stage, the uterus should be massaged if it is not contracted firmly. If the signs of placental separation have appeared, expression of the placenta should be attempted by manual fundal pressure as described in [Chapter 17](#) (see p. 432). Descent of the placenta is indicated by the cord becoming slack. If bleeding continues, manual removal of the placenta is mandatory. **Delivery of the placenta by cord traction, especially when the uterus is atonic, may cause uterine inversion.** Prevention and management of this are discussed in detail on page 833.

Prolonged Third-Stage Bleeding. Occasionally, the placenta does not separate promptly. There is still no definite answer to the question concerning the length of time that should elapse in the absence of bleeding before the placenta is removed manually. Obstetrical tradition has set somewhat arbitrary limits on third-stage duration in attempts to define *abnormally retained placenta* and thus reduce blood loss due to excessively prolonged placental separation. Combs and Laros (1991) studied 12,275 singleton vaginal deliveries and reported the median third-stage duration to be 6 minutes; for 3.3 percent of these women, it was more than 30 minutes. Several measures of hemorrhage, including curettage or transfusion, increased when the third stage was about 30 minutes or longer. Prolonged third-stage labor is discussed in [Chapter 17](#) (see p. 432).

Technique of Manual Removal. Adequate analgesia or anesthesia is mandatory. Aseptic surgical technique should be used. After grasping the fundus through the abdominal wall with one hand, the other hand is introduced into the vagina and passed into the uterus, along the umbilical cord. As soon as the placenta is reached, its margin is located and the ulnar border of the hand insinuated between it and the uterine wall ([Fig. 35-15](#)). Then with the back of the hand in contact with the uterus, the placenta is peeled off its uterine attachment by a motion similar to that used in separating the leaves of a book. After its complete separation, the placenta should be grasped with the entire hand, which is then gradually withdrawn. Membranes are removed at the same time by carefully teasing them from the decidua, using ring forceps to grasp them as necessary. Some clinicians prefer to wipe out the uterine cavity with a sponge.

Management after Delivery of Placenta. The fundus should always be palpated following placental delivery to make certain that the uterus is well contracted. If it is not firm, vigorous fundal massage is indicated. Most often, 20 U of oxytocin in 1000 mL of lactated Ringer or normal saline proves effective when administered intravenously at approximately 10 mL/min (200 mU of oxytocin per minute) simultaneously with effective uterine massage. Oxytocin should never be given as an undiluted bolus dose, because serious hypotension or cardiac arrhythmias may occur (see [Chap. 17](#), p. 434).

Figure 35-15. Manual removal of placenta. The fingers are swept from side to side and advanced until the placenta is completely detached.

UTERINE ATONY. Failure of the uterus to contract properly following delivery is a common cause of obstetrical hemorrhage. In many women, uterine atony can at least be suspected well in advance of delivery (see [Table 35-5](#)). For example, the overdistended uterus is prone to be hypotonic after delivery. Thus, the woman with a large fetus, multiple fetuses, or hydramnios is prone to hemorrhage from uterine atony. The woman whose labor is characterized by uterine activity that is either remarkably vigorous or barely effective is also likely to bleed excessively from uterine atony after delivery.

Similarly, labor either initiated or augmented with oxytocin is more likely to be followed by postdelivery uterine atony and hemorrhage.

The woman of high parity may be at increased risk for uterine atony. Fuchs and colleagues (1985) described the outcomes of nearly 5800 women para 7 or greater. They reported that the 2.7 percent incidence of postpartum hemorrhage in these women was increased fourfold compared with that of the general obstetrical population. Babinszki and colleagues (1999) reported the incidence of postpartum hemorrhage to be 0.3 percent in women of low parity, but it was 1.9 percent in those para 4 or greater. Another risk is if the woman has previously suffered postpartum hemorrhage. Finally, mismanagement of the third stage of labor involves an attempt to hasten delivery of the placenta short of manual removal. **Constant kneading and squeezing of the uterus that already is contracted likely impedes the physiological mechanism of placental detachment, causing incomplete placental separation and increased blood loss.**

Ergot Derivatives. If oxytocin given by rapid infusion as described on page 826 does not prove effective, some clinicians administer intramuscular methylergonovine (0.2 mg). This may stimulate the uterus to contract sufficiently to control hemorrhage. Any superior therapeutic effects of ergot derivatives over oxytocin are speculative, and if these agents are intravenously administered, they may cause dangerous hypertension, especially in women with preeclampsia.

Prostaglandins. The 15-methyl derivative of prostaglandin F_{2α} (carboprost tromethamine) was approved in the mid-1980s by the U.S. Food and Drug Administration (FDA) for treatment of uterine atony. The initial recommended dose is 250 μg (0.25 mg) given intramuscularly, and this is repeated if necessary at 15- to 90-minute intervals up to a maximum of eight doses. Oleen and Mariano (1990) studied use of carboprost for postpartum hemorrhage at 12 cooperating obstetrical units. Arrest of bleeding was considered successful in 208 (88 percent) of 237 women treated. Another 17 women (7 percent) required other oxytocics for control of hemorrhage. The remaining 12 women (5 percent) required surgical intervention.

Carboprost is associated with side effects in about 20 percent of women (Oleen and Mariano, 1990). In descending order of frequency, these include diarrhea, hypertension, vomiting, fever, flushing, and tachycardia. We have encountered serious hypertension in a few women so treated. In addition, Hankins and colleagues (1988) observed that intramuscular carboprost was followed by arterial oxygen desaturation that averaged 10 percent and developed within 15 minutes. They concluded that this was due to pulmonary airway and vascular constriction.

Rectally administered prostaglandin E₂ 20-mg suppositories have been used for uterine atony but not studied in clinical trials. A few reports have suggested that misoprostol (Cytotec), a synthetic prostaglandin E₁ analogue, may be effective for the treatment of uterine atony (Abdel-Aleem and associates, 2001; O'Brien and colleagues, 1998). In the larger of these uncontrolled studies, misoprostol (1000 μg) given rectally was effective in 16 of 18 women unresponsive to usual oxytocics. The mean response time was 1.4 minutes. Misoprostol has also been studied as a potential prophylactic treatment for preventing postpartum hemorrhage. Based on their study of 325 women, Gerstenfeld and Wing (2001) concluded that rectal misoprostol (400 μg) was no more effective than intravenous oxytocin in preventing postpartum hemorrhage. Moreover, Villar and co-workers (2002) found in their systematic review that oxytocin and ergot preparations administered during the third stage of labor were more effective than misoprostol for the prevention of postpartum hemorrhage.

Bleeding Unresponsive to Oxytocics. Continued bleeding after multiple administrations of oxytocics may be from unrecognized genital tract lacerations, including in some cases uterine rupture. Thus, if bleeding persists, no time should be lost in haphazard efforts to control hemorrhage, but the following management should be initiated immediately:

1. Use bimanual uterine compression ([Fig. 35-16](#)). The technique consists simply of massage of the posterior aspect of the uterus with the abdominal hand and massage through the vagina of the anterior uterine aspect with the other fist. This procedure controls most hemorrhage.
2. Obtain help!
3. Add a second large-bore intravenous catheter so that crystalloid with oxytocin may be continued at the same time blood is given.
4. Begin blood transfusions. The blood group of every obstetrical patient should be known, if possible, before labor and an indirect Coombs test done to detect erythrocyte antibodies. If the latter is negative, then crossmatching of blood is not necessary (see p. 841). In an extreme emergency, type O D-negative "universal donor" blood is given.
5. Explore the uterine cavity manually for retained placental fragments or lacerations.
6. Thoroughly inspect the cervix and vagina after adequate exposure.
7. Insert a Foley catheter to monitor urine output, which is a good measure of renal perfusion.

Resuscitation is then carried out as described subsequently on page 839. Blood transfusion should be considered in any woman with postpartum hemorrhage in whom abdominal uterine massage and oxytocic agents fail to control the bleeding. With transfusion and simultaneous manual uterine compression and intravenous oxytocin, additional measures are rarely required. Intractable atony may mandate hysterectomy as a lifesaving measure (see [Chap. 25](#), p. 599). Alternatively, uterine artery ligation ([Fig. 35-17](#)), internal iliac artery ligation ([Figs. 35-18](#) and [35-19](#)), uterine compression sutures ([Fig. 35-20](#)), or angiographic embolization as described on page 836 may prove successful.

INTERNAL ILIAC ARTERY LIGATION. Ligation of the internal iliac arteries at times reduces the hemorrhage appreciably (Allahbadia, 1993; Clark and colleagues, 1985). However, the procedure may be technically difficult and is successful in less than half of the patients in whom it is attempted (American College of Obstetricians and Gynecologists, 1998). With adequate exposure, ligation is accomplished by opening the peritoneum over the common iliac artery and dissecting down to the bifurcation of the external and internal iliac arteries (see [Figs. 35-18](#) and [35-19](#)). The areolar sheath covering the internal iliac artery is incised longitudinally, and a right-angle clamp is carefully passed just beneath the artery. Care must be taken not to perforate contiguous large veins, especially the internal iliac vein. Suture, usually nonabsorbable, is then inserted into the open

clamp, the jaws are locked, the suture is carried around the vessel, and the vessel is securely ligated. Pulsations in the external iliac artery, if present before tying the ligature, should be present afterward as well. If not, pulsations must be identified after arterial hypotension has been successfully treated to ensure that the blood flow through the external iliac vessel has not been compromised by the ligature.

The most important mechanism of action with internal iliac artery ligation is an 85-percent reduction in pulse pressure in those arteries distal to the ligation (Burchell, 1968). This converts an arterial pressure system into one with pressures approaching those in the venous circulation and more amenable to hemostasis via simple clot formation. Bilateral ligation of these arteries does not appear to interfere with subsequent reproduction. Nizard and associates (2003) documented 21 pregnancies in 17 women after bilateral internal iliac artery ligation including three abortions, three miscarriages, two ectopic pregnancies, and 13 normal pregnancies.

UTERINE COMPRESSION SUTURES. In 1997, B-Lynch and colleagues described a surgical technique performed in five women with severe postpartum hemorrhage in which a pair of vertical brace 2 chromic sutures were secured around the uterus, giving the appearance of suspenders, to compress together the anterior and posterior walls (see [Fig. 35-20](#)). A simpler modification of the technique has been described by Hayman and associates (2002). We have found this suture to be effective in some cases, however, published experience with these techniques remains limited.

UTERINE PACKING. This technique should be considered in women with refractory postpartum hemorrhage related to uterine atony who wish to preserve fertility. Popular during the first half of the 20th century, uterine packing subsequently fell out of favor because of concerns about concealed bleeding and infection (Hsu and co-workers, 2003). Newer techniques, however, have allayed some of these concerns (Roman and Rebarber, 2003). In one technique, the tip of a no. 24F Foley catheter with a 30-mL balloon is guided into the uterine cavity and filled with 60 to 80 mL of saline. The open tip permits continuous drainage from the uterus. If bleeding subsides, the catheter is typically removed after 12 to 24 hours (Roman and Rebarber, 2003). Alternatively, the uterus or pelvis may be packed directly with gauze (Gilstrap, 2002). After hysterectomy, another technique, the umbrella pack, can be constructed of a sterile x-ray cassette bag, filled with gauze rolls knotted together, providing enough volume to fill the pelvis (Howard and co-workers, 2002). The pack is introduced transabdominally with the stalk exiting the vagina. Mild traction is applied by tying the stalk to a one-liter intravenous fluid bag and hanging the bag over the foot of the bed. An indwelling urinary catheter is used to monitor urine output and to prevent urinary obstruction. Placement of percutaneous pelvic drains should be considered to monitor ongoing bleeding within the peritoneal cavity (Dildy, 2002). Broad-spectrum antimicrobials should be administered, and the umbrella pack is removed vaginally after 24 hours.

RECOMBINANT ACTIVATED FACTOR VII. This vitamin K-dependent protein has been licensed by the Food and Drug Administration for treatment of bleeding in individuals with hemophilia, acquired antibodies to components of the intrinsic pathway, and congenital factor VII deficiency. Other clinicians have explored its usefulness for the control of hemorrhage due to other causes, including traumatic and surgical bleeding (Branch and Rodgers, 2003). Bouwmeester and associates (2003) described the successful use of recombinant activated factor VII for the treatment of intractable hemorrhage in a woman with uterine atony and vaginal lacerations who did not respond to uterotonic drugs, suturing, ligation of the internal iliac arteries, subtotal hysterectomy, packing of the pelvis, and blood and component transfusions. Although this therapy looks promising, thrombotic complications have been reported, and additional study clearly is needed (Siegel and associates, 2004).

Figure 35-16. Bimanual compression of the uterus and massage with the abdominal hand usually effectively controls hemorrhage from uterine atony.

Figure 35-17. Uterine artery ligation performed superiorly at the approximate junction between the utero-ovarian ligament and the uterus and inferiorly just below the uterine incision. (From Gilstrap, 2002.)

(B) demonstrate the anterior and posterior views of the uterus showing application of the suture. Part (C) shows the anatomical appearance after completion. (From B-Lynch and colleagues, 1997, with permission.)

HEMORRHAGE FROM RETAINED PLACENTAL FRAGMENTS. Immediate postpartum hemorrhage is seldom caused by retained small placental fragments, but a remaining piece of placenta is a common cause of bleeding late in the puerperium. Inspection of the placenta after delivery must be routine. If a portion of placenta is missing, the uterus should be explored and the fragment removed, particularly with continuing postpartum bleeding. Retention of a *succenturiate lobe* is an occasional cause of postpartum hemorrhage (see [Chap. 27](#), p. 620). The late bleeding that may result from a placental polyp is discussed in [Chapter 30](#) (see p. 698).

PLACENTA ACCRETA, INCRETA, AND PERCRETA. In most instances, the placenta separates spontaneously from its implantation site during the first few minutes after delivery of the infant. Very infrequently, detachment is delayed because the placenta is unusually adherent to the implantation site, with scanty or absent decidua, so that the physiological line of cleavage through the decidual spongy layer is lacking. As a consequence, one or more cotyledons are firmly bound to the defective decidua basalis or even to the myometrium. When the placenta is densely anchored in this fashion, the condition is called placenta accreta.

Definitions. The term *placenta accreta* is used to describe any placental implantation in which there is abnormally firm adherence to the uterine wall. As the consequence of partial or total absence of the decidua basalis and imperfect development of the fibrinoid layer (*Nitabuch layer*), placental villi are attached to the myometrium in *placenta accreta*, actually invade the myometrium in *placenta increta*, or penetrate through the myometrium in *placenta percreta* ([Figs. 35-21](#) and [35-22](#)). The abnormal adherence may involve all of the cotyledons (*total placenta accreta*), a few to several cotyledons (*partial placenta accreta*), or a single cotyledon (*focal placenta accreta*). According to Benirschke and Kaufmann (2000), histological diagnosis of accreta cannot be made from the placenta alone and the entire uterus or curettings with myometrium are necessary.

Significance. An abnormally adherent placenta, although an uncommon condition, assumes considerable significance clinically because of morbidity and, at times, mortality from severe hemorrhage, uterine perforation, and infection. Indeed, Zelop and colleagues (1993) reported that abnormally adherent placentation caused 65 percent of cases of intractable postpartum hemorrhage requiring emergency peripartum hysterectomy at Brigham and Women's Hospital. The incidence of placenta accreta, increta, and percreta have increased, most likely because of the increased cesarean delivery rate (see [Chap. 25](#), p. 589). The American College of Obstetricians and Gynecologists (2002) estimates that placenta accreta complicates 1 in 2500 deliveries, a 10-fold increase over the past 50 years.

Etiology. Abnormal placental adherence is found when decidual formation is defective. Associated conditions include implantation in the lower uterine segment over a previous surgical scar or after uterine curettage. In a review of 622 cases collected between 1945 and 1969, Fox (1972) noted the following characteristics:

1. Placenta previa was identified in a third of affected pregnancies.
2. A fourth of the women had a prior cesarean delivery.
3. Nearly a fourth had previously undergone curettage.
4. A fourth were gravida 6 or more.

Zaki and associates (1998) found that 10 percent of 112 consecutive cases of placenta previa had associated accreta. Hardardottir and colleagues (1996) observed that almost 50 percent of placentas in women with a prior cesarean delivery had adherent myometrial fibers detected microscopically.

Other risk factors for placenta accreta were analyzed by Hung and co-workers (1999) in their study of over 9300 women screened for Down syndrome at 14 to 22 weeks. Compared with the normal population, they found a 54-fold increased risk for accreta with placenta previa, an 8.3-fold increased risk when maternal serum alpha-fetoprotein levels exceeded 2.5 MoM, a 3.9-fold increased risk when maternal free β -human chorionic gonadotropin (β -hCG) levels were greater than 2.5 MoM, and a 3.2-fold increased risk with maternal age of 35 years of age or older.

Clinical Course and Diagnosis. Early in pregnancy, the maternal serum alpha-fetoprotein level may be increased (see [Chap. 13](#), p. 321). Antepartum hemorrhage is common, but in the great majority of women, bleeding before delivery is the consequence of coexisting placenta previa. Myometrial invasion by placental villi at the site of a previous cesarean scar may lead to uterine rupture before labor (Berchuck and Sokol, 1983; Liang and co-workers, 2003). We have seen this as early as 12 weeks in a woman explored for an ectopic pregnancy. In women whose pregnancies go to term, however, labor will most likely be normal in the absence of an associated placenta previa or an involved uterine scar.

The possibility exists that placenta increta might be diagnosed antepartum. Lam and colleagues (2002) found that ultrasound was only 33-percent sensitive for detecting placenta accreta. However, using ultrasound Doppler color flow mapping, Twickler and colleagues (2000) found that two factors were highly predictive of myometrial invasion (sensitivity of 100 percent and positive predictive value of 78 percent): (1) a distance less than 1 mm between the uterine serosal bladder interface and the retroplacental vessels, and (2) the presence of large intraplacental lakes. Chou and co-workers (2001) also described successful use of three-dimensional color power Doppler imaging for diagnosis of placenta percreta. Maldjian and co-workers (1999) used MRI to diagnose placenta accreta, but Lam and colleagues (2002) reported that its sensitivity was only 38 percent. Baxi and associates (2004) found that elevated d-dimers may predict significant blood loss and morbidity in women with placenta accreta, perhaps reflecting trophoblastic invasion into myometrium and adjacent tissues.

Management. The problems associated with delivery of the placenta and subsequent developments vary appreciably,

depending on the site of implantation, depth of myometrial penetration, and number of cotyledons involved. It is likely that focal placenta accreta with implantation in the upper uterine segment develops much more often than is recognized. Either the involved cotyledon is pulled off the myometrium with perhaps somewhat excessive bleeding, or the cotyledon is torn from the placenta and adheres to the implantation site with increased bleeding, immediately or later. According to Benirschke and Kaufmann (2000), this may be one mechanism for formation of so-called placental polyps (see [Chap. 30](#), p. 698).

With more extensive involvement, hemorrhage becomes profuse as delivery of the placenta is attempted. Successful treatment depends on immediate blood replacement therapy as described on page 839 and nearly always prompt hysterectomy. This may be facilitated by fully developing the bladder flap and dissecting it around the percreta if possible prior to delivery. Alternative measures include uterine or internal iliac artery ligation (see p. 828) or angiographic embolization (see p. 836). Karam and colleagues (2003) described use of argon beam coagulation for hemostasis in a woman with placenta percreta with bladder invasion.

With total placenta accreta, there may be very little or no bleeding, at least until manual placental removal is attempted. At times, traction on the umbilical cord inverts the uterus, as described in the next section. Moreover, usual attempts at manual removal do not succeed, because a cleavage plane between the maternal placental surface and the uterine wall cannot be developed. In the past, the most common form of "conservative" management was manual removal of as much placenta as possible and then packing of the uterus. In the review by Fox (1972), 25 percent of women managed conservatively died. Thus, the safest treatment in this circumstance is prompt hysterectomy.

Another possible option for women who are not bleeding significantly is to leave the entire placenta in place. Although this approach has not been studied in depth, Kayem and colleagues (2002) described a case in which they left the placenta in place and also performed uterine artery embolization as prophylaxis against delayed hemorrhage. The placenta was spontaneously resorbed within 6 months, and the patient subsequently had an uncomplicated pregnancy 3 years later. Henrich and co-workers (2002) described a similar case in which the placenta was left in situ, and weekly methotrexate therapy was given postpartum. The placenta spontaneously delivered through the vagina 4 weeks later. Nijman and co-workers (2002) have reviewed other cases in which methotrexate was used to treat retained placenta percreta.

Figure 35-21. Placenta accreta, increta, and percreta.

Figure 35-22. Placenta percreta. The placenta is fungating through the fundus above the old classical cesarean scar. The variable penetration of the fundus by the placenta is evident. (From Morrison, 1978, with permission.)

INVERSION OF THE UTERUS. Complete uterine inversion after delivery of the infant is almost always the consequence of strong traction on an umbilical cord attached to a placenta implanted in the fundus ([Fig. 35-23](#)). Incomplete uterine inversion may also occur ([Fig. 35-24](#)). Contributing to uterine inversion is a tough cord that does not readily break away from the placenta, combined with fundal pressure and a relaxed uterus, including the lower segment and cervix. Placenta accreta may be implicated, although uterine inversion can occur without the placenta being so firmly adherent.

Shah-Hosseini and Evrard (1989) reported an incidence of about 1 in 6400 deliveries at the Women and Infants Hospital of Rhode Island. Of the 11 inversions identified, most were in primiparous women. Immediate vaginal replacement of the inverted uterus was successful in nine instances. Platt and Druzin (1981) reported 28 cases in over 60,000 deliveries, for an incidence of about 1 in 2100. On the busy obstetrical service at Parkland Hospital, we encounter several cases annually, and most are in "low-risk" deliveries.

Clinical Course. Uterine inversion is most often associated with immediate life-threatening hemorrhage, and without prompt treatment it may be fatal ([Fig. 35-25](#)). In the past it was stated that shock tended to be disproportionate to blood loss. Careful evaluation of the effects from transfusion of large volumes of blood in such cases does not support this concept, but instead makes it very apparent that blood loss in these circumstances was often massive but greatly underestimated (Watson and associates, 1980).

Treatment. Delay in treatment increases the mortality rate appreciably. It is imperative that a number of steps be taken immediately and simultaneously:

1. Assistance, including an anesthesiologist, is summoned immediately.
2. The freshly inverted uterus with placenta already separated from it may often be replaced simply by immediately pushing up on the fundus with the palm of the hand and fingers in the direction of the long axis of the vagina.
3. Preferably two intravenous infusion systems are made operational, and lactated Ringer solution and blood are given to treat hypovolemia.
4. If attached, the placenta is not removed until the infusion systems are operational, fluids are being given, and anesthesia, preferably halothane or enflurane, has been administered. Tocolytic drugs such as terbutaline, ritodrine, or magnesium sulfate have been used successfully for uterine relaxation and repositioning (Catanzarite and associates, 1986; Kovacs and DeVore,

1984; Thiery and Delbeke, 1985). In the meantime, the inverted uterus, if prolapsed beyond the vagina, is replaced within the vagina.

5. After removing the placenta, the palm of the hand is placed on the center of the fundus with the fingers extended to identify the margins of the cervix. Pressure is then applied with the hand so as to push the fundus upward through the cervix.

6. As soon as the uterus is restored to its normal configuration, the agent used to provide relaxation is stopped, and simultaneously oxytocin is started to contract the uterus while the operator maintains the fundus in normal relationship.

Initially, bimanual compression (see [Fig. 35-16](#)) aids in control of further hemorrhage until uterine tone is recovered. After the uterus is well contracted, the operator continues to monitor the uterus transvaginally for any evidence of subsequent inversion.

SURGICAL INTERVENTION. Most often, the inverted uterus can be restored to its normal position by the techniques described. If the uterus cannot be reinverted by vaginal manipulation because of a dense constriction ring as shown in [Figure 35-26](#), then laparotomy is imperative. The fundus then may be simultaneously pushed upward from below and pulled from above. A traction suture well placed in the inverted fundus may be of aid. If the constriction ring still prohibits reposition, it is carefully incised posteriorly to expose the fundus. This surgical technique was described by Van Vugt and associates (1981). After replacement of the fundus, the anesthetic agent used to relax the myometrium is stopped, oxytocin infusion is begun, and the uterine incision is repaired.

Figure 35-23. Most likely site of placental implantation in cases of uterine inversion. With traction on the cord and the placenta still attached, the likelihood of inversion is obvious.

Figure 35-24. Incomplete uterine inversion. The diagnosis is made by abdominal palpation of the crater-like depression and vaginal palpation of the fundal wall in the lower segment and cervix. Progressive degrees of inversion are shown in the inset.

Figure 35-25. A fatal case of inverted uterus associated with placenta accreta following delivery at home.

Figure 35-26. Completely inverted uterus viewed from above.

GENITAL TRACT LACERATIONS

Perineal Lacerations. All except the most superficial perineal lacerations are accompanied by varying degrees of injury to the lower portion of the vagina. Such tears may reach sufficient depth to involve the anal sphincter and may extend to varying depths through the walls of the vagina. Bilateral lacerations into the vagina are usually unequal in length and separated by a tongue-shaped portion of vaginal mucosa (see [Fig. 17-34](#)). Their repair should form part of every operation for the restoration of a lacerated perineum.

Vaginal Lacerations. Isolated lacerations involving the middle or upper third of the vagina but unassociated with lacerations of the perineum or cervix are observed less commonly. These are usually longitudinal and frequently result from injuries sustained during a forceps or vacuum delivery, but they may even develop with spontaneous delivery. Such lacerations frequently extend deep into the underlying tissues and may give rise to significant hemorrhage, which usually is controlled by appropriate suturing. They may be overlooked unless thorough inspection of the upper vagina is performed. **Bleeding while the uterus is firmly contracted is strong evidence of genital tract laceration, retained placental fragments, or both.**

Lacerations of the anterior vaginal wall in close proximity to the urethra are relatively common. They are often superficial with little to no bleeding, and repair is usually not indicated. If such lacerations are large enough to require extensive repair, difficulty in voiding can be anticipated, and an indwelling catheter is placed.

Injuries to Levator Ani. These are the result of overdilatation of the birth canal. Muscle fibers are separated, and diminution

in their tonicity may be sufficient to interfere with the function of the pelvic diaphragm. In such cases, pelvic relaxation may develop. If the injuries involve the pubococcygeus muscle, urinary incontinence also may develop (see [Chap. 20](#), p. 520).

Injuries to the Cervix. The cervix is lacerated in over half of all vaginal deliveries (Fahmy and associates, 1991). Most of these are less than 0.5 cm. Deep cervical tears may extend to the upper third of the vagina. In rare instances, however, the cervix may be entirely or partially avulsed from the vagina, with colporrhexis in the anterior, posterior, or lateral fornices. Such injuries sometimes follow difficult forceps rotations or deliveries performed through an incompletely dilated cervix with the forceps blades applied over the cervix. Rarely, cervical tears may extend to involve the lower uterine segment and uterine artery and its major branches, and even through the peritoneum. They may be totally unsuspected, but much more often they become manifest by excessive external hemorrhage or by hematoma formation.

Extensive tears of the vaginal vault should be explored carefully. If there is question of peritoneal perforation, or of retroperitoneal or intraperitoneal hemorrhage, laparotomy should be considered. With damage of this severity, intrauterine exploration for possible rupture is also indicated. Surgical repair is usually required, and effective anesthesia, vigorous blood replacement, and capable assistance are mandatory.

Cervical lacerations up to 2 cm must be regarded as inevitable in childbirth. Such tears heal rapidly and are rarely the source of any difficulty. In healing, they cause a significant change in the round shape of the external os, from circular before labor to appreciably widened after delivery. As the consequence of such tears, there may be eversion of the cervix with exposure of the delicate mucus-producing endocervical glands.

Occasionally, the edematous anterior lip of the cervix may be caught during labor and compressed between the head and the symphysis pubis. If ischemia is severe, the cervical lip may undergo necrosis and separation. More rarely, the entire vaginal portion may be avulsed from the rest of the cervix. Such *annular or circular detachment of the cervix* is uncommon in modern obstetrics.

DIAGNOSIS. A deep cervical tear should always be suspected in women with profuse hemorrhage during and after third-stage labor, particularly if the uterus is firmly contracted. Thorough examination is necessary, and the flabby cervix often makes digital examination alone unsatisfactory. Thus, the extent of the injury can be fully appreciated only after adequate exposure and visual inspection of the cervix. The best exposure is gained by the use of right-angle vaginal retractors by an assistant while the operator grasps the patulous cervix with a ring forceps ([Fig. 35-27](#)).

In view of the frequency with which deep tears follow major operative vaginal deliveries, the cervix should be inspected routinely at the conclusion of the third stage after all difficult deliveries, even if there is no bleeding.

TREATMENT. Deep cervical tears require surgical repair. When the laceration is limited to the cervix, or even when it extends somewhat into the vaginal fornix, satisfactory results are obtained by suturing the cervix after bringing it into view at the vulva. Visualization is best accomplished when an *assistant* applies firm downward pressure on the uterus while the operator exerts traction on the lips of the cervix with fenestrated ovum or sponge forceps. Right-angle vaginal wall retractors are often helpful (see [Fig. 35-27](#)). Because the hemorrhage usually comes from the upper angle of the wound, the first suture is placed just above the angle. Suturing proceeds outward toward the operator. Associated vaginal lacerations may be tamponaded with gauze packs to retard hemorrhage while cervical lacerations are repaired. Either interrupted or running absorbable sutures are suitable. Overzealous suturing in an attempt to restore the normal cervical appearance may lead to subsequent stenosis during uterine involution. Lichtenberg (2003) described the successful use of angiography for treatment of a high cervical tear after attempted surgical repair failed. This method is discussed on page 836.

Figure 35-27. Cervical laceration exposed for repair.

PUERPERAL HEMATOMAS. In a review of seven series, the incidence of puerperal hematomas was found to vary from 1 in 300 to 1 in 1000 deliveries (Cunningham, 2002). Nulliparity, episiotomy, and forceps delivery are the most commonly associated risk factors (Propst and Thorp, 1998; Ridgway, 1995). In other cases, hematomas may develop following injury to a blood vessel without laceration of the superficial tissues. These may occur with spontaneous or operative delivery. Occasionally, the hemorrhage is delayed.

Puerperal hematomas may be classified as vulvar, vulvovaginal, paravaginal, or retroperitoneal. Vulvar hematomas most often involve branches of the pudendal artery, including the posterior rectal, transverse perineal, or posterior labial artery, whereas paravaginal hematomas may involve the descending branch of the uterine artery (Zahn and Yeomans, 1990). Infrequently, the torn vessel lies above the pelvic fascia. In that event, the hematoma develops above it. In its early stages, the hematoma forms a rounded swelling that projects into the upper portion of the vaginal canal and may almost occlude its lumen. If the bleeding continues, it dissects retroperitoneally, and thus may form a tumor palpable above the Poupart ligament, or it may

dissect upward, eventually reaching the lower margin of the diaphragm. Branches of the uterine artery may be involved with these types of hematomas.

Vulvar Hematomas. These hematomas, such as the one shown in [Figure 35-28](#), and particularly those that develop rapidly, may cause excruciating pain. This often is the first symptom noticed. Moderate-sized hematomas may be absorbed spontaneously. The tissues overlying the hematoma may rupture as a result of necrosis caused by pressure, and profuse hemorrhage may follow. In others, the contents of the hematoma may be discharged in the form of large clots. In the subperitoneal variety, extravasation of blood beneath the peritoneum may be massive and occasionally fatal. Some of these dissect behind the ascending colon up to the hepatic flexure.

DIAGNOSIS. A vulvar hematoma is readily diagnosed by severe perineal pain and usually rapid appearance of a tense, fluctuant, and sensitive tumor of varying size covered by discolored skin. When the mass develops adjacent to the vagina, it may escape detection temporarily. Symptoms of pressure, if not pain or inability to void, should prompt a vaginal examination with discovery of a round, fluctuant tumor encroaching on the lumen. When the hematoma extends upward between the folds of the broad ligament, it may escape detection unless a portion of the tumor can be felt on abdominal palpation or unless hypovolemia develops. These are worrisome because large hematomas have led to death.

TREATMENT. Smaller vulvar hematomas identified after leaving the delivery room may be treated expectantly (Propst and Thorp, 1998). However, if the pain is severe or the hematoma continues to enlarge, the best treatment is prompt incision. This is done at the point of maximal distention along with evacuation of blood and clots and ligation of bleeding points. The cavity may then be obliterated with mattress sutures. Often, no sites of bleeding are identified after the hematoma has been drained. In such cases, the vagina, not the hematoma cavity, is packed for 12 to 24 hours. **With hematomas of the genital tract, blood loss is nearly always considerably more than the clinical estimate.** Hypovolemia and severe anemia should be prevented by adequate blood replacement. In about 50 percent of women with hematomas requiring surgical repair, transfusions are necessary (Zahn and Yeomans, 1990).

Subperitoneal and supravaginal hematomas are more difficult to treat. They can be evacuated by incision of the perineum; but unless there is complete hemostasis, which is difficult to achieve by this route, laparotomy is advisable.

ANGIOGRAPHIC EMBOLIZATION. This technique has become popular for management of intractable puerperal hematomas. It can be used primarily or usually when hemostasis is not obtained by surgical methods. [Figure 35-29](#) shows a case in which embolization was carried out with occlusion of the internal pudendal artery and its vaginal branch as well as the uterine artery. Villella and co-workers (2001) have reviewed other indications for angiographic embolization and also described two women with a vulvovaginal hematoma in which it was used.

Angiographic embolization may also be used in women with intractable postpartum hemorrhage. In the reports by Deux (2001) and Chung (2003) and all their colleagues, the procedure was successful in 55 of 58 such women. Many of them had subsequent successful pregnancies (Goldberg and associates, 2002). Similarly, in their follow-up study of 28 consecutive women who underwent pelvic embolization for postpartum hemorrhage, Ornan and co-workers (2003) reported that all six who attempted pregnancy subsequently were successful. No major complications were reported. However, Cottier and co-workers (2002) described a woman who developed ischemic uterine necrosis after arterial embolization for postpartum hemorrhage.

Figure 35-28. Vulvar hematoma bulging into the right vaginal wall.

Figure 35-29. A. Selective left internal iliac arteriogram before embolization. Note marked extravasation from vaginal (*black arrow*) and vulvar branches (*white arrow*) of the left internal pudendal artery. **B.** After embolization the branches of the left internal pudendal artery are occluded. Patency of the left uterine artery (*arrows*) and coils in the right internal iliac artery (*arrowhead*) are noted. (From Chin and colleagues, 1989, with permission.)

RUPTURE OF THE UTERUS. Uterine rupture may develop as a result of preexisting injury or anomaly, it may be associated with trauma, or it may complicate labor in a previously unscarred uterus. A classification of the etiology of uterine rupture is presented in [Table 35-7](#).

The most common cause of uterine rupture is separation of a previous cesarean hysterotomy scar. This is discussed in detail in [Chapter 26](#) (see p. 608). Other common predisposing factors to uterine rupture are previous traumatizing operations or manipulations such as curettage, perforation, or myomectomy (Fedorkow and colleagues, 1987; Kieser and Baskett, 2002; Pelosi and Pelosi, 1997). Excessive or inappropriate uterine stimulation with oxytocin, a previously frequent cause, has become uncommon. Mishra and colleagues (1995) described a 43-year-old woman who suffered a ruptured vertical cesarean incision associated with inhaled crack cocaine.

Morbidity and Mortality. Prenatal morbidity and mortality can be substantive with rupture of a prior uterine incision during labor (see [Chap. 26](#), p. 608). Rachagan and colleagues (1991) reported fetal mortality to be almost 70 percent with either spontaneous or traumatic uterine rupture. In 24 women with uterine rupture principally unassociated with prior incisions, Eden and associates (1986) reported one maternal death and a 46-percent perinatal loss. Hysterectomy may be necessary to control

hemorrhage.

Traumatic Rupture. Although the uterus is surprisingly resistant to blunt trauma, pregnant women sustaining such trauma to the abdomen should be watched carefully for signs of a ruptured uterus (see [Chap. 42](#), p. 998) as well as a placental abruption (see p. 811). Miller and Paul (1996) found that trauma accounted for a ruptured uterus in only 3 of more than 150 women. In the past, internal podalic version and extraction often caused traumatic rupture during delivery. Other causes of traumatic rupture include difficult forceps delivery, unusual fetal enlargement such as hydrocephaly, and breech extraction ([Fig. 35-30](#)).

Spontaneous Rupture. In the study by Miller and Paul (1996), the incidence of spontaneous uterine rupture was only about 1 in 15,000 deliveries. The investigators also found that rupture is more likely in women of high parity (Miller and colleagues, 1997). Oxytocin stimulation of labor has been commonly associated with uterine rupture, especially in women of high parity (Fuchs and co-workers, 1985; Rachagan and associates, 1991). Other uterotonic agents are also implicated. Uterine rupture has resulted from labor induction with prostaglandin E₂ gel or E₁ vaginal tablets (Maymon and associates, 1991; Bennett, 1997). For these reasons, all uterotonic agents should be given with great caution to induce or stimulate labor in women of high parity. Similarly, in women of high parity, a trial of labor with suspected cephalopelvic disproportion, high cephalic presentation, or abnormal presentation such as a brow must be undertaken with caution.

Pathological Anatomy. Excessive stretching of the lower uterine segment with the development of a pathological retraction ring is described in [Chapter 20](#) (see p. 519). Rupture of the previously intact uterus at the time of labor most often involves the thinned-out lower uterine segment. The rent, when it is in the immediate vicinity of the cervix, frequently extends transversely or obliquely. Usually the tear is longitudinal when it occurs in the portion of the uterus adjacent to the broad ligament (see [Fig. 35-30](#)). Although developing primarily in the lower uterine segment, it is not unusual for the laceration to extend further upward into the body of the uterus or downward through the cervix into the vagina. At times, the bladder may also be lacerated (Rachagan and colleagues, 1991). After complete rupture, the uterine contents escape into the peritoneal cavity, unless the presenting part is firmly engaged, when only a portion of the fetus may be extruded from the uterus.

In uterine rupture in which the peritoneum remains intact, hemorrhage frequently extends into the broad ligament. In such circumstances, hemorrhage tends to be less severe than with intraperitoneal rupture. Such bleeding, however, may result in a large retroperitoneal hematoma that may involve sufficient blood loss to cause death. Fatal exsanguination may also supervene after rupture of the hematoma relieves the tamponading effect of the intact broad ligament.

Clinical Course and Treatment. [Chapter 26](#) includes a discussion of the various clinical presentations of uterine rupture as well as treatment approaches (see p. 615).

Figure 35-30. Ruptured uterus with vaginal breech delivery. At laparotomy, there was extensive bleeding beneath the uterine serosa, bladder, and left broad ligament. The extent of rupture is shown by the *arrow*.

HYPOVOLEMIC SHOCK

Shock from hemorrhage evolves through several stages. Early in the course of massive bleeding, there are decreases in mean arterial pressure, stroke volume, cardiac output, central venous pressure, and pulmonary capillary wedge pressure. Increases in arteriovenous oxygen content difference reflect a relative increase in tissue oxygen extraction, although overall oxygen consumption falls (Bland and colleagues, 1985).

Blood flow to capillary beds in various organs is controlled by arterioles, which are resistance vessels that in turn are partially controlled by the central nervous system. At least 70 percent of total blood volume is contained in venules, which are passive resistance vessels controlled by humoral factors. Catecholamine release during hemorrhage causes a generalized increase in venular tone, resulting in an autotransfusion from this capacitance reservoir (Barber and colleagues, 1999). These changes are accompanied by compensatory increases in heart rate, systemic and pulmonary vascular resistance, and myocardial contractility. In addition, there is redistribution of cardiac output and blood volume by selective, centrally mediated arteriolar constriction. This results in diminished perfusion to the kidneys, splanchnic beds, skin, and uterus, with relative maintenance of blood flow to the heart, brain, adrenal glands, and organs that autoregulate their own flow (Barber and associates, 1999).

As blood volume deficit exceeds 25 percent, compensatory mechanisms usually are inadequate to maintain cardiac output and blood pressure. At this point, additional small losses of blood result in rapid clinical deterioration. Despite an initial increase in *total oxygen extraction* by maternal tissue, maldistribution of blood flow results in *local* tissue hypoxia and metabolic acidosis, producing a vicious cycle of vasoconstriction, organ ischemia, and cellular death. Hemorrhage also activates lymphocytes and monocytes, which interact with endothelial cells. These events lead to loss of capillary membrane integrity and additional loss of intravascular volume. There is also increased platelet aggregation in hypovolemic shock, resulting in the release of a number of vasoactive mediators that cause small vessel occlusion and further impairment of microcirculatory perfusion.

Often overlooked is the importance of extracellular fluid and electrolyte shifts in both pathophysiology and successful treatment of hypovolemic shock. This involves changes in the cellular transport of various ions, in which sodium and water enter skeletal muscles and cellular potassium is lost to the extracellular fluid (Chiao and colleagues, 1990). Replacement of extracellular fluid is thus an important component of therapy in hypovolemic shock. **Survival is reduced in acute hemorrhagic shock when blood alone, compared with blood and lactated Ringer solution, is administered.**

ESTIMATION OF BLOOD LOSS. Visual inspection is notoriously inaccurate. In some reports, the amount of blood estimated to have been lost by inspection was on average about half the measured loss. Importantly, in obstetrics,

part or all of the hemorrhage may be concealed. It is important to realize that in a situation of acute hemorrhage, the immediate hematocrit may not reflect actual blood loss. After the loss of 1000 mL, the hematocrit typically falls only 3 volume percent in the first hour. When resuscitation is given with rapid infusion of intravenous crystalloids, there is rapid equilibration. **During an episode of acute significant hemorrhage, the initial hematocrit is always the highest.** This is true whether it is measured in the delivery room, operating room, or recovery room.

Urine output is one of the most important "vital signs" to follow in the bleeding patient with obstetrical hemorrhage. **In the absence of diuretics, the rate of urine formation, when carefully measured, reflects the adequacy of renal perfusion and, in turn, perfusion of other vital organs, because renal blood flow is especially sensitive to changes in blood volume.** Urine flow of at least 30 mL and preferably 60 mL per hour should be maintained. With potentially serious hemorrhage, an indwelling catheter should be inserted promptly to measure urine flow. Potent diuretics such as furosemide invalidate the relationship between urine flow and renal perfusion. This need not be a problem in the management of the woman who is hemorrhaging, because diuretics should be avoided in a hypovolemic patient. Another effect of furosemide is venodilation, which further reduces cardiac venous return, thereby further compromising cardiac output.

RESUSCITATION AND ACUTE MANAGEMENT. Whenever there is any suggestion of excessive blood loss after delivery, it is essential that steps be taken immediately to identify the presence of uterine atony, retained placental fragments, or genital tract lacerations. It is imperative that at least one or two intravenous infusion systems of large caliber be established promptly to allow rapid administration of crystalloid solutions and blood. An operating room, surgical team, and anesthesiologist should always be immediately available. The management of specific causes of postpartum hemorrhage were discussed earlier in this chapter.

Fluid Replacement. Treatment of serious hemorrhage demands prompt and adequate refilling of the intravascular compartment. Crystalloid solutions typically are used for initial volume resuscitation. Such solutions rapidly equilibrate into the extravascular space and only 20 percent of crystalloid remains in the circulation of critically ill patients after 1 hour (Shoemaker and Kram, 1991). Because of such equilibration, initial fluid infusion should involve about three times as much crystalloid as the estimated blood loss.

There is debate concerning fluid resuscitation of hypovolemic shock with colloid versus crystalloid solutions. In their review, Schierhout and Roberts (1998) found a 4-percent excessive mortality in nonpregnant patients resuscitated with colloid compared with that with crystalloid. The Cochrane Injuries Group Albumin Reviewers (1998) found a 6-percent excess mortality in albumin-treated nonpregnant patients with shock. We concur with Bonnar (2000) that fluid resuscitation should be with crystalloid and blood.

Blood Replacement. Considerable debate also surrounds the hematocrit level or hemoglobin concentration that mandates blood transfusion. According to deliberations of a Consensus Development Conference (1988), cardiac output does not substantively decrease until the hemoglobin concentration falls to about 7 g/dL. Although the committee reported that otherwise healthy anesthetized animals survived isovolemic anemia with hematocrit decreases down to 5 volume percent, they further cited that there was significant functional deterioration well before that point. It is difficult to define a universal hematocrit or hemoglobin value below or above which transfusion is either mandatory or contraindicated. That said, recommendations of the Consensus Conference should be considered in clinical decision making. According to these guidelines, red blood cells are not infused for moderate anemia in stable women.

For the woman acutely bleeding, we recommend rapid blood infusion if the hematocrit is less than 25 volumes percent. Similarly, Morrison and colleagues (1993) recommend transfusion if the hematocrit is less than 24 volumes percent or if hemoglobin is less than 8 g/dL if there is imminent surgery, acute operative blood loss, acute hypoxia, vascular collapse, or other factors present. Further support for these recommendations was provided by Czer and Shoemaker (1978). In 94 critically ill postoperative patients, mortality rates were lowest when hematocrit values were maintained between 27 and 33 volumes percent.

Hebert and associates (1999) reported results from the Canadian Critical Care Trials Group. A total of 838 critically ill nonpregnant patients were randomized to restrictive red cell transfusions to maintain hemoglobin concentration over 7 g/dL, or to liberal transfusions to maintain the hemoglobin 10 to 12 g/dL. The 30-day mortality rate was similar (19 versus 23 percent in the restrictive versus liberal groups, respectively). In patients who were not as ill (APACHE score 20 or less), however, the 30-day mortality was significantly lower in the restrictive group (9 versus 26 percent). Morrison and colleagues (1991) reported no benefits of red cell transfusions given to women who had suffered postpartum hemorrhage and who were *isovolemic but anemic* with a hematocrit between 18 and 25 volume percent. **Clearly, the level to which a woman is transfused depends not only on the present red cell mass, but also on the likelihood of additional blood loss.**

Whole Blood and Blood Components. Contents and effects of transfusion of various blood components are shown in [Table 35-8](#). **Compatible whole blood is ideal for treatment of hypovolemia from catastrophic acute hemorrhage.** It has a shelf life of 40 days, and 70 percent of the transfused red cells function for at least 24 hours following transfusion. One unit raises the hematocrit by 3 to 4 volume percent. Whole blood replaces many coagulation factors, especially fibrinogen, and its plasma expands hypovolemia from hemorrhage. Importantly, women with severe hemorrhage are resuscitated with fewer blood donor exposures than with packed red cells and components. In a randomized study of 33 nonpregnant patients undergoing liver transplantation, Laine and colleagues (2003) found that whole blood, compared with component therapy, was associated with fewer donor exposures yet provided equally effective therapy for blood loss.

For women who are more stable and do not have massive blood loss, packed red blood cell transfusions are suitable. According to the National Institutes of Health (1993), component therapy provides better treatment because only the specific component needed is given. Accordingly, the infusion of whole banked blood is usually not necessary and is rarely available (Barber and colleagues, 1999; Bonnar, 2000; Laine and collaborators, 2003).

AUTOTRANSFUSION. The safety of intraoperative autologous blood salvage and autotransfusion during cesarean delivery was evaluated in a multicenter historical cohort study by Rebarber and colleagues (1998). When 139 women undergoing cesarean delivery and given autotransfusion were compared with 87 control women, there were no differences in adverse outcomes. Specifically, there was no evidence of respiratory distress or amniotic fluid embolism. The American College of

Obstetricians and Gynecologists (2002) now recommends that cell saver technology be considered for women suspected of having a placenta accreta prior to delivery.

DILUTIONAL COAGULOPATHY. When blood loss is massive, replacement with crystalloid solutions and packed red blood cells usually results in a depletion of platelets and soluble clotting factors, leading to a dilutional coagulopathy that clinically is indistinguishable from disseminated intravascular coagulopathy (see p. 843). This impairs hemostasis and further contributes to blood loss. The most frequent coagulation defect found in women with blood loss and multiple transfusions is thrombocytopenia (Counts and colleagues, 1979; Wilson and associates, 1971). Because stored whole blood is deficient in factors V, VIII, XI, and platelets, and all soluble clotting factors are absent from packed red blood cells, severe hemorrhage without factor replacement may also cause hypofibrinogenemia and prolongation of the prothrombin and partial thromboplastin times. In some women, frank consumptive coagulopathy may accompany shock and confuse the distinction between dilutional and consumptive coagulopathy. Fortunately, in most situations encountered in obstetrics, treatment of both types of coagulopathy is the same.

Various algorithms have been proposed to guide the replacement of platelets and clotting factors according to the volume of blood loss, but there is great patient variability. **Component replacement is rarely necessary with acute replacement of 5 to 10 units of packed red blood cells or less.** When blood loss exceeds this amount, consideration should be given to evaluation of platelet count, clotting studies, and plasma fibrinogen concentration. Fortunately, in practice, the level of various clotting factors required for adequate hemostasis is quite minimal.

In the bleeding woman, the platelet count should be maintained above 50,000/ μ L with the infusion of platelet concentrates. A fibrinogen level of less than 100 mg/dL or sufficiently prolonged prothrombin or partial thromboplastin times in a woman with surgical bleeding is an indication for fresh-frozen plasma administration in doses of 10 to 15 mL/kg.

TYPE AND SCREEN VERSUS CROSSMATCH. In any woman at significant risk for hemorrhage, typing and screening or crossmatching is essential. The screening procedure involves mixing the maternal serum with standard reagent red cells that contain the antigens with which most of the common clinically significant antibodies react. A crossmatch, on the other hand, involves the use of actual donor erythrocytes rather than standard red cells. Only 0.03 to 0.07 percent of patients who are determined not to have antibodies in a type-and-screen procedure subsequently have antibodies as determined by crossmatch (Boral and colleagues, 1979). Thus, administration of screened blood very rarely results in adverse clinical sequelae. Not performing a crossmatch also decreases blood bank costs. Moreover, blood that is crossmatched is held exclusively for that single potential recipient. With type-and-screening, blood is available for any potential recipient and blood wastage is reduced. For all of these reasons, type and screen is preferred in most obstetrical situations.

PACKED RED BLOOD CELLS. Cells packed from a unit of whole blood have a hematocrit of 60 to 70 volume percent, depending on the method used for preparation and storage. A unit of packed red blood cells contains the same volume of erythrocytes as whole blood and also raises the hematocrit by 3 to 4 volume percent. Packed red blood cell and crystalloid infusion are the mainstays of transfusion therapy for most cases of obstetrical hemorrhage.

PLATELETS. When transfusion is needed, it is preferable to give platelets obtained by apheresis from one donor. In this scheme, the equivalent of platelets from six individual donors is given as a one-unit one-donor transfusion. Such units generally cannot be stored more than 5 days.

If single-donor platelets are not available, random donor platelet packs are used. These are prepared from individual units of whole blood by centrifugation, and then resuspended in 50 to 70 mL of plasma. One unit of random donor platelets contains about 5.5×10^{10} platelets, and six to ten such units are generally transfused. Each unit transfused should raise the platelet count by 5000/ μ L (National Institutes of Health, 1993). The donor plasma must be compatible with recipient erythrocytes. Further, because some red blood cells are invariably transfused along with the platelets, only platelets from D-negative donors should be given to D-negative recipients. However, Lin and colleagues (2002) found that transfusion of ABO-nonidentical platelets in nonpregnant patients undergoing cardiovascular surgery was not associated with adverse effects. Platelet transfusion is considered in a bleeding patient with a platelet count below 50,000/ μ L. In the *nonsurgical patient*, bleeding is rarely encountered if the platelet count exceeds 5000 to 10,000/ μ L (Sachs, 1991).

FRESH-FROZEN PLASMA. This component is prepared by separating plasma from whole blood and then freezing it. Approximately 30 minutes are required for the frozen plasma to thaw. It is a source of all stable and labile clotting factors, including fibrinogen. It is often used in the acute treatment of women with consumptive or dilutional coagulopathy. Fresh-frozen plasma is not appropriate for use as a volume expander in the absence of specific clotting factor deficiency. It should be considered in a bleeding woman with a fibrinogen level below 100 mg/dL or with abnormal prothrombin and partial thromboplastin times.

CRYOPRECIPITATE. This component is prepared from fresh-frozen plasma. Cryoprecipitate contains factor VIII: C, factor VIII: von Willebrand factor, fibrinogen factor XIII (about 200 mg), and fibronectin in less than 15 mL of the plasma from which it was derived (American Association of Blood Banks, 1994). Cryoprecipitate is an ideal source of fibrinogen if levels are dangerously low and there is oozing from surgical incisions. There is no advantage to the use of cryoprecipitate for general clotting factor replacement in the bleeding woman instead of fresh-frozen plasma. The exception to this is in states of general factor deficiency where potential volume overload is a problem, and in a few conditions involving deficiency of specific factors.

AUTOLOGOUS TRANSFUSIONS. Under some circumstances, autologous blood storage for transfusion may be considered. In general, however, this has been disappointing. For example, McVay and colleagues (1989) reported observations from 273 pregnant women in whom blood was drawn in the third trimester. Minimal requirements were a hemoglobin concentration 11 g/dL or a hematocrit of 34 volume percent. Unfortunately, almost three fourths of these women donated only one unit, a volume of questionable value.

In many cases, the need for transfusion cannot be predicted. Sherman and colleagues (1992) studied 27 women given two or more transfusions in over 16,000 deliveries. In only 40 percent was an antepartum risk factor identified. Similar findings were reported by Rey and associates (2004). Andres and co-workers (1990) and Etchason and associates (1995) concluded that autologous transfusions were not cost effective.

Complications of Blood Transfusion. Each unit of blood or any component is associated with risk of exposure to blood-borne infections. However, during the past several decades, substantial advances have been achieved in blood transfusion safety. Currently, the most serious known risks are administrative error leading to ABO-incompatible blood transfusion, transfusion-related acute lung injury (TRALI), and bacterial and viral transmission (Goodnough, 2003).

HEMOLYTIC TRANSFUSION REACTION. The transfusion of an incompatible blood component may result in acute hemolysis characterized by disseminated intravascular coagulation, acute renal failure, and death. Preventable errors, such as mislabeling of a specimen or transfusing an incorrect patient, are responsible for the majority of these reactions. Although the rate of such errors in the United States is estimated to be 1 in 14,000 units, the rate is likely greater due to underreporting (Goodnough, 2003; Linden and co-workers, 2001).

Signs and symptoms of a transfusion reaction include fever, hypotension, tachycardia, dyspnea, chest or back pain, flushing, severe anxiety, and hemoglobinuria. Immediate supportive measures include stopping the transfusion, treating hypotension and hyperkalemia, administering a diuretic, and alkalinizing the urine. Assays for urine and plasma hemoglobin concentration and an antibody screen help confirm the diagnosis.

TRANSFUSION-RELATED ACUTE LUNG INJURY. TRALI is a life-threatening complication characterized by severe dyspnea, hypoxia, and noncardiogenic pulmonary edema that develops within 6 hours of transfusion (Silliman and associates, 2003). It is estimated to complicate at least 1 in 5000 transfusions. Although the pathogenesis of TRALI is incompletely understood, the mechanisms of injury to the pulmonary capillaries appear to involve lipid products from stored components as well as leukocyte reactions (Kopko and co-workers, 2002; Silliman and associates, 2003). Its management is discussed in [Chapter 42](#), p. 991.

BACTERIAL CONTAMINATION. The transfusion of a contaminated blood component is associated with a 60-percent mortality rate. The most commonly implicated contaminant of red cells is *Yersinia enterocolitica*. In the United States, the risk of bacterial contamination is less than 1 per million units. Currently, the greatest risk of transfusion-transmitted disease is bacterial contamination of platelets, which is estimated to affect as many as 1 in 2000 units (Goodnough, 2003).

VIRAL TRANSMISSION. Fortunately, the most feared infection — *human immunodeficiency virus (HIV)* — is the least common. With current screening methods using nucleic acid amplification testing, the time period between infection and the first appearance of viral RNA is 11 days for HIV-1 and 8 to 10 days for hepatitis C (Busch and colleagues, 2003). As a result, the risk of HIV infection in screened blood is currently estimated to be 1 in 1.5 to 2 million units transfused; indeed, only four transfusion-transmitted HIV infections have been identified since 1999 (Dodd, 2003). Similarly, the risk of hepatitis C infection is about 1 in 2 million units transfused (Stramer and associates, 2004).

The likelihood of *HIV-2* infection is even less. After implementation of a combined HIV-1/HIV-2 screening of blood donors in 1992, only three units of 74 million tested through 1995 were positive for HIV-2 (Centers for Disease Control and Prevention, 1995). The risk of *hepatitis B* transmission is higher, although it is estimated currently to be less than 1 per 100,000 units transfused (Jackson and colleagues, 2003). The risk of transmitting other infectious diseases with transfusion, such as malaria and cytomegalovirus, is estimated to be less than 1 in 1 million (National Institutes of Health, 1993). More recently, there have been reports of West Nile virus infection acquired via transfusion. Pealer and colleagues (2003) identified 23 confirmed cases between August 2002 and April 2003.

Red-Cell Substitutes. There are three varieties of these substitutes: perfluorochemicals, liposome-encapsulated hemoglobin, and hemoglobin-based oxygen carriers. Their history and development have been reviewed by Cohn (2000) and Wright-Kanuth and Smith (2002). Fluorinated hydrocarbons are biologically inert liquids with relatively high oxygen solubility. The use of such emulsions allows oxygen to be transported and delivered to tissues by simple diffusion. The most commonly used emulsion, Fluosol, must be stored frozen and thawed within 24 hours of use. Clinical benefits of these emulsions are not well established, but they may decrease the need for blood with extensive hemorrhage (Klein, 2000). Liposome-encapsulated hemoglobin has not proved promising. One formulation of a hemoglobin-based oxygen carrier, diaspirin cross-linked hemoglobin (DCLHb), proved to be dangerous (Sloan and colleagues, 1999). Mullon and co-workers (2000) have described successful use of polymerized bovine hemoglobin, HBOC-201, as a blood substitute for nonpregnant women with severe autoimmune hemolytic anemia.

CONSUMPTIVE COAGULOPATHY

In 1901, DeLee reported that "temporary hemophilia" developed in a woman with a placental abruption and another with a long-dead macerated fetus. Observations that extensive placental abruption, as well as other accidents of pregnancy, were frequently associated with hypofibrinogenemia stimulated interest in causes of intense intravascular coagulation. Although these observations were initially almost totally confined to obstetrical cases, subsequently they were made for almost all areas of medicine (Baglin, 1996). These syndromes are commonly termed *consumptive coagulopathy* or *disseminated intravascular coagulation*.

Pregnancy Hypercoagulability. Pregnancy normally induces appreciable increases in the concentrations of coagulation factors I (fibrinogen), VII, VIII, IX, and X (see [Chap. 5](#), p. 131). Other plasma factors and platelets do not change so remarkably. Plasminogen levels are increased considerably, yet plasmin activity antepartum is normally decreased compared with that of the nonpregnant state. Various stimuli act to incite the conversion of plasminogen to plasmin, and one of the most potent is activation of coagulation.

Pathological Activation of Coagulation. In normal circumstances, there is no appreciable continuous physiological intravascular coagulation. During pregnancy, there does appear to be increased activation of platelet, clotting, and fibrinolytic mechanisms. Gerbasi and colleagues (1990) found significant increases in fibrinopeptide A, β -thromboglobulin, platelet factor 4, and fibrinogen-fibrin degradation products. They concluded that this compensated, accelerated intravascular coagulation may serve to maintain the uteroplacental interface.

In pathological states, coagulation may be activated via the extrinsic pathway by thromboplastin from tissue destruction and perhaps via the intrinsic pathway by collagen and other tissue components when there is loss of endothelial integrity ([Fig. 35-](#)

31). Tissue factor is released and complexes with factor VII. This in turn activates tenase (factor IX) and prothrombinase (factor X) complexes. Common inciting factors in obstetrics include thromboplastin from placental abruption as well as endotoxin and exotoxins. Another mechanism is by direct activation of factor X by proteases, for example, as present in mucin or as produced by neoplasms. Amniotic fluid contains abundant mucin from fetal squames, and this likely causes rapid defibrination with amniotic fluid embolism.

Consumptive coagulopathy is almost always seen as a complication of an identifiable, underlying pathological process against which treatment must be directed to reverse defibrination. Thus identification and prompt elimination of the source of the coagulopathy is the first priority in dealing with it. With pathological activation of procoagulants that trigger consumptive coagulopathy, there is consumption of platelets and coagulation factors in variable quantities. As a consequence, fibrin may be deposited in small vessels of virtually every organ system. Fortunately, this seldom causes organ failure. Small vessels are protected because coagulation releases fibrin monomers that combine with tissue plasminogen activator and plasminogen, which releases plasmin. In turn, plasmin lyses fibrinogen, fibrin monomer, and fibrin polymers to form a series of fibrinogen-fibrin derivatives. Measured by immunoassay, these are known as fibrin degradation products or split products.

Significance. In addition to bleeding and circulatory obstruction, which may cause ischemia from hypoperfusion, consumptive coagulopathy may be associated with microangiopathic hemolysis. This is caused by mechanical disruption of the erythrocyte membrane within small vessels in which fibrin has been deposited. Varying degrees of hemolysis with anemia, hemoglobinemia, hemoglobinuria, and erythrocyte morphological changes are produced. According to Pritchard and colleagues (1976), this likely causes or contributes to the hemolysis encountered with the so-called *HELLP syndrome*, which is discussed in [Chapter 34](#) (see p. 773).

In obstetrical syndromes involving consumptive coagulopathy, the importance of vigorous restoration and maintenance of the circulation to treat hypovolemia and persistent intravascular coagulation cannot be overemphasized. With adequate perfusion of vital organs, activated coagulation factors and circulating fibrin and fibrin degradation products are promptly removed by the reticuloendothelial system. At the same time, hepatic and endothelial synthesis of procoagulants is promoted.

The likelihood of life-threatening hemorrhage in obstetrical situations complicated by defective coagulation depends not only on the extent of the coagulation defects but — of great importance — on whether the vasculature is intact or disrupted. With gross derangement of blood coagulation, there may be fatal hemorrhage when vascular integrity is disrupted, yet no hemorrhage as long as all blood vessels remain intact.

Clinical and Laboratory Evidence of Defective Hemostasis. *Bioassay* is an excellent method to clinically detect or suspect significant coagulopathy. **Excessive bleeding at sites of modest trauma characterizes defective hemostasis.** Persistent bleeding from venipuncture sites, nicks from shaving the perineum or abdomen, trauma from insertion of a catheter, and spontaneous bleeding from the gums or nose are signs of possible coagulation defects. Purpuric areas at pressure sites may indicate incoagulable blood, or more commonly, clinically significant thrombocytopenia. A surgical procedure provides the ultimate bioassay for coagulation. Continuous generalized oozing from the skin, subcutaneous and fascial tissues, and the vascular retroperitoneal space should at least suggest coagulopathy. Such evidence also may be gained by observing continuous oozing from episiotomy incisions or perineal lacerations.

HYPOFIBRINOGENEMIA. In late pregnancy, plasma fibrinogen levels typically are 300 to 600 mg/dL. With consumptive coagulopathy, these high levels may sometimes serve to protect against clinically significant hypofibrinogenemia. To promote clinical coagulation, fibrinogen levels must be about 150 mg/dL. If serious *hypofibrinogenemia* is present, the clot formed from whole blood in a glass tube may initially be soft but not necessarily remarkably reduced in volume. Then, over the next half hour or so, it becomes quite small, so that many of the erythrocytes are extruded and the volume of liquid clearly exceeds that of clot.

FIBRIN AND FIBRINOGEN DERIVATIVES. Fibrin degradation products in serum may be detected by a number of sensitive test systems. Monoclonal antibodies to detect d-dimers are commonly used. With clinically significant consumption coagulopathy, these measurements are always abnormally high.

THROMBOCYTOPENIA. Serious thrombocytopenia is likely if petechiae are abundant, if clotted blood fails to retract over a period of an hour or so, or if platelets are rare in a stained blood smear. Confirmation is provided by platelet count. As discussed in [Chapter 34](#) (see p. 773), there is also *qualitative platelet dysfunction* with severe preeclampsia and eclampsia.

PROTHROMBIN AND PARTIAL THROMBOPLASTIN TIMES. Prolongation of these coagulation tests may be the consequence of appreciable reductions in those coagulants essential for generating thrombin, fibrinogen concentration below a critical level of about 100 mg/dL, or appreciable amounts of circulating fibrinogen-fibrin degradation products. Prolongation of the prothrombin time and partial thromboplastin time need not be the consequence of consumptive coagulopathy.

Heparin. The infusion of heparin to try to block disseminated intravascular coagulation associated with placental abruption or other situations in which the integrity of the vascular system is compromised is mentioned only to condemn its use.

Epsilon-Aminocaproic Acid. This agent has been administered in an attempt to control fibrinolysis by inhibiting the conversion of plasminogen to plasmin. Epsilon-aminocaproic acid inhibits the proteolytic action of plasmin on fibrinogen, fibrin monomer, and fibrin polymer (clot). Failure to clear fibrin polymer from the microcirculation could result in organ ischemia and infarction, such as renal cortical necrosis. Its use in most types of obstetrical coagulopathy has not been efficacious and is not recommended.

Figure 35-31. The coagulation and fibrinolysis cascades. (From Baker and Cunningham, 1999.)

PLACENTAL ABRUPTION. This is the most common cause of severe consumptive coagulopathy in obstetrics. It is discussed on page 811.

FETAL DEATH AND DELAYED DELIVERY. Although in most women with fetal death, spontaneous labor eventually ensues, most often within 2 weeks, the psychological stress imposed by carrying a dead fetus usually prompts induction of labor at the time of discovery (see [Chap. 22](#)). This also obviates the dangers of coagulation defects that may develop.

Coagulation Changes. Prospective studies indicated that gross disruption of the maternal coagulation mechanism rarely developed before less than 1 month after fetal death (Pritchard, 1959, 1973). If the fetus was retained longer, however, about 25 percent of the women developed a coagulopathy. Typically the fibrinogen concentration falls to levels that are normal for the nonpregnant state, and in some cases it falls to potentially dangerous concentrations of 100 mg/dL or less (Pritchard, 1973). The rate of decrease commonly found is demonstrated in [Figure 35-32](#). Simultaneously, fibrin degradation products are elevated in serum. These changes are presumably mediated by thromboplastin from the dead products of conception (Jimenez and Pritchard, 1968; Lerner and associates, 1967). The platelet count tends to decrease in these instances, but severe thrombocytopenia is uncommon even if the fibrinogen level is quite low. Although coagulation defects may correct spontaneously before evacuation, this is unusual and happens quite slowly (Pritchard, 1959).

HEPARIN. Correction of coagulation defects has been accomplished using low doses of heparin (5000 U two to three times daily) under carefully controlled conditions *in women with an intact circulation* (Pacheco and colleagues, 2004). Heparin appropriately administered can block further pathological consumption of fibrinogen and other clotting factors, thereby slowing or temporarily reversing the cycle of consumption and fibrinolysis. Such correction should be undertaken only if the patient is not actively bleeding and with simultaneous steps to effect delivery.

FETAL DEATH IN MULTIFETAL PREGNANCY. It is uncommon that an obvious coagulation derangement develops in multifetal pregnancy complicated by death of at least one fetus and survival of another (Landy and Weingold, 1989). Petersen and Nyholm (1999) followed 22 multifetal pregnancies with one fetal death after the first trimester and did not detect a coagulopathy in any of these cases.

Chescheir and Seeds (1988) reported a woman in whom, following death of one of twin fetuses, there was progressive but transient fall in plasma fibrinogen concentration and rise in fibrin split products. We have encountered only a few such cases at Parkland Hospital, and one is shown in [Figure 35-33](#). Coagulation changes ceased spontaneously, and the surviving fetus, when delivered near term, was healthy. The placenta of the long-dead fetus was filled with fibrin. Most cases are in monochorionic twins with vascular anastomoses (see [Chap. 39](#), p. 928). The survivor twin has an extremely high risk of cerebral palsy and other cerebral impairment (Pharoah and Adi, 2000).

Figure 35-32. Slow development of maternal hypofibrinogenemia following fetal death and delayed delivery in Patient P.R. (From Pritchard, 1959, with permission.)

Figure 35-33. A. Death of one twin was confirmed sonographically at 28 weeks' gestation. Coagulation studies then demonstrated a somewhat low plasma fibrinogen concentration and abnormal amounts of fibrin degradation products. These abnormalities became more intense 2 weeks later. Then, spontaneously, the fibrinogen concentration rose, and the fibrin degradation product levels fell in mirror fashion. The liveborn infant was healthy, and coagulation studies on cord plasma and maternal serum were normal. **B.** The fibrin-filled placenta of the long-dead fetus is apparent. Presumably, the fibrin curtailed the escape of thromboplastin from the dead products into the maternal circulation.

AMNIONIC FLUID EMBOLISM. This is a complex disorder classically characterized by the abrupt onset of hypotension, hypoxia, and consumptive coagulopathy. There is great individual variation in its clinical manifestation, and women are encountered in whom one of these three clinical hallmarks dominates or is entirely absent. The syndrome is uncommon in an absolute sense, however, it is a common cause of maternal death. For example, amniotic fluid embolism was implicated as the cause of death in 275 (9 percent) of the 3201 pregnancy-related maternal deaths ascertained from the Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention from 1991 through 1997 (Berg and colleagues, 2003). Using data from 1.1 million deliveries in California, Gilbert and Danielsen (1999) estimated a frequency of about 1 case per 20,000 deliveries.

In obvious cases, the clinical picture frequently is dramatic. Classically, a woman in the late stages of labor or immediately postpartum begins gasping for air, and then rapidly suffers seizure or cardiorespiratory arrest complicated by consumptive coagulopathy, massive hemorrhage, and death. These are unquestionably the most dramatic cases. However, there appears to be variation in the clinical presentation of this condition. For example, we have managed a number of women in whom otherwise uncomplicated vaginal delivery was followed by severe acute consumptive coagulopathy without cardiorespiratory symptoms. Thus, in some women, consumptive coagulopathy appears to be the "forme fruste" of amniotic fluid embolism (Awad and Shorten, 2001; Davies, 1999; Porter and colleagues, 1996). Other features common to amniotic fluid embolism are

meconium staining and rapid labor.

Pathogenesis. Amniotic fluid embolism was originally described in 1941 by Steiner and Luschbaugh. Subsequent studies by Adamsons and associates (1971) and Stolte and co-workers (1967) demonstrated that amniotic fluid is innocuous, even when infused in large amounts. Some have suggested that the clinical picture is similar to that seen in human anaphylaxis (Clark and co-workers, 1995).

Amniotic fluid enters the circulation as a result of a breach in the physiological barrier that normally exists between maternal and fetal compartments. Such events appear to be common, if not universal, with both squames of presumed fetal origin and trophoblasts being commonly found in the maternal circulation (Clark and colleagues, 1986; Lee and co-workers, 1986). There may be maternal exposure to various fetal elements during pregnancy termination, following amniocentesis or trauma, or more commonly during labor or delivery as small lacerations develop in the lower uterine segment or cervix. Alternatively, cesarean delivery affords ample opportunity for mixture of maternal blood and fetal tissue.

In most cases, these events are innocuous. In certain women, however, such exposure initiates a complex series of physiological reactions mimicking those seen in human anaphylaxis and sepsis (Table 35-9). A similar process has been shown for traumatic fat embolism (Peltier, 1984). A complete understanding of the precise pathophysiological cascade remains elusive. In a case-controlled study of nine women with presumed amniotic fluid embolism, Benson and associates (2001) found that some indicators of anaphylaxis — serum tryptase and urinary histamine — were increased in some of the women, yet none had evidence of mast cell degranulation. Of note, complement levels were decreased uniformly, suggesting that complement activation may play an important role. Because such activation also occurs in seriously ill patients with acute respiratory distress syndrome, however, it is not known whether complement activation is a primary or secondary result of amniotic fluid embolism. A number of chemokines and cytokines also likely are important in the pathogenesis. For example, Khong (1998) found intense expression of endothelin-1 in fetal squames recovered from the lungs of two fatal cases.

Pathophysiology. Studies in primates using homologous amniotic fluid injection, as well as a carefully performed study in the goat model, have provided important insights into central hemodynamic aberrations (Adamsons and co-workers, 1971; Hankins and colleagues, 1993; Stolte and colleagues, 1967). The initial phase consists of pulmonary and systemic hypertension. Indeed, in a remarkable case report, Stanten and associates (2003) described the results of a transesophageal echocardiogram performed within 10 minutes of circulatory collapse related to amniotic fluid embolism. The findings, including a massively dilated akinetic right ventricle and a small, vigorously contracting, cavity-obiterated left ventricle, were all consistent with failure to transfer blood from the right to the left heart because of catastrophic pulmonary vasoconstriction. Transient but profound oxygen desaturation is often seen in the initial phase, resulting in neurological injury in most survivors (Harvey and associates, 1996).

Decreased systemic vascular resistance and left ventricular stroke work index occur following this initial phase (Clark and colleagues, 1988). In women who live beyond the initial cardiovascular collapse, a secondary phase of lung injury and coagulopathy often ensues.

The association of uterine hypertonus with cardiovascular collapse appears to be the effect of amniotic fluid embolism rather than the cause (Clark and co-workers, 1995). Indeed, uterine blood flow ceases completely when intrauterine pressures exceed 35 to 40 mm Hg (Towell, 1976). Thus, a hypertonic contraction is the *least* likely time for fetal-maternal exchange to take place. Similarly, there is no causal association between oxytocin use and amniotic fluid embolism, and the frequency of oxytocin use is not increased in these women (American College of Obstetricians and Gynecologists, 1993).

Diagnosis. In the past, the detection of squamous cells or other debris of fetal origin in the central pulmonary circulation was believed to be pathognomonic for amniotic fluid embolism. Indeed, in fatal cases, histopathological findings may be dramatic, especially in those involving meconium-stained amniotic fluid (Fig. 35-34). The detection of such debris, however, may require extensive special staining, and even then it is often not seen. For example, Hankins and colleagues (2002) injected raw amniotic fluid into eight goats. Using special staining, there was microscopic evidence of pulmonary embolization in only 25 percent. Interestingly, seven other animals who were injected with meconium-stained fluid all had histopathological evidence of embolization. In a study by Clark and associates (1995), fetal elements were detected in 75 percent of autopsies and 50 percent of specimens prepared from concentrated buffy coat aspirates taken antemortem from a pulmonary artery catheter. Further, several studies have demonstrated that squamous cells, trophoblasts, and other debris of fetal origin may commonly be found in the central circulation of women with conditions other than amniotic fluid embolism. Thus, this finding is neither sensitive nor specific, and the diagnosis is generally made by identifying clinically characteristic signs and symptoms. In less typical cases, diagnosis is contingent on careful exclusion of other causes.

Management. Although an initial period of systemic and pulmonary hypertension appears to be involved in amniotic fluid embolism, this phase is transient. Women who survive long enough to receive any treatment other than cardiopulmonary resuscitation should receive therapy directed at oxygenation and support of the failing myocardium. Circulatory support and blood and component replacement are paramount. **There are no data that any type of intervention improves maternal prognosis with amniotic fluid embolism.** In undelivered women suffering cardiac arrest, consideration should be given to emergency perimortem cesarean delivery in an effort to improve newborn outcome. Such decision making is more complex in the woman who is hemodynamically unstable, but who has not suffered cardiac arrest.

Prognosis. The dismal outcomes with amniotic fluid embolism are undoubtedly related to reporting biases. Also, the syndrome likely is underdiagnosed in all but the most severe cases. In the report by Clark and co-workers (1995), there was a 60-percent maternal mortality rate. In the California database of 1.1 million deliveries by Gilbert and Danielson (1999), only 25 percent of reported cases were fatal. Weiwen (2000) has provided preliminary data from 38 cases in the Suzhou region of China; almost 90 percent of these women died. Death can be amazingly rapid, and of the 34 women who died in the series from China, 12 died within 30 minutes.

Profound neurological impairment is common in survivors. **In the cases reported by Clark and colleagues (1995), only 8 percent of women who had a cardiac arrest in conjunction with initial symptoms survived neurologically intact.** Outcome is also poor for fetuses and is related to the cardiac arrest-to-delivery interval. Overall neonatal survival is 70 percent, but almost half suffer residual neurological impairment.

Figure 35-34. A. Fetal squames (*arrow*) packed into a small pulmonary artery from a fatal case of amniotic fluid embolism. Most of the empty spaces within the vessel were demonstrated by appropriate staining for lipid to have been filled with vernix caseosa. **B.** Levels of fibrinogen, fibrinogen-fibrin degradation products, and platelets during fatal amniotic fluid embolism in patient S.S.

SEPTICEMIA. Infections that lead to bacteremia and septic shock in obstetrics are most commonly due to septic abortion, antepartum pyelonephritis, or puerperal sepsis. Other aspects of septic shock are discussed in [Chapter 42](#) (see p. 993).

Coagulopathy. The lethal properties of bacterial toxins, and especially endotoxins, are undoubtedly mediated largely by disruption of vascular endothelium. It is unclear, however, whether this is the major mechanism that initiates consumptive coagulopathy. For example, in experimental animals, endothelial damage is greatest 24 hours after endotoxin is given, but intravascular coagulation can usually be identified during the first few hours. More likely, endotoxin activates the extrinsic clotting mechanism through cytokine-induced tissue factor expression on the surface of activated monocytes (Levi and colleagues, 1993). The intrinsic route seems unimportant in this role.

Management. The pathophysiology and clinical management of the sepsis syndrome is discussed in detail in [Chapter 42](#) (see p. 993). It has also been reviewed recently by Hotchkiss and Karl (2003). In general, treatment of the inciting cause is followed by reversal of the coagulopathy. In some cases, especially if surgical procedures are performed before sepsis is controlled and the coagulopathy is reversed, treatment with fresh-frozen plasma and platelet packs usually arrests such bleeding. **Heparin therapy is dangerous and should not be given.**

ABORTION. Remarkable blood loss may occur as the consequence of abortion. Hemorrhage during early pregnancy is less likely to be severe unless abortion was induced and the procedure was traumatic. When pregnancy is more advanced, the mechanisms responsible for hemorrhage are most often the same as those described for placental abruption and placenta previa — that is, the disruption of a large number of maternal blood vessels at the site of placental implantation.

Coagulation Defects. Serious disruption of the coagulation mechanism as the consequence of abortion may develop in the following circumstances:

1. Prolonged retention of a dead fetus, as already described.
2. The sepsis syndrome, a notorious cause.
3. Medical induction with a prostaglandin.
4. During instrumental termination of the pregnancy.
5. Intrauterine instillation of hypertonic saline or urea solutions.

The kinds of changes in coagulation that have been identified with abortion induced with *hypertonic solutions* imply at least that thromboplastin is released from placenta, fetus, decidua, or all three by the necrobiotic effect of the hypertonic solutions, which then initiates coagulation within the maternal circulation (Burkman and associates, 1977). Coagulation defects have been observed to develop rarely during induction of abortion with prostaglandin. Saraiya and colleagues (1999) reviewed 62 spontaneous abortion-related deaths reported to the Pregnancy Mortality Surveillance System. Almost 60 percent of deaths were caused by infection, and half of these women had consumptive coagulopathy.

Consumptive coagulopathy has been an uncommon but serious complication among women with *septic abortion*. The incidence of coagulation defects in the past at Parkland Hospital was highest in those with *Clostridium perfringens* sepsis and intense intravascular hemolysis (Pritchard and Whalley, 1971). Management consists of prompt restoration and maintenance of the circulation, and appropriate steps to control the infection, including evacuation of the infected products (see [Chap. 9](#), p. 247).

36. Preterm Birth

INTRODUCTION

Low birthweight defines neonates who are born too small, and *preterm* or *premature birth* are the terms used to define neonates who are born too early. With respect to gestational age, a newborn may be preterm, term, or postterm. With respect to size, a newborn may be normally grown or appropriate for gestational age, small in size or small-for-gestational age, or overgrown and consequently large-for-gestational age. In recent years, the term *small-for-gestational age* has been widely used to categorize newborns whose birthweight is usually below the 10th percentile for gestational age. Other frequently used terms have included *fetal growth restriction* or *intrauterine growth restriction*. The term *large-for-gestational age* has been widely used to categorize newborns whose birthweight is above the 90th percentile for gestational age, and the term *appropriate-for-gestational age* designates newborns whose weight is between the 10th and 90th percentiles. Thus, infants born before term can be small- or large-for-gestational age but still fit the definition of preterm.

In the United States in 2001, almost 28,000 infants died in their first year of life ([Table 36-1](#)). Preterm birth, which is defined as delivery before 37 completed weeks, was implicated in approximately two thirds of these deaths. Overall, infant mortality has continued to decline from 1990 to 2000, albeit at a slower rate than in earlier decades ([Fig. 36-1](#)). The causes of infant mortality have also declined from 1990 to 2000, except for those associated with preterm birth or low birthweight ([Fig. 36-2](#)). Importantly, singleton preterm births in this country have increased only in white non-Hispanic women. Despite this, preterm births in this country remain highest in black women ([Fig. 36-3](#)).

CONSIDERATIONS SURROUNDING PRETERM BIRTH

ESTIMATING SURVIVAL. Aside from survival, appreciable physical and intellectual compromise afflicts extremely low-birthweight infants. At what gestational age should obstetrical interventions be practiced?

Improved survival of extremely low-birthweight infants has understandably lowered the "threshold of viability." Stevenson and colleagues (1998) reported outcomes from an inborn cohort of the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network for 1993 and 1994. Death, severe neonatal morbidities, or both were common before 26 weeks, and they were almost universal before 24 weeks. Thus, gestations from 23 to 25 weeks pose the greatest dilemma for providers of obstetrical and newborn care and for their patients.

What is the best management scheme? This question of course cannot be answered, except possibly on an individual basis. Approaches to preterm labor and delivery currently are guided in large part by expectations for survival of the neonate. Perceptions of the potential for survival, however, are often confused by imprecisely known gestational age. For neonates shown in [Figure 36-4](#), the most accurate estimates of gestational age are made from last menses, obstetrical parameters, and ultrasonographical examination (American College of Obstetricians and Gynecologists, 2002). They are considered to be the "best case" outcomes. Perinatal mortality and morbidity decrease markedly from 24 to 26 weeks gestation. Survival increases from approximately 20 percent at 24⁰ weeks up to 50 percent at 25⁰ weeks, or an increase of almost 4 percent each day.

However, most survival data are based on birthweight, which may vary appreciably between 24 and 26 weeks. Neonates born between 24 and 26 weeks can vary in weight from 435 g to 1640 g (Alexander and associates, 1996). The gestational age survival rates for live births during 1995 and 1996 within the NICHD Neonatal Research Network are shown in [Figure 36-4](#). Although survival is possible for newborns weighing 500 to 750 g, many survivors are growth restricted and therefore of more advanced maturity. For example, survival of a 380-g neonate has been reported, but the gestational age was confirmed to be 25^{3/7} weeks (Ginsberg and associates, 1990). **Neonatal morbidity and mortality are primarily influenced by gestational age and thus maturity, and less so by birthweight.**

Evans and Levene (2001) described the appreciable selection bias in preterm survival studies. The Neonatal Research Network data reflect an important bias — all neonates were delivered in tertiary university centers and only liveborn infants were included. These rates also exclude deaths after 120 days.

Figure 36-4. Neonatal Research Network: Survival of preterm liveborn infants according to gestational age at birth. (Data from Lemons and colleagues, 2001, with permission.)

LONG-TERM OUTCOMES. The high rate of significant neonatal morbidity in these very immature neonates and the diminished likelihood of a normal life must be weighed against the *apparent* triumph of survival. A number of investigators have reported long-term outcomes in survivors born at the frontier of viability.

Doyle and colleagues (1994) did a follow-up study of neonates born at 24 to 26 weeks. They reported that only 20 percent were totally free of impairment at 5 years or more. Vohr and co-workers (2000) assessed outcomes at 18 to 22 months in 1151 survivors from the NICHD Neonatal Research Network centers who were born in 1993 and 1994. Their birthweight was 400 to 1000 g. Only 50 percent had a normal neurodevelopmental and sensory assessment, and those with lower birthweights had markedly worse outcomes as predicted by chronic lung disease, grades 3 and 4 intraventricular hemorrhage, and periventricular leukomalacia. Wood and associates (2000) reported similar results in the EPI Cure Study Group of the United Kingdom. They evaluated 283 infants who were born at or before 25 weeks who survived to 30 months of age. Only 1 of 138 infants born during the 22nd week had *no* neurological disability, compared with 11 of 241 (5 percent) of those born during the 23rd week; 45 of 382 (12 percent) of those born during the 24th week; and 98 of 424 (23 percent) of those born during the 25th week. Stoll and colleagues (2004) found that these extremely low-birthweight newborns compared with similarly matched uninfected neonates had increased associated risks of poor neurodevelopmental and growth outcomes in early childhood.

Hack and Fanaroff (1999) concluded that the limits of viability have been reached and that the continuing toll of major morbidity is of serious concern. In analyzing data collected from three different time periods by the NICHD Neonatal Research Network, Fanaroff and colleagues (2003) found that newborn outcomes at the threshold of viability — 24 or 25 weeks or 501 to 750 g — did not improve from 1993 to 1994 compared with 1999 to 2000. This followed a dramatic improvement in both mortality and morbidity between 1987 and 1988 and 1993 to 1994. Similarly, Horbar and colleagues (2002) studied outcomes in 118,448 very-low-birthweight newborns in the Vermont-Oxford Trials Database from 1991 through 1999. There were no additional improvements in mortality or morbidity after 1995, ending a decades-long trend of improving outcomes.

LOWER LIMIT OF SURVIVAL: COUNSELING CONSIDERATIONS. Perinatal care at the threshold of viability, defined as 25 or fewer weeks of gestation, has been reviewed by the American College of Obstetricians and Gynecologists (2002). It concluded that "parents can be counseled that infants delivered before 24 weeks are not likely to survive, and those who do are not likely to survive intact. Disabilities in mental and psychomotor development, neuromotor function, or sensory and communication function are present in approximately one half of survivors." Maternal-fetal transport to a tertiary care center prior to delivery should be considered when possible. Importantly, all members of the health care team should maintain a consistent theme with family members regarding neonatal assessment and prognosis, as well as recommendations and plans for care.

Amon and co-workers (1992) and Bottoms and co-workers (1997) surveyed obstetricians to determine their clinical opinions regarding intrapartum management of the extremely preterm fetus requiring delivery. According to their survey results, cesarean delivery was not performed at less than 24 weeks. Almost 90 percent of respondents were willing to perform cesarean delivery for fetal distress or breech presentation at 26 weeks or 750 g fetal weight. Doron and co-workers (1998) analyzed delivery room decisions by neonatologists to provide or withhold resuscitation between 23 and 26 weeks' gestation. They concluded that resuscitation of these extremely preterm neonates may provide time to gather additional information about neonatal prognosis and an opportunity for decision making regarding continued care.

The decision not to perform cesarean delivery or use intrapartum monitoring does not necessarily imply that the fetus is "nonviable" or "written off." Kitchen and co-workers (1992) analyzed the outcomes of liveborn neonates weighing 500 to 999 g and found that although 50 percent of newborns survived and only 7 percent were severely disabled, these outcomes were unrelated to the use of cesarean delivery or electronic fetal monitoring.

We believe that these data do not support the aggressive approach to cesarean delivery between 23 and 26 weeks that is described by Redman and Gonik (2002) and that has been documented as the national trend ([Fig. 36-5](#)).

Figure 36-5. Cesarean delivery rates for the United States from 1990 to 2000 at 22 to 26 weeks' gestation. Except for 22-week gestations, there is an obvious trend toward increasing cesarean deliveries. (From DeRoche and colleagues, 2002, with permission.)

UPPER LIMIT FOR ADVERSE OUTCOMES FROM PRETERM DELIVERY.

Survival of larger preterm newborns now approaches that for term newborns (see [Fig. 36-4](#); see [Table 29-2](#), p. 656). This raises the question: Is there a birthweight or gestational age threshold after which attempts to delay delivery are unwarranted? DePalma and co-workers (1992) found that the threshold for neonatal mortality at Parkland Hospital was 1600 g, and it was 1900 g for neonatal morbidity. They concluded that aggressive attempts to prevent births for fetuses whose weight estimates exceeded 1900 g offered few apparent benefits. In the United States, 1950 g is the 10th percentile for 34 weeks and the 50th percentile for 32 weeks (see [Table 38-1](#), p. 896). Nationwide, the survival rate for newborns at 34 weeks is within 1 percent of those born at or beyond 37 weeks (American College of Obstetricians and Gynecologists, 1995).

ECONOMIC IMPACT OF PRETERM BIRTH. Resources used to care for low-birthweight newborns is one measure of the financial burden of preterm birth. In the United States, Lewit and co-workers (1995) found that more

than a third of the dollars expended for infant health care during the first year of life is spent on the 7 percent of neonates born who weigh less than 2500 g. Additional expenditures for developmental handicaps during the remainder of childhood should also be considered.

CAUSES OF PRETERM BIRTH

A wide spectrum of causes and demographic factors have been implicated in preterm birth.

MEDICAL AND OBSTETRICAL COMPLICATIONS. The NICHD Maternal-Fetal Medicine Units Network has analyzed the causes of delivery before 37 weeks. The report by Meis and colleagues (1995b, 1998) showed that 28 percent of these preterm singleton births were indicated as being due to several factors; about a half were for preeclampsia; a fourth for fetal distress; and a fourth for fetal growth restriction, placental abruption, or fetal death. The remaining 72 percent were due to spontaneous preterm labor, with or without prematurely ruptured membranes. Kimberlin and colleagues (1999) studied 411 newborns who weighed 1000 g or less and found that outcomes were similar if preterm delivery was indicated or spontaneous.

THREATENED ABORTION. Vaginal bleeding in early pregnancy is associated with increased adverse outcomes. Weiss and associates (2002) reported data on vaginal bleeding at 6 to 13 weeks in nearly 14,000 women. Both light bleeding (described as spotting) and heavy bleeding (similar to menses) were associated with subsequent pregnancy loss prior to 24 weeks, preterm labor, and placental abruption.

LIFESTYLE FACTORS. Cigarette smoking, inadequate maternal weight gain during pregnancy, and illicit drug use play important roles in both the incidence and the outcome of low-birthweight neonates (see [Chap. 14](#)). Some of these effects are undoubtedly due to restricted fetal growth, but Hickey and colleagues (1995) linked prenatal weight gain specifically with preterm birth. Other maternal factors implicated include young or advanced maternal age; poverty; short stature; Vitamin C deficiency; and occupational factors such as prolonged walking or standing, strenuous working conditions, and long weekly work hours (Casaneuva, 2005; Gielchinsky, 2002; Kramer, 1995; Luke, 1995; Meis, 1995b; Satin, 1994, and all their colleagues). Santiago and colleagues (2005) found no increased incidence of recurrent preterm birth in women with a history of preterm birth and whose work during their current pregnancies was outside the home or required physical exertion.

Psychological and physical stress have seldom been formally studied but seem intuitively important. Both stress and higher levels of maternal serum cortisol have been associated with spontaneous preterm birth (Copper and colleagues, 1996; Mercer and associates, 2002). Neggers and colleagues (2004) found a significant link between low birthweight and preterm birth in women injured by physical abuse (see [Chap. 42](#), p. 997). McCollum and colleagues (2003), however, reported that maternal depression was not associated with birth prior to 35 weeks.

The association of *cigarette smoking* and fetal growth restriction is unequivocal. The impact of smoking during pregnancy was summarized in a report by the March of Dimes (Berns, 2002). Specifically, 20 percent of low-birthweight neonates, 8 percent of preterm births, and 5 percent of perinatal deaths were caused by smoking. Smoking was associated with a 2- to 5-fold risk of preterm prematurely ruptured membranes, a 1.2- to 2-fold risk of preterm delivery, and a 1.5- to 3.5-fold risk of fetal growth restriction (see [Chap. 14](#), p. 354). Castles and associates (1999) also reviewed five meta-analyses and concluded that smoking increased the incidence of ectopic pregnancy, placental abruption, and placenta previa. Counseling is discussed in [Chapter 8](#) (see p. 209).

GENETIC FACTORS. The recurrent, familial, and racial nature of preterm birth has led to the suggestion that genetics may play a causal role (Hoffman and Ward, 1999). The gene for decidual relaxin is one candidate. Fetal mitochondrial trifunctional protein defects or polymorphism in the interleukin-1 gene complex, β_2 -adrenergic receptor, or tumor necrosis factor- α (TNF- α) may also be involved in preterm membrane rupture (Genc, 2002; Landau, 2002; Netta, 2003; Tashima, 2002; Yang, 2002, and all their colleagues). Studies to evaluate gene-environment interactions are also needed. For example, when Bytautiene and colleagues (2003) induced an allergic reaction in pregnant guinea pigs that resulted in preterm delivery, they found that the rate was reduced threefold by pretreatment with an antihistamine and cromolyn sulfate.

CHORIOAMNIONITIS. Infection of the membranes and amniotic fluid caused by a variety of microorganisms has emerged as a possible explanation of some cases of ruptured membranes, preterm labor, or both. Bacteria are recovered by transabdominal amniocentesis from as many as 20 percent of women in preterm labor without overt clinical infection and with intact fetal membranes (Cox and associates, 1996; Watts and co-workers, 1992). Viral products have also been recovered (Reddy and colleagues, 2001). Infection is not limited to amniotic fluid. In studies done at cesarean delivery in 609 women with intact membranes, Hauth and co-workers (1998) confirmed that recovery of organisms from the chorioamnion was significantly increased with spontaneous preterm labor. As shown in [Figure 36-6](#), recovery of pathogens was also inversely correlated with gestational age. The pathogenesis of upper genital tract infection and preterm birth is considered further in [Chapter 6](#) (see p. 178).

The pathway for bacteria to enter amniotic fluid with intact membranes is unclear. Gyr and colleagues (1994) have shown that *Escherichia coli* can permeate living membranes; thus, they are not an absolute barrier to ascending infection. Another pathway for bacterial initiation of preterm labor may not require bacteria in the amniotic fluid. Cox and co-workers (1993) found that the cytokine network of cell-mediated immunity can be activated within the decidual tissue that lines the presenting fetal membranes. In this scheme, bacterial products such as endotoxin stimulate decidual monocytes to produce cytokines, which in turn stimulate arachidonic acid and then prostaglandin production. Prostaglandins E_2 and $F_{2\alpha}$ act in a paracrine fashion to stimulate adjacent myometrium to contract.

Figure 36-6. Chorioamnionic bacterial colonization as a function of gestational age in women with spontaneous labor and in those in whom delivery was indicated for

medical or obstetrical complications. The P values represent comparisons between the two groups for each epoch plotted. (From Hauth and colleagues, 1998, with permission.)

IDENTIFICATION OF WOMEN AT RISK FOR SPONTANEOUS PRETERM LABOR

The first step in prevention of preterm labor is early identification of women at risk. The American College of Obstetricians and Gynecologists (2001) has reviewed selected risk factors to predict spontaneous preterm birth.

RISK-SCORING SYSTEMS. There has been considerable interest in risk-scoring systems to identify women at greatest risk for preterm birth. In their review, Hueston and colleagues (1995) found no benefits of this programmatic approach. Mercer and colleagues (1996) concluded that risk assessment failed to identify most women who deliver preterm neonates. In another study, Klerman and co-workers (2001) randomly assigned 619 Medicaid-eligible black women with a modified risk assessment score for preterm delivery of 10 or higher to receive augmented or customary prenatal care. Mean birthweight and the incidences of preterm delivery and low-birthweight newborns were similar in both groups as well as in the general obstetrical population.

PRIOR PRETERM BIRTH. Prior preterm delivery strongly correlates with subsequent preterm labor. Shown in [Table 36-2](#) is the incidence of recurrent preterm birth in nearly 16,000 women delivered at Parkland Hospital (Bloom and colleagues, 2001b). The risk of recurrent preterm delivery for women whose first delivery was preterm was increased threefold compared with that of women whose first neonate was born at term. More than a third of women whose first two newborns were preterm subsequently delivered a third preterm newborn. The majority (70 percent) of the recurrent births in this study occurred within 2 weeks of the gestational age of the prior preterm delivery. Importantly, the causes of prior preterm delivery (i.e., preterm labor with intact membranes, preterm membrane rupture, or indicated delivery) also recurred. Although women with prior preterm births were clearly at risk for recurrence, they contributed only 10 percent of the total preterm births. Expressed in another way, 90 percent of the preterm births at Parkland Hospital could not be predicted based on a history of preterm birth.

INCOMPETENT CERVIX. *Cervical incompetence* is a clinical diagnosis characterized by recurrent, painless cervical dilatation and spontaneous midtrimester birth in the absence of spontaneous membrane rupture, bleeding, or infection (American College of Obstetricians and Gynecologists, 2001). It is considered in detail in [Chapter 9](#) (see p. 236).

CERVICAL DILATATION. Asymptomatic cervical dilatation after midpregnancy has gained attention as a risk factor for preterm delivery, although some clinicians consider it to be a normal anatomical variant, particularly in parous women. Recent studies, however, have suggested that parity alone is not sufficient to explain cervical dilatation discovered early in the third trimester. Cook and Ellwood (1996) longitudinally evaluated cervical status with transvaginal ultrasonography between 18 and 30 weeks in both nulliparous and parous women who all subsequently gave birth at term. Cervical length and diameter were identical in both groups throughout these critical weeks. The results of routine cervical examinations performed between 26 and 30 weeks in 185 women cared for at Parkland Hospital are shown in [Table 36-3](#). Approximately 25 percent of women whose cervixes were dilated 2 or 3 cm delivered prior to 34 weeks. Many of these women had experienced the same complication in earlier pregnancies. Other investigators have verified cervical dilatation as a predictor of increased risk of preterm delivery (Copper and associates, 1995; Papiernik and colleagues, 1986).

Although women with dilatation and effacement in the third trimester are at increased risk for preterm birth, it has not been established that detection improves pregnancy outcome. Buekens and colleagues (1994) randomly assigned 2719 women to undergo routine cervical examinations at each prenatal visit and compared them with 2721 women without examinations. Knowledge of antenatal cervical dilatation did not affect any pregnancy outcome related to preterm birth or the frequency of interventions for preterm labor. The investigators also reported that cervical examinations were not related to preterm membrane rupture. It seems therefore that prenatal cervical examinations are neither beneficial nor harmful.

Ultrasonographic Measurement of Cervical Length. Vaginal-probe ultrasonographic cervical assessment has been evaluated extensively over the past decade. Technique is important, and Yost and colleagues (1999) have cautioned that special expertise is needed. Iams and co-workers (1996) measured cervical length at approximately 24 weeks and again at 28 weeks in 2915 women not at risk for preterm birth. The mean cervical length at 24 weeks was about 35 mm, and those women with progressively shorter cervixes experienced increased rates of preterm birth. In women with a previous birth before 32 weeks, Owen and associates (2001) reported a significant correlation of cervical length at 16 to 24 weeks and subsequent preterm birth before 35 weeks. In a secondary analysis of these data, Yost and colleagues (2004) found that dilatation of 2 to 4 mm identified during second-trimester cervical ultrasonographic scanning independently predicted an increase in births prior to 35 weeks. In their review, Owen and colleagues (2003) concluded that the value of cervical length to predict birth before 35 weeks is apparent only in women at high risk for preterm birth ([Table 36-4](#)).

To evaluate the effects of cerclage in women with ultrasonographically measured cervical dilatation, the investigators summarized five retrospective cohort series and two randomized trials (Owen and associates, 2003). Four of the seven reports cited a beneficial effect, and three showed no benefit.

It seems that the use of ultrasonographic cervical measurements can increase the ability to predict spontaneous birth prior to 35 weeks in high-risk women. We agree with Iams (2003) that routine cervical ultrasonography currently has no role in the screening of normal-risk pregnant women. The efficacy of cerclage for women with shortened cervical length is inconclusive, and an NICHD multicenter randomized trial concerning this issue is currently underway.

SIGNS AND SYMPTOMS. In addition to painful or painless uterine contractions, symptoms such as pelvic pressure, menstrual-like cramps, watery vaginal discharge, and pain in the low back have been empirically associated with impending preterm birth. Such symptoms are thought by some to be common in normal pregnancy and are therefore often dismissed by patients, clinicians, and nurses. The importance of these signs and symptoms as a harbinger of labor has been emphasized by some but not all investigators (Copper and colleagues, 1990; Iams and associates, 1990; Kragt and Keirse, 1990). Iams and colleagues (1994) found that the signs and symptoms signaling preterm labor, including uterine contraction, appeared only within 24 hours of preterm labor.

AMBULATORY UTERINE MONITORING. Uterine activity monitoring has received considerable interest. An external tocodynamometer is belted around the abdomen and connected to an electronic waist recorder. Uterine activity is transmitted via telephone daily. Women are educated concerning signs and symptoms of preterm labor, and clinicians are kept apprised of their progress.

The 1985 approval of this monitor by the U.S. Food and Drug Administration prompted its widespread clinical use. Subsequently, the American College of Obstetricians and Gynecologists (1995) concluded that the use of this expensive, bulky, and time-consuming system does not reduce the rate of preterm birth. Studies that followed confirmed this conclusion. In the Collaborative Home Uterine Monitoring Study (1995), sham transducers were used in 655 women and outcomes compared with those of 637 women with functioning monitors. The rate of preterm birth was similar in both groups. Iams and colleagues (2002) analyzed data from almost 35,000 hours of daily home monitoring from 306 women. They verified that contraction frequency increased with gestational age but that no pattern efficiently predicted preterm birth.

In a study by Dyson and colleagues (1998), women were randomly assigned to receive weekly contact with a nurse or to use home contraction monitoring. There were no differences in the rates of preterm delivery before 35 weeks or in the incidence of birthweights less than 1500 g or less than 2500 g. Moreover, women who used home monitoring had a significant increase in the number of unscheduled visits and women with twins had increased use of tocolytic therapy.

FETAL FIBRONECTIN. This glycoprotein is produced in 20 different molecular forms by a variety of cell types, including hepatocytes, fibroblasts, and endothelial cells, and by fetal amnion. Present in high concentrations in maternal blood and in amniotic fluid, it is thought to play a role in intercellular adhesion during implantation and in the maintenance of placental adhesion to the decidua (Leeson and colleagues, 1996). Fetal fibronectin is detected in cervicovaginal secretions in women who have normal pregnancies with intact membranes at term, and it appears to reflect stromal remodeling of the cervix prior to labor.

Lockwood and co-workers (1991) reported that fibronectin detection in cervicovaginal secretions prior to membrane rupture was a possible marker for impending preterm labor. This report stimulated considerable interest in the use of fibronectin assays for the prediction of preterm birth. Fetal fibronectin is measured using an enzyme-linked immunosorbent assay, and values exceeding 50 ng/mL are considered positive. Contamination of the sample by amniotic fluid and maternal blood should be avoided.

A positive value for cervical or vaginal fetal fibronectin assay, even as early as 8 to 22 weeks, has been found to be a powerful predictor of subsequent preterm birth (Goldenberg and co-workers, 2000). In a randomized trial, a negative fibronectin assay in women with threatened preterm labor was associated with fewer admissions and decreased hospital stay (Lowe and associates, 2004).

Subsequent studies of cervicovaginal fibronectin have allowed better assessment of its positive and negative predictive value. Swamy and colleagues (2001) found that in 404 pregnancies, a positive assay result at 22 to 34 weeks had a positive predictive value for delivery within 1 week of 30 percent or within 2 weeks of 41 percent. The negative predictive value was 98 and 96 percent, respectively. The less informative positive predictive value likely results from factors such as cervical manipulation and infection, which can stimulate fetal fibronectin release (Goldenberg and associates, 1996; Jackson and colleagues, 1996; Thorp and Lukes, 1996). These findings may implicate infection in the initiation of preterm labor in some women.

Intervention with Positive Fibronectin Assay. Because the positive predictive value along with evidence that a positive fibronectin assay may suggest infection, Andrews and colleagues (2003) studied the effectiveness of antimicrobial treatment to reduce the incidence of preterm birth. Of 16,317 women screened for fetal fibronectin between 21 and 26 weeks, 6.6 percent had a positive result. In women given antimicrobial treatment or placebo, no differences were observed in rates of spontaneous preterm birth before 37 weeks (14.4 versus 12.4 percent), before 35 weeks (6.9 versus 7.5 percent), or before 32 weeks (4.3 versus 2.2 percent).

BACTERIAL VAGINOSIS. Bacterial vaginosis is not an infection but rather a condition in which the normal, hydrogen peroxide-producing lactobacillus-predominant vaginal flora is replaced with anaerobes, *Gardnerella vaginalis*, *Mobiluncus* species, and *Mycoplasma hominis* (Hillier and colleagues, 1995; Nugent and co-workers, 1991). Its diagnosis and management are discussed in [Chapter 59](#) (see p. 1319). Using Gram staining, relative concentrations of the bacterial morphotypes characteristic of bacterial vaginosis are determined and graded as the *Nugent score*.

Bacterial vaginosis has been associated with spontaneous abortion, preterm labor, preterm ruptured membranes, chorioamnionitis, and amniotic fluid infection (Hillier, 1995; Kurki, 1992; Leitich, 2003a,b; and all their colleagues). Bacterial vaginosis may precipitate preterm labor by a mechanism similar to that proposed for amniotic fluid infection (Platz-Christensen and co-workers, 1993). In 3600 Danish women, however, when bacterial vaginosis was detected before 24 weeks, it was not related to preterm membrane rupture before 37 weeks or to low birthweight (Thorsen and associates, 1996).

Conflicting reports may relate to the imprecise diagnosis of bacterial vaginosis (Hauth and colleagues, 2003; Simhan and co-workers, 2003). Women with bacterial vaginosis whose vaginal secretions contained *sialidase*, but not *prolidase*, had a significantly increased risk of preterm delivery (Hitti and associates, 2001). Finally, therapy modifies the conditions, and treatment with metronidazole decreased cervical concentrations of interleukin-1 β , -6, and -8 (Yudin and colleagues, 2003).

Environmental factors appear to be important in the development of bacterial vaginosis. Exposure to chronic stress, ethnic differences, and frequent or recent douching have all been associated with increased rates of the condition (Culhane and co-workers, 2002; Ness and associates, 2002). Despite this, prospective studies of women who regularly douched reported no relationship with preterm birth (Fiscella and colleagues, 2002; Nuthalapaty and associates, 2003). A gene-environment interaction was identified by Macones and colleagues (2004). Women with bacterial vaginosis who had a susceptible TNF- α genotype had a ninefold increased incidence of preterm birth. Romero and colleagues (2004) have reviewed bacterial vaginosis and the role of genetic epidemiology in the prevention of preterm birth.

From all of these studies there seems no doubt that adverse vaginal flora, such as in bacterial vaginosis, is associated with spontaneous preterm birth. Unfortunately, to date, screening and treatment have not been shown to prevent preterm birth (see p. 869).

LOWER GENITAL TRACT INFECTION. Some investigators have implicated a number of other genital infections as a cause of preterm labor. Meis and co-workers (1995a) evaluated 2929 women at 24 and 28 weeks for *Trichomonas* or *Candida* species. Women who had one or both of these organisms were not at greater risk for preterm birth. Conversely, Cotch and associates (1997) found that the neonates of women with *Trichomonas* had increased risk of having low-birthweight, a 30-percent increased risk of preterm birth, and a twofold risk of perinatal death. Based on this report, Klebanoff and colleagues (2001) evaluated 617 asymptomatic women with trichomoniasis in midtrimester. Preterm birth was significantly *greater* in women randomly assigned to receive metronidazole compared with that of those receiving placebo (19 versus 11 percent).

Chlamydia trachomatis likely does not play a role in increased preterm delivery (see [Chap. 59](#), p. 1306). The MFM Units Network has found no association of preterm birth in women with midtrimester chlamydial infection. Similarly, Goepfert and co-workers (2002) found similar incidences of preterm delivery in women with and without chlamydial or trichomonal infection. In the Vaginal Infections and Prematurity Study, 414 women with chlamydial infection were randomly selected to receive either erythromycin or placebo. Martin and colleagues (1997) found similar incidences of preterm birth. Currently, screening and treatment to prevent preterm birth in women with either *C trachomatis* or *Trichomonas vaginalis* is not recommended.

Finally, other studies implicate nonspecific markers of infection in increasing the risk of preterm birth. In a study of 3160 asymptomatic women, Ramsey and colleagues (2003) found that a midtrimester vaginal Gram-stained smear with an increased polymorphonuclear:epithelial cell ratio was predictive of birth before 35 weeks. Knudtson and associates (2003) reported that nonpregnant women with interpartum chronic endometritis, characterized by plasma cells, were 2.5 times more likely to deliver before 35 weeks in a subsequent pregnancy.

SALIVARY ESTRADIOL. Goodwin (1996), Heine (1999), and their co-workers described an association between increased maternal salivary estradiol concentration and subsequent preterm birth. We agree with Goodwin (1999) that this test requires further evaluation before it can be recommended for clinical use.

PERIODONTAL DISEASE. Oral bacteria, especially *Fusobacterium nucleatum* and *Capnocytophaga* species, have been associated with upper genital tract infection in pregnant women (Ernest and Wasilaukas, 1985; Wallace, 1986). Offenbacher and associates (1996) found that women with periodontitis had a sevenfold risk of preterm birth compared with that of controls. Hauth and colleagues (2001b) confirmed this in a prospective trial of more than 1300 women assessed at midpregnancy for periodontal inflammation. In each gestational age category, periodontal disease was associated with increased preterm delivery ([Table 36-5](#)). Indeed, 24 of the 28 women who delivered before 32 weeks had periodontitis; this is a fourfold increase compared with that of women without disease. Goepfert and colleagues (2004) observed that women who delivered spontaneous before 32 weeks were significantly more likely to have severe periodontal disease than controls.

Bogges and co-workers (2001) found that preterm newborns of mothers with periodontal disease were 23 percent smaller than those of mothers without disease. Devine and associates (2001) have suggested that this may be related to decreased maternal antibody titers.

Treatment for Periodontitis. Jeffcoat and colleagues (2003) randomly assigned 366 women with periodontitis at midpregnancy to one of three protocols: simple teeth cleaning and polishing (prophylaxis) plus placebo antimicrobial therapy, deep root scaling and planing (intervention) plus metronidazole, or deep root scaling and planing (intervention) with placebo antimicrobial therapy. The incidence of preterm birth before 35 weeks was 4.9 percent in women who had prophylaxis; 3.3 percent for those who had intervention and metronidazole; and only 0.8 percent in those who had intervention and placebo. There were significantly fewer births before 37 weeks in women who had intervention and placebo (4.1 percent) compared with women who had intervention and metronidazole (12.5 percent).

Two multicenter trials sponsored by the National Institute of Dental and Craniofacial Research are underway to determine whether midpregnancy identification and treatment of women with periodontal disease prevents preterm birth.

ROLE OF PROGESTERONE IN THE MAINTENANCE OF PREGNANCY

Currently, it is accepted that in primate pregnancy, including human pregnancy, progesterone withdrawal does not precede the initiation of parturition. As discussed in [Chapter 3](#) (see p. 76), maternal plasma progesterone levels increase throughout pregnancy. Despite this, the use of progesterone to maintain uterine quiescence and to "block" labor initiation as espoused by Csapo (1956) deserves continued evaluation. Progesterone and estrogen levels vary directly but markedly with gestational age. Taken together, studies have been used to support the concept of an adverse progesterone:estrogen ratio to explain preterm labor (Mazor and colleagues, 1993; Romero and co-workers, 1988). Moreover, progesterone antagonists given at term increase the rate of spontaneous labor (Chwalisz, 1991; Frydman, 1992 and all their colleagues). In animal studies, medroxyprogesterone treatment prevented labor and possessed anti-inflammatory activity in vivo (Elovitz and Wang, 2003, 2004). In that role, activation of both TH₁ and TH₂ cytokine pathways were suppressed in the uterus and cervix. These

cytokines are thought to play a role in the maintenance of pregnancy, and later in the initiation of parturition (see [Chap. 6](#), p. 180).

The most commonly used progestin in human clinical trials is 17 α -hydroxyprogesterone caproate. Weekly intramuscular administration to women at risk for preterm labor resulted in lower rates of preterm birth and perinatal mortality when compared with that with placebo (Johnson and associates, 1975, 1979; Yemini and co-workers, 1985). Results of the recent report by Meis and collaborators (2003) are shown in [Table 36-6](#). In addition, da Fonseca and colleagues (2003) reported the effectiveness of a 100-mg vaginal suppository of natural progesterone to reduce preterm delivery in high-risk women. Not all investigators have reported improved benefits from progesterone administration (Hauth and colleagues, 1983). The American College of Obstetricians and Gynecologists (2003) has reviewed the use of progesterone to reduce the incidence of preterm birth.

MANAGEMENT OF PRETERM RUPTURED MEMBRANES AND PRETERM LABOR

Women who have been identified as being at risk for preterm birth and women who present with signs and symptoms of preterm labor have become candidates for a number of interventions intended to improve neonatal outcomes. In the absence of maternal or fetal indications warranting intentional delivery, interventions are intended to forestall preterm birth. Although many of these interventions are described in the following sections, they are not necessarily recommended. Some may produce borderline improvement at best, and others are unproven. Many interventions used to delay delivery undergo continuing review by the American College of Obstetricians and Gynecologists (1995, 1998a,b, 2001, 2002).

PRETERM RUPTURED MEMBRANES. Diagnosis of ruptured membranes is detailed in [Chapter 17](#) (see p. 425). Prior to term, the precision of this diagnosis is of great importance. A history of vaginal leakage of fluid, either continuously or as a gush, should prompt a sterile speculum examination to visualize gross vaginal pooling of amniotic fluid, clear fluid from the cervical canal, or both. Confirmation of ruptured membranes is usually accompanied by ultrasonographic examination to assess amniotic fluid volume; to identify the presenting part; and if not previously determined, to estimate gestational age.

Management may be to effect delivery or to await spontaneous labor. It may be necessary to decide about administration of either antimicrobials, corticosteroids, or both.

Natural History of Preterm Membrane Rupture. Cox and associates (1988) described pregnancy outcomes of 298 consecutive women who gave birth following spontaneous rupture of membranes between 24 and 34 weeks. Although this complication was identified in only 1.7 percent of pregnancies, it contributed to 20 percent of all perinatal deaths. By the time they presented, 75 percent of the women were already in labor, 5 percent were delivered for other complications, and another 10 percent were delivered within 48 hours. In only 7 percent was delivery delayed 48 hours or more after membrane rupture. This latter subgroup, however, appeared to benefit from delayed delivery, because there were no neonatal deaths. This contrasted with a neonatal death rate of 80 per 1000 in newborns delivered within 48 hours of membrane rupture. Nelson and colleagues (1994) reported similar results.

The time period from preterm rupture of membranes to delivery is inversely proportional to the gestational age when the membranes rupture (Carroll and associates, 1995). As shown in [Figure 36-7](#), very few days were gained when membranes ruptured during the third compared with the second trimester.

Hospitalization. Most clinicians hospitalize women with preterm prematurely ruptured membranes. Concerns about the costs of lengthy hospitalizations are usually moot, because most women enter labor within a week or less after membrane rupture. Carlan and co-workers (1993) randomly assigned 67 pregnant women with ruptured membranes to home or hospital management. No benefits were found for hospitalization, and maternal hospital stays were reduced by 50 percent in those sent home (14 versus 7 days). Importantly, the investigators emphasized that this study was too small to conclude that home management was safe.

Intentional Delivery. Prior to the mid-1970s, labor was usually induced in women with preterm ruptured membranes because of fear of infection. Two randomized trials compared labor induction with expectant management in such pregnancies. Mercer and colleagues (1993) randomly selected 93 women with pregnancies between 32 and 36 weeks to undergo delivery or expectant management. *Fetal lung maturity was documented in all cases.* Intentional delivery reduced the length of maternal hospitalization and also reduced infection rates in both mothers and neonates. Cox and Leveno (1995) similarly apportioned 129 women between 30 and 34 weeks. One fetal death resulted from sepsis in the pregnancies managed expectantly. There were three neonatal deaths among those intentionally delivered; two were due to sepsis and one was due to pulmonary hypoplasia. Thus, neither management approach proved to be superior.

Expectant Management. Despite extensive literature concerning expectant management of preterm ruptured membranes, tocolysis has been used in few studies. In these randomized studies, which assigned women with prematurely ruptured membranes to receive either tocolytic or expectant management, the authors concluded that active interventions did not improve perinatal outcomes (Garite and associates, 1981, 1987; Nelson and co-workers, 1985).

Other considerations with expectant management involve the use of digital cervical examination and cerclage. Alexander and colleagues (2000) compared findings in expectantly managed women between 24 and 32 weeks who had one or two digital cervical examinations with those of women who had no such examinations. Women who were examined digitally had a rupture-to-delivery interval of 3 days compared with 5 days in those who were not examined. This difference did not worsen maternal or neonatal outcomes. McElrath and colleagues (2002) studied 114 women with a cerclage in place who later had ruptured membranes prior to 34 weeks. They were matched with 288 controls who had not received a cerclage. Pregnancy outcomes were equivalent in both groups. As discussed in [Chapter 9](#) (see p. 237), such management is controversial.

RISKS OF EXPECTANT MANAGEMENT. Maternal and fetal risks vary with the gestational age at membrane rupture and include the consequences of uterine infection and sepsis. When contemplating expectant management before 25 weeks,

additional consideration is given to fetal risks of oligohydramnios with resultant pulmonary hypoplasia and limb compression deformities (see [Chap. 21](#), p. 531). Morales and Talley (1993) expectantly managed 94 singleton pregnancies with ruptured membranes prior to 25 weeks. They found that 41 percent of infants survived to 1 year of age, however, only 27 percent were neurologically normal. The average time gained was 11 days. Similar results were reported by Farooqi (1998) and Winn (2000) and their associates.

The volume of amniotic fluid remaining after rupture appears to have prognostic importance in pregnancies before 26 weeks. Hadi and associates (1994) described 178 pregnancies with ruptured membranes between 20 and 25 weeks. In 40 percent of women, oligohydramnios developed as defined by the absence of fluid pockets 2 cm or larger. Virtually all women with oligohydramnios delivered before 25 weeks, whereas 85 percent with adequate amniotic fluid volume were delivered in the third trimester. Carroll and colleagues (1995) observed no cases of pulmonary hypoplasia in fetuses born after membrane rupture at 24 weeks or beyond, suggesting that 23 weeks or less is the threshold for the development of lung hypoplasia.

Other risk factors have also been evaluated. Prolonged latency after membrane rupture has not been associated with an increased incidence of fetal neurological damage (McElrath and co-workers, 2003). In neonates born to women with active herpetic lesions who were expectantly managed, the infectious morbidity risk appeared to be outweighed by risks associated with preterm delivery (Major and associates, 2003).

CLINICAL CHORIOAMNIONITIS. If there are no untoward perinatal outcomes from an entangled or prolapsed cord or from placental abruption, most authors, with few exceptions, have found prolonged membrane rupture associated with increased infectious morbidity (Ho and colleagues, 2003). If chorioamnionitis is diagnosed, prompt efforts to effect delivery, preferably vaginally, are initiated. Fever is the only reliable indicator for this diagnosis. A temperature of 38°C (100.4°F) or higher accompanying ruptured membranes implies infection. Maternal leukocytosis alone has not been found to be reliable by most investigators. During expectant management, monitoring for sustained maternal or fetal tachycardia, for uterine tenderness, and for a malodorous vaginal discharge is warranted.

With chorioamnionitis, fetal and neonatal morbidity is substantively increased. Alexander and colleagues (1998) studied 1367 very-low-birthweight neonates delivered at Parkland Hospital. Approximately 7 percent were born to women with overt chorioamnionitis, and their outcomes were compared with those of newborns without clinical infection. Newborns in the infected group had a higher incidence of sepsis, respiratory distress syndrome, early-onset seizures, intraventricular hemorrhage, and periventricular leukomalacia. The investigators concluded that these very-low-birthweight neonates were vulnerable to neurological injury attributable to chorioamnionitis.

There is other evidence that very small newborns exposed to intrauterine infection are at increased risk. Yoon and colleagues (2000) found that intra-amniotic infection in preterm neonates was related to increased rates of cerebral palsy at 3 years. Petrova and colleagues (2001) studied more than 11 million singleton live births from 1995 to 1997 who were in the database of the National Center for Health Statistics linked birth-infant death cohort. During labor, 1.6 percent of all women had fever, and this was a strong predictor of infection-related death in both term and preterm neonates. Bullard and associates (2002) reported similar results.

ACCELERATED PULMONARY MATURATION. A variety of clinical events — some well defined and others not — were once proposed to accelerate fetal surfactant production (Gluck, 1979). These included chronic renal or cardiovascular disease, hypertensive disorders, heroin addiction, fetal growth restriction, placental infarction, chorioamnionitis, and preterm membrane rupture. Although this view was widely held for many years, subsequent observations do not support this association (Hallak and Bottoms, 1993; Owen and associates, 1990).

ANTIMICROBIAL THERAPY. The proposed microbial pathogenesis for spontaneous preterm labor or ruptured membranes has prompted investigators to give various antimicrobials in an attempt to forestall delivery. Mercer and Arheart (1995) reviewed 13 randomized trials performed to evaluate antimicrobial compared with placebo treatment for women with membranes ruptured before 35 weeks. Meta-analysis indicated that only 3 of 10 outcomes were *possibly* benefited: Fewer women developed chorioamnionitis, fewer newborns developed sepsis, and pregnancy was more often prolonged 7 days in women given antimicrobials. Neonatal survival, however, was unaffected, as was the incidence of necrotizing enterocolitis, respiratory distress, or intracranial hemorrhage.

To further address this issue, the NICHD Maternal-Fetal Medicine Units Network designed a trial to study expectant management combined with a 7-day treatment of either ampicillin, amoxicillin plus erythromycin, or placebo. The women had membrane rupture between 24 and 32 weeks. Neither tocolytics nor corticosteroids were given. Antimicrobial-treated women had significantly fewer newborns with respiratory distress syndrome, necrotizing enterocolitis, and composite adverse outcomes (Mercer and colleagues, 1997). The latency period was significantly longer; 50 percent of women given an antimicrobial regimen remained undelivered after 7 days of treatment compared with only 25 percent of those given a placebo. There was also significant prolongation of pregnancy at 14 and 21 days. Cervicovaginal group B streptococcal colonization did not alter these results.

More recent studies have examined the efficacy of shorter treatment lengths and other antimicrobial combinations. Three-day treatment compared with 7-day regimens using either ampicillin or ampicillin-sulbactam appeared equally effective in regard to perinatal outcomes (Lewis and associates, 2003; Segel and colleagues, 2003). Similarly, erythromycin compared with placebo offered a range of significant neonatal benefits. The amoxicillin-clavulanate regimen was not recommended, however, because of its association with an increased incidence of necrotizing enterocolitis (Kenyon and colleagues, 2001a).

Prolonged antimicrobial therapy in such pregnancies may have unwanted consequences. Carroll and colleagues (1996) and Mercer and associates (1999) cautioned that such therapy potentially increases the risk for selection of resistant bacteria. Stoll and colleagues (2002) studied 5447 neonates weighing from 400 to 1500 g and born from 1998 to 2000 at centers of the Neonatal Research Network. These were compared with 7606 neonates of similar birthweight born from 1991 to 1993. The overall rate of early-onset sepsis did not change. However, group B streptococcal sepsis decreased in the 1991-1993 group compared with the 1998-2000 group (5.9 to 1.7 per 1000 births), whereas *E coli* sepsis increased (3.2 to 6.8 per 1000 births). Almost 85 percent of coliform isolates from the more recent cohort were ampicillin resistant. Neonates with early-onset sepsis were more likely to die, especially if they were infected with coliforms.

MEMBRANE REPAIR. Use of a gelatin sponge for cervical plugging was described by O'Brien and colleagues (2002) in 15 women with early midtrimester membrane rupture. This technique is still investigational.

Recommended Management of Preterm Membrane Rupture at Parkland Hospital and the University of Alabama at Birmingham. After confirmation of ruptured membranes, the following steps are taken:

1. Cervical dilatation and effacement are estimated visually during a sterile speculum examination.
2. For pregnancies less than 34 weeks, if there are no maternal or fetal indications for delivery, the woman and her fetus are initially observed in the labor unit. Broad-spectrum parenteral antimicrobials are begun to prevent chorioamnionitis. Fetal heart rate and uterine activity are monitored for cord compression, fetal compromise, and early labor.
3. For pregnancies less than 32 weeks, betamethasone (two 12-mg doses intramuscularly 24 hours apart) or dexamethasone (5 mg intramuscularly every 12 hours for four doses) is given.
4. If the fetal status is reassuring, and if labor does not ensue, the woman is usually transferred to an antepartum unit and observed for labor, infection, or fetal jeopardy. We do not use continuous fetal monitoring.
5. For pregnancies 34 weeks or beyond, if labor does not begin spontaneously, then it is induced with intravenous oxytocin unless contraindicated. Cesarean delivery is performed for usual indications, including failed induction of labor.
6. During labor or induction, a parenteral antimicrobial is given for prevention of group B streptococcal infection.

Figure 36-7. Relationship of time interval between preterm membrane rupture and delivery in 172 singleton pregnancies. (Squares = survivors; circles = deaths due to prematurity; triangles = deaths due to pulmonary hypoplasia.) (From Carroll and co-workers, 1995, with permission.)

PRETERM LABOR WITH INTACT FETAL MEMBRANES. It is axiomatic that management of preterm labor requires a correct diagnosis.

Diagnosis. Early differentiation between true and false labor is difficult before there is demonstrable cervical effacement and dilatation. Uterine activity alone can be misleading because of *Braxton Hicks contractions* (see [Chap. 18](#), p. 466). These contractions, described as irregular, nonrhythmical, and either painful or painless, can cause considerable confusion in the diagnosis of preterm labor. Not infrequently, women who deliver before term have uterine activity that is attributed to Braxton Hicks contractions, prompting an incorrect diagnosis of false labor. Because uterine contractions alone may be misleading, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (1997) proposed the following criteria to document preterm labor:

1. Contractions of four in 20 minutes or eight in 60 minutes plus progressive change in the cervix.
2. Cervical dilatation greater than 1 cm.
3. Cervical effacement of 80 percent or greater.

Management. Women with signs and symptoms of preterm labor with intact membranes are managed much the same as described above for those with preterm ruptured membranes. The cornerstone of treatment is to avoid delivery prior to 34 weeks, if possible. Drugs intended to abate or suppress preterm uterine contractions are subsequently discussed.

AMNIOCENTESIS TO DETECT INFECTION. In centers studying amniocentesis in the management of preterm labor, several tests have been used to diagnose intra-amnionic infection. Romero and colleagues (1993) evaluated the diagnostic value of amniotic fluid containing an elevated leukocyte count, a low glucose level, a high interleukin-6 concentration, or a positive Gram stain result in 120 women with preterm labor and intact fetal membranes. Women with positive amniotic fluid culture results were considered infected. These investigators found that a negative Gram stain reading was the most reliable test to exclude amniotic fluid bacteria; it had a specificity of 99 percent. A high interleukin-6 level was the most sensitive test for detection of amniotic fluids containing bacteria; it had a sensitivity of 82 percent. Other investigators have also found good correlation between amniotic fluid interleukin-6 or leukocyte levels and chorioamnionic infection (Andrews and colleagues, 1995; Yoon and associates, 1996). Despite these associations, it has not been shown that amniocentesis to diagnose infection is associated with improved pregnancy outcomes in women with or without membrane rupture (Feinstein and colleagues, 1986).

GLUCOCORTICOID THERAPY TO ENHANCE FETAL LUNG MATURATION. Corticosteroids accelerated lung maturation in preterm sheep fetuses, and Liggins and Howie (1972) evaluated this treatment in women. Glucocorticoid therapy was effective in lowering the incidence of respiratory distress and neonatal mortality if birth was delayed for at least 24 hours after *initiation* of betamethasone. Its effects persisted for up to 7 days after completion of steroid therapy.

The work by Liggins and Howie (1972) stimulated more than 20 years of fetal lung research. In 1995, a National Institutes of Health Consensus Development Panel recommended corticosteroids for fetal lung maturation in threatened preterm birth. There since has been the nearly universal acceptance and implementation of these recommendations (Leviton and associates, 1999). Evidence supporting the recommendations of this panel is reviewed in [Chapter 27](#) of the 21st edition of *Williams Obstetrics* (2001).

In a later meeting, the Consensus Development Panel concluded that data were insufficient to assess the effectiveness of corticosteroids in pregnancies complicated by hypertension, diabetes, multiple gestation, fetal growth restriction, and fetal

hydrops. It concluded, however, that it was reasonable to administer corticosteroids for these complications (Bloom and Leveno, 2003). However, it further determined that data were insufficient to comment on the benefits or risks of repeated treatments. Jobe and Soll (2004) recently suggested that studies to investigate if betamethasone is superior to dexamethasone be performed. Indeed, Spinillo and colleagues (2004) reported that fetal exposure to multiple maternal doses of dexamethasone was associated with a significantly increased risk of leukomalacia and with the overall occurrence of two-year infant neurodevelopmental abnormalities compared with infants exposed to betamethasone.

Subsequent investigators found that corticosteroid treatment was not beneficial for women with preterm prematurely ruptured membranes who were delivered of low- or very-low-birthweight neonates (Chapman and colleagues, 1996; Hershkovitz and colleagues, 2001). Conversely, Thomas and associates (2001) reported that a single course of betamethasone administered to women with preterm ruptured membranes was associated with a significantly reduced incidence of periventricular leukomalacia.

ADVERSE EFFECTS OF CORTICOSTEROIDS. There is controversy surrounding additional effectiveness and safety of weekly glucocorticoid administration. Initially, neither perinatal benefits nor adverse maternal and newborn effects had been associated with multiple- as opposed to single-course therapy (Lee, 2004; Lopez, 2001; Ogunyemi, 2001; Pschirrer, 2001; and all their colleagues). Long-term follow-up studies in the 1970s showed no adverse neurodevelopmental outcomes of exposed children up to 12 years (National Institutes of Health Consensus Development Panel, 1995).

Adverse immediate and long-term effects, however, have now been reported with multiple-course treatment. Investigators have found that early-onset neonatal sepsis, chorioamnionitis, and neonatal death are associated with multiple courses of betamethasone therapy (Lee and associates, 2004; Vermillion and colleagues, 2000).

A randomized NICHD Maternal-Fetal Medicine Units Network trial of single versus weekly courses of betamethasone showed less morbidity in newborns given weekly doses who were delivered before 32 weeks (Wapner and colleagues, 2003). However, this trial was discontinued because repetitive courses adversely impacted both birthweight and the incidence of fetal growth restriction. Esplin and colleagues (2000) compared development of 429 low-birthweight neonates exposed to multiple courses of corticosteroids with that of neonates either exposed to a single course or to no exposure. The investigators found no benefits for repeated doses, however, multiple courses were independently and significantly associated with abnormal psychomotor development. Thorp and co-workers (2001) described a significant reduction in head circumference in newborns exposed to multiple courses of steroids. Bloom and colleagues (2001a) analyzed births at Parkland Hospital and found that dexamethasone-exposed newborns had significantly lower birthweight compared with that of unexposed neonates. Similarly, Mercer and associates (2001) reported a dose-dependent decrease in birthweight and length in neonates exposed to multiple courses. There were 19 growth-restricted fetuses and absent or reversed end-diastolic umbilical artery flow. Maternal betamethasone administration was followed by worsening of these indices in nine fetuses; two died and two had severe acidosis (Simchen and colleagues, 2004). The American College of Obstetricians and Gynecologists (2001) and National Institutes of Health Consensus Panel (2000) subsequently expressed concern about possible adverse fetal and maternal effects of weekly treatment. The former recommended that following the initial therapy, repeated doses after 1 week should be given only when the threat of preterm delivery recurred. The latter recommended that repeated courses of corticosteroids, *including rescue therapy*, should be used only in clinical trials.

Short-term maternal adverse effects include pulmonary edema, infection, and more difficult glucose control in diabetic women. No long-term adverse maternal effects have been reported.

THYROTROPIN-RELEASING HORMONE FOR FETAL LUNG MATURATION. Tri-iodothyronine enhances surfactant synthesis. Knight and colleagues (1994) found that an intravenously administered 400- μ g dose of thyrotropin-releasing hormone, given in combination with betamethasone, further augmented lung maturation compared with betamethasone alone. These findings have subsequently been nullified by studies in which women with preterm labor were assigned to receive thyrotropin-releasing hormone plus corticosteroids or to take corticosteroids alone. Investigators found that the incidence of neonatal lung disease was unchanged in women who received thyrotropin-releasing hormone (Ballard and associates, 1998; Crowther and colleagues, 1995). Thus, administration of thyrotropin-releasing hormone is not recommended.

ANTENATAL PHENOBARBITAL AND VITAMIN K. Several investigators have suggested that phenobarbital and vitamin K given to pregnant women may reduce neonatal intracranial hemorrhage. Thorp and colleagues (1995) randomly selected 272 women at risk for preterm birth to receive placebo or phenobarbital and vitamin K. Therapy did not reduce the frequency or severity of intracranial hemorrhage. In a follow-up study, Thorp and colleagues (2003) reported that phenobarbital exposure did not affect intelligence or achievement scores in 291 children tested at 7 years of age. The combination of phenobarbital and vitamin K is not recommended for the prevention of neonatal intraventricular hemorrhage.

Interventions to Delay Preterm Birth

ANTIMICROBIALS. As with preterm ruptured membranes, antimicrobials have been given to arrest preterm labor. Results have been disappointing. A Cochrane meta-analysis by King and Flenady (2000) of 10 randomized trials found no difference in the rates of newborn respiratory distress syndrome or of sepsis between placebo- and antimicrobial-treated groups, but did find an increase in perinatal morbidity in the antimicrobial-treated group. Kenyon and colleagues (2001b) for the ORACLE Collaborative Group, studied 6295 women in spontaneous preterm labor with intact membranes and without evidence of clinical infection. Women were randomly assigned to antimicrobial or placebo therapy. The primary outcomes of neonatal death, chronic lung disease, and major cerebral abnormality were similar in both groups. In his review, Goldenberg (2002) also concluded that antimicrobial treatment of women with preterm labor for the sole purpose of preventing delivery is generally not recommended.

EMERGENCY CERCLAGE. Several researchers support the concept that cervical incompetence and preterm labor are not distinct entities but rather part of a spectrum leading to preterm delivery. Consequently, investigators have evaluated the role of cerclage in the treatment and prevention of preterm birth. Harger (1983) concluded that if cervical incompetence is recognized in threatened preterm labor, emergency cerclage can be attempted, albeit with an appreciable risk of infection and pregnancy loss. Althuisius and associates (2002) randomly assigned 23 women with cervical incompetence prior to 27 weeks to bed rest, with or without emergency McDonald cerclage. Delivery delay was significantly greater in the cerclage group compared with bed rest alone (54 versus 24 days). Terkildsen and associates (2003) studied 116 women who underwent

second-trimester emergency cerclage. Nulliparity, membranes extending beyond the external cervical os, and cerclage prior to 22 weeks were associated with a significantly decreased chance of pregnancy continuation to 28 weeks or beyond. Cerclage is discussed further in [Chapter 9](#), p 236.

TREATMENT FOR BACTERIAL VAGINOSIS. Bacterial vaginosis is associated with excess rates of preterm birth (see p. 862). A number of studies have evaluated the effects of various antimicrobials on its eradication. Metronidazole has been evaluated most extensively. Oral metronidazole was found to resolve bacterial vaginosis for at least 10 weeks in 78 percent of treated pregnant women compared with spontaneous resolution in only 37 percent assigned to placebo (Klebanoff and colleagues, 2004a,b).

Clinical studies done to evaluate treatment are conflicting (Leitich and associates, 2003b). Neither the study by McDonald and co-workers (1997) nor the NICHD Maternal-Fetal Medicine Units Network study by Carey and colleagues (2000) found any perinatal benefits from metronidazole treatment. Conversely, in studies of women with prior preterm birth, Hauth and associates (1995, 2001a) found that the incidence of preterm birth was lower in women treated with either metronidazole plus erythromycin or metronidazole plus azithromycin compared with placebo.

Most randomized trials show that intravaginal clindamycin cream used to treat bacterial vaginosis does not prevent preterm birth (Joeseof, 1995; Kekki, 2001; Kurkinen-Raty, 2000; McGregor, 1994, and all their colleagues). Studies in which earlier treatment was initiated are more promising. Ugwumadu and associates (2003) randomly selected 494 women with bacterial vaginosis to receive 300-mg oral clindamycin or placebo twice daily for 5 days. The clindamycin group had fewer pregnancy losses between 13 and 24 weeks and fewer spontaneous preterm births. Ugwumadu and colleagues (2004) reported that prior to 20 weeks oral clindamycin eradicated bacterial vaginosis and intermediate flora in 90 percent of women compared with spontaneous resolution in 31 percent. Lamont and colleagues (2003) also reported that preterm birth was significantly reduced in women treated with clindamycin vaginal cream before 20 weeks (from 10 to 4 percent). Further studies are needed to confirm that treatment for bacterial vaginosis with either oral or vaginal clindamycin is of benefit.

Ralph and colleagues (1999) detected bacterial vaginosis in 190 of 771 women at the time of in vitro fertilization. Women with bacterial vaginosis had a similar rate of conception but an increased risk of first-trimester loss compared with that of uninfected women.

Inhibition of Preterm Labor. Although a number of drugs and other interventions have been used to prevent or inhibit preterm labor, none has been shown to be completely effective. Because of these uncertainties, the American College of Obstetricians and Gynecologists (1998b) has recommended that tocolysis be *considered* when there are regular uterine contractions plus documented cervical change or appreciable dilatation and effacement.

BED REST. The efficacy of bed rest either in the hospital or at home to prevent preterm labor was reviewed by Goldenberg and colleagues (1994), who found no conclusive evidence that either was helpful. Kovacevich and associates (2000) reported that bed rest for 3 days or more increased thromboembolic complications to 16 per 1000 women compared with only 1 per 1000 with normal ambulation.

HYDRATION AND SEDATION. Helfgott and associates (1994) compared hydration and sedation with bed rest in a randomized trial of 119 women with threatened preterm labor. Women randomly selected to receive 500 mL of crystalloid over 30 minutes and 8 to 12 mg of intramuscular morphine sulfate had outcomes similar to those with bed rest. Although women with preterm contractions treated with 0.25-mg subcutaneous terbutaline may have contractions that cease more quickly and may be discharged significantly earlier compared with women not treated, pregnancy outcomes are similar (Guinn and associates, 1997).

BETA-ADRENERGIC RECEPTOR AGONISTS. A number of compounds react with β -adrenergic receptors to reduce intracellular ionized calcium and prevent activation of myometrial contractile proteins (see [Chap. 6](#), p. 162). In the United States, ritodrine and terbutaline have been used in obstetrics, but only ritodrine had been approved for preterm labor by the U.S. Food and Drug Administration.

Ritodrine. In a multicenter trial, neonates whose mothers were treated with ritodrine for presumed preterm labor had less mortality and respiratory distress, and they achieved a gestational age of 36 weeks or a birthweight of 2500 g more often than did those of untreated mothers (Merkatz and colleagues, 1980). In a randomized trial at Parkland Hospital, Leveno and associates (1986b) allocated 106 women between 24 and 33 weeks to receive either intravenous ritodrine or no tocolysis. Although drug treatment delayed delivery for 24 hours, there were no other benefits. The transient tocolytic effects of ritodrine and its ultimate failure to arrest labor may be due to β -adrenergic receptor desensitization (Hausdorff and co-workers, 1990).

The infusion of β -adrenergic agonists has resulted in frequent and at times, serious and fatal side effects ([Table 36-7](#)). Pulmonary edema is of special concern, and its contribution to morbidity is discussed in [Chapter 42](#) (see p. 990). Tocolysis was the third most common cause of acute respiratory distress and death in pregnant women during a 14-year period in Mississippi (Perry and associates, 1996). **The cause of pulmonary edema is multifactorial, and risk factors include tocolytic therapy with β -adrenergic receptor agonists, multifetal gestation, concurrent glucocorticoid therapy, tocolysis for more than 24 hours, and large intravenous crystalloid volume infusion.** Because β -agonists cause retention of sodium and water, with time (usually 24 to 48 hours), they can lead to volume overload (Hankins and colleagues, 1988). The drugs have been implicated as a cause of increased capillary permeability, disturbance of cardiac rhythm, and myocardial ischemia. Maternal sepsis appreciably increases this risk (see [Chap. 42](#), p. 993).

Schiff and colleagues (1993) challenged the efficacy of oral ritodrine on pharmacokinetic grounds, and its manufacturer discontinued distribution of tablets in 1995. According to the *Federal Register*, ritodrine was withdrawn voluntarily in 2003 by its manufacturer and is not available in the United States.

Terbutaline. This β -agonist is commonly used to forestall preterm labor. Like ritodrine, it can cause pulmonary edema (Angel and associates, 1988). Long-term low-dose terbutaline given by subcutaneous pump in nine pregnancies was described by Lam and colleagues (1988). The Tokos Corporation promptly marketed this approach, and between 1987 and 1993, these pumps were used in nearly 25,000 women with suspected preterm labor (Perry and colleagues, 1995). Adverse reports concerning terbutaline pumps describe a sudden maternal death and a newborn with myocardial necrosis after the mother

used the pump for 12 weeks (Fletcher and colleagues, 1991; Hudgens and Conradi, 1993).

Two randomized trials found no benefit for terbutaline pump therapy. In one, Wenstrom and colleagues (1997) randomly assigned 42 women with preterm labor to a terbutaline pump, to a saline pump, or to oral terbutaline. In the other, Guinn and associates (1998) randomly treated 52 women with terbutaline or with saline pump therapy. Terbutaline did not significantly prolong pregnancy, prevent preterm delivery, or improve neonatal outcomes in either of these studies.

Oral terbutaline therapy to prevent preterm delivery has not been effective (How and associates, 1995; Parilla and co-workers, 1993). In a double-blind trial, Lewis and colleagues (1996) studied 203 women with arrested preterm labor at 24 to 34 weeks. They were randomly assigned to receive 5-mg terbutaline tablets or placebo every 4 hours. Delivery rates at one week were similar in both groups, as was median latency, mean gestational age at delivery, and the incidence of recurrent preterm labor.

OVERVIEW OF BETA-ADRENERGIC DRUGS TO INHIBIT PRETERM LABOR. Analyses of *parenteral* β -agonists to prevent preterm birth have confirmed a delay of delivery for at least 48 hours (Canadian Preterm Labor Investigators Group, 1992). Unfortunately, this delay has not proven to be beneficial. Macones and colleagues (1995) used meta-analysis to assess the efficacy of *oral* β -agonist therapy and found no benefits. Keirse (1995b) suggests that this brief delay may facilitate maternal transport or effect fetal lung maturation with glucocorticoids. Although this is intriguing, no data support this viewpoint.

MAGNESIUM SULFATE. Ionic magnesium in a sufficiently high concentration can alter myometrial contractility. Its role is presumably that of a calcium antagonist. Clinical observations are that magnesium in pharmacological doses may inhibit labor. Steer and Petrie (1977) concluded that intravenously administered magnesium sulfate — a 4-g loading dose followed by a continuous infusion of 2 g/hr — usually arrests labor. In a retrospective study, Elliott (1983) found tocolysis with magnesium sulfate to be 87-percent effective, an extraordinarily high success rate.

There have been only two randomized controlled studies of tocolysis with magnesium sulfate. Cotton and associates (1984) compared magnesium sulfate, ritodrine, and placebo in 54 women in preterm labor. They identified few differences in outcomes. Cox and associates (1990) randomly assigned 156 women to receive magnesium sulfate or normal saline infusions. These women were at appreciable risk, and few reached 33 weeks. Magnesium-treated women and their fetuses had identical outcomes as those given placebo. Because of these findings, this method of tocolysis was abandoned at Parkland Hospital.

Women given magnesium sulfate must be monitored closely for evidence of hypermagnesemia. The pharmacology and toxicology of magnesium are considered in more detail in [Chapter 34](#), p. 789.

Neonatal Effects of Magnesium. Very-low-birthweight neonates (less than 1500 g) whose mothers were treated with magnesium sulfate for preterm labor or preeclampsia had a reduced incidence of cerebral palsy at 3 years (Grether and associates, 2000; Nelson and Grether, 1995). Although it is tempting to link these as cause and effect, in a study from England, where magnesium is not generally used for preeclampsia, Murphy and colleagues (1995) observed that severe preeclampsia or cesarean delivery alone was protective against cerebral palsy. Kimberlin and colleagues (1998) concluded that tocolysis with magnesium was not associated with improved outcomes in 308 newborns with birthweights of less than 1000 g. An ongoing NICHD Maternal-Fetal Medicine Units Network trial was designed to explore any neonatal beneficial effects of antenatal magnesium sulfate therapy (BEAM trial).

Crowther and colleagues (2003) recently reported results from the Australian Collaborative Trial of Magnesium Sulfate. They described outcomes from over 1050 women who gave birth before 30 weeks and who were randomly assigned to receive either intravenous magnesium sulfate or a normal saline placebo. Total neonatal mortality and cerebral palsy at 2 years of age were less frequent in magnesium-exposed infants, albeit with nonsignificant differences. A significant finding was that fewer survivors exposed to magnesium had substantial motor dysfunction at 2 years of age compared with those in the control group (3.4 versus 6.6 percent). The relationships also are considered in [Chapter 29](#) (see p. 658).

PROSTAGLANDIN INHIBITORS. Drugs that inhibit prostaglandins have been of considerable interest because prostaglandins are intimately involved in contractions of normal labor (see [Chap. 6](#), p. 166). Antagonists act by inhibiting prostaglandin synthesis or by blocking their action on target organs. A group of enzymes collectively termed *prostaglandin synthase* is responsible for the conversion of free arachidonic acid to prostaglandins. A number of drugs block this system, including acetylsalicylate and indomethacin.

Indomethacin was first used as a tocolytic for 50 women by Zuckerman and associates (1974). Studies followed that reported the efficacy of indomethacin in halting contractions and delaying preterm birth (Muench and colleagues, 2003; Niebyl and associates, 1980). Morales and co-workers (1989, 1993), however, compared indomethacin with either ritodrine or magnesium sulfate and found no difference in their efficacy to forestall preterm delivery.

Indomethacin is administered orally or rectally. A dose of 50 to 100 mg is followed by a total 24-hour dose not greater than 200 mg. Serum concentrations usually peak 1 to 2 hours after oral administration, whereas levels after rectal administration peak slightly sooner. Most studies have limited indomethacin use to 24 to 48 hours because of concerns about oligohydramnios, which can develop with these doses. If amniotic fluid is monitored, oligohydramnios can be detected early, and it is reversible with discontinuation of indomethacin.

Case-control studies have been performed to assess neonatal effects of indomethacin exposure given for preterm labor. In a study of neonates born before 30 weeks, Norton and colleagues (1993) identified necrotizing enterocolitis in 30 percent of 37 indomethacin-exposed newborns compared with 8 percent of 37 control newborns. Higher incidences of intraventricular hemorrhage and patent ductus arteriosus were also documented in the indomethacin group. The impact of treatment duration and its timing in relation to delivery were not reported. In contrast, several investigators have challenged the association between indomethacin exposure and necrotizing enterocolitis (Muench and co-workers, 2001; Parilla and colleagues, 2000). Finally, Gardner and associates (1996) and Abbasi and co-workers (2003) showed no link between indomethacin use and intraventricular hemorrhage, patent ductus arteriosus, sepsis, necrotizing enterocolitis, or neonatal death.

Schmidt and colleagues (2001) followed 574 newborns who were randomly assigned to receive either indomethacin or placebo to prevent pulmonary hypertension from patent ductus arteriosus. The infants, who weighed 500 to 1000 g, were followed to a corrected age of 18 months. Those given indomethacin had a significantly *reduced* incidence of both patent ductus as well as

severe intraventricular hemorrhage. Survival without impairment, however, was similar in both groups. Peck and Lutheran (2003) reported that indomethacin therapy for 7 or more days prior to 33 weeks does not increase the risk of neonatal or childhood medical problems.

CALCIUM CHANNEL BLOCKERS. Myometrial activity is directly related to cytoplasmic free calcium, and a reduction in its concentration inhibits contraction. Calcium channel blockers act to inhibit, by a variety of mechanisms, the entry of calcium through channels in the cell membrane. They were developed to treat hypertension. However, their use in the arrest of preterm labor has been the subject of research since the late 1970s.

Using the Cochrane Database, Keirse (1995a) compared nifedipine and β -agonists and concluded that although nifedipine treatment reduced births of neonates of less than 2500 g, significantly more of these were admitted for intensive care. Other investigators have also concluded that calcium channel blockers, especially nifedipine, are safer and more effective tocolytic agents than beta-mimetics (King and colleagues, 2003; Papatsonis and colleagues, 1997). Oral nifedipine, however, does not significantly prolong pregnancy in women initially treated with intravenous magnesium sulfate for preterm labor (Carr and colleagues, 1999).

Nifedipine-induced decreased vascular resistance can lead to hypotension and decreased uteroplacental perfusion. Parisi and colleagues (1986) described hypercapnia, acidosis, and hypoxemia in fetuses of hypertensive ewes given nifedipine. Similarly, Lirette and associates (1987) observed a fall in uteroplacental blood flow in pregnant rabbits. Childress and Katz (1994) and Papatsonis and colleagues (1997), however, did not find these adverse fetal effects.

The combination of nifedipine with magnesium for tocolysis is potentially dangerous. Ben-Ami and co-workers (1994) and Kurtzman and associates (1993) reported that nifedipine enhances neuromuscular blocking effects of magnesium that can interfere with pulmonary and cardiac function. Smith and colleagues (2000) concluded that nifedipine is effective for severe gestational hypertension or preterm labor but that randomized trials are needed.

ATOSIBAN. This nonapeptide oxytocin analogue is a competitive antagonist of oxytocin-induced contractions. Goodwin and colleagues (1995) described its pharmacokinetics in pregnant women. In randomized clinical trials, however, atosiban failed to improve relevant neonatal outcomes and was linked with significant neonatal morbidity (Moutquin and colleagues, 2000; Romero and associates, 2000). U.S. Food and Drug Administration approval for atosiban use to arrest preterm labor was denied because of concerns regarding efficacy and fetal-newborn safety.

NITRIC OXIDE DONORS. These potent smooth muscle relaxants affect the vasculature, gut, and uterus. In randomized clinical trials, nitroglycerin administered orally, transdermally, or intravenously, was not effective or showed no superiority to other tocolytics. In addition, maternal hypotension was a common side effect (Buhimschi, 2002; Clavin, 1996; El-Sayed, 1999; Lees, 1999, and all their colleagues).

Summary of Tocolytic Use for Preterm Labor. In many women, tocolytics stop contractions temporarily but rarely prevent preterm birth. In a meta-analysis of tocolytic therapy, Gyetvai and colleagues (1999) concluded that although delivery may be delayed long enough for administration of corticosteroids, treatment does not result in any improved perinatal outcomes. Berkman and colleagues (2003) reviewed 60 reports and concluded that tocolytic therapy can prolong gestation, but that beta-mimetics were not better than other drugs and pose potential maternal danger. They also concluded that there were no benefits of maintenance tocolytic therapy.

As a general rule, if tocolytics are given, they should be given concomitantly with corticosteroids. The gestational age range for their use is debated, but because corticosteroids are not generally used after 33 weeks, and because the perinatal outcomes in preterm neonates are generally good after this time, most practitioners do not recommend use of tocolytics at or after 34 weeks (Goldenberg, 2002).

Recommended Management of Preterm Labor. The following considerations should be given to women in preterm labor:

1. Confirmation of preterm labor as detailed on p. 867.
2. For pregnancies less than 34 weeks in women with no maternal or fetal indications for delivery, close observation with monitoring of uterine contractions and fetal heart rate is appropriate, and serial examinations are done to assess cervical changes.
3. For pregnancies less than 34 weeks, glucocorticoids are given for enhancement of fetal lung maturation.
4. For pregnancies less than 34 weeks in women who are not in advanced labor, some practitioners believe it is reasonable to attempt inhibition of contractions to delay delivery while the women are given glucocorticoid therapy and group B streptococcal prophylaxis. Although tocolytic drugs are not used at Parkland Hospital, they are given at The University of Alabama at Birmingham Hospital.
5. For pregnancies at 34 weeks or beyond, women with preterm labor are monitored for labor progression and fetal well-being.
6. For active labor, an antimicrobial is given for prevention of neonatal group B streptococcal infection.

Intrapartum Management. In general, the more immature the fetus, the greater the risks of labor and delivery.

LABOR. Whether labor is induced or spontaneous, abnormalities of fetal heart rate and uterine contractions should be sought. We prefer continuous electronic monitoring. Fetal tachycardia, especially with ruptured membranes, is suggestive of sepsis. There is some evidence that intrapartum acidemia may intensify some of the neonatal complications usually attributed to preterm delivery. For example, Low and colleagues (1995) observed that intrapartum acidosis — umbilical artery blood pH less than 7.0 — had an important role in neonatal complications. Similarly, Kimberlin and colleagues (1996) found that increasing umbilical artery blood acidemia was related to more severe respiratory disease in preterm neonates. Despite this, no effects were found in short-term neurological outcomes that included intracranial hemorrhages.

PREVENTION OF NEONATAL GROUP B STREPTOCOCCAL INFECTIONS. As discussed in [Chapter 58](#) (see p. 1284), group B streptococcal infections are common and dangerous in the preterm neonate. Since 1996, the Centers for Disease Control and Prevention, along with the American College of Obstetricians and Gynecologists, recommend either penicillin G or ampicillin intravenously every 6 hours until delivery for women in preterm labor.

DELIVERY. In the absence of a relaxed vaginal outlet, an episiotomy for delivery may be necessary once the fetal head reaches the perineum. Perinatal outcome data do not support routine forceps delivery to protect the "fragile preterm fetal head." Staff proficient in resuscitative techniques commensurate with the gestational age of the newborn and fully oriented to any specific problems should be present at delivery. Principles of resuscitation described in [Chapter 28](#) are applicable. The importance of the availability of specialized personnel and facilities in the care of preterm newborns is underscored by the improved survival of these neonates when they are delivered in tertiary care centers (American College of Obstetricians and Gynecologists, 2002; Powell and colleagues, 1995).

PREVENTION OF NEONATAL INTRACRANIAL HEMORRHAGE. Preterm newborns frequently have germinal matrix bleeding that can extend to more serious intraventricular hemorrhage (see [Chap. 29](#), p. 652). It was hypothesized that cesarean delivery to obviate trauma from labor and vaginal delivery might prevent these complications. This has not been validated by most subsequent studies. Malloy and colleagues (1991) analyzed 1765 newborns with birthweights less than 1500 g and found that cesarean delivery did not lower the risk of mortality or intracranial hemorrhage. Anderson and colleagues (1988), however, made an interesting observation regarding the role of cesarean delivery in the prevention of neonatal intracranial hemorrhages. These hemorrhages related to whether or not the fetus had been subjected to the active phase of labor, defined as the interval before 5 cm cervical dilatation. They emphasized that avoidance of active-phase labor is impossible in most preterm births because the route of delivery cannot be decided until the active phase labor is firmly established.

37. Postterm Pregnancy

INTRODUCTION

The terms *postterm*, *prolonged*, *postdates*, and *postmature* are often loosely used interchangeably to signify pregnancies that have exceeded a duration considered to be the upper limit of normal. *Postmature* should be used to describe the infant with recognizable clinical features indicating a pathologically prolonged pregnancy. *Postdates* probably should be abandoned, because the real issue in many postterm pregnancies is "post-what dates?" Therefore, *postterm* or *prolonged pregnancy* is the preferred expression for an extended pregnancy, and "postmature" is reserved for a specific clinical fetal syndrome. Because few infants from prolonged pregnancies have stigmata of the postmaturity syndrome, use of this term can falsely imply a pathologically prolonged pregnancy.

The standard internationally recommended definition of prolonged pregnancy, endorsed by the American College of Obstetricians and Gynecologists (1997), is 42 completed weeks (294 days) or more from the first day of the last menstrual period. It is important to emphasize the phrase "42 completed weeks." Pregnancies between 41 weeks 1 day and 41 weeks 6 days, although in the 42nd week, do not complete 42 weeks until the seventh day has elapsed. Thus, technically speaking, prolonged pregnancy could begin either on day 294 or on day 295 following the onset of the last menses. Which is it? Day 294 or 295? We cannot resolve this question, and emphasize this dilemma only to ensure that litigators and others understand that some imprecision is inevitable when attempting to define prolonged pregnancy. Amersi and Grimes (1998) have cautioned against use of ordinal numbers such as "42nd week" because of their imprecision. For example, "42nd week" refers to 41 weeks and 1 through 6 days, whereas the cardinal number "42 weeks" refers to precisely 42 completed weeks.

ESTIMATED GESTATIONAL AGE USING MENSTRUAL DATES

The definition of postterm pregnancy as one that persists for 42 weeks or more from the onset of a menstrual period assumes that the last menses was followed by ovulation 2 weeks later. This said, some pregnancies may not actually be postterm, but rather are the result of an error in estimation of gestational age because of faulty recall of the dates of menstruation or delayed ovulation. Thus, there are two categories of pregnancies that reach 42 completed weeks:

1. Those truly 40 weeks past conception.
2. Those of less advanced gestation due to inaccurate estimate of gestational age.

Munster and associates (1992) described a high incidence of large variations in menstrual cycles in normal women. Boyce and associates (1976) studied 317 French women with conceptional basal body temperature profiles and found that 70 percent who completed 42 postmenstrual weeks had less advanced gestations based on ovulation dates. Blondel and colleagues (2002) analyzed postterm pregnancy rates according to six algorithms for gestational age estimates based on either the last menstrual period, ultrasound at 16 to 18 weeks, or both. This Canadian study included 44,623 women giving birth between 1978 and 1996 at the Royal Victoria Hospital in Montreal. The proportion of births at 42 weeks or longer was 6.4 percent when based on the last menstrual period alone and 1.9 percent when based on ultrasound alone. This raises the possibility that the menstrual dates are frequently inaccurate in predicting postterm pregnancy. The recent study of Bennett and associates (2004) confirmed this. Because a few women ovulate earlier than expected, it is possible that 40 completed postconceptional weeks could be achieved after 41 weeks of amenorrhea.

Therefore, most pregnancies that are reliably 42 completed weeks beyond the last menses probably are not biologically prolonged. Conversely, a few that are not yet 42 weeks might be postterm. These variations in menstrual cycle likely explain, at least partially, why a relatively small proportion of fetuses delivered postterm have evidence of *postmaturity*. Because there is no method to identify pregnancies that are truly prolonged, all pregnancies judged to be 42 completed weeks should be managed as if abnormally prolonged.

INCIDENCE

As shown in [Figure 37-1](#), approximately 7 percent of 4 million infants born in the United States during 2001 were estimated to have been delivered at 42 weeks or more. In comparison, 12 percent of live births were preterm, defined as 36 weeks or less.

Contradictory results have been found concerning the significance of a variety of maternal demographic factors, such as parity, prior postterm birth, socioeconomic class, and age. One interesting feature — the tendency for some mothers to have repeated postterm births — suggests that some prolonged pregnancies are biologically determined. In an analysis of 27,677 births to Norwegian women, the incidence of a subsequent postterm birth increased from 10 to 27 percent if the first birth was postterm. This was increased to 39 percent if there had been two previous, successive postterm deliveries (Bakketeig and Bergsjø, 1991). Mogren and colleagues (1999) reported that prolonged pregnancy also recurred across generations in Swedish women. When mother and daughter had had a prolonged pregnancy, the risk for a daughter's subsequent postterm pregnancy was increased two- to threefold. In another Swedish study, Laursen and associates (2004) found that maternal, but not paternal, genes influenced prolonged pregnancy. Fetal-placental factors that have been reported as predisposing to postterm pregnancy include anencephaly, adrenal hypoplasia, and X-linked placental sulfatase deficiency (MacDonald and Siiteri, 1965; Naeye, 1978; Rabe and colleagues, 1983). These cause a lack of the usually high estrogen levels of normal pregnancy (see [Chap. 3](#), p. 77). Finally, reduced cervical nitric oxide release may be a factor (Vaisanen-Tommiska and co-workers, 2004).

Figure 37-1. Gestational age at delivery of 4 million live births in the United States during 2001. (Adapted from Martin and colleagues, 2002.)

PERINATAL MORTALITY

The historical basis for the concept of an upper limit of human pregnancy duration was the observation that perinatal mortality increased after the expected due date was passed. This is best seen when perinatal mortality is analyzed from times before widespread use of interventions for pregnancies exceeding 42 weeks. In two large Swedish studies shown in [Figure 37-2](#), after reaching a nadir at 39 to 40 weeks, perinatal mortality increased as pregnancy exceeded 41 weeks. Lucas and co-workers (1965) compared perinatal outcomes in 6624 postterm pregnancies with those of almost 60,000 singleton pregnancies delivered between 38 and 41 weeks. All components of perinatal mortality — antepartum, intrapartum, and neonatal deaths — were increased at 42 weeks and beyond. The most significant increases occurred intrapartum. The major causes of death included pregnancy hypertension, prolonged labor with cephalopelvic disproportion, "unexplained anoxia," and malformations. Similar outcomes were reported by Olesen and colleagues (2003) in their analysis of 78,022 women with postterm pregnancies delivered before routine labor induction was adopted in Denmark.

Alexander and colleagues (2000a) reviewed 56,317 consecutive singleton pregnancies delivered at 40 or more weeks between 1988 and 1998 at Parkland Hospital. As shown in [Table 37-1](#), labor was induced in 35 percent of pregnancies reaching 42 weeks. The rate of cesarean delivery for dystocia and fetal distress was significantly increased at 42 weeks compared with that of earlier deliveries. More infants were admitted to intensive care in postterm pregnancies. The incidence of neonatal seizures and deaths doubled at 42 weeks. Caughey and Musci (2004) reported similar outcomes in 45,673 pregnancies.

Smith (2001) has challenged analyses such as these because the population at risk for perinatal mortality in a given week consists of all ongoing pregnancies rather than just the births in a given week. [Figure 37-3](#) shows perinatal mortality rates calculated using only births in a given week of gestation from 37 to 43 completed weeks compared with the cumulative probability (perinatal index) of death when all ongoing pregnancies are included in the denominator. Smith found that delivery at 38 weeks was associated with the lowest risk of perinatal death.

Figure 37-2. Perinatal mortality in late pregnancy according to gestational age in Sweden of all births during 1943-1952 compared with those during 1977-1978. The logarithmic scale is used for convenience in depiction. (Adapted from Bakketeig and Bergsjö, 1991, and Lindell, 1956.)

Figure 37-3. Perinatal risk index (○) and perinatal mortality rate (●) related to births between 37 and 43 weeks of gestation in Scotland, 1985 through 1996, expressed as deaths per 1000 births. The perinatal risk index is the cumulative probability of perinatal death multiplied by 1000. The perinatal mortality rate is the number of perinatal deaths with delivery in a given gestational week divided by the total number of births in that week multiplied by 1000. (Modified from Smith, 2001, with permission.)

PATHOPHYSIOLOGY

Clifford (1954) described a recognizable clinical syndrome that did much to dispel the prevailing obstetrical opinion that prolonged human pregnancy did not exist (Calkins, 1948). Infants, either live or stillborn, demonstrating these clinical characteristics, are now diagnosed to be pathologically *postmature*. Many of the postmature infants described by Clifford died, and many were seriously ill due to birth asphyxia and meconium aspiration. Several survivors were brain damaged. Interestingly, Ballantyne (1902) reported this same postmature infant more than 50 years before Clifford did.

POSTMATURITY SYNDROME. The postmature infant presents a unique and characteristic appearance ([Fig. 37-4](#)). Features include wrinkled, patchy, peeling skin; a long, thin body suggesting wasting; and advanced maturity because the infant is open-eyed, unusually alert, and appears old and worried-looking. Skin wrinkling can be particularly prominent on the palms and soles. The nails are typically quite long. Most such postmature infants are not growth restricted because their birthweight seldom falls below the 10th percentile for gestational age. Severe growth restriction, however, which logically must have preceded completion of 42 weeks, may occur.

The incidence of postmaturity syndrome in infants at 41, 42, or 43 weeks, respectively, has not been conclusively determined. In one of the rare contemporary reports that chronicle postmaturity, Shime and colleagues (1984) found this syndrome in about 10 percent of pregnancies between 41 and 43 weeks. The incidence increased to 33 percent at 44 weeks. Associated oligohydramnios substantially increases the likelihood of postmaturity. Trimmer and colleagues (1990) diagnosed oligohydramnios when the ultrasonic maximum vertical amniotic fluid pocket measured 1 cm or less at 42 weeks and 88 percent of the infants were postmature.

Figure 37-4. Postmature infant delivered at 43 weeks of gestation. Thick, viscous meconium coated the desquamating skin. Note the long, thin appearance and wrinkling of the palms of the hands.

PLACENTAL DYSFUNCTION. Clifford (1954) proposed that the skin changes of postmaturity were due to loss of the protective effects of vernix caseosa. He also attributed the postmaturity syndrome to placental senescence, although he did not find placental degeneration histologically. Still, the concept that postmaturity is due to placental insufficiency has persisted despite an absence of morphological or significant quantitative findings (Larsen and co-workers, 1995; Rushton, 1991). Of interest, Smith and Baker (1999) reported that placental apoptosis — programmed cell death — was significantly increased at 41 to 42 completed weeks compared with that at 36 to 39 weeks. The clinical significance of such apoptosis is unclear at this time.

Jazayeri and co-workers (1998) investigated cord erythropoietin levels in 124 appropriately grown newborns delivered from 37 to 43 weeks. They sought to assess whether fetal oxygenation was compromised due to placental aging in postterm pregnancies. Decreased partial oxygen pressure is the only known stimulator of erythropoietin. Each woman studied had an uncomplicated labor and delivery. Cord erythropoietin levels were significantly increased in pregnancies reaching 41 weeks or more. Although Apgar scores and umbilical cord blood gases were normal in these infants, the investigators concluded that there was decreased fetal oxygenation in some postterm gestations.

The postterm fetus may continue to gain weight and thus be an unusually large infant at birth. This at least suggests that placental function is not compromised. Indeed, continued fetal growth, although at a slower rate, is characteristic between 38 and 42 weeks (Fig. 37-5). Nahum and colleagues (1995) confirmed that fetal growth continues until at least 42 weeks.

Figure 37-5. Mean daily fetal growth during previous week of gestation. (From Jazayeri and co-workers, 1998, with permission.)

FETAL DISTRESS AND OLIGOHYDRAMNIOS. The principal reasons for increased risks to postterm fetuses were described by Leveno and associates (1984). They reported that both antepartum fetal jeopardy and intrapartum fetal distress were the consequence of cord compression associated with oligohydramnios. In their analysis of 727 postterm pregnancies, intrapartum fetal distress detected with electronic monitoring was not associated with late decelerations characteristic of uteroplacental insufficiency. Instead, one or more prolonged decelerations such as shown in Figure 37-6 preceded three fourths of emergency cesarean deliveries for fetal jeopardy. In all but two cases, there were also variable decelerations (Fig. 37-7). Another common fetal heart rate pattern, although not ominous by itself, was the saltatory baseline shown in Figure 37-8. These findings are consistent with cord occlusion as the proximate cause of fetal distress. Other correlates found were oligohydramnios and viscous meconium.

Decreased amniotic fluid volume commonly develops as pregnancy advances beyond 42 weeks (Fig. 37-9). It is also likely that meconium release into an already reduced amniotic fluid volume causes thick, viscous meconium implicated in meconium aspiration syndrome (see Chap. 29, p. 675).

Trimmer and co-workers (1990) measured hourly fetal urine production using sequential ultrasonic bladder volume measurements in 38 pregnancies of 42 weeks or more. Diminished urine production was found to be associated with oligohydramnios. They hypothesized, however, that decreased fetal urine flow was likely the result of preexisting oligohydramnios that limited fetal swallowing. Oz and co-workers (2002), using Doppler waveforms, reported that fetal renal blood flow is reduced in postterm pregnancies with oligohydramnios.

Figure 37-6. Prolonged fetal heart rate deceleration prior to emergency cesarean delivery in a postterm pregnancy with oligohydramnios. (From Leveno and co-workers, 1984.)

Figure 37-7. Severe — less than 70 bpm for 60 seconds or longer — variable decelerations in a postterm pregnancy with oligohydramnios and cesarean delivery for fetal jeopardy. (From Leveno and co-workers, 1984.)

Figure 37-9. Volume of amniotic fluid during the last weeks of pregnancy. (Adapted from Elliott and Inman, 1961.)

FETAL GROWTH RESTRICTION. Until recently, the clinical significance of fetal growth restriction in the otherwise uncomplicated pregnancy has received little attention. Divon and co-authors (1998) and Clausson and co-workers (1999) analyzed births of almost 700,000 women between 1991 and 1995 using the National Swedish Medical Birth registry. As shown in [Table 37-2](#), stillbirths were more common among growth-restricted infants who were delivered at 42 weeks or beyond. Indeed, one third of the postterm stillbirths were growth restricted. During the years of these births in Sweden, labor induction and antenatal fetal testing usually commenced at 42 weeks. Alexander and colleagues (2000d) studied infant outcomes for 355 postterm infants 42 weeks or greater whose birthweights were at or below the third percentile. They compared their outcomes with those of 14,520 infants above the third percentile delivered at Parkland Hospital and found that morbidity and mortality were significantly increased in the growth-restricted infants. Notably, one fourth of all stillbirths associated with prolonged pregnancy were in this comparatively small number of growth-restricted infants.

MANAGEMENT

It is generally accepted that antepartum interventions are indicated in management of prolonged pregnancies. The type(s) of interventions and when to use them are somewhat controversial. One major issue is whether to intervene at 41 or 42 weeks. Another is whether labor induction is warranted compared with expectant management using antepartum fetal testing. Roussis and colleagues (1993) surveyed members of the Society for Maternal-Fetal Medicine in 1990 and found that about two thirds of respondents induced labor at 41 weeks if the cervix was favorable. Antepartum fetal testing was advocated beginning at 41 weeks when the cervix was unfavorable. At 42 weeks, virtually all respondents induced labor when the cervix was favorable, and 58 percent did so even when the cervix was unfavorable. Others (42 percent) recommended antepartum testing when the cervix was unfavorable at 42 weeks. Clearly, cervical favorability has considerable impact on management (see [Chap. 22](#), p. 537).

UNFAVORABLE CERVIX. It is difficult to precisely define an "unfavorable cervix" in prolonged pregnancies, because investigators have used different criteria. For example, Harris and colleagues (1983) reported that 92 percent of women at 42 weeks had an unfavorable cervix defined by a Bishop score of less than 7. Hannah and colleagues (1992) found that only 40 percent of 3407 women with 41-week pregnancies had an undilated cervix. Alexander and associates (2000b) evaluated 800 women induced for postterm pregnancy at Parkland Hospital. They reported that women in whom there was no cervical dilatation had a twofold increased cesarean delivery rate for "dystocia." Yang and co-workers (2004) presented preliminary findings that cervical length of 3 cm or less determined by transvaginal ultrasonography was predictive of successful induction.

A number of investigators have evaluated prostaglandin E₂ for cervical ripening in women with prolonged pregnancies and an unfavorable cervix. National Institute of Child Health and Development Network of Maternal-Fetal Medicine Units (1994) evaluated prostaglandin E₂ gel and found that it was not more effective than placebo. Alexander and associates (2000c) studied 393 women with postterm pregnancy who were given prostaglandin E₂ for cervical ripening. These women were treated even if the cervix was "favorable." The investigators reported that almost half of the 84 women with cervical dilatation of 2 to 4 cm entered labor with prostaglandin E₂ use alone. The American College of Obstetricians and Gynecologists (1997) has concluded that prostaglandin gel can be used safely in postterm pregnancies. Use of prostaglandins for cervical ripening is discussed in [Chapter 22](#) (see p. 537).

Sweeping or stripping of the membranes, to induce labor and prevent postterm pregnancy has been studied in 15 randomized trials during the 1990s. Boulvain and co-authors (1999) performed a meta-analysis of these and found that membrane stripping at 38 to 40 weeks decreased the frequency of postterm pregnancy. Such stripping, however, did not modify the risk for cesarean delivery, and maternal and neonatal infections were not increased. The authors emphasized that membrane stripping could be painful and might provoke vaginal bleeding and irregular contractions. Wong and colleagues (2002), in a randomized trial evaluating 120 women, found that sweeping the membranes did not reduce the need to induce labor (see [Chap. 22](#), p. 539).

Station of the vertex is likewise important in predicting successful postterm induction. Shin and colleagues (2004) studied 484 nulliparas who underwent induction after 41 weeks. The cesarean delivery rate was directly related to station. It was 6 percent if the vertex was -1, 20 percent at -2, 43 percent at -3, and 77 percent at -4.

INDUCTION VERSUS FETAL TESTING. A logical plan for reducing perinatal mortality and morbidity associated with prolonged pregnancy is to terminate pregnancy before such events occur. There have been doubts about the value of labor induction, mainly because it was feared that induction would result in more operative intervention without preventing perinatal death. As a result, many clinicians prefer to use fetal testing to avoid inductions. Major studies designed to resolve these questions have been done in both Canada and the United States.

Hannah and colleagues (1992) randomized 3407 Canadian women with pregnancies at 41 or more weeks to labor induction or fetal testing. Women assigned to fetal testing were asked to count the number of times they felt the fetus move over a 2-hour period each day, and they also underwent nonstress testing three times weekly. Amniotic fluid volume was assessed two to three times each week, and pockets less than 3 cm were considered abnormal. Labor induction resulted in a significantly lower cesarean rate (21 percent) compared with pregnancies managed with antepartum testing (24 percent). There were two stillbirths in the fetal testing group and none in the induction group. The lower cesarean rate in the induction group was due to fewer procedures for fetal distress. A cost-effectiveness analysis of the Canadian data was later reported by Goeree and colleagues (1995). The mean cost was \$3132 per patient managed with fetal testing compared with \$2939 for those who underwent labor induction. Thus, labor induction for postterm pregnancy resulted in more favorable outcomes than fetal testing and at a lower cost.

Menticoglou and Hall (2002) from Winnipeg have subsequently lamented that induction of labor at 41 weeks has become the standard of care in Canada. They concluded that "ritual induction at 41 weeks" had become the current practice. They opined that this practice was based on evidence that was seriously flawed, and that it constituted "an abuse of biological norms." They recommended that this *nonsensus consensus* be discontinued because it caused interference that had the potential to do more

harm than good and have staggering resource implications.

The Maternal-Fetal Medicine Network trial of induction versus fetal testing was reported by Gardner and associates (1996). Nonstress tests and ultrasonic estimations of amniotic fluid volume were performed twice weekly in 175 women whose pregnancies had reached 41 weeks or more. Perinatal outcomes in these women were compared with those of 265 women randomized to induction with or without cervical ripening. There were no perinatal deaths in any study subgroup, and the rate of cesarean delivery was not different between management groups. Thus, this study supported the validity of either management scheme.

Crowley (1997) used the Oxford Database of Perinatal Trials to perform a meta-analysis of 18 studies in which management of postterm pregnancy was assessed. Routine induction after 41 weeks resulted in reduced perinatal mortality without increased risk of cesarean or instrumental delivery. Similar results were reported by Sanchez-Ramos and colleagues (2003) in their meta-analysis of 16 trials. In a study of 540,116 births, Roberts and colleagues (1999) concluded that Crowley's meta-analysis prompted routine induction after 41 weeks to be widely adopted in New South Wales, Australia. Specifically, from 1990 to 1996, there was a significant decrease in births at 42 completed weeks or more — compared with 2.8 percent, respectively. Correspondingly, there was an increased induction rate at 41 weeks, and the cesarean delivery rate also increased. Because infant outcomes were not described in this report, any beneficial neonatal effects are undetermined.

Alexander and colleagues (2001) examined the effect of labor induction at 42 weeks on rates of cesarean delivery at Parkland Hospital. Pregnancy outcomes in 638 women in whom labor was induced were compared with those of 687 women with spontaneous labor at 42 weeks. Rates of cesarean delivery were significantly increased in the induced group because of failure to progress (19 versus 14 percent). When corrected for risk factors using logistic regression, however, the researchers concluded that factors intrinsic to the patient, rather than labor induction itself, led to the increased cesarean deliveries. These factors included nulliparity, an unfavorable cervix, and epidural analgesia.

Evidence to substantiate intervention — whether induction or fetal testing — commencing at 41 versus 42 weeks is limited. Most evidence used to justify intervention at 41 weeks is from the randomized Canadian and American investigations cited earlier. No randomized studies have specifically assessed intervention at 41 weeks versus an identical intervention used at 42 weeks. Importantly, a national policy of intervention for prolonged pregnancy at 41 versus 42 weeks would mean that approximately 500,000 additional women would be subjected to interventions that have not been conclusively proved necessary or harmless.

Usher and colleagues (1988) analyzed several outcomes in 7663 pregnancies with gestational ages determined to be 40, 41, or 42 weeks confirmed by early ultrasound examinations. Perinatal death rates, corrected for malformations, were 1.5, 0.7, and 3.0 per 1000 for 40, 41, and 42 weeks, respectively. These results could be used to challenge the concept of routine intervention at 41 instead of 42 weeks. Interestingly, Divon and colleagues (1996) found that, although adverse fetal outcomes increased at 41 compared with those at 40 weeks, these were associated with growth restriction. They suggested that management strategies should be focused on fetal growth rather than simply gestational age in pregnancies reaching 41 weeks.

Based on results summarized in [Table 37-1](#), 41-week pregnancies without other complications such as hypertension are considered normal pregnancies at Parkland Hospital. No interventions are practiced solely on the basis of fetal age until 42 completed weeks. It is our view that large, randomized studies should be performed before 41-week gestations are routinely considered pathologically prolonged.

OLIGOHYDRAMNIOS. It has been suggested that the identification of diminished amniotic fluid determined by various ultrasonic methods may help identify a postterm fetus in jeopardy. There is no doubt that when amniotic fluid is decreased in a postterm pregnancy — or for that matter in any pregnancy — the fetus is at increased risk. Many different criteria for ultrasonic diagnosis of oligohydramnios have been proposed. Fischer and colleagues (1993) attempted to determine which criteria were most predictive of normal versus abnormal outcomes in postterm pregnancies. As shown in [Figure 37-10](#), the smaller the amniotic fluid pocket, the greater the likelihood that there was clinically significant oligohydramnios. Normal amniotic fluid volume, however, did not preclude abnormal outcomes. Alfievic and co-authors (1997) randomized 500 women with postterm pregnancies — defined as 290 days or longer gestation — to assessment of amniotic fluid volume using either the amniotic fluid index (AFI) or the deepest vertical pocket. They concluded that the AFI overestimated the number of abnormal outcomes in postterm pregnancies.

Regardless of the criteria used to diagnose oligohydramnios in postterm pregnancies, most investigators have found an increased incidence of "fetal distress" during labor. Thus, oligohydramnios by most definitions is a clinically meaningful finding. Conversely, reassurance of continued fetal well-being in the presence of "normal" amniotic fluid volume is tenuous because it is unknown how quickly pathological oligohydramnios develops. Clement and co-workers (1987) reported six postterm pregnancies in which amniotic fluid volume diminished abruptly over 24 hours and one fetus died.

Figure 37-10. Comparison of the diagnostic value of various ultrasonic estimates of amniotic fluid volume in prolonged pregnancies. Abnormal outcomes include cesarean or operative vaginal delivery for fetal jeopardy, 5-minute Apgar score of 6 or less, umbilical arterial blood pH less than 7.1, or admission to the neonatal intensive care unit. (Adapted from Fischer and associates, 1993.)

MACROSOMIA. The incidence of macrosomia (defined as birthweight greater than 4500 g) increases from 1.4 percent at 37 to 41 weeks to 2.2 percent at 42 weeks or more (Martin and colleagues, 2002). This raises the possibility that both the maternal and fetal morbidity associated with macrosomia might be avoidable with timely labor induction to preempt further growth. The American College of Obstetricians and Gynecologists (2000) has reviewed such interventions. It concluded that current evidence does not support a policy of early labor induction in women at term who have suspected fetal macrosomia. Moreover, in the absence of maternal diabetes, vaginal delivery is not contraindicated for women with estimated

fetal weights up to 5000 g. Cesarean delivery was recommended for estimated fetal weights greater than 4500 g in the presence of a prolonged second-stage labor or a second-stage arrest of descent.

RECOMMENDATIONS OF THE AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS. These recommendations are summarized in [Table 37-3](#). Although providing flexibility in the evaluation and management of pregnancies completing 42 weeks, the recommendations are that either antenatal testing or labor induction should be commenced at 42 weeks. There was insufficient evidence to recommend a management strategy between 40 and 42 completed weeks.

Postterm pregnancy has been identified by the American College of Obstetricians and Gynecologists (1999) as a high-risk condition in which twice-weekly antepartum fetal testing may be indicated. Doppler velocimetry was not recommended. Oligohydramnios detected using ultrasound, defined as no vertical pocket of amniotic fluid greater than 2 cm or an AFI of 5 cm or less, is considered an indication for either delivery or close fetal surveillance.

MANAGEMENT AT PARKLAND HOSPITAL. In women with a *certain* gestational age, labor is induced at the completion of 42 weeks. Almost 90 percent of such women are induced successfully or enter labor within 2 days of induction. For those who do not deliver with the first induction, a second induction is performed within 3 days. Almost all women are delivered using this plan of management, but in the unusual few who are not delivered, management decisions involve a third (or more) induction versus cesarean delivery.

Women classified as having *uncertain* postterm pregnancies are followed on a weekly basis and without intervention unless fetal jeopardy is suspected. The latter is based on clinical or sonographic perception of decreased amniotic fluid volume. Equally worrisome is diminished fetal movement reported by the mother. If fetal jeopardy is suspected by either method, labor induction is carried out as described previously for the woman with a certain postterm gestation.

MEDICAL OR OBSTETRICAL COMPLICATIONS. In the event of a medical or other obstetrical complication, it is generally unwise to allow a pregnancy to continue past 42 weeks. Indeed, in many such instances *early* delivery is indicated. Timing of delivery depends on the individual complication. Common examples include hypertensive disorders due to pregnancy, prior cesarean delivery, and diabetes.

INTRAPARTUM MANAGEMENT. Labor is a particularly dangerous time for the postterm fetus. Therefore, it is important that women whose pregnancies are known or suspected to be postterm come to the hospital as soon as they suspect they are in labor. On arrival, while being observed for possible labor, we recommend that fetal heart rate and uterine contractions be monitored electronically for variations consistent with fetal distress (American College of Obstetricians and Gynecologists, 1995).

When to perform amniotomy is problematic. Further reduction in fluid volume following amniotomy can certainly enhance the possibility of cord compression. Conversely, amniotomy aids diagnosis of thick meconium, which may be dangerous to the fetus if aspirated. Moreover, once the membranes are ruptured, a scalp electrode and intrauterine pressure catheter can be placed, which usually provide more precise data concerning fetal heart rate and uterine contractions.

Identification of *thick meconium* in the amniotic fluid is particularly worrisome. The viscosity probably signifies the lack of liquid and thus oligohydramnios. Aspiration of thick meconium may cause severe pulmonary dysfunction and neonatal death (see [Chap. 29](#), p. 675). Wenstrom and Parsons (1989) proposed *amnioinfusion* during labor as a way of diluting meconium to decrease the incidence of meconium aspiration syndrome. As discussed in [Chapter 18](#) (see p. 462), the benefits of amnioinfusion remain controversial. In a recent randomized trial by Rathore and colleagues (2002), amnioinfusion was associated with fewer cesarean deliveries for fetal distress and fewer neonatal intensive care unit admissions for neonates with moderate to thick meconium-stained amniotic fluid. In contrast, Yoder and colleagues (2002) found that increased use of amnioinfusion — 0 to 36 percent of women with moderate to thick amniotic fluid meconium — had no impact on the incidence of meconium aspiration syndrome.

The likelihood of a successful vaginal delivery is reduced appreciably for the nulliparous woman who is in early labor with thick, meconium-stained amniotic fluid. Therefore, when the woman is remote from delivery, strong consideration should be given to prompt cesarean delivery, especially when cephalopelvic disproportion is suspected or either hypotonic or hypertonic dysfunctional labor is evident. Some practitioners choose to avoid oxytocin use in these cases.

Aspiration of meconium may be minimized but not eliminated by effective suctioning of the pharynx as soon as the head is delivered but before the thorax is delivered. If meconium is identified, the trachea should be aspirated as soon as possible after delivery. Immediately thereafter, the infant should be ventilated as needed.

38. Fetal Growth Disorders

INTRODUCTION

Each year, about 20 percent of the almost 4 million infants in the United States are born at the low and high extremes of fetal growth. Low-birthweight infants make up just less than half of these 700,000 births and include preterm infants as well as those whose growth has been impaired in utero. Although the majority of these infants are preterm, the National Institutes of Health estimated that approximately 40,000 are at term, having suffered abnormal fetal growth (Frigoletto, 1986). In 1997, 8 percent of infants weighed less than 2500 g at birth, and 10 percent weighed more than 4000 g (Ventura and colleagues, 1999). Between 1981 and 2001, the percentage of low-birthweight infants (less than 2500 g) and very-low-birthweight infants (less than 1500 g) increased by 13 percent and 24 percent, respectively (Martin and colleagues, 2002). Macrosomia, defined as birthweight of 4000 g or greater, occurred in 1 out of every 10 births in the United States in 1997. However, the incidence of macrosomia has been declining since 1991 after peaking at about 11 percent in the 1980s (Ventura and colleagues, 1999).

NORMAL FETAL GROWTH

Human fetal growth is characterized by sequential patterns of tissue and organ growth, differentiation, and maturation that are determined by maternal provision of substrate, placental transfer of these substrates, and fetal growth potential governed by the genome. Steer (1998) has summarized the potential effects of evolutionary pressures on human fetal growth. During the past 3.5 million years, the human species has become adapted to an upright posture, and the pelvis has evolved to facilitate walking. During the past 500,000 years, human brain volume has increased from about 750 mL (*Homo erectus*) to about 1000 to 1800 mL (*Homo sapiens*). The head has to pass through the pelvis during parturition; thus, an increasing conflict between the need to walk — requiring a narrow pelvis — and the need to think — requiring a large brain — has developed. This leads to difficulty in labor because of dystocia.

The difficulty posed by a large-sized head or brain and small pelvic capacity has been resolved to some extent by an evolutionary modification known as *neoteny*, whereby humans are born increasingly early. For example, if humans were born with the same level of functional maturity as the chimpanzee, human gestation would last 17 months. The human species may be resolving this dilemma in another way — by acquiring the ability to restrict growth late in pregnancy. This characteristic "tail off" of growth from 38 weeks onward as seen in human pregnancies is not evident in other mammals. Thus, the ability to "growth restrict" may be adaptive rather than pathological.

Lin and Santolaya-Forgas (1998) have divided cell growth into three consecutive phases. The initial phase of hyperplasia is during the first 16 weeks and is characterized by a rapid increase in cell number. The second phase, which extends up to 32 weeks, includes both cellular hyperplasia and hypertrophy. After 32 weeks, fetal growth is by cellular hypertrophy, and it is during this phase that most fetal fat and glycogen deposition takes place. The corresponding fetal growth rates during these three phases are 5 g/day at 15 weeks, 15 to 20 g/day at 24 weeks, and 30 to 35 g/day at 34 weeks (Williams and co-authors, 1982). As shown in [Figure 38-1](#), there is considerable biological variation in the velocity of fetal growth determined by sonography in the last half of gestation.

Although many factors have been implicated in the process of fetal growth, the precise cellular and molecular mechanisms by which normal fetal growth occurs are not well understood. In early fetal life the major determinant of growth is the fetal genome, but later in pregnancy environmental, nutritional, and hormonal influences become increasingly important (Holmes and colleagues, 1998).

For example, there is considerable evidence that insulin and insulin-like growth factor-I (IGF-I) and IGF-II have a role in the regulation of fetal growth and weight gain (Verhaeghe and colleagues, 1993). Insulin is secreted by fetal pancreatic cells primarily during the second half of gestation and is believed to stimulate somatic growth and adiposity. The IGFs are produced by virtually all fetal organs beginning early in development. They are potent stimulators of cell division and differentiation. Verhaeghe and colleagues (1993) have found that fetal serum levels of IGF-I, IGF-II, and insulin are all related to fetal growth and weight gain. In cord serum, IGF-I correlates best with birthweight. Moreover, a polymorphism in the IGF-I gene may be associated with low birthweight (Vaessen and colleagues, 2002).

Since the discovery of the *obesity gene* and its protein product, *leptin*, which is synthesized in adipose tissue, there has been interest in maternal and fetal serum leptin levels. Fetal concentrations increase during the first two trimesters, and they correlate with birthweight (Sivan, 1998; Tamura, 1998; Tovi, 2005a,b, and all their colleagues). This relationship is controversial in growth-restricted fetuses (Grisaru-Granovsky and colleagues, 2003).

Fetal growth is also dependent on an adequate supply of nutrients. Indeed, Williams (1903) aptly commented in the first edition of this textbook that "the increase in size of the foetus affords conclusive evidence that materials in solution must, pass from the maternal to the foetal circulation...." Glucose transfer has been extensively studied during pregnancy (see [Chap. 4](#), p. 100). Both excessive and diminished maternal glucose availability to the fetus affect fetal growth. Excessive glycemia produces macrosomia, whereas diminished glucose levels have been associated with fetal growth restriction. Indeed, the macrosomic infant of the mildly diabetic mother is the prototypical example of the effects of excessive maternal glucose supply. Characteristics of these infants include fetal hyperinsulinism and elevated umbilical cord levels of IGF-I and IGF-II (Roth and colleagues, 1996).

There is less information concerning the physiology of maternal-fetal transfer of other nutrients such as amino acids and lipids. Ronzoni and colleagues (1999) studied maternal-fetal concentrations of amino acids in 26 normal pregnancies at the time of cesarean delivery. An increase in maternal amino acid levels led to an increase in fetal levels. In growth-restricted fetuses, amino acid disturbance similar to the biochemical changes seen in postnatal protein-starvation states has been detected (Economides and colleagues, 1989b). Jones and colleagues (1999) studied 38 growth-restricted infants and found impaired utilization of circulating triglycerides consistent with peripheral adipose depletion.

 **Figure 38-1.** Increments in fetal weight in grams per day from 24 to 42 weeks'

gestation. The lines represent the mean and ± 2 standard deviations. (Adapted from Owen and colleagues, 1996, with permission.)

FETAL GROWTH RESTRICTION

Low-birthweight infants who are small-for-gestational age are designated as suffering from *fetal growth restriction*. The term fetal growth retardation has been discarded because "retardation" implies abnormal mental function. It is estimated that 3 to 10 percent of infants are growth restricted (Divon and Hsu, 1992).

In 1961, Warkany and co-workers reported normal values for infant weights, lengths, and head circumferences that served to define fetal growth restriction. Gruenwald (1963) reported that approximately one third of infants born weighing less than 2500 g were mature and that their small size could be explained by *chronic placental insufficiency*. These observations generated the concept that birthweight was governed not only by gestational length but also by fetal growth rate.

It also has been suggested that fetal size is largely determined in the first trimester (Dickey and Gasser, 1993; Gluckman and Liggins, 1984). Smith and colleagues (1998) compared outcomes of 4229 pregnancies with the difference between measured and expected crown-rump length measured ultrasonically in the first trimester. Suboptimal first-trimester growth was associated with fetal growth restriction as well as preterm delivery between 24 and 32 weeks. It may be that a suboptimal environment in the first weeks of gestation limits fetal growth for the remainder of pregnancy and that such an environment may precipitate extremely preterm delivery.

DEFINITION. In 1963, Lubchenco and co-workers from Denver published detailed comparisons of gestational ages with birthweights in an effort to derive norms for expected fetal size at a given gestational week. Battaglia and Lubchenco (1967) then classified *small-for-gestational-age* (SGA) infants as those whose weights were below the 10th percentile for their gestational age. Such infants were shown to be at increased risk for neonatal death. For example, the neonatal mortality rate of SGA infants born at 38 weeks was 1 percent compared with that of 0.2 percent in those with appropriate birthweights.

Many infants with birthweights less than the 10th percentile are not pathologically growth restricted but are small simply because of normal biological factors. Indeed, Manning and Hohler (1991) and Gardosi and colleagues (1992) concluded that 25 to 60 percent of SGA infants were, in fact, appropriately grown when maternal ethnic group, parity, weight, and height were considered.

Because of these disparities, other classifications were proposed. Seeds (1984) suggested a definition based on birthweight below the fifth percentile. Usher and McLean (1969) proposed that fetal growth standards should be based on mean weights-for-age with normal limits defined by ± 2 standard deviations. This definition would limit SGA infants to 3 percent of births instead of 10 percent. Clinically, this definition is very meaningful. As shown in [Figure 38-2](#), most poor outcomes are in infants below the third percentile. In a study of 122,754 pregnancies delivered at Parkland Hospital, McIntire and colleagues (1999) also showed that mortality and morbidity were significantly increased among term infants whose birthweights were at or below the third percentile.

Normal Infant Birthweight.

Normative data for fetal growth based on birthweight have evolved considerably following the pioneering work done by Lubchenco and co-workers (1963). Their data were derived exclusively from births to white and Hispanic women who resided at high altitudes. Such infants are smaller than those born at sea level. For example, term infants average 3400 g at sea level, 3200 g at 5000 feet, and 2900 g at 10,000 feet. Other researchers have developed fetal growth curves using various populations and geographic locations throughout the United States (Brenner and colleagues, 1976; Ott, 1993; Overpeck and colleagues, 1999; Williams, 1975). Each of these curves was based on specific ethnic or regional groups; therefore, they are not representative of the entire population. To address this, fetal growth graphs were derived on a nationwide basis in both the United States ([Table 38-1](#)) and Canada (Alexander and colleagues, 1996; Arbuckle and colleagues, 1993). Data from over 3.1 million mothers with singleton liveborn infants in the United States during 1991 were used to derive the growth curve shown in [Figure 38-3](#). In general, the previously published fetal growth curve data underestimated birthweights when compared with national data. Importantly, there are significant ethnic or racial variations in neonatal mortality rates within the national neonatal mortality rate as well as within birthweight and gestational age categories (Alexander and colleagues, 1999, 2003).

Birthweight Versus Growth.

Most of what is known about normal and abnormal human fetal growth is actually based on birthweight standards, which is the end point of fetal growth. These standards do not reveal the *rate* of fetal growth. Indeed, such birthweight curves reveal compromised growth only at the extreme of impaired growth. Thus, they cannot be used to identify the fetus who fails to achieve an expected or potential size but whose birthweight outlies the 10th percentile. Birthweight percentile is an incomplete measure of growth failure. Infants who are of apparently appropriate birthweight, but who "cross centiles," may be exhibiting signs of malnutrition because they have not achieved their full genetic potential (Owen and colleagues, 1996, 2003). The rate or velocity of human fetal growth depends on serial ultrasonic fetal anthropometry. Reports suggest that a diminished growth velocity is related to perinatal morbidity (Owen and co-workers, 1997; Owen and Khan, 1998).

Metabolic Abnormalities.

Fetal blood sampling from the umbilical vein for karyotyping of severely growth-restricted fetuses has permitted remarkable insights into the pathophysiology of fetal growth (see [Chap. 13](#), p. 330). In 38 growth-restricted fetuses, Soothill and colleagues (1987) found that the severity of hypoxia correlated significantly with hypercapnia, acidosis, lactic acidemia, hypoglycemia, and erythroblastosis. Subsequently, Economides and Nicolaidis (1989a) found that the major cause of hypoglycemia in SGA fetuses was reduced supply rather than increased fetal consumption or diminished fetal glucose production. Economides and co-workers (1989c) found that these fetuses also had hypoinsulinemia and hypoglycemia. The

degree of fetal growth restriction, however, did not correlate with plasma insulin, suggesting that it is not the primary determinant of poor fetal growth.

In children with *kwashiorkor*, the ratio of nonessential to essential amino acids is increased, presumably because of decreased intake of essential amino acids. Economides and colleagues (1989b) measured the glycine/valine ratio in cord blood from growth-restricted fetuses and found ratios similar to those observed in children with protein deprivation and *kwashiorkor*. Moreover, protein deprivation correlated with fetal hypoxemia. Economides and associates (1990) measured plasma triglyceride concentrations in small fetuses and infants and compared those with the concentrations of appropriately grown fetuses. Growth-restricted fetuses demonstrated hypertriglyceridemia that was correlated with the degree of fetal hypoxemia. They hypothesized that hypoglycemic, growth-restricted fetuses mobilize adipose tissue, and that the hypertriglyceridemia is the result of lipolysis of fetal fat stores.

Elevated plasma concentrations of interleukin-10, placental atrial natriuretic peptide, and endothelin-1, as well as a defect in epidermal growth factor function, have also been described in growth-restricted fetuses (Varner and colleagues, 1996). These findings suggest a possible role for abnormal immune activation and abnormal placentation in the genesis of growth-restricted fetuses (Gabriel, 1994; Heyborne, 1994; Kingdom, 1994; McQueen, 1993; Neerhof, 1995, and all their associates). In animals, chronic reduction in nitric oxide, an endothelium-derived, locally acting vasorelaxant, has also been shown to result in diminished fetal growth (Diket and associates, 1994).

Figure 38-2. Relationship between birthweight percentile and perinatal mortality and morbidity in 1560 small-for-gestational-age fetuses. A progressive increase in both mortality and morbidity is observed as birthweight percentile falls. (From Manning, 1995.)

Figure 38-3. Comparison of fetal growth curves for infants born in different regions of the United States and compared with those of the nation at large. (Modified from Alexander and colleagues, 1996, with permission.)

MORBIDITY AND MORTALITY. As shown in [Figure 38-2](#), fetal growth restriction is associated with substantive perinatal morbidity and mortality. Fetal demise, birth asphyxia, meconium aspiration, and neonatal hypoglycemia and hypothermia are all increased, as is the prevalence of abnormal neurological development (Paz and associates, 1995; Piper and colleagues, 1996). This is true for both term and preterm infants (Minior and Divon, 1998). Finally, the risk of long-term mortality in preterm growth-restricted infants is significantly increased compared with that of appropriately grown preterm infants (Kok and colleagues, 1998).

Postnatal growth and development of the growth-restricted fetus depends on the cause of restriction, nutrition in infancy, and the social environment (Kliegman, 1997). Infants with growth restriction due to congenital, viral, chromosomal, or maternal size typically remain small throughout life. If growth restriction is due to placental insufficiency, infants must often have catch-up growth to approach their inherited growth potential. Similarly, the neurodevelopmental outcome of the growth-restricted fetus is influenced by both pre- and postnatal environments. Infants born to families of higher socioeconomic status demonstrate fewer developmental problems than those born to indigent families.

ACCELERATED MATURATION. There have been numerous reports describing accelerated fetal pulmonary maturation in complicated pregnancies associated with growth restriction (Perelman and colleagues, 1985). One explanation for this phenomenon is that the fetus responds to a stressed environment by increasing adrenal glucocorticoid production, which leads to earlier or accelerated fetal lung maturation (Laatikainen and associates, 1988). Although this concept pervades modern perinatal thinking, there is scant verification for it.

Owen and associates (1990) analyzed perinatal outcomes in 178 women delivered primarily because of hypertension. They compared these with those of 159 women delivered because of spontaneous preterm labor or ruptured membranes. They concluded that a "stressed" pregnancy, which often resulted in SGA infants, did not confer an appreciable survival advantage. Similar findings were reported by Friedman and colleagues (1995) in women with severe preeclampsia. Two studies from Parkland Hospital substantiate that fetal growth restriction accrues no apparent advantages to the preterm infant (McIntire and colleagues, 1999; Tyson and colleagues, 1995). Moreover, Smulian and colleagues (2000) reported that growth-restricted infants had higher 1-year infant mortality compared with infants from normal pregnancies.

SYMMETRICAL VERSUS ASYMMETRICAL GROWTH RESTRICTION. Campbell and Thoms (1977) described the use of the sonographically determined *head-to-abdomen circumference ratio (HC/AC)* to differentiate growth-restricted fetuses. Those that were *symmetrical* were proportionately small, and those that were *asymmetrical* had disproportionately lagging abdominal growth. These authors constructed an HC/AC ratio nomogram from approximately 500 normal fetuses. Although asymmetrical fetuses were "preferentially protected from the full effects of the growth-retarding stimulus," they more likely were associated with pregnancies complicated by severe preeclampsia, fetal distress, operative intervention, and lower Apgar scores than their symmetrical counterparts.

It is compelling to relate the type of growth restriction to the onset or etiology of a particular insult. An early insult could theoretically result in a relative decrease in cell number as well as cell size, which might be caused by chemical exposure, viral infection, or inherent cellular development abnormality due to aneuploidy. The resultant proportionate reduction in these cases of both head and body size has been termed *symmetrical growth restriction*.

On the other hand, a late pregnancy insult such as placental insufficiency from hypertension theoretically could primarily affect cell size. Placental insufficiency may result in diminished glucose transfer and hepatic storage, thus, fetal abdominal circumference — which reflects liver size — would be reduced. This sequence of events can theoretically result in *asymmetrical growth restriction*. This concept has been challenged (Roberts and co-authors, 1999). Such somatic growth restriction is proposed to result from preferential shunting of oxygen and nutrients to the brain, which allows normal brain and head growth. Because the fetal brain is normally relatively large and the liver relatively small, the ratio of brain weight to liver weight over the last 12 weeks — usually about 3 to 1 — may be increased to 5 to 1 or more in severely growth-restricted infants.

Although these generalizations about the potential pathophysiology of symmetrical versus asymmetrical growth restriction are interesting from a conceptual standpoint, there is considerable evidence that fetal growth patterns are more complex. Nicolaides and co-authors (1991) found that fetuses with aneuploidy typically had disproportionately large head sizes and thus were *asymmetrically* growth restricted. Similarly, most preterm infants with growth restriction due to preeclampsia and associated uteroplacental insufficiency demonstrate symmetrical growth impairment (Salafia and co-authors, 1995).

Crane and Kopta (1980) analyzed several anthropometric measurements in growth-restricted newborns and concluded that the concept of brain sparing could not be used to identify the cause(s) of fetal growth restriction. Dashe and colleagues (2000) analyzed 8722 consecutive liveborn singletons who underwent an ultrasound examination within 4 weeks of delivery. Although only 20 percent of growth-restricted fetuses demonstrated sonographic head-to-abdomen asymmetry, these fetuses were at increased risk for intrapartum and neonatal complications. Symmetrically growth-restricted fetuses were not at increased risk for adverse outcomes when compared with those appropriately grown. The researchers concluded that asymmetrical fetal growth restriction represented significantly disordered growth, whereas symmetrical growth restriction more likely represented normal, genetically determined small stature.

RISK FACTORS

Constitutionally Small Mothers.

Small women typically have smaller infants. If a woman begins pregnancy weighing less than 100 pounds, the risk of delivering an SGA infant is increased at least twofold (Simpson and colleagues, 1975). Moreover, intergenerational effects on birthweight are transmitted through the maternal line (Emanuel and associates, 1992). There is also evidence that reduced intrauterine growth of the mother is a risk factor for reduced intrauterine growth of her offspring (Klebanoff and co-authors, 1997).

Whether the phenomenon of a small mother giving birth to a small infant is nature or nurture is unclear. Brooks and co-authors (1995) analyzed 62 births after ovum donation to examine the relative influence of the donor versus the recipient on birthweight. They concluded that the environment provided by the donor mother was more important than the genetic contribution to birthweight.

Poor Maternal Nutrition.

In the woman of average or low body mass index (BMI), poor weight gain throughout pregnancy may be associated with fetal growth restriction (Simpson and colleagues, 1975). Lack of weight gain in the second trimester especially correlates with decreased birthweight (Abrams and Selvin, 1995). If the mother is large and otherwise healthy, however, below-average maternal weight gain without maternal disease is unlikely to be associated with appreciable fetal growth restriction.

As discussed in [Chapter 43](#) (see p. 1011), marked restriction of weight gain after midpregnancy should not be encouraged. Even so, it appears that caloric restriction to less than 1500 kcal/day adversely affects fetal growth only minimally (Lechtig and co-workers, 1975). The best documented effect of famine on fetal growth was in the "hunger winter" of 1944 in Holland. The German Army restricted dietary intake to 600 kcal/day for civilians, including pregnant women. The famine persisted for 28 weeks. Although this resulted in an average birthweight decrease of only 250 g, fetal mortality rates increased significantly (Stein and colleagues, 1975).

Social Deprivation.

The effect of social deprivation on birthweight is interconnected to the effects of associated lifestyle factors such as smoking, alcohol or other substance abuse, and poor nutrition. In a study of 7493 British women, Wilcox and associates (1995) found that the most socially deprived mothers had the smallest infants. Similarly, Dejin-Karlsson and colleagues (2000) prospectively studied a cohort of Swedish women and found that lack of psychosocial resources increased the risk of growth-restricted infants. Indeed, more than 100 years ago, Williams (1903) wrote in the first edition of this textbook: "The social condition of the mother and the comforts by which she is surrounded also exert a marked influence on the child's weight, heavier children being more common in the upper walks of life."

Fetal Infections.

Viral, bacterial, protozoan, and spirochetal infections have been implicated in up to 5 percent of cases of fetal growth restriction (Klein and Remington, 1995). The best known of these are infections caused by rubella and cytomegalovirus (Lin and Evans, 1984; Stagno and associates, 1977). Mechanisms affecting fetal growth appear to be different with these two viral infections. *Cytomegalovirus* is associated with direct cytolysis and loss of functional cells. *Rubella* infection causes vascular insufficiency by damaging the endothelium of small vessels. Rubella also reduces cell division (Pollack and Divon, 1992).

Hepatitis A and B are associated with preterm delivery but may also adversely affect fetal growth (Waterson, 1979). *Listeriosis*, *tuberculosis*, and *syphilis* have been reported to cause fetal growth restriction. Paradoxically, with syphilis, the placenta is almost always increased in weight and size due to edema and perivascular inflammation (Varner and Galask, 1984). *Toxoplasmosis* is the protozoan infection most often associated with compromised fetal growth, but *congenital malaria* may produce the same result (Varner and Galask, 1984).

Congenital Malformations.

In a study of over 13,000 infants with major structural anomalies, 22 percent had accompanying growth restriction (Khoury and associates, 1988). In general, the more severe the malformation, the more likely the fetus is to be SGA. This is especially evident in fetuses with chromosomal abnormalities or those with serious cardiovascular malformations.

Chromosomal Aneuploidies.

Placentas of fetuses with *autosomal trisomies* have a reduced number of small muscular arteries in the tertiary stem villi (Rochelson and associates, 1990). Depending on which chromosome is extra, there may be associated growth restriction.

In *trisomy 21*, fetal growth restriction is generally mild (Thelander and Pryor, 1966). Whether there is a lag in crown-rump length is controversial (Golbus 1978; Stephens and Shepard, 1980). However, after the first trimester, all long-bone growth lags behind that of normal fetuses (Fitzsimmons and colleagues, 1990). Both shortened femur length and hypoplasia of the middle phalanx occur with increased frequency in trisomy 21.

By contrast, fetal growth in *trisomy 18* is virtually always significantly affected. In one series, 10 of 11 newborns weighed less than 2500 g (Moerman and associates, 1982). Growth failure has been documented as early as the first trimester. By the second trimester, long-bone measurements typically fall below the third percentile for age, and the upper extremity is even more severely affected (Droste and co-workers, 1990). Visceral organ growth is also abnormal (Droste, 1992).

Fetuses with *trisomy 13* have some degree of growth restriction but generally not as severely as those with trisomy 18.

Trisomy 16 is the most common trisomy in spontaneous miscarriage and is usually lethal in the nonmosaic state (Lindor and associates, 1993). As discussed in [Chapter 12](#) (see p. 295), patches of trisomy 16 (or others) in the placenta — *confined placental mosaicism* — can cause placental insufficiency that may account for many cases of previously unexplained fetal growth restriction (Kalousek and colleagues, 1993; Towner and colleagues, 2001). It is emphasized that in these pregnancies, the chromosomal abnormality is confined to the placenta.

Significant fetal growth restriction is not seen with *Turner syndrome* (45,X) or *Klinefelter syndrome* (47,XXY) (Droste, 1992).

Disorders of Cartilage and Bone.

Numerous inherited syndromes such as *osteogenesis imperfecta* and various chondrodystrophies are associated with fetal growth restriction (see [Chap. 12](#), p. 296).

Teratogens.

Any teratogen is capable of adversely affecting fetal growth. Many are considered in detail in [Chapter 14](#). Examples include anticonvulsants and antineoplastic agents. In addition, cigarette smoking, opiates and related drugs, alcohol, and cocaine may cause growth restriction, either primarily or by decreasing maternal food intake.

Vascular Disease.

Especially when complicated by superimposed preeclampsia, chronic vascular disease commonly causes growth restriction (see [Chap. 34](#), p. 764). Preeclampsia may cause fetal growth failure and is an indicator of its severity, especially when the onset is before 37 weeks (Gainer, 2005; Odegard, 2000; Xiong, 1999, and all their colleagues).

Renal Disease.

Chronic renal insufficiency is often associated with underlying hypertension and vascular disease. Chronic nephropathies are commonly accompanied by restricted fetal growth (Cunningham and colleagues, 1990; Stettler and Cunningham, 1992).

Chronic Hypoxia.

When exposed to a chronically hypoxic environment, some fetuses have significantly reduced birthweight. As discussed earlier, fetuses of women who reside at high altitude usually weigh less than those born to women who live at a lower altitude (Krampl, 2002; Lichty and colleagues, 1957). As discussed in [Chapter 44](#) (see p. 1028), severe hypoxia from maternal cyanotic heart disease frequently is associated with severely growth-restricted fetuses (Patton and co-workers, 1990).

Anemia.

In most cases, maternal anemia does not cause fetal growth restriction. Exceptions include sickle cell disease and some other inherited anemias. Conversely, curtailed maternal blood volume expansion has been linked to fetal growth restriction (Duvekot and colleagues, 1995). This is further discussed in [Chapter 51](#) (see p. 1145).

Placental and Cord Abnormalities.

A number of placental abnormalities may cause fetal growth restriction (see [Chap. 27](#)). They include chronic placental abruption, extensive infarction, chorioangioma, marginal or velamentous cord insertion, circumvallate placenta, or placenta previa. Growth failure in these cases is often presumed to be due to *uteroplacental insufficiency*. Some women with otherwise unexplained fetal growth restriction and a grossly normal placenta have reduced uteroplacental blood flow when compared with normally grown fetuses (Kotini and colleagues, 2003; Lunell and Nylund, 1992; Papageorghiou and colleagues, 2001). Similar reductions have also been reported in growth-restricted fetuses with congenital malformations. These results suggest that maternal blood flow may in part be regulated by the fetus (Howard, 1987; Rankin and McLaughlin, 1979). Interestingly, there is no evidence that macrosomic infants have increased uteroplacental blood flow.

Multiple Fetuses.

As shown in [Figure 38-4](#), pregnancy with two or more fetuses is more likely to be complicated by diminished growth of one or more fetuses when compared with normal singletons (see [Chap. 39](#), p. 922).

Antiphospholipid Antibody Syndrome.

Two classes of antiphospholipid antibodies — *anticardiolipin antibodies* and *lupus anticoagulant* — have been associated with fetal growth restriction (Lockwood and Rand, 1994). These syndromes are considered in detail in [Chapters 47](#) (p. 1078) and [54](#) (p. 1215). Pregnancy outcome in women with these antibodies is often poor and may involve early-onset preeclampsia and fetal demise (Levine and associates, 2002; Lockwood, 2002). Specifically, these antibodies may be found in women with repetitive second-trimester fetal loss or early-onset fetal growth restriction, especially when accompanied by early and severe hypertensive disease. Not all researchers have reported these adverse outcomes. Infante-Rivard and colleagues (2002) did not find an association between maternal or newborn thrombophilia polymorphisms and risk of fetal growth restriction. Pathophysiological mechanisms in the fetus appear to be caused by maternal platelet aggregation and placental thrombosis.

Extrauterine Pregnancy.

If the placenta is implanted outside the uterus, the fetus is usually growth restricted (see [Chap. 10](#), p. 265). Also, some uterine malformations have been linked to impaired fetal growth (see [Chap. 40](#), p. 953).

Figure 38-4. Birthweight and gestational age relationships in multifetal gestations. (From McKeown and Record, 1952, with permission.)

IDENTIFICATION OF FETAL GROWTH RESTRICTION. *Early establishment of gestational age, attention to maternal weight gain, and careful measurement of uterine fundal growth throughout pregnancy identify many cases of abnormal fetal growth in low-risk women. Risk factors, including a previously growth-restricted fetus, increases the possibility of recurrence. In women with significant risk factors, consideration should be given to serial sonography. Although frequency of examinations varies depending on clinical circumstances, an initial dating examination, ideally in the first trimester followed by a second examination at 32 to 34 weeks, or when clinically indicated, should serve to identify many cases of growth restriction. Even so, definitive diagnosis frequently cannot be made until delivery.*

Identification of the inappropriately growing fetus remains a challenge. However, there are both simple clinical techniques and more complex technologies that may prove useful in helping to exclude and diagnose fetal growth restriction.

Uterine Fundal Height.

Carefully performed serial fundal height measurements are a simple, safe, inexpensive, and reasonably accurate *screening* method to detect SGA fetuses (Gardosi and Francis, 1999). As a screening tool, its principal drawback is imprecision. For example, Jensen and Larsen (1991) and Walraven and colleagues (1995) found that this method helped correctly identify only 40 percent of such infants. Thus, SGA fetuses were both overlooked and overdiagnosed. Despite this, these results do not diminish the importance of carefully performed fundal measurements as a simple screening method. The method used by most for fundal height measurement was described by Jimenez and colleagues (1983). Briefly, this consists of a tape calibrated in centimeters applied over the abdominal curvature from the upper edge of the symphysis to the upper edge of the uterine fundus, which is identified by palpation or percussion. The tape is applied with the markings away from the examiner to avoid bias. Between 18 and 30 weeks, the uterine fundal height in centimeters coincides with weeks of gestation. If the measurement is more than 2 to 3 cm from the expected height, inappropriate fetal growth may be suspected.

Ultrasonic Measurements.

Central to the debate over whether all pregnancies should routinely undergo ultrasonic evaluation is the potential for diagnosis of growth restriction (Ewigman and colleagues, 1993). Typically, such routine screening incorporates an initial ultrasound examination at 16 to 20 weeks to establish gestational age and identify anomalies. This is repeated at 32 to 34 weeks to evaluate fetal growth (see [Chap. 16](#), p. 392). Ironically, Gardosi and Geirsson (1998) found that accurate gestational dating at the initial examination resulted in a lower diagnosis rate of fetal growth restriction.

The optimal ultrasonic method of estimating fetal size, and therefore growth restriction, was reviewed by Manning (1995). Combining head, abdomen, and femur dimensions should in theory enhance the accuracy of predictions of fetal size. Unfortunately, any potential improvement is apparently lost by the cumulative error inherent in measurement of each individual fetal dimension. As a result, abdominal circumference measurements have been accepted by most experts as the most reliable index of fetal size (Manning, 1995; Smith and colleagues, 1997; Snijders and Nicolaides, 1994). In these studies, the estimated fetal weight calculated with abdominal circumference measurements was almost always within 10 percent of the actual birthweight ([Fig. 38-5](#)).

Abdominal circumference measured directly in the newborn was also shown to be an important anatomical marker of growth restriction (Deter and colleagues, 1995). The elegant observations on the metabolic effects of fetal growth restriction, performed at Kings College Hospital and described earlier, were determined in fetuses whose ultrasonically determined abdominal circumference was less than the fifth percentile (Snijders and Nicolaides, 1994). As shown in [Fig. 38-6](#), such small circumferences are linked to decreased Po_2 and pH. These observations emphasize that ultrasonic measurements of the abdominal circumference can meaningfully signify pathological growth restriction.

Unfortunately, the use of ultrasound for detection of fetal growth restriction does not preclude missed diagnoses. Dashe and

colleagues (2000) studied 8400 live births at Parkland Hospital in which fetal ultrasound had been performed within 4 weeks of delivery. They reported that 30 percent of growth-restricted fetuses were not detected. In a study of 1000 high-risk fetuses, Larsen and colleagues (1992) performed serial ultrasound beginning at 28 weeks and every 3 weeks thereafter. They found that reporting the results to the clinicians significantly increased the diagnosis of SGA fetuses. Although elective deliveries in this group were also increased, there was no overall improvement in neonatal outcome. An association between pathological fetal growth restriction and oligohydramnios has long been recognized (see [Chap. 21](#), p. 532). As shown in [Figure 38-7](#), the smaller the pocket of amniotic fluid, the greater the perinatal mortality. One likely explanation for oligohydramnios is diminished fetal urine production caused by hypoxia and diminished renal blood flow (Nicolaides and associates, 1990).

Doppler Velocimetry.

Abnormal umbilical artery Doppler velocimetry — characterized by absent or reversed end-diastolic flow — has been uniquely associated with fetal growth restriction (see [Chap. 16](#), p. 401). An example of this is shown in [Fig. 38-8](#). The use of Doppler velocimetry in the management of fetal growth restriction has been recommended as a possible adjunct to techniques such as nonstress testing or a biophysical profile (American College of Obstetricians and Gynecologists, 2000b).

Figure 38-5. Correlation of fetal weight estimation using abdominal circumference (AC) with actual birthweight in 175 fetuses with birthweights ranging from 400 to 3600 g. Within this weight range, the range of error was ± 10 percent. (From Manning, 1995.)

Figure 38-6. Abdominal circumference and umbilical venous blood P_{O_2} and pH in growth-restricted fetuses (\blacktriangle = fetal deaths; \bullet = neonatal deaths). The lines within and bordering the shaded areas are the mean, 5th, and 95th percentiles for gestational age. (From Hecher and colleagues, 1995, with permission.)

Figure 38-7. Relationship of amniotic fluid volume, as determined by the largest vertical pocket, to perinatal mortality. Mortality rises significantly when the largest pocket of fluid falls below 2cm. (From Manning, 1995.)

Figure 38-8. Umbilical arterial Doppler velocimetry studies, ranging from normal to markedly abnormal. **A.** Normal velocimetry pattern with an S/D ratio of < 30 . **B.** The diastolic velocity approaching zero reflects increased placental vascular resistance. **C.** During diastole, arterial flow is reversed (negative S/D ratio), which is an ominous sign that may precede fetal demise. (Courtesy of Dr. Diane Twickler.)

MANAGEMENT. Once fetal growth restriction is suspected, efforts should be made to confirm the diagnosis, assess fetal condition, and evaluate for anomalies. Although cordocentesis allows rapid karyotyping for detection of a lethal aneuploidy and thus may simplify management, the American College of Obstetricians and Gynecologists (2000b) has concluded that there are not enough data to warrant cord blood sampling in this situation. The timing of delivery is crucial, and the risks of fetal death versus the hazards of preterm delivery must be assessed as reported in the Growth Restriction Intervention Trial (GRIT) by Thornton and colleagues, 2004.

Growth Restriction Near Term.

Prompt delivery is likely best for the fetus at or near term who is considered growth restricted. In fact, most clinicians recommend delivery at 34 weeks or beyond if there is clinically significant oligohydramnios. With a reassuring fetal heart rate pattern, vaginal delivery may be attempted. Some of these fetuses do not tolerate labor, and cesarean delivery is necessary.

Uncertainty about the diagnosis should preclude intervention until fetal lung maturity is assured. Expectant management can be guided using antepartum fetal surveillance techniques described in [Chapter 15](#).

Growth Restriction Remote from Term.

When growth restriction is diagnosed in an anatomically normal fetus prior to 34 weeks, and amniotic fluid volume and fetal surveillance are normal, observation is recommended. Screening for toxoplasmosis, rubella, cytomegalovirus, herpes, and other infections is recommended by some clinicians, however, we have not found this to be productive.

As long as fetal growth continues and fetal evaluation remains normal, pregnancy is allowed to continue until fetal maturity. In some cases, amniocentesis may be helpful to assess pulmonary maturity. Although the onset of oligohydramnios is highly suggestive of fetal growth failure, importantly, normal amniotic fluid volume does not preclude growth restriction. Owen and colleagues (2001) reported that 4- and 6-week evaluation intervals were superior to 2-week intervals for predicting growth restriction. Depending on the gestational age of the fetus when fetal growth restriction is first suspected, this interval may be impractical clinically, and sonography is typically repeated more frequently.

With growth restriction remote from term, no specific treatment ameliorates the condition. There is no evidence that bed rest results in accelerated growth or improved outcome. Despite this, many clinicians advise a program of modified rest. Nutrient supplementation, attempts at plasma volume expansion, oxygen therapy, antihypertensive drugs, heparin, and aspirin have all been shown to be ineffective (American College of Obstetricians and Gynecologists, 2000b).

In most cases of growth restriction diagnosed prior to term, neither a precise etiology nor a specific therapy is apparent. Management decisions hinge on an assessment of the relative risks of fetal death with expectant management versus the risks from preterm delivery. Although reassuring fetal testing may allow observation with continued maturation of the preterm growth-restricted fetus, there is concern regarding long-term neurological outcome (Blair and Stanley, 1992; Thornton and colleagues, 2004).

Some authorities challenge that various tests of fetal well-being are unnecessary to reduce risks for stillbirth. Weiner and colleagues (1996) performed nonstress tests, biophysical profiles, and umbilical artery velocimetry within 3 days of delivery in 135 fetuses confirmed at birth to have growth restriction. Other than metabolic acidosis at delivery, which was predicted by absent or reversed end-diastolic umbilical blood flow, morbidity and mortality were determined primarily by gestational age and birthweight and not by abnormal fetal testing. Importantly, there is no convincing evidence that such testing schemes reduce the risk of long-term neurological deficits (American College of Obstetricians and Gynecologists, 2000a). A review of the status of Doppler velocimetry to aid in delivery timing was provided by Baschat (2004). **The optimal management of the preterm growth-restricted fetus remains problematic.**

LABOR AND DELIVERY. Fetal growth restriction is commonly the result of placental insufficiency due to faulty maternal perfusion, ablation of functional placenta, or both. If present, these conditions are likely aggravated by labor. Importantly, diminished amniotic fluid volume increases the likelihood of cord compression during labor. For these reasons, a woman with a suspected growth-restricted fetus should undergo "high-risk" intrapartum monitoring, as discussed in [Chapter 18](#) (see p. 465). The incidence of cesarean delivery is increased.

The infant may need expert assistance in making a successful transition at birth. The risk of being born hypoxic and of having aspirated meconium is increased. Care for the newborn should be provided immediately by someone who can skillfully clear the airway below the vocal cords and ventilate the infant as needed (see [Chap. 28](#), p. 635). The severely growth-restricted newborn is particularly susceptible to hypothermia and may also develop other metabolic derangements such as hypoglycemia, polycythemia, and hyperviscosity. In addition, low-birthweight infants are at increased risk for motor and other neurological disabilities. Risk is highest at the lowest extremes of birthweight (Nelson and Grether, 1997).

LONG-TERM SEQUELAE. In his book *Fetal and Infant Origins of Adult Disease*, Barker (1992) hypothesizes that adult mortality and morbidity are related to fetal and infant health. In the context of fetal growth restriction, there are numerous reports of a relationship between suboptimal fetal nutrition and an increased risk of subsequent adult hypertension and atherosclerosis. However, recent reports challenge this hypothesis (Hubinette and colleagues, 2001; Huxley and co-workers, 2002). In another study, Smith and colleagues (2001) found that pregnancy complications resulting in low-birthweight infants were associated with increased risk of subsequent ischemic heart disease in the mother. This suggests that common genetic risk factors might explain the link between low birthweight and risk of heart disease in both the developing fetus and the mother.

MACROSOMIA

The term *macrosomia* is used rather imprecisely to describe a very large fetus or neonate. Although there is general agreement among obstetricians that newborns weighing less than 4000 g are not excessively large, a similar consensus has not been reached for the definition of macrosomia. Indeed, the term macrosomia does not appear in the *New Shorter Oxford English Dictionary* (1993), although *Stedman's Medical Dictionary* (1995) offers the definition of "abnormally large size of the body."

The key word is "abnormal." What is the threshold for the upper limit of normal human fetal growth above which birthweight is abnormal? Which criteria should be used to define "abnormal"? Specifically, should the threshold for abnormally high birthweight be simply mathematically derived or should it include features of adverse pregnancy outcome? Given that the major hazard of excessive fetal growth is birth injury due to shoulder dystocia, should the definition include the risk of brachial plexus injury? This approach would not entirely suffice to diagnose excessive growth because shoulder dystocia would not be expected in an overgrown but preterm and thus physically small infant.

Newborn weight rarely exceeds 11 pounds (5000 g), and excessively large infants are a curiosity. The birth of a 16-pound (7300 g) infant in the United States in 1979 was widely publicized. Two of the largest newborn weights ever recorded were those of a nearly 24-pound (10,800 g) infant described by Beach in 1879 (Barnes, 1957), and a 25-pound stillborn. Among over 216,000 singleton infants who were delivered at Parkland Hospital between 1988 and 2002, only two weighed 6000 g or more for an incidence of less than 1 in 100,000 births. One infant weighed 6025 g (13 lb 4 oz) and the other 6500 g (14 lb 5 oz). The incidence of excessively large infants has increased during the 20th century. For example, according to Williams (1903), the incidence of birthweight over 5000 g was 1 to 2 per 10,000 births at the beginning of the 20th century. This compares with 15 per 10,000 at Parkland Hospital from 1988 through 2002. The latter mothers had a mean BMI of 37.8 kg/cm², and 20 percent were diabetic.

DEFINITION. Precise definitions of macrosomia on which all authorities agree do not exist. However, there are several definitions in general clinical use. In one scheme, macrosomia is viewed as those weights that exceed certain percentiles for populations. Another common scheme includes use of empirical birthweights.

Birthweight Distribution.

Commonly, macrosomia is defined based on mathematical distributions of birthweight. Those infants exceeding the 90th

percentile for a given gestational week are usually used as the threshold for macrosomia. For example, the 90th percentile at 39 weeks is 4000 g. If, however, birthweights two standard deviations above the mean are used, the threshold would be between the 97th and 99th percentile — substantially larger infants when compared with the 90th percentile. Specifically, the birthweight threshold at 39 weeks would be approximately 4500 g for the 97th percentile rather than 4000 g for the 90th percentile.

Empirical Birthweight.

Absolute birthweight exceeding a specific threshold is another commonly used definition of macrosomia. Newborn weight exceeding 4000 g, or 8 lb 13 oz, is a frequently used threshold. Others use 4250 g or even 4500 g which is almost 10 lb. As shown in [Table 38-2](#), birthweights of 4500 g or more are rare. Over a 12-year period at Parkland Hospital, during which time there were over 216,000 singleton births, only 1.25 percent of newborns weighed 4500 g or more. We are of the view that the upper limit of fetal growth, above which growth can be deemed abnormal, is likely two standard deviations above the mean, representing perhaps 3 percent of births. At 40 weeks such a threshold would correspond to approximately 4500 g. This definition of excessive growth is clearly more restrictive than using the upper 10 percent to define macrosomia. The American College of Obstetricians and Gynecologists (2000b) concluded that the term "macrosomia" was an appropriate designation for fetuses who, at birth, weigh 4500 g or more.

RISK FACTORS. Maternal diabetes is an important risk factor for development of fetal macrosomia (see [Chap. 52](#), p. 1173). As shown in [Table 38-2](#), the incidence of maternal diabetes increases as birthweight above 4000 g increases. However, it should be emphasized that maternal diabetes is associated with only a small percentage of such large infants. Of the 13,805 infants in [Table 38-2](#) who weighed 4000 g or more, only 6 percent were born to diabetic mothers. In macrosomic fetuses of diabetic women, there is a greater shoulder circumference and a greater shoulder circumference-to-head circumference ratio. Consequent to this is a greater risk of shoulder dystocia compared with that of similar weight fetuses of nondiabetic women (Modenlau and colleagues, 1982; Neiger, 1992; Sachs, 1993). Among macrosomic fetuses of similar weight, the presence of a relatively greater proportion of body fat is associated independently with an increased risk of labor dystocia and cesarean delivery (Bernstein and Catalano, 1994). Although known risk factors for macrosomia were identified by Boyd and associates (1983) in only 40 percent of women who deliver macrosomic infants, several factors favor the likelihood of a large fetus:

1. Large size of parents, especially the mother who is obese. The risk of fetal macrosomia is 30 percent if maternal weight is *more than* 300 pounds.
2. Multiparity.
3. Prolonged gestation.
4. Increased maternal age.
5. Male fetus.
6. Previous infant weighing more than 4000 g.
7. Race and ethnicity. These factors are additive. Among women who are simultaneously diabetic, obese, and postterm, the incidence of fetal macrosomia ranges from 5 to 15 percent (Arias, 1987; Chervenak, 1992).

DIAGNOSIS. Because there are no current methods to estimate excessive fetal size accurately, the diagnosis of macrosomia cannot be definitely made until delivery. Inaccuracy in clinical estimates of fetal weight by physical examination is often attributable, at least in part, to maternal obesity. Numerous attempts have been made to improve the accuracy of fetal weight estimations obtained by ultrasonography. A number of formulas have been proposed to estimate fetal weight using ultrasonic measurements of the head, femur, and abdomen. The estimates provided by these computations, although reasonably accurate for predicting the weight of small, preterm fetuses, are less valid in predicting the weight of very large fetuses. For example, as shown in [Figure 38-9](#), an infant predicted to weigh 4000 g can actually weigh considerably more or less than predicted. Rouse and co-authors (1996) reviewed 13 studies completed between 1985 and 1995 to assess ultrasonic prediction of macrosomic fetuses. They found only fair sensitivity (60 percent) in the accurate diagnosis of macrosomia but higher specificity (90 percent) in excluding excessive fetal size.

A formula has not been derived that gives estimates of fetal macrosomia with sufficiently accurate predictive value to be useful in constructing clinical management decisions (American College of Obstetricians and Gynecologists, 2000a). Not surprisingly, Adashek and colleagues (1996) found that women who underwent ultrasonic evaluation in the last 4 weeks of pregnancy were at significantly increased risk for cesarean delivery if the estimated fetal size exceeded 4000 g.

We can only conclude that the estimation of fetal weight from ultrasonic measurements is not reliable. Certainly its routine use to identify macrosomia cannot be recommended. Indeed, the findings of several studies are indicative that clinical estimates of fetal weight are as reliable as, or even superior to, those made from ultrasonic measurements (Sherman and colleagues, 1998).

CONTROVERSIES

"Prophylactic" Labor Induction.

Some clinicians have proposed labor induction when fetal macrosomia is diagnosed in nondiabetic women. This obviates further fetal growth and thereby reduces potential delivery complications. Such prophylactic induction should theoretically reduce the risk of shoulder dystocia as well as that of cesarean delivery by preempting further fetal growth. Gonen and colleagues (1997) randomized 273 nondiabetic women with ultrasonic fetal weight estimates of 4000 to 4500 g to either induction or expectant management. Labor induction did not decrease the rate of cesarean delivery or shoulder dystocia. Similar results were reported by Leaphart and colleagues (1997) with the added finding that induction unnecessarily increased the rate of cesarean delivery. We agree with the American College of Obstetricians and Gynecologists (2000b) that current evidence does not support a policy for early induction for suspected macrosomia.

Elective Cesarean Delivery.

Rouse and colleagues (1996, 1999) analyzed the potential effects of a policy of elective cesarean delivery for ultrasonically diagnosed fetal macrosomia compared with standard obstetrical management. They concluded that for women who are not diabetic, a policy of elective cesarean delivery was medically and economically unsound. Conversely, in *diabetic* women with macrosomic fetuses, such a policy of elective cesarean delivery was tenable. Conway and Langer (1998) described a protocol of routine cesarean delivery for ultrasonic estimates of 4250 g or greater in diabetic women that significantly reduced the rate of shoulder dystocia from 2.4 to 1.1 percent.

Prevention of Shoulder Dystocia.

A major concern in the delivery of macrosomic infants is shoulder dystocia and attendant risks of permanent brachial plexus palsy. Such dystocia occurs when the maternal pelvis is of sufficient size to permit delivery of the fetal head but not large enough to allow delivery of the larger-diameter fetal shoulders. In this circumstance, the anterior shoulder becomes impacted against the maternal symphysis pubis (see [Chap. 20](#), p. 513). Even with expert obstetrical assistance at delivery, stretching and injury of the brachial plexus of the affected shoulder may be inevitable (see [Chap. 29](#), p. 683). According to the American College of Obstetricians and Gynecologists (1997), fewer than 10 percent of all shoulder dystocia cases result in a persistent brachial plexus injury.

Planned cesarean delivery on the basis of suspected macrosomia is an unreasonable strategy in the *general population*. Ecker and colleagues (1997) analyzed 80 cases of brachial plexus injury in 77,616 consecutive infants born at Brigham and Women's Hospital. They concluded that an excessive number of otherwise unnecessary cesarean deliveries would be needed to prevent a single brachial plexus injury in infants born to women without diabetes. Conversely, planned cesarean delivery may be a reasonable strategy for diabetic women with an estimated fetal weight exceeding 4250 to 4500 g.

39. Multifetal Gestation

INTRODUCTION

The number and rate of twin and other higher-order multiple births have increased in the United States at an unprecedented pace over the past two decades (Martin and colleagues, 2002). This increase has been fueled largely by infertility therapy (Jewell and Yip, 1995). Between 1980 and 2001, the number of twin deliveries rose 77 percent, and the number of higher-order multiple births soared 459 percent (Fig.39-1). The rate of twin births continues to increase, and the number of higher-order multiple births has plateaued. In contrast, the singleton birth rate rose only 11 percent during the same time period. More than 3 percent of all neonates born in the United States are now the product of a multiple gestation (Martin and colleagues, 2002).

This extraordinary increase in multiple births is a public health concern; the higher rate of preterm delivery of these neonates compromises their survival chances and increases their risk of lifelong disability. Powers and Kiely (1994) evaluated birth and death certificates of neonates in the United States from 1985 and 1986 to measure the impact of twinning on national neonatal morbidity and mortality rates. Although twins accounted for only 1 in 94 pregnancies, they accounted for 14 percent of low-birthweight neonates and 11 percent of neonatal deaths. Similarly, at Parkland Hospital in 2002, twin neonates represented only 1 in 100 delivered neonates and yet accounted for 1 in 12 perinatal deaths (Table 39-1).

In addition to the perinatal mortality and morbidity attributable to preterm delivery, fetuses in multiple gestations are vulnerable to a variety of complications such as malformations and twin-to-twin transfusion syndrome. Maternal complications are also increased with multiple gestations. Conde-Agudelo and co-workers (2000) studied more than 15,000 twin pregnancies and found that the risks of preeclampsia, postpartum hemorrhage, and maternal death were increased twofold.

Figure 39-1. Number of twin (A) and triplet or higher-order multiple births (B), United States, 1980-2001. (From Martin and colleagues, 2002; Martin and Park, 1999.)

ETIOLOGY OF MULTIPLE FETUSES

Twin fetuses commonly result from fertilization of two separate ova and are termed double-ovum, dizygotic, or fraternal twins. About a third as often, twins arise from a single fertilized ovum that subsequently divides into two similar structures, each with the potential for developing into a separate individual. These twins are termed single-ovum, monozygotic, or identical twins. Either or both processes may be involved in the formation of higher numbers of fetuses. Quadruplets, for example, may arise from as few as one to as many as four ova.

Fraternal Versus Identical Twins. Dizygotic twins are not in a strict sense true twins because they result from the maturation and fertilization of two ova during a single ovulatory cycle (Fig. 39-2). Also, monozygotic or identical twins are usually not identical. As discussed subsequently, the process of division of one fertilized zygote into two does not necessarily result in equal sharing of protoplasmic materials. Furthermore, the process of monozygotic twinning is in a sense a teratogenic event, and monozygotic twins have an increased incidence of often discordant malformations. In fact, dizygotic or fraternal twins of the same sex may appear more nearly identical at birth than monozygotic twins, and growth of monozygotic twin fetuses may be discordant, at times dramatically so.

Genesis of Monozygotic Twins. Evidence regarding the physiological basis of monozygotic twinning now suggests that the division of the fertilized ovum may result from a delay in the timing of normal developmental events. In humans, delayed ovum transport through the fallopian tube increases the risk of twinning. Because progestational agents and combination contraceptives decrease tubal motility, delayed tubal transport and implantation are believed to increase the risk of twinning in pregnancies conceived in close temporal proximity to contraceptive use (Bressers and colleagues, 1987). Minor trauma to the blastocyst during assisted reproductive technology (ART) may possibly lead to the increased incidence of monozygotic twinning observed in pregnancies conceived in this manner (Wenstrom and co-workers, 1993).

The outcome of the twinning process depends on when the division occurs:

- If division occurs within the first 72 hours after fertilization, the inner cell mass (morula) has yet to form and the outer layer of blastocyst has not yet committed to become chorion. Two embryos, two amnions, and two chorions develop, and a monozygotic, diamniotic, dichorionic twin pregnancy evolves (Fig. 39-3). Two distinct placentas or a single fused placenta may develop (Fig. 39-4).
- If division occurs between the fourth and eighth day, the inner cell mass has formed and cells destined to become chorion have already differentiated, but those of the amnion have not. From this division, two embryos develop, each in a separate amniotic sac covered by a common chorion. This division gives rise to a monozygotic, diamniotic, monochorionic twin pregnancy (see Fig. 39-4C).
- If, however, the chorion and the amnion have already differentiated, by about 8 days after fertilization, division results in two embryos within a common amniotic sac, a monozygotic, monoamniotic, monochorionic twin pregnancy.
- If division is initiated even later, that is, after the embryonic disk has formed, cleavage is incomplete and conjoined twins result.

It has long been accepted that monochorionicity incontrovertibly indicated monozygosity. Rarely, however, monochorionic twins may in fact be dizygotic (Souter and colleagues, 2003). How this could happen is a matter of speculation, but it may result from the zygotic manipulations that accompany ART (Redline, 2003).

Superfetation and Superfecundation. In superfetation, an interval as long as or longer than a menstrual cycle intervenes between fertilizations. Superfetation requires ovulation and fertilization during the course of an established pregnancy, which would theoretically be possible until the uterine cavity is obliterated by the fusion of the decidua capsularis to the decidua vera. Although known to occur in mares, superfetation is as yet unproven to occur in humans. Most authorities believe that the alleged cases of human superfetation result from marked inequality in growth and development of twin fetuses of the same gestational age.

Superfecundation refers to the fertilization of two ova within the same menstrual cycle but not at the same coitus, nor necessarily by sperm from the same male. An instance of superfecundation, documented by Harris (1982), is demonstrated in [Figure 39-5](#). The mother was sexually assaulted on the 10th day of her menstrual cycle and had intercourse 1 week later with her husband. She was delivered of a black neonate whose blood type was A and a white neonate whose blood type was O. The blood type of both the mother and her husband was O. Terasaki and co-workers (1978) described the use of HLA typing to establish that a specific set of dizygotic twins were sired by different fathers.

Frequency of Twins. The frequency of monozygotic twin births is relatively constant worldwide, at approximately one set per 250 births, and is largely independent of race, heredity, age, and parity. The frequency was once thought to be independent of infertility therapy, however, there is now evidence that the incidence of zygotic splitting is increased following ART. The incidence of dizygotic twinning, however, is influenced remarkably by race, heredity, maternal age, parity, and especially, fertility drugs.

THE "VANISHING TWIN." Advanced technology has improved ultrasonographic studies of early gestations. These studies show that the first-trimester incidence of twins is much greater than the incidence of twins at birth. Monochorionic twins have a significantly greater risk of abortion than dichorionic twins (Sebire and colleagues, 1997). In some cases, the entire pregnancy aborts. In many cases, however, only one fetus dies, and the remaining fetus delivers as a singleton. Undoubtedly, some threatened abortions have resulted in actual abortion of one embryo from an unrecognized twin gestation while the other embryo continued its growth and development (Jauniaux and co-workers, 1988). Studies in which fetuses were evaluated with ultrasonography in the first trimester have shown that one twin is lost or "vanishes" before the second trimester in 21 to 63 percent of spontaneous twin conceptions (Dickey, 2002; Kol, 1993; Landy, 1986; Parisi, 1983, and all their co-workers).

Dickey and colleagues (2002) described outcomes following spontaneous reduction of a multifetal pregnancy. Prior to 12 weeks, one or more embryos died in 36 percent of twin pregnancies, 53 percent of triplet pregnancies, and 65 percent of quadruplet pregnancies. Interestingly, pregnancy duration and birthweight were inversely related to the initial gestational sac number regardless of the final number of fetuses at delivery. This effect was most pronounced in twins who started as quadruplets. Others have not found this (Yaron and associates, 1999).

A vanishing twin may cause an elevated serum maternal serum alpha-fetoprotein level, an elevated amniotic fluid alpha-fetoprotein level, and a positive amniotic fluid acetylcholinesterase assay (Winsor and associates, 1987). It is important, therefore, to establish the diagnosis of vanishing twin, because this may complicate maternal serum screening for Down syndrome or for neural-tube defects. Similarly, the vanishing twin can cause a discrepancy between the karyotype established by chorionic villus sampling and the karyotype of the surviving twin when tissue from the vanished twin is inadvertently sampled. For these reasons, amniocentesis for karyotype may be preferable (Reddy and associates, 1991).

RACE. The frequency of multifetal births varies significantly among different races and ethnic groups ([Table 39-2](#)). Myriantopoulos (1970) identified the birth of twins in 1 of every 100 pregnancies among white women, compared with 1 of 80 pregnancies for black women. In some areas of Africa, the frequency of twinning is high. Knox and Morley (1960), in a survey of one rural community in Nigeria, found that twinning occurred once in every 20 births! These marked differences in twinning frequency may be the consequence of racial variations in the levels of follicle-stimulating hormone (FSH) (Nylander, 1973).

HEREDITY. As a determinant of twinning, the family history of the mother is much more important than that of the father. White and Wyshak (1964), in a study of 4000 genealogical records of the General Society of the Church of Jesus Christ of Latter-day Saints, found that women who themselves were a dizygotic twin gave birth to twins at the rate of 1 set per 58 births. Women who were not a twin, but whose husbands were a dizygotic twin, gave birth to twins at the rate of 1 set per 116 pregnancies. One explanation is that the tendency to release multiple ova is inherited. A Belgian-Dutch group has reported that dizygotic twinning may be influenced by an autosomal dominant gene carried by approximately 15 percent of the population (Meulemans and colleagues, 1996). If true, this gene may exert its effects only in women.

MATERNAL AGE AND PARITY. The rate of natural twinning rises from 0 at puberty, a time of minimal ovarian activity, to a peak at 37 years of age, when maximal hormonal stimulation increases the rate of double ovulation (Bulmer, 1959). This is in accordance with the first consistently observed sign of reproductive aging, an isolated rise in serum FSH (Klein and co-workers, 1996). The fall in incidence after 37 years of age probably reflects depletion of the Graafian follicles.

Increasing maternal age and parity have been shown to increase the incidence of twinning independently in all populations studied. Waterhouse demonstrated that twin pregnancies were a third as common in women younger than 20 years of age with no previous children, compared with women 35 to 40 years of age with four or more previous children (1950). In Sweden, Pettersson and associates (1976) determined that the frequency of multiple fetuses in first pregnancies was 1.3 percent, compared with 2.7 percent in the fourth pregnancy. In Nigeria, Azubuike (1982) showed that the frequency of twinning increased from 1 in 50 pregnancies (2 percent) among women pregnant for the first time to 1 in 15 (6.6 percent) for women pregnant six or more times!

NUTRITIONAL FACTORS. In animals, the litter size increases in proportion to nutritional sufficiency. Evidence from a variety of sources indicates that this occurs in humans as well. Nylander (1971) showed a definite increasing gradient in the twinning rate related to greater nutritional status as reflected by maternal size. Taller, heavier women had a twinning rate 25 to 30 percent greater than short, nutritionally deprived women. MacGillivray (1986) also found that dizygotic twinning is more

common in large and tall women than in small women. Evidence acquired during and after World War II showed that twinning correlated more with nutrition than body size. Widespread undernourishment in Europe during those years was associated with a marked fall in the dizygotic twinning rate (Bulmer, 1959).

PITUITARY GONADOTROPIN. The common factor linking race, age, weight, and fertility to multifetal gestation may be FSH levels (Benirschke and Kim, 1973). This theory is supported by the fact that increased fecundity and a higher rate of dizygotic twinning have been reported in women who conceive within 1 month after stopping oral contraceptives, but not during subsequent months (Rothman, 1977). This may be due to the sudden release of pituitary gonadotropin in amounts greater than usual during the first spontaneous cycle after stopping hormonal contraception.

INFERTILITY THERAPY. The induction of ovulation by use of FSH plus chorionic gonadotropin or clomiphene citrate remarkably enhances the likelihood of multiple ovulations. The incidence of multifetal gestation following conventional gonadotropin therapy is 16 to 40 percent, 75 percent of which are twins (Schenker and co-workers, 1981). Tuppin and colleagues (1993) reported that in France, the incidence of twin and triplet deliveries and the sale of human menopausal gonadotropin (hMG) rose in parallel between 1972 and 1989. By 1989, half of triplet pregnancies resulted from ovulation induction. Superovulation therapy, which increases the chance of pregnancy by recruiting multiple follicles, results in multifetal gestation rates of 25 to 30 percent (Bailey-Pridham and associates, 1990).

Risk factors for multiple fetuses after ovarian stimulation with hMG include increased estradiol levels on the day of chorionic gonadotropin injection and sperm characteristics such as increased concentration and motility (Dickey and associates, 1992; Pasqualotto and colleagues, 1999). With recognition of these factors plus the ability to monitor follicular growth and size ultrasonographically, physicians may cancel cycles likely to lead to a multifetal gestation. This approach has reduced the incidence of multiple births. Previously, clomiphene therapy was associated with a lower incidence of multifetal gestation compared with hMG use. Researchers speculate that judicious management of hMG-stimulated ovaries has decreased the incidence of these pregnancies. The majority of multifetal gestations resulting from ovulation induction are currently caused by clomiphene citrate (Rein and colleagues, 1990).

Ovulation induction increases both dizygotic and monozygotic twinning. Derom and colleagues (1987) studied the incidence of monozygotic twinning in almost 1000 pairs of twins delivered in East Flanders, Belgium, and reported that the incidence of zygotic splitting was doubled after induced ovulation.

Assisted Reproductive Technology. Techniques such as ART, which are designed to increase the probability of pregnancy, increase the probability of multifetal gestation as well. Typically, patients undergo superovulation, in vitro fertilization is attempted in all retrieved ova, and two to four embryos are transferred to the uterus. In general, the greater the number of embryos that are transferred, the greater the risk of twins and of higher-order multiple gestation.

Higher-order multiple gestation confers significant risk to both mother and fetuses and reduces the chances of both a live birth and the birth of a child without significant handicap. The only remedy is a selective reduction procedure, which also increases fetal risk. In addition, higher-order multiple gestation is financially costly. Goldfarb and colleagues (1996) estimated the combined costs of in vitro fertilization plus prenatal care and delivery totalled \$39,249 for singletons or twins, and this increased to \$342,788 for triplets or higher-order multiple gestation. Most of the costs for singletons or twins were attributed to in vitro fertilization, whereas most of the costs with triplets or more were due to neonatal intensive care.

Reducing Multiple Gestation. The American Society for Reproductive Medicine (1999) has initiated a concerted effort to reduce the incidence of higher-order multiple gestation because of associated morbidity and mortality. In their recent review, Jain and colleagues (2004) cited the consistent decreases in both the number of embryos transferred per cycle and the percentage of pregnancies with three or more fetuses (see [Fig. 39-1B](#)). Concurrently, there also has been a consistent increase in the percentage of live births per cycle. This has occurred for a number of reasons. For example, culturing embryos for 5 days to the blastocyst stage allowed identification of the most viable blastocysts and an acceptable chance of pregnancy implantation with a transfer of fewer embryos (Scholtes and Zeilmaker, 1996). Two-embryo transfer for women with a good prognosis for conception has been advocated as a way to maintain a high pregnancy implantation rate while decreasing the number of higher-order multiple gestations (Meldrum and Gardner, 1998). Data analyzed by Ozturk and Templeton (2002) from 27,230 ART cycles supported this approach. Two-embryo transfer was associated with a decreased rate of triplet birth but an equivalent overall live birth rate compared with the rate when more embryos were transferred. Kovacs and colleagues (2003) analyzed 2606 fresh embryo transfers and reported that transfer of only one embryo achieved a pregnancy rate similar to that with transfer of two. Conservative gonadotropin stimulation has proved of limited value (Gleicher and colleagues, 2000). These issues were reviewed recently by Adashi (2004) as well as Templeton (2004).

Sex Ratios with Multiple Fetuses. In humans, as the number of fetuses per pregnancy increases, the percentage of male conceptuses decreases. Strandkov and co-workers (1946) found the percentage of males for 31 million singleton births in the United States to be 51.6 percent. For twins, it was 50.9 percent; for triplets, 49.5 percent; and for quadruplets, 46.5 percent. An even greater number of females in twins result from late twinning events.

Seventy percent of monochorionic-monoamniotic twins and 75 percent of conjoined twins are female (Machin, 1996). Two explanations have been offered. First, there is a well-known differential fetal mortality between the sexes, which persists for the newborn, child, and adult. Generally, mortality rates are lower in females. Nutritional and space limitations associated with multiple fetuses in utero may exaggerate this biological tendency. Second, genetically female zygotes have a greater tendency to divide into twins or higher multiples.

Determination of Zygosity. The main reason to determine zygosity antenatally is that it can aid obstetrical risk assessment and guide management of multifetal gestation (Fisk and Bryan, 1993). The rate of twin-specific complications varies in relation to zygosity ([Table 39-3](#)). Clearly, monochorionic twin gestations are at increased risk for a variety of pregnancy complications, some of which may be minimized by early antepartum recognition.

Determination of zygosity frequently requires sophisticated genetic tests because dizygotic twins can look alike, whereas monozygotic twins are not always identical. Monozygotic twins may actually be discordant for genetic mutations as the result of a postzygotic mutation, or may have the same genetic disease but with marked variability in expression. In female fetuses, skewed lyonization can produce differential expression of X-linked traits or diseases.

Most interestingly, monozygotic twins may be discordant for malformations that involve asymmetrical organs, for example, the heart (Machin, 1996).

Ultrasonographic Evaluation. Chorionicity can be determined ultrasonographically as early as the first trimester. The presence of two separate placentas and a thick — generally 2 mm or greater — dividing membrane (Fig. 39-6A) supports the presumption of the diagnosis of dichorionicity. Fetuses of opposite gender are almost always dizygotic (Mahony and co-workers, 1985).

In pregnancies in which a single placental mass is identified, it may be difficult to distinguish one large placenta from two placentas lying side by side or "fused." Examining the point of origin of the dividing membrane on the placental surface may clarify this situation. If a triangular projection of placental tissue is seen to extend beyond the chorionic surface between the layers of the dividing membrane, then two fused placentas are actually present (see Fig. 39-6). This finding is termed the "twin-peak" sign.

Monochorionic pregnancies have a dividing membrane that is so thin it may not be seen until the second trimester. The membrane is generally less than 2 mm in thickness, and magnification reveals only two layers (Scardo and associates, 1995). This right-angle relationship between the membranes and placenta with no apparent extension of placenta between the dividing membrane is called the "T" sign. Ultrasonographic evaluation of the dividing membrane is easiest and most accurate in the first half of pregnancy, because the fetuses are smaller (Stagiannis and colleagues, 1995) (Fig. 39-7).

Scardo and colleagues (1995) used the combination of placental location, dividing membrane thickness, presence or absence of the "twin-peak" sign, and fetal gender to determine the chorionicity, amnionicity, and zygosity in 110 consecutive twins at midgestation. Compared with the pathological diagnosis made by examining the placenta after delivery, the ultrasonographic determination had 91 percent sensitivity and specificity. However, zygosity could not be determined even by placental pathology in 35 percent of cases, emphasizing that determination of zygosity often requires sophisticated genetic testing. In another study of 150 twin pregnancies at 10 to 14 weeks, Carroll and colleagues (2002) used a variety of ultrasonographic signs and identified chorionicity with a high degree of accuracy. The "twin-peak" sign in combination with an assessment for separate placentas had 97 percent sensitivity and 100 percent specificity for dichorionicity. The respective values for monochorionicity using the "T" sign were 100 percent and 98 percent.

Placental Examination. A carefully performed visual examination of the placenta and membranes serves to establish zygosity promptly in about two thirds of cases. The following system for examination is recommended: as the first neonate is delivered, one clamp is placed on a portion of its cord (Fig. 39-8). Cord blood is not collected until after delivery of the other twin, unless it has been clearly shown that there are two placentas. As the second neonate is delivered, two clamps are placed on that cord. Three clamps are used to mark the cord of a third neonate, and so on as necessary. Until the delivery of the last fetus, each cord segment must remain clamped to prevent fetal hypovolemia and anemia caused by blood leaving the placenta via anastomoses and then lost via an unclamped cord.

The placenta should be carefully delivered to preserve the attachment of the amnion and chorion to the placenta, because identification of the relationship of the membranes to each other is critical. With one common amniotic sac, or with juxtaposed amnions not separated by chorion arising between the fetuses, the fetuses are monozygotic. If adjacent amnions are separated by chorion, the fetuses could be either dizygotic or monozygotic, but dizygosity is more common (see Figs. 39-4, 39-9, and 39-10). If the neonates are of the same sex, blood typing of cord blood samples may be helpful. Different blood types confirm dizygosity, although demonstrating the same blood type in each fetus is not enough to confirm monozygosity. For definitive diagnosis, more complicated techniques such as DNA fingerprinting can be used, but these tests are generally not performed at birth unless there is a pressing medical indication (Azuma and associates, 1989).

Infant Sex and Zygosity. Twins of opposite sex are almost always dizygotic. Rarely, monozygotic twins may be discordant for phenotypic sex. This occurs when one twin is phenotypically female due to Turner syndrome (45,X) and her sibling is 46,XY.

Figure 39-8. Placenta from a triplet gestation showing umbilical cord clamps placed in order of delivery of the infants. This identification system aids determination of zygosity.

Figure 39-9. A. The membrane partition that separated twin fetuses is elevated. **B.** The membrane partition consists of chorion (c) between two amnions (a).

Figure 39-10. Quintuplet placenta with five separate amniotic sacs delivered at 32 weeks. Amniotic sacs of numbers 3 and 5 were not separated by chorion, and therefore those infants are monozygous. Infant birthweights ranged from a high of 1530 g (no. 1) to 860 g (no. 5). All of the infants survived.

DIAGNOSIS OF MULTIPLE FETUSES

HISTORY AND CLINICAL EXAMINATION. A maternal family history of twins, advanced maternal age, high parity, large maternal size, and a personal history of twins provide weak clues to the diagnosis of multifetal gestation. Knowledge of recent administration of either clomiphene citrate or gonadotropins or pregnancy accomplished by ART provide strong ones.

Clinical examination with accurate measurement of fundal height, as described in [Chapter 8](#) (see p. 212), is essential. During the second trimester, the uterine size is typically larger than expected for the gestational age determined from menstrual data. Rouse and co-workers (1993) reported fundal heights in 336 well-dated twin pregnancies. Between 20 and 30 weeks, fundal heights were on average about 5 cm greater than expected for singletons of the same fetal age.

In women with a uterus that appears large for gestational age, the following possibilities are considered:

1. Multiple fetuses
2. Elevation of the uterus by a distended bladder
3. Inaccurate menstrual history
4. Hydramnios
5. Hydatidiform mole
6. Uterine myomas
7. A closely attached adnexal mass
8. Fetal macrosomia (late in pregnancy)

When uterine palpation leads to the diagnosis of twins, it is most often because two fetal heads have been detected, often in different uterine quadrants. In general, however, before the third trimester it is difficult to diagnose twins by palpation of fetal

parts. Even late in pregnancy it may be difficult to identify twins by abdominal palpation, especially if one twin overlies the other, if the woman is obese, or if hydramnios is present.

Late in the first trimester, fetal heart action may be detected with Doppler ultrasonic equipment. Thereafter, it becomes possible to identify two fetal heart beats if their rates are clearly distinct from each other and from that of the mother. Careful examination with an aural fetal stethoscope can identify fetal heart sounds in twins as early as 18 to 20 weeks.

ULTRASONOGRAPHY. By careful ultrasonographic examination, separate gestational sacs can be identified early in twin pregnancy ([Fig. 39-11](#)). Subsequently, each fetal head should be seen in two perpendicular planes so as not to mistake a cross section of the fetal trunk for a second fetal head. Ideally, two fetal heads or two abdomens should be seen in the same plane, to avoid scanning the same fetus twice and interpreting it as twins. Ultrasonographic examination should detect practically all sets of twins. Indeed, one argument in favor of ultrasonographic screening is earlier detection of multiple fetuses (see [Chap. 16](#), p. 390). In a large randomized trial, LeFevre and co-workers (1993) demonstrated that routine midgestation ultrasonographic examinations detected virtually all multifetal gestations (99 percent) before 26 weeks, whereas when performed only for specific indications just 62 percent were detected before this gestational age. Higher-order multiple gestations are more difficult to evaluate. Even in the first trimester it can be difficult to determine the correct number of fetuses and their position, which is important for nonselective pregnancy reduction and essential for selective termination (discussed later).

OTHER DIAGNOSTIC AIDS

Radiological Examination. A radiograph of the maternal abdomen can be helpful when the number of fetuses in a higher-order multiple gestation is uncertain. Radiographs, however, are generally not useful and may lead to an incorrect diagnosis in the following circumstances:

1. The film is taken before 18 weeks, when fetal skeletons are insufficiently radiopaque.
2. The film is of poor quality from inappropriate exposure time or from malposition of the mother so that her upper abdomen and the fetus therein are excluded from the radiograph.
3. The mother is obese.
4. There is hydramnios.
5. One or more fetuses moves during the exposure.

Biochemical Tests. The amounts of chorionic gonadotropin in plasma and in urine, on average, are higher than those found with a singleton pregnancy, but not so high as to allow a definite diagnosis of multiple fetuses. Twins are frequently diagnosed during an evaluation for an elevated maternal serum alpha-fetoprotein level, although this level alone is not diagnostic (see [Chap. 13](#), p. 320). Currently, there is no biochemical test that reliably differentiates between the presence of one and more than one fetus.

MATERNAL ADAPTATION

In general, the degree of maternal physiological change is greater with multiple fetuses than with a single fetus. Beginning in the first trimester, women with multiple gestation often have nausea and vomiting in excess of that characterizing singleton pregnancies, for reasons that are not clear. The normal maternal blood volume expansion is greater in twin pregnancies (Pritchard, 1965). Whereas the average increase in late pregnancy is about 40 to 50 percent with a single fetus, it is about 50 to 60 percent with twins (i.e., an additional 500 mL). The red cell mass increases as well, but proportionately less in twin pregnancies than in singletons, resulting in a more pronounced "physiological anemia." The average blood loss with vaginal delivery of twins is 935 mL, or nearly 500 mL more than with delivery of a single fetus. Both the remarkable increase in maternal blood volume and the increased iron and folate requirements predispose to a greater prevalence of maternal anemia.

Kametas and associates (2003) used two-dimensional and M-mode echocardiography to assess cardiac function in 119 women with twin pregnancies from 10 to 40 weeks. Cardiac output was increased 20 percent compared with that of singleton pregnancies, predominantly due to greater stroke volume, and to a much lesser degree, increased heart rate. Interestingly, formally assessed pulmonary function does not differ between women carrying twins and those carrying singletons (McAuliffe and colleagues, 2002).

Women carrying twins also have a typical pattern of arterial blood pressure change. Compared with the diastolic blood pressure of mothers carrying singletons, theirs is lower at 20 weeks but increases more by delivery. The increase is at least 15 mm Hg in 95 percent of women carrying twins compared with only 54 percent of women pregnant with singleton pregnancies (Campbell, 1986).

Uterine growth in multifetal gestation increases during pregnancy. The uterus and its nonfetal contents may achieve a volume of 10 L or more and weigh in excess of 20 pounds! Especially with monozygotic twins, rapid accumulation of excessive

amounts of amniotic fluid (i.e., acute hydramnios) may develop. In these circumstances, maternal abdominal viscera and lungs may be appreciably compressed and displaced by the expanding uterus. The size and weight of the large uterus may preclude more than a sedentary existence for these women.

In multifetal gestation complicated by hydramnios, maternal renal function may become seriously impaired, most likely as the consequence of obstructive uropathy. Quigley and Cruikshank (1977) described two women each carrying twins in whom acute and severe hydramnios led to maternal oliguria and azotemia. Maternal urine output and plasma creatinine levels promptly returned to normal after delivery. In severe hydramnios, therapeutic amniocentesis may be used to provide relief for the mother, to improve obstructive uropathy, and to lower the risk of preterm delivery from preterm labor or premature rupture of membranes (see [Chap. 21](#), p. 529). Unfortunately, the hydramnios is often characterized by acute onset remote from term and by rapid reaccumulation following amniocentesis.

The various stresses of pregnancy and the likelihood of serious maternal complications are almost invariably greater with multiple fetuses than with a singleton. This should be taken into account, especially when counseling the woman whose health is compromised and whose multifetal gestation is recognized early. The same is true for a woman who is not pregnant but is considering infertility treatment by ovulation induction or ART.

PREGNANCY OUTCOME

ABORTION. Spontaneous abortion is more likely with multiple fetuses. Detailed reviews have identified three times more twins among aborted than among term pregnancies (Livingston and Poland, 1980; Uchida and co-authors, 1983). Monochorionic abortuses greatly outnumber dichorionic abortuses (18 to 1), implicating monozygosity as a risk factor for spontaneous abortion.

MALFORMATIONS. The incidence of congenital malformations is appreciably increased in twin and higher-order multiple gestation compared with singletons. Major malformations develop in 2 percent and minor malformations in 4 percent of twins (Cameron and colleagues, 1983; Kohl and Casey, 1975). This increase is almost entirely due to the high incidence of structural defects in monozygotic twins. According to Schinzel and associates (1979), anomalies in monozygotic twins generally fall into one of three categories:

1. Defects resulting from twinning itself, which some consider to be a teratogenic event. This category includes conjoined twinning, acardiac anomaly, sirenomelia, neural-tube defects, and holoprosencephaly.
2. Defects resulting from vascular interchange between monochorionic twins. Vascular anastomoses can give rise to reverse flow with acardia in one twin. Alternatively, if one twin dies and intravascular coagulation develops, these connections can allow emboli to reach the living twin. Vascular connections may also conduct dramatic blood pressure fluctuations, causing defects such as microcephaly, hydranencephaly, intestinal atresia, aplasia cutis, or limb amputation.
3. Defects that occur as the result of crowding. Examples include talipes equinovarus (clubfoot) or congenital hip dislocation. Dizygotic twins are also subject to this.

Baldwin (1991) has comprehensively reviewed anomalies that develop in twins. Persistent hydramnios is associated with fetal anomalies of one or both twins. Hashimoto and colleagues (1986) subjectively identified increased amniotic fluid in one fourth of 75 twin pregnancies. In nine pregnancies, hydramnios was transient, and all of these fetuses were normal. In 9 of 10 pregnancies in which hydramnios persisted, fetuses had anomalies.

BIRTHWEIGHT. Multifetal gestations are more likely to be characterized by low birthweight than singleton pregnancies, due mostly to restricted fetal growth and preterm delivery (Buekens and Wilcox, 1993). In general, the larger the number of fetuses, the greater the degree of growth restriction. Two thirds of twin and even more triplet pregnancies are complicated by fetal growth restriction. However, this assessment of growth is based on growth curves established for singletons. Several authorities have made the argument that fetal growth in multiple gestation is different from that of singleton pregnancies, and that abnormal growth should be diagnosed only when fetal size is less than expected for *multifetal gestation*. Both twin and triplet growth curves have been created for this purpose (Ong and associates, 2002; Rodis and associates, 1999).

In dizygotic pregnancies, marked size discordancy usually results from unequal placentation, with one placental site receiving a better blood supply than the other. However, size differences may also reflect different genetic fetal growth potentials. In the third trimester, the larger fetal mass leads to accelerated placental maturation and relative placental insufficiency. Size discordancy can also result from umbilical cord abnormalities such as velamentous insertion, marginal insertion, or vasa previa; discordancy for fetal malformations; genetic syndromes; or infection. [Figure 39-12](#) shows dizygotic twins, one of whom weighed 2300 g and the other 785 g, delivered at Parkland Hospital. Both survived.

The degree of growth restriction in monozygotic twins is likely to be greater than that in dizygotic pairs. The allocation of blastomeres may not be equal between monochorionic embryos, vascular anastomoses within the placenta may cause unequal distribution of nutrients and oxygen, and discordant structural anomalies resulting from the twinning event itself may affect growth. For example, the quintuplets shown in [Figure 39-13](#) represent three dizygotic and two monozygotic fetuses. When delivered at 31 weeks, the three neonates from separate ova weighed 1420, 1530, and 1440 g, whereas the two derived from the same ovum weighed 990 and 860 g.

When birthweights in more than 500,000 male singleton neonates were compared with those from more than 10,000 male twin neonates, twin birthweights closely paralleled those of singletons until about 28 to 30 weeks. Subsequently, twin birthweights progressively lagged with advancing gestational age those of singletons ([Fig. 39-14](#)). At approximately 34 to 35 weeks and thereafter, twin birthweights clearly diverge from those of singletons. Twin growth restriction intensifies as the third trimester continues. At 38 weeks or later, the incidence of overt growth restriction quadruples to include almost half of twin births.

Other circumstantial evidence shows that in utero crowding by multiple fetuses may overtax the capacity of the mother, the uterus, or both to provide nutrients. For example, Lipitz and co-workers (1996), Smith-Levitin and colleagues (1996), and Yaron and associates (1999) have reported that selective reduction of triplets to twins before 12 weeks results in a growth pattern typical of twins rather than triplets. Dickey and co-workers (2002) did not observe this with spontaneous reduction (see p. 941).

Casele and co-authors (1996), who studied maternal metabolic responses to eating and extended overnight fasting, provide another example that the maternal supply line is affected by the number of fetuses. Women with twins were more vulnerable to starvation ketosis after fasting compared with women with singleton pregnancies.

Figure 39-12. Marked discordance in dizygotic twins. The larger infant weighed 2300 g and was appropriate for gestational age. The markedly growth-restricted smaller infant weighed only 785 g. Both thrived.

Figure 39-14. Birthweight percentiles (25 to 75) for singleton male infants compared with the 50th birthweight percentile for twin males, Canada, 1986-1988. (Modified from Arbuckle and colleagues, 1993, with permission.)

DURATION OF GESTATION. As the number of fetuses increases, the duration of gestation decreases ([Fig. 39-15](#)). According to Martin and colleagues (2002), 57 percent of twins born in the United States in 2001 were delivered preterm, and their mean gestational age at delivery was 35 weeks. With triplets, 92 percent were delivered preterm, and their mean gestational age at delivery was 32 weeks. Virtually all quadruplets and quintuplets were delivered preterm, with average gestational ages at delivery of 30 and 29 weeks, respectively.

Figure 39-15. Cumulative percent of singleton, twin, and triplet or higher-order multiple births according to gestational age at delivery in the United States during 1990. (From Luke, 1994.)

PRETERM BIRTH. Delivery before term is the major reason for the increased risk of neonatal death and morbidity in twins. Gardner and associates (1995) found that the causes of preterm birth differed between twins and singletons. Spontaneous preterm labor accounted for a larger proportion of twin preterm birth, whereas the reverse was true for preterm ruptured membranes. Indicated preterm delivery accounted for equal proportions of prematurely delivered twins and singletons.

The rate of preterm birth among multifetal gestations has increased over the past two decades. In an analysis of nearly 350,000 twin births in the United States, Kogan and colleagues (2002) showed that during the 16-year period from 1981 to 1997, the rate of term birth among twins declined by 22 percent. Joseph and colleagues (2001) attributed this decline to an increased rate of preterm labor induction for medical indications among twins, which happily was associated with decreases in perinatal morbidity and mortality among twins that reached 34 weeks. Likewise, twin gestations in women receiving more than the recommended number of prenatal visits showed higher rates of preterm birth but lower neonatal mortality (Kogan and colleagues, 2000).

Although the causes of preterm delivery in twins and singletons may be different, once delivered, the neonatal outcome is generally the same at similar gestational ages (Gardner, 1995; Kilpatrick, 1996, and their colleagues). The primary neonatal problem with twin gestation is simply more frequent preterm delivery, not increased vulnerability to the morbidities of preterm delivery.

The previous statements apply to twins who are essentially concordant. As one would expect, the neonatal outcome for preterm twins who are markedly discordant may not be comparable to that of singletons because whatever caused the discordance may have long-lasting effects. Sonntag and co-workers (1996) compared 27 weight-discordant twin pairs with 72 pairs of concordant twins. They found that the discordant twins had a significantly higher neonatal mortality (19 versus 2

percent) and were more likely to have severe intracranial hemorrhage and persistent ductus arteriosus. Most of the increase in morbidity and mortality was due to the sequelae of chronic twin-to-twin transfusion syndrome. Nearly half of the discordant pairs in this study fulfilled the criteria for this disorder.

Population studies also reveal the harmful effects of discordancy. After analyzing matched birth and death certificates of 150,000 pairs of twins, Demissie and associates (2002) concluded that birthweight discordancy correlated directly with the risk of stillbirth. In an analysis of the same data, Blickstein and Keith (2004) demonstrated that among twins discordant by at least 25 percent, the risk of neonatal death for the smaller twin was increased only if its weight was less than the tenth percentile. Rydhstrom (1994) observed that adverse pregnancy outcomes and discordancy were linked only in like-sexed twin pairs. The author hypothesized that monochorionicity was responsible for the adverse outcomes.

PROLONGED PREGNANCY. More than 30 years ago, Bennett and Dunn (1969) suggested that a twin pregnancy of 40 weeks or more should be considered postterm. They based this conclusion on the observation that twin stillborn infants delivered at 40 weeks or beyond had features similar to those of postmature singletons (see [Chap. 37](#), p. 884). Based on an analysis of almost 300,000 twin births delivered in the United States from 1995 to 1998, Kahn and colleagues (2003) calculated that at and beyond 39 weeks, the risk of subsequent stillbirth was greater than the risk of neonatal mortality. At Parkland Hospital, twin gestations have empirically been considered to be prolonged at about 40 weeks.

SUBSEQUENT DEVELOPMENT. In a study in Norway, Nilsen and associates (1984) evaluated the physical and intellectual development of male twins at 18 years of age. Compared with singletons, twice as many twins were found to be physically unfit for military service. They attributed this to sequelae of preterm delivery such as visual impairment rather than to twinning. General intelligence did not appear to differ.

At least one study has suggested that long-term physical development might be different for twins. Silva and colleagues (1982, 1985) carefully monitored 24 twins up to 11 years of age, and compared their outcomes with those of 1013 singletons who had similar gestational ages and weights at birth and who experienced similar antenatal and neonatal complications. Twins had delays in achieving developmental milestones, and at 11 years of age lagged behind singletons in intelligence quotient (IQ) scores. At each age, twins were similar in height to singletons 3 months younger, and similar in weight to singletons 6 months younger.

The pattern of subsequent development of discordant twins varies. For example, Babson and Phillips (1973) reported that in monozygotic twins whose birthweights differed on average 35 percent, the twin who was smaller at birth remained so into adulthood. Height, weight, head circumference, and intelligence often remained greater in the twin who weighed more at birth. Fujikura and Froelich (1974), however, failed to confirm a significant difference in mental and motor scores. Baigts and co-workers (1982) studied a pair of 17-year-old monozygotic twins who had similar body frames, but remarkably dissimilar weights, which had persisted since birth. The investigators documented hyperplasia of adipocytes in the heavier twin compared with those in her lower-weight sister. They suggested that intrauterine nutritional status helps determine adipocyte numbers and the way the body evolves. Others have concluded that genetic factors in twins are more influential than environment in determining body mass (Bouchard and co-workers, 1990; Stunkard and co-workers, 1990).

UNIQUE COMPLICATIONS

A number of unique complications develop in multiple fetuses. Although these have been best described in twins, they also occur in higher-order multiple gestation.

MONOAMNIONIC TWINS. Approximately 1 percent of monozygotic twins are monoamniotic (Hall, 2003). Diamniotic twins can become monoamniotic, and have all the associated morbidity and mortality, if the dividing membrane ruptures (Gilbert and colleagues, 1991). A high fetal death rate is associated with this rare variety of monozygotic twinning. Allen and colleagues (2001) in a comprehensive review reported that monoamniotic twins that are diagnosed antenatally and are still alive at 20 weeks have about a 10-percent risk of subsequent intrauterine demise. Intertwining of their umbilical cords, a common cause of death, is estimated to complicate at least half of cases ([Fig. 39-16](#)).

Once diagnosed, management of monoamniotic twins is somewhat problematic due to the unpredictability of fetal death resulting from cord entanglement and to the lack of an effective means of monitoring for it. Some data suggest that morbid cord entanglement is likely to occur early, and that monoamniotic pregnancies that have successfully reached 30 to 32 weeks are at greatly reduced risk. Carr and co-authors (1990) reviewed 24 sets of monoamniotic twins in which all the fetuses were known to be alive before 18 weeks. At 30 weeks, 70 percent of the fetuses were alive and no additional fetuses died prior to delivery, at an average age of 36 weeks. The investigators concluded that the risks due to early delivery to prevent cord accidents outweighed the risks of fetal death from cord entanglement, especially after 30 weeks. Similarly, there were no fetal deaths after 32 weeks reported by Tessin and Zlatnik (1991) in their description of 20 monoamniotic twin pregnancies at the University of Iowa Hospital. Demaria and associates (2004) reported no fetal deaths in 15 women after 29 weeks.

Umbilical cords of twins frequently entangle, but the factors that lead to pathological umbilical vessel constriction during entanglement are unknown. Belfort and colleagues (1993) and Aisenbrey and co-workers (1995) used color-flow Doppler ultrasonography to diagnose umbilical cord entanglement in 10 monoamniotic twin pregnancies. The recognition of cord entanglement in seven of these pregnancies prompted hospital admission, increased fetal surveillance, or both. Interestingly, only one set of twins with entangled cords required immediate delivery. In fact, the remaining six pregnancies continued for an average of 6 weeks after the diagnosis, and one of these continued for 12 weeks!

At the University of Alabama, presumed monoamniotic twins are managed with twice-weekly fetal assessment testing starting at 28 weeks. If testing reveals fetal heart rate variability and no heart rate decelerations, amniocentesis is done to assess fetal lung maturity beginning at 34 weeks. Cesarean delivery is performed when tests indicate pulmonary maturity, or at 36 weeks. Betamethasone for fetal maturation is used on an individualized basis (see [Chapter 36](#)).

Figure 39-16. Monozygotic twins in a single amniotic sac. The smaller fetus

apparently died first. and the second subsequently succumbed when the umbilical cords entwined.

CONJOINED TWINS. In the United States, united or conjoined twins (see [Fig. 39-2](#)) are commonly referred to as Siamese twins, after Chang and Eng Bunker of Siam (Thailand), who were displayed worldwide by P.T. Barnum. When twins are conjoined, the shared body site may be:

1. Anterior (thoracopagus).
2. Posterior (pygopagus).
3. Cephalic (craniopagus).
4. Caudal (ischiopagus).

The majority are of the thoracopagus variety shown in [Figures 39-17](#) and [39-18](#).

When the bodies are duplicated only partly, the attachment is usually lateral. The incomplete division of the embryonic disc may begin at either or both poles and may produce two heads; two, three, or four arms; two, three, or four legs; or some combination thereof. The frequency of conjoined twins is not well established. At Kandang Kerbau Hospital in Singapore, Tan and co-workers (1971) identified seven cases of conjoined twins among more than 400,000 deliveries (1 in 60,000).

As reviewed by van den Brand and associates (1994), the diagnosis of conjoined twins can frequently be made at midpregnancy using ultrasonography, which allows parents to decide whether to continue the pregnancy. A thorough targeted ultrasonographic examination, including a careful evaluation of the point of connection and the organs involved, is essential before counseling is provided. Surgical separation of nearly completely joined twins may be successful when organs essential for life are not shared, and when it can be performed on a planned, as opposed to an emergency basis (Spitz and Kiely, 2003). Consultation with a pediatric surgeon often assists antenatal parental decision making. Conjoined twins may have discordant structural anomalies that further complicate decisions about whether or not to continue the pregnancy. For example, one of the conjoined twins shown in [Figure 39-19](#) was anencephalic.

Viable conjoined twins should be delivered by cesarean. However, vaginal delivery of conjoined twins for the purpose of pregnancy termination is possible, because the union is most often pliable, although dystocia is common. If the fetuses are mature, vaginal delivery may be traumatic to the maternal uterus or cervix.

ACARDIAC TWIN. *Twin reversed-arterial-perfusion (TRAP) sequence* is a rare (1 in 35,000 births) but serious complication of monochorionic, monozygotic multiple gestation. In the TRAP sequence, there is usually a normally formed donor twin who has features of heart failure as well as a recipient twin who lacks a heart (acardius) and various other structures (van Allen and colleagues, 1983). It has been hypothesized that the TRAP sequence is caused in the embryo by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt. The perfusion pressure of the donor twin overpowers that in the recipient twin, who thus receives reverse blood flow from its twin sibling (Jones, 1997). The "used" arterial blood reaching the recipient twin preferentially goes to the iliac vessels and thus perfuses only the lower part of the body, leading to disruption or deterioration of growth and development of the upper body. Failure or disrupted growth of the head is called *acardius acephalus*; a partially developed head with identifiable limbs is called *acardius myelacephalus*; and failure of any recognizable structure to form is *acardius amorphous* (Robie and colleagues, 1989). An acardiac twin demonstrating acephalus as well as complete malformation of the upper torso is shown in [Figure 39-20](#).

Without treatment, the donor or "pump" twin has been reported to die in 50 to 75 percent of cases (Moore and colleagues, 1990). Quintero and colleagues (1994) have reviewed methods of in utero treatment of acardiac twinning in which the goal is

interruption of the vascular communication between the donor and recipient twins. They also have described successful use of transabdominal fetoscopy to ligate the umbilical cord of 11 acardiac twins at approximately 21 weeks (Quintero and co-workers, 1996). Tsao and colleagues (2002) reported the survival of 12 of 13 donor twins when, under ultrasonographic guidance, a 14-gauge radioablation needle was used to cauterize the umbilical vessels and terminate blood flow to the recipient twin at the site of cord insertion into the umbilicus. Ablation was performed at 18 to 24 weeks.

Recently, survival was reported for 9 of 10 donor twins managed expectantly (Sullivan and associates, 2003). The authors of this report advocated that expectant management with close fetal surveillance be considered as another management option.

Figure 39-20. Acardiac twin photographed from the rear and showing acephalus with total deformity of the upper torso. (Courtesy of Dr. Paul Wendel.)

VASCULAR ANASTOMOSES BETWEEN FETUSES. With rare exceptions, vascular anastomoses between twins are present only in monochorionic twin placentas (Baldwin, 1991; Hall, 2003; Robertson and Neer, 1983). Nearly 100 percent of monochorionic twin placentas have vascular anastomoses, but there are marked variations in the number, size, and direction of these seemingly haphazard connections. Artery-to-artery anastomoses on the chorionic surface of the placenta have been identified in up to 75 percent of monochorionic twin placentas and are the most common pattern (Fig. 39-21). Vein-to-vein and artery-to-vein communications are each found in approximately 50 percent of monochorionic twin placentas. One vessel may have several connections, sometimes to both arteries and veins. In contrast to these vascular connections on the surface of the chorion, artery-to-vein communications extend through the capillary bed of the villous tissue of the placenta. These deep arteriovenous anastomoses create a common villous compartment or third circulation that has been identified in approximately half of monochorionic twin placentas (Fig. 39-22).

Most of these vascular communications are hemodynamically balanced and of little fetal consequence. In others, however, they can cause hemodynamically significant shunts between fetuses. Two patterns of hemodynamically significant anastomotic circulations include acardiac twinning (described above) and the twin-to-twin transfusion syndrome. The incidence of the latter syndrome is unclear, but up to approximately a fourth of monochorionic twins have some clinical features of this syndrome (Galea and co-workers, 1982).

Twin-To-Twin Transfusion Syndrome. In this syndrome, blood is transfused from a donor twin to its recipient sibling such that the donor becomes anemic and its growth may be restricted, whereas the recipient becomes polycythemic and may develop circulatory overload manifest as hydrops. The donor twin is pale, and its recipient sibling is plethoric (Fig. 39-23). Similarly, one portion of the placenta often appears pale compared with the rest of the placenta.

The neonatal period may be complicated by circulatory overload with heart failure if severe hypervolemia and hyperviscosity are not identified promptly and treated. Occlusive thrombosis is also much more likely to develop in this setting. During the neonatal period, polycythemia may lead to severe hyperbilirubinemia and kernicterus (see Chap. 29, p. 672).

PATHOPHYSIOLOGY. Bajoria and colleagues (1995) perfused 30 monochorionic twin placentas with an anticoagulant solution immediately after delivery and then delineated anastomoses using dye-contrast injection. Those without twin-to-twin transfusion syndrome had multiple superficial anastomoses. In contrast, those with the twin-to-twin transfusion syndrome had solitary, deep arteriovenous channels within the capillary beds of the villous tissue. They hypothesized that multiple superficial vascular communications protected against the transfusion syndrome because this arrangement permitted bidirectional, and thus balanced, blood flow. Conversely, Bermudez and colleagues (2002) assessed 131 monochorionic twin placentas and observed that the presence of superficial anastomoses did little to mitigate the risk conferred by deep anastomoses.

Another hemodynamic explanation for twin-to-twin transfusion syndrome was offered by Fries and co-workers (1993). They postulated that a velamentous umbilical cord insertion may contribute to the development of unequal fetal blood volumes because the membranously inserted cord can be easily compressed, restricting blood flow to one twin. Talbert and colleagues (1996) used a computerized model to study the hemodynamics of unidirectional and bidirectional transfusion between twins via placental anastomoses. They determined that the net direction of blood flow is determined by the donor arterial pressure and not the number of anastomoses.

FETAL BRAIN DAMAGE. Cerebral palsy, microcephaly, porencephaly, and multicystic encephalomalacia are serious complications associated with vascular anastomoses in twin gestations. Multicystic encephalomalacia in a surviving fetus has been reported after the death at 12 weeks of its monochorionic twin (Weiss and co-workers, 2004). Whether this association was causal, however, is speculative. Neurological damage is most likely caused by ischemic necrosis leading to cavitory brain lesions. In the donor twin, ischemia results from hypotension, anemia, or both (Fig. 39-24). In the recipient, ischemia develops from blood pressure instability and episodes of severe hypotension (Larroche and colleagues, 1990). In one study, Bejar and associates (1990) reported this in 15 percent of 89 twins and 12 triplets. Denbow and colleagues (1998) reviewed data from 17 sets of liveborn, monochorionic twins who had twin-to-twin transfusion syndrome. They found that one twin had a cerebral infarction and 10 other neonates had other antenatally acquired cerebral lesions. Both donors and recipients were affected. Sutcliffe and colleagues (2001) reported a 13-percent cerebral palsy rate for both donor and recipient twins who survived in utero laser ablation therapy for the twin-to-twin transfusion syndrome.

Cerebral pathology in the survivor most likely results from acute hypotension at the time of the death of one twin (Benirschke, 1993). A less likely cause is from emboli of thromboplastic material originating from the dead fetus. Fusi and co-workers (1990, 1991) observed that at the time of death of one twin fetus, acute twin-to-twin anastomotic transfusion from the high-pressure vessels of the living twin to the low-resistance vessels of the dead twin leads rapidly to hypovolemia and ischemic antenatal brain damage in the survivor. This group described eight monochorionic twin pregnancies in which one twin died but

the pregnancy continued. Postpartum evaluation showed that none developed disseminated intravascular coagulopathy, and yet there was a high frequency of neurological damage. Pharoah and Adi (2000) surveyed 348 survivors whose twin sibling had died in utero. The prevalence of cerebral palsy was 83 per 1000 live births — a 40-fold increased risk. Okamura and colleagues (1994) performed cordocentesis on seven surviving twin fetuses within 24 hours of their sibling's death. Each surviving twin had acute anemia, and the investigators hypothesized that cerebral abnormalities were produced by hypotensive cerebral ischemia due to acute blood transfer. This result has been reported as early as 16 weeks (Anderson and co-workers, 1990).

The acute nature of the twin-to-twin transfusion and subsequent hypotension following the death of one twin makes successful intervention for the survivor nearly impossible. Even with delivery immediately after the demise is recognized, the hypotension that occurs at the moment of death has likely already caused irreversible damage (Langer and associates, 1997; Wada and co-workers, 1998).

DIAGNOSIS. The diagnosis of twin-to-twin transfusion syndrome, whether made antenatally or postnatally, is problematic. The postnatal diagnosis was classically made based on a weight discordancy between twins of 15 or 20 percent and a hemoglobin level difference of 5 g/dL or greater, with the smaller twin being anemic. It is now recognized, however, that significant weight differences between twins can have a variety of causes such as discordancy for anomalies, infection, or nutritional support.

In addition, hemoglobin level discordancy can develop acutely at the time of delivery. Wenstrom and colleagues (1992) illustrated this by reviewing the birthweights and hemoglobin concentrations in 97 monochorionic twin pregnancies. They found that 37 percent of weight concordant twins and 50 percent of discordant twins had a significant hemoglobin level discordancy. The twin delivered second had the higher hemoglobin value in 63 percent of pairs, including a third of the discordant twins in which this second twin was the smaller. This suggests that the hemoglobin level discordancy resulted from acute transfusion after the delivery of the first twin and before the delivery of the second twin. Although this pattern met the criteria for twin-to-twin transfusion, it was not clinically important because it was an acute phenomenon. Classic features of twin-to-twin transfusion, namely weight discordancy with the smaller twin being anemic, occurred in only 11 of these 97 twin pairs. Danskin and Neilson (1989) also concluded that this syndrome cannot be established definitively if based solely on birthweight or newborn hemoglobin level differences.

Clinically important twin-to-twin transfusion syndrome frequently is chronic and results from significant antenatal vascular volume differences between the twins. The syndrome typically presents in the midtrimester when the donor fetus becomes oliguric due to decreased renal perfusion (Mari and co-authors, 1993). This fetus develops oligohydramnios, and the recipient fetus develops severe hydramnios, presumably due to increased urine production. Virtual absence of amniotic fluid in the donor sac prevents fetal motion, giving rise to the descriptive term *stuck twin* (Berry and co-workers, 1995). This hydramnios-oligohydramnios combination can lead to growth restriction, contractures, and pulmonary hypoplasia in one twin, and premature rupture of the membranes and heart failure in the other.

The goal of antenatal diagnosis is to prevent fetal morbidity and mortality by selecting candidates for prenatal therapy or delivery. Antenatal criteria recommended for defining the twin-to-twin transfusion syndrome include the following: same sex fetuses, monochorionicity with placental vascular anastomoses, weight difference between twins greater than 20 percent, hydramnios in the larger twin, oligohydramnios or stuck twin in the smaller twin, and hemoglobin difference greater than 5 g/dL (Bruner and Rosemond, 1993). All of these criteria except hemoglobin levels can be determined ultrasonographically.

Situations in which the diagnosis must be confirmed, for example, before consideration of a high-risk therapy (see later discussion), may warrant invasive testing because the ultrasonographic diagnosis is sometimes incorrect. Saunders and co-workers (1991) used cordocentesis to show that none of four sets of monochorionic twins with all the ultrasonographic features of twin-to-twin transfusion actually had discordant hemoglobin concentrations. Bruner and Rosemond (1993) used cordocentesis and adult red blood cell infusion to show that only four of nine monochorionic twin pregnancies with ultrasonographic features of twin-to-twin transfusion actually had the syndrome. The cause of the discordant amniotic fluid volumes in these cases is unknown. When fetal hemoglobin concentrations have not been determined antenatally, it may be more accurate to refer to this situation as the *stuck twin syndrome* or the *hydramnios-oligohydramnios syndrome*, thus acknowledging that twin-to-twin transfusion has not been confirmed as the cause of the ultrasonographic findings.

THERAPY AND OUTCOME. The prognosis for multifetal gestations complicated by twin-to-twin transfusion syndrome is extremely guarded. Hazards are brain damage, antenatal death of one twin, and neonatal death due to preterm delivery. Lutfi and colleagues (2004) found the increased morbidity and mortality linked to preterm delivery rather than to weight discordancy or the effects of twin-to-twin transfusion syndrome. Unfortunately, the most serious form of twin-to-twin transfusion syndrome, with acute hydramnios in one sac and a stuck twin with anhydramnios in the other sac, usually presents between 18 and 26 weeks. The survival rate for those diagnosed before 28 weeks has been reported to vary widely, from 7 to 75 percent (Berghella and Kaufmann, 2001).

Several therapies are currently used for twin-to-twin transfusion, including amnioreduction, septostomy, laser ablation of vascular anastomoses, and selective feticide. Recently, but only in preliminary form, comparative data from randomized trials for some of these techniques have become available.

Saade and colleagues (2002) compared amnioreduction and septostomy (intentional creation of a communication in the dividing amniotic membrane) in a multicentered randomized trial. Repeated procedures were performed for symptoms or when the greatest vertical pocket of amniotic fluid exceeded 12 cm. Perinatal outcomes were the same in each group. Overall survival was 65 percent, and there was at least one survivor in 77 percent of pregnancies. The average number of procedures was two in the amnioreduction group compared with one in the septostomy group.

More recently, in a randomized trial of 142 women with severe twin-to-twin transfusion syndrome diagnosed before 26 weeks, Senat and colleagues (2004) reported increased survival of at least one twin with laser ablation of vascular anastomoses compared with serial amnioreduction (76 percent versus 51 percent). In an ongoing National Institutes of Health-sponsored multicentered trial, laser ablation is being compared with amnioreduction. Long-term evaluation of the neonates in both arms is important, because the rate of cerebral palsy in a recent cohort who survived twin-to-twin transfusion was 21 percent (Lopriore and co-workers, 2003).

Selective reduction has generally been considered when severe amniotic fluid and growth disturbances develop early (e.g., before 20 weeks), leading to the likelihood that both fetuses will die without intervention. Selection of the twin to be terminated has been based on evidence of damage to either fetus and comparison of their prognoses. Any substance injected into one twin may affect the other twin. Feticidal techniques include saline cardiac tamponade followed by intracardiac potassium chloride; injection of an occlusive substance into the umbilical vein; and fetoscopic ligation, laser coagulation, monopolar coagulation, or bipolar cautery of the umbilical cord (Challis and co-workers, 1999; Donner and associates, 1997; Weiner, 1987; Wittmann and colleagues, 1986). After these procedures, the risks to the remaining fetus are appreciable.

Figure 39-21. Monozygotic twin placenta from which the amnion has been stripped. The arteries of cord 1 (*arrow*) have been injected with barium solution and a direct communication with an artery from cord 2 (*label*) is apparent. A major artery of cord 2 was injected with India ink and a communication with veins in placenta 1 is evident, indicating a deep vascular communication. (From Fox, 1978.)

Figure 39-22. Schematic representation of arteriovenous anastomosis deep with the villous tissue forming a "common villous district" or "third circulation" that has been identified in monozygotic placentas. Also shown is a growth-restricted discordant twin fetus with markedly reduced amniotic fluid, causing it to be "stuck."

Figure 39-23. Twin-to-twin transfusion syndrome at 23 weeks. Pale donor twin (690 g) is shown on the left. The plethoric recipient twin (730 g) on the right also had hydramnios. The donor twin had oligohydramnios. (From Mahone and co-authors, 1993, with permission.)

Figure 39-24. Cranial magnetic resonance imaging study of a diamniotic-monozygotic twin performed on day 2 of life. The subarachnoid space and lateral ventricles are markedly enlarged. There are large cavitory lesions in the white matter adjacent to the ventricles. The bright signals (*arrowheads*) in the periphery of the cavitory lesions most probably correspond to gliosis. (From Bejar and colleagues, 1990, with permission.)

DISCORDANT TWINS. Size inequality of twin fetuses, which may be a sign of pathological growth restriction in one fetus, is calculated using the larger twin as the index. Generally, as the weight difference within a twin pair increases, perinatal mortality increases proportionately. Restricted growth of one twin fetus usually develops late in the second and early third trimester and is often asymmetrical (Leveno and co-workers, 1979). Earlier discordancy is usually symmetrical and indicates higher risk for fetal demise. Generally, the earlier in pregnancy discordancy develops, the more serious the sequelae. In an extreme example, Weissman and colleagues (1994) diagnosed weight discordancy between 6 and 11 weeks in five twin gestations, and all of the smaller twins had major malformations.

Pathology. The cause of birthweight inequality in twin fetuses is often unclear, but evidence indicates that the etiology in monozygotic twins differs from that in dichorionic twins. In monozygotic twins, discordancy is usually attributed to placental vascular anastomoses that cause hemodynamic imbalance between the twins. Reduced pressure and perfusion of the donor twin may result in its placenta failing to grow (Benirschke, 1993). Occasionally, monozygotic twins are discordant in size because they are discordant for structural anomalies.

A variety of factors are believed to cause discordancy in dichorionic twins. Dizygotic fetuses may have different genetic growth potential, especially if they are of opposite genders. Alternatively, because the placentas are separate and require more implantation space, one of the placentas may have a suboptimal implantation site. Mordel and colleagues (1993) observed that the incidence of discordancy is twice as great in triplets as it is in twins. This finding lends additional credence to the view that in utero crowding plays a role in fetal growth restriction.

Eberle and co-workers (1993) performed an evaluation of placental pathology in 147 twin gestations that provides important insight into the etiology of discordant twins. They quantified placental lesions that are usually associated with singleton growth restriction. Placentas from the smaller fetus in discordant dichorionic twin pairs demonstrated the lesions typical of singleton fetal growth restriction, whereas these lesions were not found in discordant monozygotic twin pairs.

Diagnosis. There are two areas of uncertainty in determination of discordancy in twins. One, which ultrasonographic anatomical measurements most reliably predict discordancy? Two, what fetal weight difference is clinically significant? Size discordancy between twins can be determined in several ways.

One common method of determining discordancy uses all fetal measurements to compute the estimated weight of each twin and then to compare the weight of the smaller twin with that of the larger twin (weight of larger twin minus weight of smaller twin, divided by weight of larger twin). Alternatively, considering that growth restriction is the primary concern and that abdominal circumference reflects fetal nutrition, some authors diagnose discordancy when abdominal circumferences differ by more than 20 mm.

Hill and colleagues (1994) evaluated the ultrasonographic assessment of twin discordancy and found that abdominal circumference was superior to head circumference, femur length, or transverse cerebellar diameter as the most useful index of size discordancy. Several different weight disparities between twins have been used to define discordancy. Accumulated data suggest that a greater than 25- to 30-percent weight discordancy, usually with growth restriction in one or both twins, most accurately predicts an adverse perinatal outcome.

Hollier and co-workers (1999) retrospectively evaluated 1370 twin pairs delivered at Parkland Hospital and stratified twin weight discordancy in 5-percent increments within a range of 15 to 40 percent. They found that the incidence of respiratory distress, intraventricular hemorrhage, seizures, periventricular leukomalacia, sepsis, and necrotizing enterocolitis increased directly with the degree of weight discordancy. These conditions increased substantially when discordancy was greater than 25 percent. The relative risk of fetal death increased significantly to 5.6 when there was more than 30-percent discordancy, and but increased to 18.9 when there was over 40-percent discordancy.

Management. Ultrasonographic monitoring of growth within a twin pair has become a mainstay in the management of twin gestations. Other ultrasonographic findings, such as oligohydramnios, may be helpful in gauging fetal risk. Depending on the degree of discordancy and the gestational age, fetal surveillance may be indicated, especially if one or both fetuses exhibit growth restriction. Delivery is usually not performed for size discordancy alone, except occasionally at advanced gestational ages.

DEATH OF ONE FETUS. On occasion, one fetus dies remote from term, but the pregnancy continues with one living fetus. Saito and co-workers (1999) reviewed 481 twin pregnancies and reported that the risk of single fetal death in a twin pregnancy was 6.2 percent. Factors influencing pregnancy loss in twins have been described by Rydhstrom (1994), who used the Medical Birth Registry in Stockholm to review fetal death in 15,066 twin pairs weighing 500 g or more. Same-sex twins were at highest risk. One or both twins died in 1.1 percent of opposite-sex twins and 2.6 percent of same-sex twins. Weight discordancy also increased the risk of death. In opposite-sex twins, however, the risk of death remained constant at 1.2 percent until the weight discordancy exceeded 40 to 50 percent or 1000 g. In same-sex twins, discordancy of only 20 percent or 250 g increased the risk. After the death of one twin, the risk of subsequent death in the surviving twin was sixfold greater in same-sex twins. Although chorionicity was not known in all cases, the authors estimated that the death rate for same-sex dizygotic twins was the same as for opposite-sex twins (0.8 percent), and that monochorionic twins had the greatest risk of death (3 percent).

At delivery, the dead fetus with placenta and membranes may be identifiable but may be compressed appreciably (fetus compressus) or may be flattened remarkably through loss of fluid and most of the soft tissue (fetus papyraceus). The papyraceous fetus shown in [Figure 39-25](#) died at midpregnancy, whereas the surviving fetus and placenta thrived. The dead fetus shown in [Figure 39-26](#) has become almost a shadow of itself compressed onto its placenta, which was separate from the placenta of the surviving twin.

The prognosis for the surviving twin depends on the gestational age at the time of the demise, the chorionicity, and the length of time between the demise and delivery of the surviving twin. Early demise such as a "vanishing twin" does not appear to increase the risk of death in the surviving fetus after the first trimester. It is intriguing that selective reduction of a higher-order multiple pregnancy (discussed subsequently) increases the risk of aborting all fetuses but does not appear to increase the risk of other maternal or fetal complications.

Later in gestation, the death of one of multiple fetuses could theoretically trigger coagulation defects in the mother. Only a few cases of maternal coagulopathy after a single fetal death in a twin pregnancy have been reported, probably because the surviving twin is usually delivered within a few weeks of the demise (see [Chap. 35](#), p. 845).

We have observed transient, spontaneously corrected consumptive coagulopathy when one fetus died and was retained in utero along with its surviving twin. The fibrinogen concentration initially decreased but then increased spontaneously, and the level of serum fibrinogen-fibrin degradation products decreased to normal. At delivery, the portions of the placenta that supplied the living fetus appeared normal. In contrast, the part that had once provided for the dead fetus was the site of massive fibrin deposition, which may have accounted directly for the decrease in maternal fibrinogen levels and in turn, an increase in the level of fibrin degradation products. Alternatively, this site may have served to block the escape of thromboplastin from the fetus and the placenta into the maternal circulation and thereby prevented disseminated intravascular coagulation. Both mechanisms may also have been operational until extensive fibrosis was achieved. The surviving fetus continued to thrive in utero and had normal plasma fibrinogen levels, serum fibrinogen-fibrin degradation product levels, and platelet counts at birth.

Management decisions should be based on the cause of death and the risk to the surviving fetus. The majority of cases of a single fetal death in twin pregnancy involve monochorionic placentation. Evidence indicates that morbidity in the monochorionic twin survivor is almost always due to vascular anastomoses, which first cause the demise of one twin and then produce sudden hypotension in the other. Benirschke (1993) concluded that it is implausible that degenerating material from a dead fetus could travel back to a living twin sibling. Considering that coagulopathy takes at least 5 weeks to develop, it is unlikely that there would still be shared circulation at that time.

Less frequently, fetal death results from a maternal complication such as diabetic ketoacidosis or severe preeclampsia with abruption. Pregnancy management is based on the diagnosis and the status of both mother and surviving fetus. When the death of one dichorionic twin is due to a discordant congenital anomaly, its cause of death should not affect its surviving twin. Santema and co-workers (1995b) assessed the cause and outcome of 29 consecutive twin pregnancies in which one of the fetuses died after 20 weeks. The causes of fetal death were not clear in all cases. The most common associations were monochorionic placentation and severe preeclampsia. These investigators concluded that in most cases the benefit derived from continuation of a multifetal pregnancy exceeded the risks of preterm delivery after diagnosis of fetal death. They recommended conservative management of the living fetus.

Impending Death of One Fetus. Abnormal antepartum test results of fetal health in one twin fetus but not the other pose a particular dilemma. Delivery may be the best option for the compromised fetus yet may result in death from immaturity of the

second (Fig. 39-27). When fetal lung maturity is confirmed, salvage of both the healthy fetus and its jeopardized sibling is possible. Unfortunately, ideal management when twins are immature is problematic but should be based on the chances of intact survival for both fetuses. Often the compromised fetus is severely growth restricted or anomalous. An advantage of performing amniocentesis for fetal karyotyping in women of advanced maternal age carrying twin pregnancies, even for those who would continue their pregnancies regardless of the diagnosis, is that the detection of aneuploidy in one fetus allows rational decisions about intervention to be made.

Death of Both Twin Fetuses. Rydhstrom (1996) reported that, excluding abortions, both fetuses died in 0.5 percent of twin pregnancies. Causes implicated in these deaths were monochorionic placentation and discordant fetal growth.

Figure 39-25. To the left is a fetus papyraceous that died at midpregnancy, its cord, and its pale placenta. To the right are the normal placenta and cord of the healthy 3200-g twin.

Figure 39-26. A long-dead twin fetus compressed onto its placenta. A separate placenta supported the surviving twin fetus.

Figure 39-27. Antepartum fetal heart rate recordings in discordant twin fetuses at 31 weeks. **A.** Accelerations in response to movements are seen for twin A, whose birthweight was 1200 g. **B.** Spontaneous uteroplacental insufficiency-type decelerations were observed in twin B, whose birthweight was 700 g. This fetus also failed to move or accelerate its heart rate. Because of these findings, cesarean delivery was performed. Both twins died 3 days after delivery; twin A died of hyaline membrane disease and twin B died due to hypoxic encephalopathy.

COMPLETE HYDATIDIFORM MOLE AND COEXISTING FETUS. This entity is different from a partial molar pregnancy because there are two separate conceptuses, with a normal placenta supplying nutrition to one twin and a complete molar gestation supporting the other. Optimal management is uncertain, but preterm delivery is frequently required because of bleeding or severe preeclampsia. Bristow and colleagues (1996) reviewed 26 cases and found that 73 percent required evacuation before the time of fetal viability, but the remainder continued without serious complications until fetal viability was reached. Sebire and colleagues (2002) reported a live birth rate of almost 40 percent in 53 such pregnancies. Any pregnancy consisting of a complete mole carries significant risk for subsequent gestational trophoblastic neoplasia (see [Chap. 11](#), p. 279).

ANTEPARTUM MANAGEMENT OF TWIN PREGNANCY

To reduce perinatal mortality and morbidity in pregnancies complicated by twins, it is imperative that:

1. Delivery of markedly preterm infants be prevented.
2. Failure of one or both fetuses to thrive be identified and fetuses so afflicted be delivered before they become moribund.
3. Fetal trauma during labor and delivery be avoided.
4. Expert neonatal care be available.

DIET. The requirements for calories, protein, minerals, vitamins, and essential fatty acids are further increased in women with multiple fetuses. The Recommended Dietary Allowances made by the Food and Nutrition Board of the National Research Council for uncomplicated pregnancy should not only be met but in most instances exceeded (see [Chap. 8](#), p. 213). Caloric consumption should be increased by another 300 kcal/day. Brown and Carlson (2000) have recommended that weight gain be based in part on prepregnancy weight but that women with triplet pregnancies should gain at least 50 pounds. Supplementation with 60 to 100 mg/day of iron and with 1 mg of folic acid is recommended.

MATERNAL HYPERTENSION. Hypertensive disorders due to pregnancy are more likely to develop with multiple fetuses. The exact incidence attributable to twin gestation is difficult to determine, because twin pregnancies are more likely to deliver preterm before preeclampsia can develop, and because women with twin pregnancies are often older and multiparous. For example, the incidence of pregnancy-related hypertension in women with twins is 20 percent at Parkland Hospital. Santema and co-workers (1995a) performed a case-control study in which 187 twin and 187 singleton pregnancies were matched for maternal age, parity, and gestational age at delivery. The incidence of hypertension was significantly higher in women carrying twin pregnancies (15 versus 6 percent). Coonrad and colleagues (1995) reviewed the outcomes of 3407 twin and 8287 singleton pregnancies and found that twin pregnancy carries an overall fourfold increased risk of preeclampsia independent of race and parity. Mastrobattista and colleagues (1997) compared 53 triplet with 53 twin pregnancies and observed that the rate of severe preeclampsia was significantly higher in women carrying triplets (23 versus 6 percent).

These data suggest that fetal number and placental mass are involved in the pathogenesis of preeclampsia. With multifetal gestation, hypertension not only develops more often but also tends to develop earlier and to be more severe. Interestingly, Hardardottir and colleagues (1996) have reported that women with preeclampsia due to higher-order multifetal gestations more often develop epigastric pain, hemolysis, and thrombocytopenia as a result of their disease.

ANTEPARTUM SURVEILLANCE. As discussed earlier, fetal growth is slower in multifetal pregnancies than in singleton gestations, and it also may be unequal within a twin pair. For these reasons, serial ultrasonographic examinations are usually performed throughout the third trimester. Appropriate interval growth is reassuring, and size discordancy is of greatest concern when one fetus is growth restricted.

Assessment of amniotic fluid volume is also important, because associated oligohydramnios may indicate uteroplacental pathology and should prompt further evaluation of fetal well-being. Quantifying amniotic fluid volume in multiple gestation, however, can be difficult. Some clinicians measure the deepest vertical pocket in each sac, or assess the fluid subjectively. If the sacs are side by side, as opposed to one on top of the other, measurement of the amniotic fluid index (AFI) may be helpful. Using data from 405 uncomplicated twin pregnancies, Porter and associates (1996) described a protocol for measuring the AFI in twin gestations and provided normal values. As in singletons, the deepest vertical pocket in each quadrant was measured, regardless of the location of the dividing membrane. An AFI of less than 8 cm (below the 5th percentile) or greater than 24 cm (above the 95th percentile) was considered abnormal at gestational ages from 28 to 40 weeks. If the overall AFI is abnormal, the ultrasonographer must determine which sac is involved and attempt to quantify the degree of abnormality. Subjective assessment is often required and is not always accurate. Magann and co-workers (1995) reported that oligohydramnios, defined as less than 500 mL, is poorly identified by any ultrasonographic method in twin gestations.

Tests of Fetal Well-Being. As described throughout [Chapter 15](#), there are several methods of assessing fetal health in singleton pregnancies. The nonstress test or biophysical profile is commonly used in management of twin or higher-order multiple gestations. The complexity of complications associated with multifetal gestations as well as the potential technical difficulties in differentiating fetuses during antepartum testing appears to limit the usefulness of these methods. For example, Saacks and co-workers (1995) observed that the antepartum death rate of twin fetuses did not change between the two 10-year intervals 1952 to 1962 and 1983 to 1993 despite the availability of fetal testing during the later decade. Elliott and Finberg (1995) used the biophysical profile as the primary method for monitoring of higher-order multiple gestations. They reported that 4 of 24 monitored pregnancies had a poor outcome despite reassuring biophysical profile scores. In a randomized trial of 526 twin pregnancies, the addition of umbilical artery Doppler velocimetry to management compared with fetal testing based on fetal growth parameters alone resulted in no improvement in perinatal outcome (Giles and associates, 2003).

Whatever method is used, care must be taken to evaluate each fetus separately. Gallagher and colleagues (1992) analyzed fetal heart rate accelerations, fetal movement, and other behavioral states in 15 twin pairs. If one twin of a pair was awake or asleep so was its sibling, however, accelerations and movements were usually not coincidental ([Fig. 39-28](#)).

Doppler Velocimetry. As discussed in [Chapters 15](#) and [16](#), Doppler evaluation of vascular resistance may provide a measure of fetal well-being. Increased resistance with diminished diastolic flow velocity often accompanies restricted fetal growth. Doppler values in twins and triplets are the same as in singletons and can thus be used in a similar manner (Akiyama and co-workers, 1999). As in singletons, however, the clinical utility of this technology is controversial.

Gerson and co-workers (1987) used duplex Doppler ultrasonography to measure umbilical venous blood flow and arterial systolic-diastolic velocity ratios to predict concordant and discordant growth in twins. Normal studies correctly predicted concordancy in 44 of 45 concordant twin pairs. Abnormal values, especially those from the umbilical artery, correctly predicted differences in 9 of 11 sets of discordant twins. Conversely, DiVou and co-workers (1989) reported that velocimetry alone was not consistently useful in identifying twin discordancy. Ezra and colleagues (1999) found that in triplets and quadruplets, as in singletons, absent end-diastolic blood flow in the umbilical artery was associated with low birthweight and perinatal mortality.

Figure 39-28. Simultaneous antepartum fetal heart rate recordings from twin fetuses showing that accelerations are not necessarily synchronous.

PREVENTION OF PRETERM DELIVERY. Several techniques have been applied in attempts to prolong multifetal gestations. These include bed rest, especially through hospitalization, prophylactic administration of beta-mimetic drugs, and prophylactic cervical cerclage.

Bed Rest. Most evidence suggests that routine hospitalization is not beneficial in prolonging multifetal pregnancy. For example, Crowther and co-workers (1990) randomly chose hospitalization or routine care for 139 Zimbabwean women with twin pregnancies. They found that hospitalized bed rest did not prolong pregnancy or improve neonatal survival, although it did improve fetal growth. At Parkland Hospital, elective hospitalization at 26 weeks was compared with outpatient management, and no advantages were found for routine hospitalization (Andrews and colleagues, 1991). It is worth noting, however, that almost half of the twin pregnancies studied required admission for specific indications such as hypertension or threatened preterm delivery.

Limited physical activity, early work leave, more frequent health care visits and ultrasonographic examinations, and structured maternal education on the risks of preterm delivery have been advocated to be effective in reducing preterm births in women with multiple fetuses. Unfortunately, there is little evidence that these measures substantially change outcome. For example, Pons and co-workers (1998) found virtually no difference in outcomes of 70 triplet pregnancies managed intensively from 1987 to 1993 compared with 21 triplet pregnancies managed routinely between 1975 and 1986. The only major difference between these two periods was that neonates born in the later time period group had significantly less hyaline membrane disease (13 versus 31 percent), which these investigators attributed to the use of corticosteroids.

Tocolytic Therapy. As for singleton pregnancies, there is no valid evidence that tocolytic therapy improves neonatal outcomes in multifetal gestation (Gyvetvai and co-workers, 1999). Importantly, tocolytic therapy in these women entails a higher risk than in singletons. This is in part because the increased plasma volume and cardiovascular demands increase susceptibility to hydration-associated pulmonary edema. Gabriel and colleagues (1994) compared the outcomes of 26 twin and 6 triplet pregnancies with those of 51 singletons treated with a beta-mimetic for preterm labor without ruptured membranes. Women with a multifetal gestation had significantly more cardiovascular complications (43 versus 4 percent), including three cases of pulmonary edema.

Corticosteroids for Lung Maturation. Although corticosteroids are less studied in multifetal gestations than in singletons, there is no biological reason that these drugs would not benefit multiple fetuses (Crowley, 2003). Therefore, guidelines for the use of corticosteroids are not different for multifetal gestation (American College of Obstetricians and Gynecologists, 2004).

Cerclage. Prophylactic cervical cerclage has not been shown to improve perinatal outcome in multifetal pregnancies. Studies have included women who were not specially selected as well as those who were selected because of a shortened cervix as assessed by transvaginal ultrasonography (Dor and associates, 1982; Elimian and colleagues, 1999; Newman and colleagues, 2002).

PRETERM LABOR PREDICTION. Goldenberg and colleagues (1996) prospectively screened 147 twin pregnancies for more than 50 potential risk factors for preterm birth and found that only cervical length and fetal fibronectin levels predicted preterm birth. At 24 weeks, a cervical length of 25 mm or less was the best predictor of birth before 32 weeks. At 28 weeks, an elevated fetal fibronectin level was the best predictor. Similarly, Souka and co-workers (1999) ultrasonographically measured the cervixes of 215 women with twin pregnancies at 23 weeks. They found that a length of 25 mm or less predicted preterm birth with a sensitivity of 100 percent at 28 weeks, 80 percent at 30 weeks, 47 percent at 32 weeks, and 35 percent at 34 weeks. Conversely, McMahon and colleagues (2002) found that women with multifetal gestation at 24 weeks who had a closed internal os on digital cervical examination, a normal cervical length by ultrasonographic examination, and a negative fetal fibronectin test result were at *low* risk to deliver before 32 weeks. Interestingly, a closed internal os by digital examination was as predictive as the combination of normal cervical length and negative fetal fibronectin test results.

PULMONARY MATURATION. As measured by determination of the lecithin-sphingomyelin ratio, pulmonary maturation is usually synchronous in twins (Leveno and associates, 1984). Moreover, although this ratio usually exceeds 2 by 36 weeks in singleton pregnancies, it often does so by about 32 weeks in multifetal pregnancy. In some cases, however, pulmonary function may be markedly different, with the smallest, most stressed fetus being more mature. We observed the lecithin-sphingomyelin ratio with quintuplets to vary from less than 2 for the largest infant, who weighed 1530 g at 32 weeks and was of appropriate size, to greater than 5 for the severely growth-restricted smallest infant, who weighed 860 g. The largest infant developed respiratory distress, whereas the smallest infant did not.

PRETERM MEMBRANE RUPTURE. Twin gestations with preterm ruptured membranes are managed expectantly much like singleton pregnancies (see [Chap. 36](#), p. 864). Mercer and colleagues (1993) compared outcomes of twin and singleton pregnancies, both with prematurely ruptured membranes at 19 to 36 weeks. They found that labor ensued earlier in twins. Specifically, the median time from rupture to delivery was 1.1 days in twins compared with 1.7 days in singletons. More than 90 percent in both groups delivered within 7 days of membrane rupture. Similarly, Hsieh and colleagues (1999) studied 131 twin pregnancies and 48 singleton pregnancies with preterm premature membrane rupture. They found, regardless of the gestational age at rupture, that 50 percent of twins compared with 27 percent of singletons delivered within 48 hours and that 92 percent of twins and 86 percent of singletons delivered within 7 days.

DELAYED DELIVERY OF SECOND TWIN. Infrequently, after preterm birth of the presenting fetus, it may be advantageous for the undelivered fetus(es) to remain within the uterus. Trivedi and Gillett (1998) reviewed the English literature and found 45 case reports of asynchronous birth in multifetal gestation. Most often, the first birth resulted from preterm rupture of the membranes, and the survival rate for these infants was poor. The pregnancies with a surviving retained twin or triplet continued for an average of 49 days. Management with tocolytics, prophylactic antimicrobials, and cerclage appeared to make no difference. After delivery of one fetus, Farkouh and colleagues (2000) treated 24 women with twin or triplet pregnancies with tocolytics, local and systemic antimicrobials, and cervical cerclage and reported a mean delivery delay in the remaining sibling(s) of 36 days. Whether these interventions are beneficial is a matter of speculation, because these women were not randomized. Livingston and colleagues (2004) described 14 pregnancies in which an active attempt was made to delay delivery of 19 fetuses after delivery of the twin. Only one fetus survived without major sequelae, and one mother developed sepsis syndrome with shock.

If asynchronous birth is attempted, there must be careful evaluation for infection, abruption, and congenital anomalies. The mother must be thoroughly counseled, particularly about the potential for serious, even life-threatening infection. The range of gestational age in which the benefits outweigh the risks of delayed delivery is likely narrow. Avoidance of delivery from 23 to 26 weeks would seem most beneficial. In our experience, good candidates for delayed delivery are rare.

DELIVERY OF TWIN FETUSES

LABOR. Many complications of labor and delivery, including preterm labor, uterine contractile dysfunction, abnormal presentation, prolapse of the umbilical cord, premature separation of the placenta, and immediate postpartum hemorrhage are encountered more often with multiple fetuses than with singletons. For these reasons, certain precautions and special arrangements are prudent when delivery of two or more fetuses is expected. Recommendations for intrapartum management include:

1. An appropriately trained obstetrical attendant should remain with the mother throughout labor. Continuous external electronic monitoring or, if the membranes are ruptured and the cervix dilated, simultaneous evaluation of both the presenting

fetus by internal electronic monitoring and the remaining sibling(s) by external monitors, is typically used.

2. Blood transfusion products should be readily available.
3. An intravenous infusion system capable of delivering fluid rapidly should be established. In the absence of hemorrhage or metabolic disturbance during labor, lactated Ringer or an aqueous dextrose solution is infused at a rate of 60 to 120 mL/hr.
4. An obstetrician skilled in intrauterine identification of fetal parts and in intrauterine manipulation of a fetus should be present.
5. An ultrasonography machine should be readily available to help evaluate the position and status of the remaining fetus(es) after delivery of the first.
6. An experienced anesthesiologist should be immediately available in the event that intrauterine manipulation or cesarean delivery is necessary.
7. For each fetus, two people, one of whom is skilled in resuscitation and care of newborns, are appropriately informed of the case and remain immediately available.
8. The delivery area should provide adequate space for all members of the team to work effectively. Moreover, the site should be appropriately equipped to take care of any maternal problems plus resuscitation and maintenance of each neonate.

Presentation and Position. With twins, all possible combinations of fetal positions may be encountered. The most common presentations at admission for delivery are cephalic-cephalic, cephalic-breech, and cephalic-transverse ([Fig. 39-29](#)). Importantly, these presentations, especially those other than cephalic-cephalic, are unstable before and during labor and delivery. Compound, face, brow, and footling breech presentations are relatively common, especially when the fetuses are small, amniotic fluid is excessive, or maternal parity is high. Prolapse of the cord is also common in these circumstances. The presentation can often be ascertained by ultrasonography. If any confusion about the relationship of the twins to each other or to the maternal pelvis persists, a single anteroposterior radiograph of the abdomen may be helpful.

Induction or Stimulation of Labor. Although labor is generally shorter with twins, it can be desultory (Schiff and associates, 1998). If women meet all criteria for the administration of oxytocin, it may be used as described in [Chapter 22](#) (see p. 540).

Analgesia and Anesthesia. During labor and delivery of multiple fetuses, decisions regarding analgesia and anesthesia may be complicated by the frequency of and problems imposed by preterm labor, preeclampsia, desultory labor, need for intrauterine manipulation, and development of uterine atony and hemorrhage after delivery.

Epidural analgesia is recommended by many clinicians because it provides excellent pain relief and can be rapidly extended cephalad if internal podalic version or cesarean delivery is required (Koffel, 1999). Special care must be taken in hypertensive women or those who have hemorrhaged because epidural analgesia may cause hypotension with inadequate perfusion of vital organs, especially the placenta (see [Chap. 19](#), p. 483). Therefore, placement and maintenance of continuous epidural analgesia should be performed by health care providers knowledgeable in obstetrics, and it should be preceded by adequate hydration and administered slowly. Because women pregnant with multiple fetuses are especially vulnerable to supine hypotension during labor and delivery, they should be placed in full lateral position during and after induction of epidural analgesia. Left uterine displacement should be maintained for cesarean delivery.

When general anesthesia is used, the increased maternal oxygen demand associated with multifetal gestation increases the risk of hypoxemia, thus making adequate preoxygenation essential. Pudendal block when administered along with nitrous oxide plus oxygen can provide relief of pain for spontaneous delivery. When intrauterine manipulation is necessary, as with internal podalic version, uterine relaxation can be accomplished rapidly with the inhalation anesthetic isoflurane. Because such agents provide effective relaxation for intrauterine manipulation, they also cause an increase in blood loss during the third stage. Some clinicians use intravenous or sublingual nitroglycerin to achieve uterine relaxation yet avoid the aspiration and hypoxia risks associated with general anesthetics (Vinatier and associates, 1996).

Figure 39-29. Presentations of twin fetuses on admission for delivery. (Data from Divon and colleagues, 1993.)

VAGINAL DELIVERY. The presenting twin typically bears the major force of dilating the cervix and the remaining soft tissues of the birth canal. When the first twin is cephalic, delivery can usually be accomplished spontaneously or with forceps.

As in singletons, when the first fetus presents as a breech, major problems are most likely to develop if:

1. The fetus is unusually large and the aftercoming head is larger than the capacity of the birth canal.
2. The fetus is sufficiently small so that the extremities and trunk are delivered through a cervix inadequately effaced and dilated to allow the head to escape easily.
3. The umbilical cord prolapses.

When these problems are anticipated or identified, cesarean delivery is often the preferred route of delivery, except in those instances in which the fetuses are so immature that they will not survive. Fetuses with breech presentation may be delivered as described in [Chapter 24](#).

The phenomenon of locked twins is rare. According to Cohen and co-workers (1965), it occurred only once in 817 twin gestations. For twins to lock, the first fetus must present breech and the second cephalic. With descent of the breech through the birth canal, the chin of the first fetus locks between the neck and chin of the second, cephalic fetus. Cesarean delivery is recommended when the potential for locking is identified.

Hogle and colleagues (2003) performed an extensive literature review and concluded that planned cesarean delivery does not improve neonatal outcome when both twins are cephalic. The optimal delivery route for cephalic-noncephalic twins is controversial. Several reports attest to the safety of vaginal delivery of second noncephalic twins who weigh more than 1500 g (Blickstein, 1987; Chervanek, 1985; Gocke, 1989, and all their associates). According to the American College of Obstetricians and Gynecologists (1998), vaginal delivery of a nonvertex second twin is reasonable when the estimated fetal weight is greater than 1500 g. When the estimated fetal weight is less than 1500 g, the issue is less clear, although comparable or even improved fetal outcomes have been reported with vaginal relative to cesarean delivery (Caukwell and Murphy, 2002; Davidson and co-workers, 1992; Rydhstrom, 1990). Muleba and associates (2005) identified increased rates of respiratory distress in the second twin of preterm pairs regardless of the mode of delivery or corticosteroid use.

Mauldin and colleagues (1998) retrospectively reviewed the delivery courses of 84 cephalic-noncephalic twins. They found that vaginal delivery of the presenting twin followed by breech extraction of the second twin resulted in significantly shorter maternal and neonatal hospital stays, in part because vaginally extracted breech twins had less respiratory disease and infections.

When the first twin is breech, most physicians plan a cesarean delivery. The American College of Obstetricians and Gynecologists (1998b) has concluded that, in general, cesarean delivery is the method of choice when the first twin is noncephalic. More recently, however, Blickstein and colleagues (2000) reported the collective experience from 1990 to 1997 of 13 European centers that attempted vaginal delivery in 374 of 613 twin pairs when the presenting twin was breech. In their report, vaginal delivery did not increase the mortality of breech-presenting first twins who weighed at least 1500 g.

Vaginal Delivery of the Second Twin. As soon as the presenting twin has been delivered, the presenting part of the second twin, its size, and its relationship to the birth canal should be quickly and carefully ascertained by combined abdominal, vaginal, and at times intrauterine examination. Ultrasonography is also valuable in some cases. If the fetal head or the breech is fixed in the birth canal, moderate fundal pressure is applied and membranes are ruptured. Immediately afterward, digital examination of the cervix is repeated to exclude prolapse of the cord. Labor is allowed to resume, and the fetal heart rate is monitored. With reestablishment of labor there is no need to hasten delivery unless a nonreassuring fetal heart rate or bleeding develops. Hemorrhage may indicate placental separation, which can be harmful to both the fetus and the mother. If contractions do not resume within approximately 10 minutes, dilute oxytocin may be used to stimulate contractions.

If the occiput or the breech presents immediately over the pelvic inlet but is not fixed in the birth canal, the presenting part can often be guided into the pelvis by one hand in the vagina while a second hand on the uterine fundus exerts moderate pressure caudally. Alternatively, an assistant can maneuver the presenting part into the pelvis using ultrasonography for guidance and to monitor heart rate. Intrapartum external version of the noncephalic second twin has also been described (Chervanek and co-workers, 1983).

A presenting shoulder may be gently converted into a cephalic presentation. If the occiput or the breech is not over the pelvic inlet and cannot be so positioned by gentle pressure, or if appreciable uterine bleeding develops, delivery of the second twin can be problematic.

It is essential to have an obstetrician skilled in intrauterine fetal manipulation and an anesthesiologist skilled in providing anesthesia to effectively relax the uterus for vaginal delivery of a noncephalic second twin to obtain a favorable outcome. To take maximum advantage of the dilated cervix before the uterus contracts and the cervix retracts, delay must be avoided. Prompt cesarean delivery of the second fetus is preferred if no one present is skilled in the performance of internal podalic version (described in the following section) or if anesthesia that will provide effective uterine relaxation is not immediately available.

INTERNAL PODALIC VERSION. With this maneuver, the fetus is turned to a breech presentation by the operator's hand placed into the uterus ([Fig. 39-30](#)). The obstetrician grasps the fetal feet to then effect delivery by breech extraction. Chauhan and colleagues (1995) compared outcomes of 23 second twins delivered by podalic version and breech extraction with those of 21 who underwent external cephalic version. Breech extraction was considered superior to external version, because less fetal distress developed. The technique of breech extraction is described in [Chapter 24](#).

INTERVAL BETWEEN FIRST AND SECOND TWINS. In the past, the safest interval between delivery of the first and second twins was commonly cited as less than 30 minutes. Subsequently, as shown by Rayburn and colleagues (1984), as well as others, if continuous fetal monitoring is used, a good outcome is achieved even when this interval is longer. The American College of Obstetricians and Gynecologists (1998b) has determined that the interval between delivery of twins is not critical in determining the outcome of the twin delivered second. However, vigilance is required. Leung and colleagues (2002) demonstrated a direct correlation between worsening umbilical cord blood gas values and increasing time interval between delivery of first and second twins.

Figure 39-30. Internal podalic version. Upward pressure on the head is applied as downward traction is exerted on the feet.

CESAREAN DELIVERY. Twin fetuses create unusual intraoperative problems. Hypotension commonly develops in women carrying twins when they are placed in the supine position. Therefore, it is important to place patients in a left lateral

tilt so as to deflect the uterine weight off the aorta (see [Chap. 5](#), p. 135). The uterine incision should be large enough to allow atraumatic delivery of both fetuses. In some cases, a vertical incision in the lower uterine segment may be advantageous. For example, if a fetus is in transverse position, with the back down, and the arms are inadvertently delivered first, it is much easier and safer to extend a vertical uterine incision upward than to extend a transverse incision. If the second twin is breech and delivery of the head is obstructed, Piper forceps can be used just as for a vaginal delivery. It is important that the uterus remain well contracted during completion of the cesarean delivery and thereafter. Remarkable blood loss may be concealed within the uterus and vagina and beneath the drapes during the time taken to close the incisions.

At times, attempts to deliver the second twin vaginally after delivery of the first twin are not only unwise but also impossible, and prompt cesarean delivery is required. Cesarean delivery of the second twin may be necessary, for example, when the second fetus is much larger than the first, and is breech or transverse. Even more perplexing, cesarean delivery may be required because the cervix promptly contracts and thickens after delivery of the first infant and does not dilate subsequently or because a nonreassuring fetal heart rate pattern develops.

TRIPLET OR HIGHER-ORDER GESTATION

Fetal heart rate monitoring during labor is challenging. A scalp electrode can be attached to the presenting fetus, but it is difficult to ensure that the other two triplets are each being monitored separately. With vaginal delivery, the first infant is usually born spontaneously or with little manipulation. Subsequent fetuses, however, are delivered according to the presenting part. This often requires complicated obstetrical maneuvers such as total breech extraction with or without internal podalic version or even cesarean delivery. Associated with malposition of the fetuses is an increased incidence of cord prolapse. Moreover, reduced placental perfusion and hemorrhage from separating placentas are more likely during delivery.

For all these reasons, many clinicians believe that pregnancies complicated by three or more fetuses are best delivered by cesarean delivery. Vaginal delivery is reserved for those circumstances in which survival is not expected because the fetuses are markedly immature or maternal complications make cesarean delivery hazardous to the mother. Other clinicians believe that vaginal delivery is safe under certain circumstances. For example, Alamia and colleagues (1998) evaluated a protocol for vaginal delivery of triplet pregnancies in which the presenting fetus was cephalic. A total of 23 sets of triplets were analyzed, and a third of these were delivered vaginally. Neonatal outcomes were the same in the vaginal and cesarean groups, with no morbidity and 100 percent fetal survival. Grobman and colleagues (1998) and Alran and co-workers (2004) reported vaginal delivery completion rates of 88 and 84 percent, respectively, in women carrying triplets who underwent a trial of labor. Neonatal outcomes did not differ from those of a matched group of triplet pregnancies delivered by elective cesarean. As in any obstetrical procedure, the safety of vaginal triplet delivery depends on the skill and experience of the operator.

SELECTIVE REDUCTION OR TERMINATION

In some cases of higher-order multifetal gestation, reduction in the number of fetuses to two or three improves survival of the remaining fetuses. Selective reduction implies early pregnancy intervention, whereas selective termination is performed later.

SELECTIVE REDUCTION. Reduction of a selected fetus or fetuses in a dichorionic multifetal gestation may be chosen as a therapeutic intervention to enhance survival of the other fetuses. Multifetal pregnancy reduction was developed at Mount Sinai Medical Center in New York to improve the poor prognosis of pregnancies with three or more fetuses (Berkowitz and associates, 1988). Pregnancy reduction can be performed transcervically, transvaginally, or transabdominally, but the transabdominal route is usually easiest. Transabdominal fetal reductions are typically performed between 10 and 13 weeks. This gestational age was chosen because any spontaneous abortions have already occurred, the remaining fetuses are large enough to be evaluated ultrasonographically, the amount of devitalized fetal tissue remaining after the procedure is small, and the risk of aborting the entire pregnancy as a result of the procedure is low. The smallest fetuses and any anomalous fetuses are chosen for reduction. Potassium chloride is then injected into the heart or thorax of each selected fetus under ultrasonographic guidance, taking care not to enter or traverse the sacs of the fetuses selected for retention. In most cases, pregnancies are reduced to twins to increase the chances of delivering at least one viable fetus.

Evans and associates (2001) reported continued improvement in fetal outcomes with this procedure. They analyzed more than 1000 pregnancies managed in 11 centers from 1995 to 1998. The pregnancy loss rate varied from a low of 4.5 percent for triplets who were reduced to twins, increased with each addition to the starting number of fetuses, and peaked at 15 percent for six or more fetuses. By comparison, the respective rates in their earlier report (Evans and co-workers, 1996) were 8 and 23 percent. The investigators believed that operator skill and experience were responsible for their low and declining rates of pregnancy loss. Early preterm deliveries were more likely in pregnancies starting as higher-order gestations, reinforcing the concept that higher-order multiple gestations are hazardous to both the fetuses and the mothers ([Fig. 39-31](#)).

Figure 39-31. Histogram showing the rate of pregnancy losses at less than 24 weeks and preterm birth at 25 to 28 weeks as a function of the initial number of multiple fetuses in over 1000 women who underwent selective reduction of pregnancy from 1995 to 1998. (Modified from Evans and associates, 2001, with permission.)

SELECTIVE TERMINATION. With the identification of multiple fetuses discordant for structural or genetic abnormalities, three options are available: abortion of all fetuses, selective termination of the abnormal fetus, and continuation of the pregnancy. Because anomalies are typically not discovered until the second trimester, selective termination is performed later in gestation than selective reduction and entails more risk. This procedure is therefore usually not performed unless the anomaly is severe but not lethal, meaning that the anomalous fetus would survive and require lifetime care, or the estimated risk of continuing the pregnancy is greater than the risk of the procedure.

Thus, a triplet pregnancy in which one fetus has Down syndrome might be a candidate for selective termination, whereas a twin pregnancy in which one has trisomy 18 might not. In some cases, termination is considered because the abnormal fetus may jeopardize the normal one. For example, pathological hydramnios in a twin with esophageal atresia could lead to preterm birth of its sibling. Audibert and colleagues (2003) reported the selective termination of a severely growth-restricted twin fetus at 32 weeks, with marked improvement in the severity of maternal preeclampsia and subsequent delivery of a healthy sibling twin at 38 weeks. Prerequisites to selective termination include a precise diagnosis for the anomalous fetus and absolute certainty as to its location. Thus, when genetic amniocentesis is performed on a multifetal gestation, a map of the uterus with the locations of all the fetuses clearly labeled should be made at the time of the diagnostic procedure. Unless a special procedure such as umbilical cord interruption is used, selective termination should be performed only in dichorionic multiple gestation to avoid damaging the surviving fetus.

Evans and co-workers (1999) have provided the most comprehensive results to date on second-trimester selective termination for fetal abnormalities. A total of 402 cases were analyzed from the eight centers worldwide with the most experienced operators. Included were 345 twin, 39 triplet, and 18 quadruplet pregnancies. Selective termination using potassium chloride resulted in the delivery of a viable neonate or neonates in more than 90 percent of cases, with a mean age at delivery of 35.7 weeks. The pregnancy loss rate was 7.1 percent in pregnancies reduced to singletons and was 13 percent in those reduced to twins. The gestational age at the time of the procedure did not appear to affect pregnancy loss; the rate was 5.4 percent when the procedure was performed at 9 to 12 weeks, 8.7 percent at 13 to 18 weeks, 6.8 percent at 19 to 24 weeks, and 9.1 percent at 25 weeks. Several losses occurred because the pregnancy was actually monochorionic and potassium chloride killed the normal fetus through placental vascular anastomoses. Lynch and colleagues (1996) reported that termination of the presenting fetus or selective termination after 20 weeks significantly increased the risk of preterm premature membrane rupture and delivery.

ETHICS. The ethical issues associated with these techniques are almost limitless. The interested reader is referred to the excellent reviews by Evans and co-workers (1988) and Simpson and Carson (1996).

INFORMED CONSENT. Prior to selective termination or reduction, a couple should be counseled about the risks and benefits and informed consent obtained. Counseling should include a discussion of the morbidity and mortality expected if the pregnancy is continued; the morbidity and mortality expected with twins or triplets, whichever the couple would reduce to; and the risks of the procedure itself.

Ideally, the issue of selective reduction should be discussed *prior* to conception. Indeed, Ryan and colleagues (2004) reported that a minority of infertility patients expressed a preference for a multifetal gestation at their first visit. Grobman and associates (2001) documented that women seeking infertility treatment were generally unaware of the risks associated with multifetal gestation and when apprised of the risks, were less desirous of having a multifetal gestation.

Specific risks that are common to selective termination or reduction include:

1. Abortion of the remaining fetuses
2. Abortion of the wrong (normal) fetus(es)
3. Retention of genetic or structurally abnormal fetuses after a reduction in number
4. Damage without death to a fetus
5. Preterm labor
6. Development of discordancy or growth-restricted fetuses
7. Maternal infection, hemorrhage, or possible disseminated intravascular coagulopathy because of retained products of conception

The procedure should be performed by an operator skilled and experienced in ultrasonographic-guided procedures. Because selective reduction increases the maternal serum alpha-fetoprotein level, the couple should be informed that this screening test will not help them after the procedure (Lynch and Berkowitz, 1993). Instead, they are offered a second-trimester targeted ultrasonographic evaluation or possibly amniocentesis.

PSYCHOLOGICAL REACTION. Women and their spouses who elect to undergo selective termination or reduction find this decision highly stressful. Schreiner-Engel and associates (1995) retrospectively studied the emotional reactions of 100 women following selective reduction. Although 70 percent of the women mourned for their dead fetus(es), most grieved only for 1 month. Persistent depressive symptoms were mild, although moderately severe sadness and guilt continued for many for them. Fortunately, the majority were reconciled to the termination of some fetuses to preserve the lives of a remaining few. Indeed, 93 percent of the women would have made the same decision again.

40. Abnormalities of the Reproductive Tract

INTRODUCTION

In some cases, pregnancy is complicated by preexisting abnormalities of the reproductive tract. In general, these are developmental anomalies incurred during embryogenesis. However, they may be acquired during adulthood, sometimes during pregnancy.

DEVELOPMENTAL REPRODUCTIVE TRACT ABNORMALITIES

A number of genitourinary defects from abnormal embryogenesis occur sporadically. Serious defects often result in significant fetal and maternal hazards. In some, even minor defects may result in an increased incidence of threatened miscarriage and abnormal fetal lie.

EMBRYOGENESIS OF THE REPRODUCTIVE TRACT. To understand the etiology of developmental abnormalities of the vagina, cervix, and uterus, it is important to first understand their embryogenesis. This is discussed in [Chapter 4](#) and summarized in [Figure 40-1](#).

Briefly, development begins between the third and fifth gestational weeks, when the metanephric ducts emerge and connect with the cloaca. Between the fourth and fifth weeks, two ureteric buds develop distally from the mesonephric ducts and begin to grow cephalad toward the mesonephros. Mullerian (paramesonephric) ducts form bilaterally between the developing gonad and the mesonephros. The mullerian ducts extend downward and laterally to the mesonephric ducts, and they finally turn medially to meet and fuse together in the midline. The fused mullerian duct descends to the urogenital sinus to join the mullerian tubercle. **The close association between the mullerian and mesonephric ducts has clinical relevance because damage to either duct system is often associated with anomalies that involve the uterine horn, kidney, and ureter.**

The uterus is formed by the union of the two mullerian ducts at about the 10th week. Fusion begins in the middle and then extends caudally and cephalad. The characteristic uterine shape is now formed, with cellular proliferation at the upper portion and a simultaneous dissolution of cells at the lower pole, thus establishing the first uterine cavity. This cavity is at the lower pole with a thick wedge of tissue above. The upper thick wedge of tissue (septum) is dissolved slowly, creating the uterine cavity. This process is usually completed by the 20th week. Any failure to fuse the two mullerian ducts or failure to resorb the cavity between them results in separate uterine horns or some degree of persistent uterine septum.

The vagina forms between the urogenital sinus and the mullerian tubercle by a dissolution of the cell cord between the two structures. It is believed that this dissolution starts at the hymen and moves upward toward the cervix. Failure of this process is associated with persistence of the cell cord. Vaginal agenesis or lesser abnormalities of this cell cord dissolution result in varying degrees of septum formation.

Genesis and Classification of Mullerian Abnormalities. Because fusion of the two mullerian ducts forms the upper two thirds of the vagina as well as the cervix and uterine body, the principal groups of deformities arising from three types of embryological defects can be classified as follows:

1. Defective canalization of the vagina results in a transverse septum, or in the most extreme form, vaginal agenesis.
2. Unilateral maturation of the mullerian duct with incomplete or absent development of the opposite duct results in defects associated with upper urinary tract abnormalities.
3. The most common abnormality is absent or faulty midline fusion of the mullerian ducts. Fusion anomalies are thought to be polygenic or multifactorial (see [Chap. 12](#), p. 300). Complete lack of fusion results in two entirely separate uteri, cervixes, and vaginas. Incomplete tissue resorption between the two fused mullerian ducts results in a uterine septum.

Various classifications of these anomalies have been proposed. Buttram and Gibbons (1979) suggested one based on the failure of normal development. This classification separates a diversity of anomalies into groups with similar clinical characteristics, prognosis for pregnancy, and treatment. It has been adapted by the American Society for Reproductive Medicine — formerly American Fertility Society ([Table 40-1](#)). The classification includes a category for abnormalities associated with fetal exposure to diethylstilbestrol. Vaginal anomalies have not been classified, because they are not associated with fetal loss. In this scheme, vaginal anomalies are most often associated with uterine didelphys and bicornuate anomalies. Class I segmental defects can affect the vagina, cervix, uterus, or tubes ([Fig. 40-2](#)).

Figure 40-1. Development of the female reproductive systems from the genital ducts and urogenital sinus. Vestigial structures are also shown. **A.** Reproductive system at 6 weeks before differentiation. **B.** In the female, the mullerian (paramesonephric) ducts extend and enter the urogenital sinus and become fused. **C.** Uterine cavitation occurs at site of fused mullerian ducts and the uterus grows downward. **D.** Cavitation is complete and the lower segment and cervix, along with the upper vagina, are formed.

Figure 40-2. Class I mullerian anomaly: Segmental mullerian agenesis or hypoplasia with subdivisions.

VULVAR ABNORMALITIES. Complete *atresia of the vulva* includes atresia of the lower third of the vagina. Usually, vulvar atresia is incomplete and results from adhesions or scars following injury or infection. The defect may present a considerable obstacle to vaginal delivery. Although the resistance usually is overcome, deep perineal tears may result.

Labial fusion is most commonly due to congenital adrenal hyperplasia (see [Chap. 4](#), p. 114). Other causes include fetal exogenous androgen exposure or abdominal wall defects. *Imperforate hymen* is persistence of the fusion between the sinovaginal bulbs with the urogenital sinus. Typically, it is associated with primary amenorrhea and hematocolpos and is not encountered often during pregnancy. Occasionally, *vulvar venous malformations* are encountered. These must be differentiated from both vulvar varicosities of pregnancy and tumors (Marrocco-Trischitta and colleagues, 2001).

VAGINAL ABNORMALITIES. Developmental abnormalities of the normal single vagina include:

1. *Atresia*. This may be partial or complete. Vaginal agenesis is usually due to the Rokitansky-Kuster-Hauser syndrome or from androgen insensitivity syndrome (formerly testicular feminization).
2. *Double vagina*. It is often difficult to distinguish the double from the completely septate vagina. The true double vagina includes a double introitus and resembles a double-barreled shotgun, with each passage terminating in a distinct, separate cervix. At times, one passage ends blindly.
3. *Longitudinally septate vagina*. More or less complete longitudinal septum.
4. *Transversely septate vagina*. This results from faulty canalization of the fused müllerian anlage rather than faulty longitudinal fusion. The septate vagina is usually discovered during routine pelvic examination or with tampon insertion.

Obstetrical Significance. Vaginal anomalies usually present few problems. However, occasionally they obstruct vaginal delivery.

ATRESIA. Complete vaginal atresia, unless corrected operatively, forms an effective barrier to pregnancy (Chakravarty and colleagues, 2000). **About one third of women with vaginal atresia have associated urological abnormalities.** With complete müllerian agenesis, pregnancy is impossible, but vaginal dilatation techniques are successful in forming a functional vagina in as many as 90 percent of cases (Croak and associates, 2003; Roberts and colleagues, 2001). In some women, surgical correction is necessary (American College of Obstetricians and Gynecologists, 2002b).

Incomplete atresia can be a manifestation of faulty development, as shown in [Figure 40-2](#), or the result of scarring from injury or inflammation (see p. 960). In most cases of partial atresia, because of pregnancy-induced tissue softening, obstructions during labor are gradually overcome.

SEPTAE AND STRICTURES. A complete longitudinal septum usually does not cause dystocia because the half of the vagina through which the fetus descends gradually dilates satisfactorily. However, an incomplete septum occasionally interferes with descent. In these cases, the septum may become stretched around the presenting part as a band of varying thickness. Occasionally, it must be divided or cesarean delivery performed. Burgis (2001) described an obstructive septum in one vagina of a woman with uterine didelphys and a double vagina.

Sometimes the upper vagina is separated from the rest of the canal by a *transverse septum* with a small opening, as shown in [Figure 40-3](#). Some of these are associated with in utero exposure to diethylstilbestrol (DES) (see p. 957). Such strictures may be mistaken for the upper limit of the vaginal vault. If so, at the time of labor, the septal opening is misidentified as an undilated cervical os. After the external os has dilated completely, the head impinges on the septum and causes it to bulge downward. If the septum does not yield, slight pressure on its opening usually leads to further dilatation, but occasionally cruciate incisions may be required to permit delivery (Blanton and Rouse, 2003).

Figure 40-3. Sagittal view of a transverse vaginal septum with communication through a small opening into the distal vagina.

CERVICAL ABNORMALITIES. There are a number of anatomical and developmental anomalies of the normal single cervix.

1. *Atresia*. The entire cervix may fail to develop. This may be combined with incomplete development of the upper vagina or lower uterus (see [Fig. 40-2](#)).
2. *Double cervix*. Each distinct cervix results from separate müllerian duct maturation. Both septate and true double cervixes are frequently associated with a longitudinal vaginal septum. Many septate cervixes are erroneously classified as double.
3. *Single hemicervix*. This arises from unilateral müllerian maturation.
4. *Septate cervix*. This consists of a single muscular ring partitioned by a septum. The septum may be confined to the cervix, or more often, it may be the downward continuation of a uterine septum or the upward extension of a vaginal septum.

Obstetrical Significance. Complete cervical atresia is incompatible with conception (Chakravarty and associates, 2000). Cicatricial *cervical stenosis* may follow various forms of cervical trauma (see p. 960). Because there usually is tissue softening during pregnancy, stenosis usually yields during labor, but occasionally cesarean delivery is necessary.

UTERINE MALFORMATIONS. As outlined in [Table 40-1](#), a large variety of congenital uterine malformations may be encountered. Some of these are simply oddities to be noted, whereas others may preclude normal procreation.

Diagnosis. Some uterine anomalies are discovered by routine pelvic examination. Frequently they are discovered at cesarean delivery or during manual exploration of the uterine cavity after delivery. Fundal notching, palpated abdominally, is most often indicative of a malformed uterus. Ultrasonic screening for uterine anomalies, although 98-percent specific, is only 43-percent sensitive (Nicolini and associates, 1987). It is difficult to distinguish a septate from a bicornuate uterus without radiological examination, high-resolution sonography, or *magnetic resonance imaging* (MRI) (Raga and colleagues, 1996; Salle and co-workers, 1996). In some cases, *hysteroscopy* and *hystero-graphy* are of value in ascertaining the configuration of the uterine cavity. Minto and colleagues (2001) reported that preoperative evaluation with MRI was helpful in determining the surgical approach in nine women with complex mullerian anomalies. Hundley and co-workers (2001) described excellent imaging of a septate uterus with a double cervix and septate vagina using three-dimensional MRI reconstruction. Laparoscopy may be necessary for confirmation of the absence or presence of an external division of the uterus or a rudimentary horn. Alborzi and associates (2002) used *sonohysterography* to differentiate septate and bicornuate uteri. Woelfer and co-workers (2001) used *three-dimensional sonography* to identify uterine anomalies in 106 women.

Incidence. Accurate figures are not available for the incidence of uterine anomalies. Green and Harris (1976) found the incidence to be about 1 in 400 for nearly 32,000 deliveries. Detection was greatest during a period when an especially interested staff member espoused routine uterine exploration at delivery. When an anomaly was suspected, they performed hysterosalpingography 6 to 8 weeks postpartum. Mullerian anomalies are more common in women with recurrent spontaneous miscarriage. Valli and associates (2001) reported that 32 percent of 344 such women were found to have an anomaly compared with 6 percent of 922 women in the control group.

Urological Defects. When asymmetrical development of the reproductive tract is found, urological evaluation should be considered because of the frequent association with urinary tract anomalies. When unilateral uterine atresia is present or when one side of a double vagina terminates blindly, an ipsilateral urological anomaly is common (Fedele and associates, 1987; Heinonen, 1983, 1984; Wiersma and colleagues, 1976).

Auditory Defects. As many as one third of women with mullerian defects have been reported to have auditory defects (Letterie and Vauss, 1991). These are typically mild to severe sensorineural hearing deficits in the high-frequency range.

Uterine Anomalies in Wilms Tumor Survivors. Survivors of this rare malignancy appear to have an increased incidence of congenital urinary and reproductive tract anomalies (Nicholson and colleagues, 1996). This observation might partially explain the increased rate of infertility reported in female survivors.

Obstetrical Significance. Major difficulties arise from many uterine anomalies. Uterine defects that result from development of only one mullerian duct or from lack of fusion often give rise to a hemiuterus that fails to dilate and hypertrophy appropriately. This may result in miscarriage, ectopic pregnancy, rudimentary horn pregnancy, preterm delivery, fetal growth restriction, abnormal fetal lie, uterine dysfunction, or uterine rupture (Ben-Rafael and associates, 1991; Michalas, 1991). Valli and colleagues (2001) reported a fivefold increase of recurrent miscarriage in 344 women with a septate or unicornuate uterus compared with that of 922 case controls. Even in women with only a uterine septum, miscarriage is increased (Buttram and Gibbons, 1979; Raga and associates, 1997). That said, the American College of Obstetricians and Gynecologists (2001) cautions that repair of such defects may not prevent miscarriage.

UNICORNUATE UTERUS (CLASS II). Developmental anomalies that result in a unicornuate uterus are shown in [Figure 40-4](#). The incidence of a unicornuate uterus, as diagnosed by hysterosalpingography, in a series of 1160 uterine anomalies was 14 percent (Zanetti and associates, 1978). This was likely an underestimate, because hysterosalpingography cannot be used to identify noncommunicating rudimentary horns, by far the most common anomaly. Women with a unicornuate uterus have an increased incidence of infertility, endometriosis, and dysmenorrhea (Fedele and associates, 1987, 1995; Heinonen, 1983).

As shown in [Table 40-2](#), implantation in the normal-sized hemiuterus is associated with increased incidences of preterm delivery, fetal growth restriction, breech presentation, dysfunctional labor, and cesarean delivery. Pregnancies in the rudimentary horn are usually disastrous. Rolan and associates (1966) reported that uterine rupture occurred prior to 20 weeks in most of 70 rudimentary horn pregnancies. An example is shown in [Figure 40-5](#). Nahum (2002) reviewed the literature from 1900 to 1999 and identified reports of 588 such pregnancies. In 419 cases, the communication status was known, half of these had uterine rupture — 80 percent before the third trimester. Eighty-five percent were of the noncommunicating type, and the rupture rate in these was 85 percent. With a noncommunicating horn, the rupture rate was 85 percent. Fetal survival was 6 percent overall. Most of the 23 maternal deaths were before 1950. More liberal use of high-resolution ultrasound and MRI may result in an earlier diagnosis of such problems with surgical or medical therapy before the pregnancy ruptures (Edelman and associates, 2003; Vo and colleagues, 2003).

UTERINE DIDELPHYS (CLASS III). This anomaly is distinguished from bicornuate and septate uteri by the presence of complete nonfusion of the cervix and hemiuterine cavity ([Fig. 40-6](#)). Heinonen (1984) reported that all 26 women with a uterine didelphys had a longitudinal vaginal septum as well. A few cases in which there was a septate uterus instead of two hemiuteri have been reported (Hundley and associates, 2001; Wai and colleagues, 2001). Occasionally, one hemivagina is obstructed by an oblique or transverse vaginal septum (Hinckley and Milki, 2003).

Except for ectopic and rudimentary horn pregnancies, problems associated with uterine didelphys are similar to those seen with a unicornuate uterus. Heinonen (1984) reported a 70-percent successful pregnancy outcome. There was preterm delivery in 20 percent, fetal growth restriction in 10 percent, breech presentation in 43 percent, and the cesarean delivery rate was 82 percent. A trial of labor in a subsequent pregnancy following cesarean delivery resulted in a higher uterine rupture rate than expected (Ravasia and colleagues, 1999).

Multifetal gestation is unusual in women with uterine didelphys (Olah, 2002). Mashlach and associates (1981) reported a case of triplets with a delivery interval of 72 days!

BICORNUATE AND SEPTATE UTERI (CLASSES IV AND V). In both of these types of anomalies, which are shown in [Figures 40-7](#) and [40-8](#), there is a marked increase in miscarriages that is likely due to the abundant muscle tissue in the septum (Dabirashrafi and colleagues, 1995). Miscarriage with a septate uterus is more common than with a bicornuate uterus (Proctor and Haney, 2003). Pregnancy losses in the first 20 weeks were observed by Buttram and Gibbons (1979) to be 70 percent for bicornuate and 88 percent for septate uteri. Woelfer and colleagues (2001) reported a first-trimester loss rate for septate uteri of 42 percent. This extraordinarily high pregnancy wastage likely is due to partial or complete implantation on the largely avascular septum. The majority of women with mullerian anomalies have lateral placental implantation with poor perinatal outcomes (Leible and associates, 1998). There also is an increased incidence of preterm delivery, abnormal fetal lie, and cesarean delivery. Heinonen (1999) described three newborns with a limb-reduction defect born to women with a septate uterus. In one series, a subsequent trial of labor after cesarean delivery was associated with an increased risk of uterine rupture (Ravasia and associates, 1999).

ARCuate UTERUS (CLASS VI). This malformation is only a mild deviation from the normally developed uterus. Raga and associates (1997) reported no impact on reproductive outcomes. Conversely, Woelfer and colleagues (2001) found excessive second-trimester losses and preterm labor.

Management. Women with nonobstructive defects such as uterine didelphys and unicornuate uterus usually do not need surgical correction (Stenchever, 2001). Although abnormal fetal presentations are commonly seen, external cephalic version is less likely to be successful.

CERCLAGE. In women with repetitive pregnancy losses, a number of investigators have reported that cervical cerclage may lead to better outcomes (Golan, 1990b, 1992; Golan and Caspi, 1992; Maneschi, 1988; Seidman, 1991, and all their co-workers). Transabdominal cerclage may offer the best prognosis in women with partial cervical atresia or cervical hypoplasia (Hampton and colleagues, 1990; Mackey and co-workers, 2001).

Caspi and associates (1990) have described a modified Shirodkar cerclage for women with short or lacerated cervixes and in women with previous McDonald cerclage failures. The results obtained were similar to those achieved with a Shirodkar cerclage. Transvaginal cervical cerclage has been used successfully in DES-exposed women with cervical hypoplasia (Ludmir and co-workers, 1991).

Cerclage should not be necessary after successful resection of a uterine septum. It probably should still be used following abdominal metroplasties for uterine didelphys and bicornuate uteri. If active labor supervenes, the cervical ligature is removed to prevent uterine rupture. Cerclage is discussed in detail in [Chapter 9](#) (p. 237).

METROPLASTY. Women with septate or bicornuate anomalies and poor reproductive outcomes may benefit from uterine surgery (Ayhan and colleagues, 1992). Repair of a bicornuate uterus is by transabdominal metroplasty involving septal resection and recombination of the fundi (Candiani and associates, 1990; Kessler and co-workers, 1986). Following repair, uterine activity is normal if anatomically symmetrical uterine horns have been conjoined (Oliva and associates, 1992).

Repair of a septate uterus is best done by hysteroscopic resection of the septum (Daly, 1989; Grigoris, 1998; Hassiakos, 1990; Israel, 1984; Jourdain, 1998, and all their co-workers). In a review of pregnancy outcome following repair of a septate uterus, Stenchever (2001) reported that slightly over half of 351 pregnancies were liveborn. Preterm labor is common (Litta and colleagues, 2004; Pabuccu and Gomel, 2004). Despite minimal uterine wall invasion with septal resection, disastrous fundal rupture has been reported (Angell and co-workers, 2002).

Figure 40-4. Class II mullerian anomalies: Unicornuate uterus either with rudimentary horn (**A**) or without rudimentary horn (**B**). Those with a rudimentary horn are divided into groups with an endometrial cavity (**A-1**) or without an endometrial cavity (**A-2**). Those with an endometrial cavity either have a communication with the opposite uterine horn (**A-1-a**) or do not have a communication with the opposite horn (**A-1-b**).

Figure 40-5. A. A 15-week pregnancy in a woman with three prior vaginal breech deliveries. This pregnancy is in the left noncommunicating rudimentary uterine horn as seen at laparotomy. The tense, vascular rudimentary uterus was bleeding from veins over its extremely vascular surface. The attached oviduct (*arrow*) was patent and the adjacent left ovary contained the corpus luteum of pregnancy. **B.** Hysterectomy specimen with left hemiuterus opened to display the fetus and placenta. The intact mass (*arrow*) consists of left tube and ovary.

Figure 40-7. Class IV mullerian anomaly: Complete bicornuate uterus (**A**) and partial (**B**); Class VI arcuate uterus (**C**).

Figure 40-8. Class V mullerian anomaly: Septate uterus with complete septum to the cervical os (A) or partial septum (B).

DIETHYLSTILBESTROL-INDUCED REPRODUCTIVE TRACT ABNORMALITIES.

From the late 1940s through the early 1960s, diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was prescribed for an estimated 3 million pregnant women in the United States. Early reports claimed the drug was useful in treating abortion, preeclampsia, diabetes, and preterm labor. It was remarkably ineffective for these indications, however, almost 20 years later, Herbst and co-workers (1971) found that DES exposure in utero was linked to the later development of vaginal clear cell adenocarcinoma. Pitkin (2003) describes this as one of the most seminal discoveries in obstetrics and gynecology of the past century. The risk of vaginal malignancy is about 1 per 1000 exposed daughters. Subsequently, it was established that daughters also had an increased risk of developing cervical intraepithelial neoplasia as well as small cell cervical carcinoma (Herbst, 2000). About one third have vaginal adenosis. In addition to carcinogenesis, several nonneoplastic abnormalities of the vagina and cervix have become apparent following DES exposure in utero.

Structural Abnormalities. As many as one fourth of women exposed to DES in utero have identifiable structural variations in the cervix and vagina (Herbst, 2000), which are in class VII of the American Fertility Society classification system (1988). These include transverse septa, circumferential ridges involving the vagina and cervix, and cervical collars. Half of all exposed women have uterine cavity anomalies evident on hystero-graphy. Women with cervicovaginal abnormalities are more likely to have uterine anomalies. Significantly smaller uterine cavities, shortened upper uterine segments, and T-shaped and irregular cavities have been described (Barranger and associates, 2002). Finally, abnormalities of the oviduct have been described, including shortening, narrowing, and fimbrial absence. Kipersztok and colleagues (1996) believe that hysterosalpingography remains the imaging procedure of choice in the identification of these anomalies.

Structural anomalies in males have also been linked to fetal exposure to DES. These include cryptorchidism, testicular hypoplasia, microphallus, and hypospadias (Hernandez-Daz, 2002). Klip and colleagues (2002) provided evidence suggesting a transgenerational effect in which male fetuses conceived by daughters of DES-exposed women have hypospadias.

Reproductive Performance. Women exposed to DES in utero in general have impaired conception rates (Goldberg and Falcone, 1999; Palmer and colleagues, 2001; Senekjian and co-workers, 1988). Reduced fertility in these women is poorly understood but is associated with cervical hypoplasia and atresia. Of those who conceive, the incidence of miscarriage, ectopic pregnancy, and preterm delivery are increased; the risk is greatest in women with structural abnormalities (Goldberg and Falcone, 1999; Kaufman and associates, 1984, 2000). Spontaneous uterine rupture during pregnancy is increased; Porcu and colleagues (2003) reported a woman with spontaneous rupture at 12 weeks.

ECTOPIC PREGNANCY. The incidence of ectopic pregnancy was reported to be 7 percent compared with none for controls (Herbst, 2000; Herbst and colleagues, 1989). The etiology is likely due to tubal anomalies, but decreased uterine size may also be a factor. Also, DES-exposed women with salpingitis may develop adhesions that aggravate tubal dysfunction.

PRETERM LABOR. The incidence of preterm delivery is increased, likely due to uterine and cervical anomalies (de Haas and associates, 1991; Herbst, 2000). Cervical incompetence is associated with midpregnancy losses and preterm delivery (Ludmir and colleagues, 1987). In 5 of 21 pregnancies, Michaels and co-workers (1989) documented preterm cervical effacement and dilatation using serial ultrasonic evaluation. They recommend weekly visits for these women, with serial ultrasound performed beginning at 14 weeks and continuing through 27 weeks. If there is cervical effacement and dilatation, they perform cerclage. Ayers and associates (1988) and Ludmir and co-workers (1987, 1991) also recommend cerclage for most of these women, especially those with cervical hypoplasia. Hampton and colleagues (1990) recommend abdominal cerclage for women in this latter group (see p. 956). In general, we do not perform cerclage beyond 23 weeks (see [Chap. 9](#), p. 237).

Surgical Repair. With some uterine structural defects, surgical repair may improve reproductive performance. Katz and colleagues (1996) reported improved pregnancy outcomes with hysteroscopic resection of intrauterine tissue. Garbin and associates (1998) and Barranger and colleagues (2002) performed hysteroscopic metroplasty in a total of 54 women. Following metroplasty, they reported that over 75 percent had liveborn infants.

ACQUIRED REPRODUCTIVE TRACT ABNORMALITIES

VULVAR ABNORMALITIES. A number of acute and chronic vulvar conditions may prove vexing to both the woman and her obstetrician.

Edema. Many women have some degree of vulvar edema during pregnancy. At times it can be impressive and without an identifiable pathological cause. In women with the nephrotic syndrome and hypoproteinemia, vulvar edema may be problematic as early as midpregnancy (see [Fig. 48-5](#), p. 1101). During labor, the vulva may become edematous, especially in women with severe preeclampsia. Venous thromboses and hematomas occasionally cause edema and significant pain. In postpartum women, edema associated with a paravaginal, vulvar, or perineal hematoma occurring from lacerations or an episiotomy may be extensive (see [Chap. 35](#), p. 836).

Inflammatory Lesions. Extensive perineal inflammation and scarring from *hidradenitis suppurativa*, *lymphogranuloma venereum*, or *Crohn disease* may create difficulty with vaginal delivery, episiotomy, and repair. A mediolateral episiotomy may prevent some of these difficulties.

Bartholin Gland Lesions. Cysts of the Bartholin glands are usually sterile and need no treatment during pregnancy. If the cysts are large enough to cause difficulty at delivery, then needle aspiration as a temporary measure is sufficient. If an abscess is present, broad-spectrum antimicrobials are given and drainage is established. For a large abscess with extensive cellulitis, drainage is best performed in the operating room. The cut edges of the abscess cavity are marsupialized and packed with

gauze, which is removed the next day. Alternatively, a Word catheter is used as shown in [Figure 40-9](#). In some cases, especially in diabetic or immunocompromised women, life-threatening *necrotizing fasciitis* may develop (see [Chap. 31](#), p. 720).

Urethral and Bladder Lesions. Trauma to the urethra or infection of its glands may result in periurethral abscesses, cysts, and diverticula. Abscesses usually resolve spontaneously, some with asymptomatic cyst formation. A urethral diverticulum may fill with debris that intermittently empties through the urethra to give rise to proteinuria of obscure etiology. In general, surgical excision of cysts or diverticula should not be done during pregnancy.

Bladder lesions during pregnancy are uncommon. Obstruction of labor by *bladder stones* has been reported (Penning and associates, 1997; Rai and Ramesh, 1998). Hendry (1997) reviewed the literature concerning *bladder tumors* and concluded that cesarean delivery was required in some cases of bladder cancer.

Condyloma Acuminata. Genital infection with the human papillomavirus results in condyloma acuminata. These so-called *veneraeal warts* can be so extensive that vaginal delivery may be prohibited. These sexually transmitted lesions are discussed in [Chapter 59](#) (see p. 1318).

Female Genital Mutilation. Inaccurately called female circumcision, mutilation refers to medically unnecessary vulvar and perineal modification. Forms of female genital mutilation are practiced in countries throughout Africa and the Middle East and in Muslim populations of Indonesia and Malaysia. Between 80 and 110 million women are affected worldwide. According to the World Health Organization (1992), mutilation is associated with poverty, illiteracy, and low social status of women. Jones and colleagues (1997) estimated that nearly 170,000 women who have had genital mutilation live in the United States. Cultural sensitivity is imperative, because many women may be offended by the suggestion that they have been mutilated (American College of Obstetricians and Gynecologists, 2002a).

The World Health Organization (1997) classifies genital mutilations into four types ([Table 40-3](#)). Other commonly used terms include *sunna* (type 1), *excision* (type 2), and *infibulation* or *pharaonic circumcision* (type 3). A type 1 procedure performed under sterile conditions (often not the case) rarely has long-term adverse physical consequences (Toubia, 1994). A type 3 procedure, an extreme form of mutilation, consists of the removal of the entire clitoris, the entire labia minora, and at least two thirds of the labia majora ([Fig. 40-10](#)). The procedure is typically performed at 7 years of age without anesthesia by midwives or village women. Commonly used instruments are razor blades, kitchen knives, scissors, glass, and in some regions, the teeth of the midwife. The two sides of the vulva are stitched together by silk or catgut or are held together by thorns. A small opening is left (usually made by the insertion of a matchstick) for the passage of menstrual blood and urine. The legs of the girl are then bound from hip to ankle for as many as 40 days so that scar tissue will form. Immediate dangers are exsanguination and severe infections. Urinary retention is common.

Long-term sequelae depend on the severity of mutilation. Okonofua and associates (2002) reported that half of women attending clinics in Nigeria had been mutilated. Of these, 70 percent had undergone type 1 procedures, and 25 percent had undergone type 2 procedures. These women had normal sexual function but a threefold risk of vaginal infection or genital ulcers. Complications of type 3 procedures include sterility, dysmenorrhea, and dyspareunia (Chen and associates, 2004; Knight and colleagues, 1999; Nour, 2004). Infibulation may also predispose to human immunodeficiency virus (HIV) infection (Kun, 1997). A case of clitoral amputation neuroma has been described by Fernandez-Aguilar and Noel (2003).

The American College of Obstetricians and Gynecologists (2002a), along with the International Federation of Gynecology and Obstetrics, the American Medical Association, the United Nations International Children's Emergency Fund, and the World Health Organization, has supported legislation to eliminate female genital mutilation in the United States. The American Academy of Pediatrics (1998) encourages development of community educational programs for immigrant populations. Currently, it is a federal crime to perform unnecessary genital surgery on a girl younger than 18 years of age. In some countries where female genital mutilation has been routinely performed, laws are being enacted to prohibit such mutilation (Ciment, 1999; Eke and Nkanginieme, 1999). A slide lecture kit — *Female Circumcision/Female Genital Mutilation: Clinical Management of Circumcised Women* — is available to ACOG members from the ACOG Distribution Center (800-762-2264).

PREGNANCY. A number of obstetrical complications due to birth canal obstruction from scar tissue occur in women who have undergone female genital mutilation. Many of these women do not desire deinfibulation until pregnant; therefore, Nour (2004) recommends that this be done at midpregnancy using spinal analgesia. Another option is to wait and incise scarred tissue between the index and middle fingers inserted between the crowning fetal head and the scar. In our experiences, in many cases intrapartum deinfibulation allows successful vaginal delivery without major complications.

Figure 40-9. Management of a Bartholin gland abscess using a Word catheter. **A.** A stab wound is made into the abscess using a No. 15 scalpel blade. **B.** Insertion of catheter into cavity. **C.** Properly inflated balloon tip with external catheter tip to be tucked into the vagina. (From Wendel, 2002.)

Figure 40-10. Sequelae of infibulation or pharaonic circumcision: This ritual mutilation procedure included clitoridectomy, excision of labia minora, and incision of labia majora. Remnant labia majora have been approximated, leaving a small neo-introitus. (From Nour, 2000, with permission.)

Figure 48-5. Massive vulvar edema at 32 weeks in a woman with the nephrotic syndrome secondary to diabetic nephropathy. (From Jakobi and colleagues, 1995,

with permission.)

VAGINAL ABNORMALITIES. Compared with developmental anomalies, acquired vaginal abnormalities are uncommon. Even after major trauma, long-term sexual and reproductive functions are the norm (Fallat and colleagues, 1998). Vaginal stenosis may develop as a result of mucositis from graft-versus-host reaction following organ transplantation (Louis-Sylvestre and associates, 2003).

Partial Atresia. Incomplete atresia may result from infection or trauma that leads to extensive scarring. During labor, this is usually overcome by pressure from the presenting part, but occasionally incisions or even cesarean delivery are necessary.

Genital Tract Fistulas. Fistulas seen during pregnancy likely existed previously, but in rare cases they develop during pregnancy. McKay and Hanlon (2003) described a *vesicovaginal fistula* that developed following a McDonald cerclage done at 20 weeks. In prolonged obstructed labor, which is unfortunately common in developing countries, the genital tract may be compressed between the fetal head and the bony pelvis. Brief pressure is not significant, but prolonged pressure may result in necrosis with subsequent fistula formation. Miklos and colleagues (1995) described a *vesicouterine fistula* that developed following vaginal delivery after prior cesarean delivery. Rarely, the anterior cervical lip is compressed against the symphysis pubis with development of a *vesicocervical fistula*. Some of these fistulas heal spontaneously, but more often subsequent repair is necessary. Murray and associates (2002) report a high rate of successful closures performed since 1975 in over 15,000 fistulas at The Fistula Hospital in Addis Ababa, Ethiopia. Unfortunately, despite repair, urinary incontinence persists in 55 percent of cases. Wall (2002) has provided a poignant chronicle of the societal impact of these abnormalities on Nigerian culture.

CERVICAL ABNORMALITIES. Cicatricial *cervical stenosis* was once a problem (Melody, 1957). Cervical conization was a common cause (Gibbs and Moore, 1968). Cryotherapy and laser therapy occasionally produce stenosis, but large-loop excision of the transformation zone (LLETZ) usually does not (Cruikshank and associates, 1995; Spitzer and colleagues, 1995). Cervical stenosis almost always yields during labor. A so-called *conglutinated cervix* may undergo almost complete effacement, but the cervical os may not dilate. Thus, the presenting part is often separated from the vagina by only a thin layer of cervical tissue. Ordinarily, complete dilatation promptly follows pressure with a fingertip, although in rare instances, manual dilatation or cruciate incisions may be required.

In some women, extensive *cervical carcinoma* may impair vaginal delivery. Carcinoma of the cervix complicating pregnancy is discussed in [Chapter 57](#) (see p. 1264).

UTERINE ABNORMALITIES. A number of uterine disorders may adversely affect pregnancy as well as fertility.

Anteflexion. Exaggerated degrees of anteflexion frequently observed in early pregnancy are without significance. In later months, particularly when the abdominal wall is very lax, the uterus may fall forward. This may be so exaggerated that the fundus lies considerably below the lower margin of the symphysis pubis. Marked anteflexion of the enlarging pregnant uterus usually is associated with *diastasis recti* and a pendulous abdomen. The abnormal uterine position sometimes prevents proper transmission of contractions; this is overcome by repositioning with an abdominal binder.

Retroflexion. Occasionally during pregnancy, the growing normally retroflexed uterus remains incarcerated in the hollow of the sacrum ([Fig. 40-11](#)). Symptoms include abdominal discomfort and inability to void normally. As pressure from the full bladder increases, small amounts of urine are passed involuntarily, but the bladder never empties entirely — *paradoxical incontinence*. Acute urinary retention may also occur (Myers and Scotti, 1995). Such blockage also can cause severe obstructive nephropathy.

Management is repositioning. After bladder catheterization, the uterus can usually be pushed out of the pelvis when the woman is placed in the knee-chest position. Occasionally spinal analgesia or general anesthesia is necessary. Following repositioning, an indwelling catheter is left in place until bladder tone returns. Insertion of a soft pessary for a few weeks usually prevents reincarceration. Lettieri and colleagues (1994) described seven cases of uterine incarceration not amenable to these simple procedures. In two women, laparoscopy was used at 13 to 14 weeks to reposition the uterus using the round ligaments for traction. Seubert and associates (1999) used colonoscopy to dislodge an incarcerated uterus in five women. Hamoda and co-workers (2002) simply observed one woman and performed cesarean delivery of a healthy infant at 36 weeks.

Sacculation. Persistent entrapment of the pregnant uterus in the pelvis may result in an anterior uterine sacculation. Extensive dilatation of the lower uterine segment takes place to accommodate the fetus (Jackson and associates, 1988; Lettieri and co-workers, 1994). Cesarean delivery is necessary. Spearing (1978) stressed the importance of identifying the distorted anatomy. An elongated vagina passing above the level of a fetal head that is deeply placed into the pelvis is suggestive of a sacculation or an abdominal pregnancy. The Foley catheter is frequently palpated above the level of the umbilicus! Spearing (1978) recommended extending the abdominal incision to above the umbilicus and delivery of the entire uterus from the abdomen before an attempt is made to incise it. **This simple procedure will restore anatomy to the correct relationships and prevent inadvertent incisions into and through the vagina and bladder.**

Friedman and associates (1986) described a rare case of posterior uterine sacculation following aggressive treatment for intrauterine adhesions, or *Asherman syndrome*. Uterine retroversion and a true uterine diverticulum have been mistaken for uterine sacculations (Engel and Rushovich, 1984; Hill and associates, 1993).

Uterine Prolapse. The cervix, and occasionally a portion of the body of the uterus, may protrude to a variable extent from the vulva during early pregnancy. With further growth, the uterus usually rises above the pelvis and may draw the cervix up with it. If the uterus persists in its prolapsed position, symptoms of incarceration may develop from 10 to 14 weeks. To prevent this, the uterus is replaced early in pregnancy and held in position with a suitable pessary. Successful vaginal

deliveries have been reported following sacrospinous uterosacral fixation done before pregnancy to correct severe uterine prolapse (Kovac and Cruikshank, 1993).

Cystocele and Rectocele. Attenuation of fascial support between the vagina and the bladder can lead to prolapse of the bladder into the vagina, or cystocele. Attenuation of fascia between the vagina and the rectum results in a rectocele. A large defect may fill with feces that, at times, can only be manually evacuated. During labor, either a cystocele or a rectocele can block normal fetal descent unless they are emptied and pushed out of the way. Urinary stasis with a cystocele predisposes to infection. Pregnancy may worsen associated *urinary stress incontinence*, because urethral closing pressures do not increase sufficiently to compensate for the progressive increase in bladder pressure caused by increasing uterine weight (Iosif and Ulmsten, 1981).

Enterocoele. In rare instances, an enterocele of considerable size may complicate pregnancy. If symptomatic, the protrusion should be replaced and the woman kept in a recumbent position. If the mass interferes with delivery, it should be pushed up or held out of the way.

Uterine Torsion. Rotation of the uterus, most often to the right, is common during pregnancy. Jensen (1992) has provided an extensive review of uterine torsion. Torsion of sufficient degree to arrest uterine circulation is rare. Bakos and Axelsson (1987) reported a case of severe levotorsion associated with repeated fetal heart rate decelerations that prompted cesarean delivery. Because of extreme uterine torsion, the incision inadvertently was made in the posterior wall of the uterus! The severely malpositioned uterus should be removed from the abdomen prior to hysterotomy (Spearing, 1978). Sherer and colleagues (1994) stress that torsion can be confused with an abdominal pregnancy. If suspected, antepartum diagnosis of either may be improved with MRI (Dietz and co-workers, 1998; Nicholson and associates, 1995). Although the vagina normally appears as an H-shaped structure, with torsion it appears X-shaped — the so-called "X sign." Olah (2002) described a case in which one horn of a bicornuate uterus became ischemic from torsion.

Figure 40-11. Incarcerated, retroflexed uterus. (p = sacral promontory; s = symphysis.)

UTERINE LEIOMYOMAS. Also known as myomas and erroneously called *fibroids*, uterine leiomyomas are benign smooth muscle tumors commonly found during pregnancy. Rice and colleagues (1989) reported that 1.4 percent of more than 6700 pregnancies were complicated by myomas. Sheiner and co-workers (2004) cited an incidence of 0.65 percent in nearly 106,000 pregnancies. Katz and associates (1989) reported that 1 in 500 of all pregnant women were admitted for a complication related to a leiomyoma.

Myomas may be located immediately beneath the endometrial or decidual surface of the uterine cavity (*submucous*), immediately beneath the uterine serosa (*subserous*), or may be confined within the myometrium (*intramural*). As an intramural myoma grows, it may develop a significant subserous component, a submucous component, or both. Submucous and subserous myomas may be pedunculated and may undergo torsion with necrosis. At times, a subserous myoma may become *parasitic*, and much or all of its blood is supplied through the highly vascularized omentum.

Myomas during pregnancy or the puerperium occasionally undergo *red or carneous degeneration* that is caused by hemorrhagic infarction. The symptoms and signs are focal pain, with tenderness on palpation, and sometimes low-grade fever. Moderate leukocytosis is common. On occasion, the parietal peritoneum overlying the infarcted myoma becomes inflamed, and a peritoneal friction rub develops. Myoma degeneration may be difficult to differentiate from appendicitis, placental abruption, ureteral stone, or pyelonephritis, but imaging techniques discussed subsequently will likely prove helpful (Kawakami and associates, 1994).

Treatment of symptomatic myomas consists of analgesia and observation. Most often, signs and symptoms abate within a few days, but inflammation may stimulate labor. Surgical management will be discussed (see page 964).

Infertility and Treatment. In spite of the relatively high prevalence of myomas in young women, it is not clear whether they diminish fertility, other than by possibly causing early miscarriage (Stewart, 2001). In a review of 11 studies, Pritts (2001) concluded that only submucous myomas had a significant negative impact on fertility. He also reported that hysteroscopic myomectomy improved infertility and early miscarriage rates in women with submucous tumors. **Intramural myomectomy is especially hazardous for subsequent pregnancy.** Thus, when myoma resection from the abdominal approach results in a defect into or immediately adjacent to the endometrial cavity, uterine rupture may occur remote from labor and sometimes even early in pregnancy (Golan and associates, 1990a). In these instances, cesarean delivery is recommended before active labor begins.

Arterial embolization of uterine myomas has been used to treat symptomatic leiomyoma in nonpregnant women. Many procedures are performed for uterine bleeding in perimenopausal women (Walker and Pelage, 2002). Their effect on the outcomes of subsequent pregnancies is unclear. Ravina and colleagues (2000) reported generally good outcomes. However, Goldberg and associates (2002) reviewed 50 published cases and cited increased risks for preterm birth, malpresentation, cesarean delivery, and postpartum hemorrhage. Because of the paucity of data, the American College of Obstetricians and Gynecologists (2004) considers embolization for leiomyoma investigational.

Effects of Pregnancy on Myomas. The stimulatory effects of pregnancy on the growth of uterine myomas may be impressive. It originally made sense to assume that growth was stimulated via estrogen and progesterone receptors. It now seems apparent, however, that normal rapid uterine expansion during pregnancy results from a complex mechanism mediated not only by estrogen and progesterone but also by growth factors that include *platelet-derived growth factor*, *epidermal growth*

factor, endothelin-1 (subtype ET_A), and insulin-like growth factor 1 (Honore, 2000; Ichimura, 1998; Rein, 1995, and all their associates). Angiogenic growth factors, basic fibroblast growth factor, and at least one gene (*HMGIC*) are also involved (Stewart, 2001).

Estrogen receptors are reduced in normal myometrium during the secretory phase of the menstrual cycle and during pregnancy (Benassayag and colleagues, 1999). In myomas, estrogen receptors are present throughout the menstrual cycle, but they are suppressed during pregnancy. Progesterone receptors are present in both myometrium and myomas throughout the menstrual cycle and pregnancy. Thus, myoma growth in early pregnancy is stimulated by similar hormonal and growth factors that cause normal uterine growth.

Paradoxically, myomas respond differently in individual women, and thus, accurate prediction of their growth is not possible. For example, in the study shown in [Table 40-4](#), only half of myomas changed significantly in size during pregnancy. During the first trimester, myomas of all sizes either remained unchanged or increased in size — a possible early response to increased estrogen. During the second trimester, smaller myomas (2 to 6 cm) usually remained unchanged or increased in size, whereas larger myomas became smaller — probably from initiation of estrogen receptor downregulation. Regardless of initial myoma size, during the third trimester, myomas usually remained unchanged or decreased, reflecting estrogen receptor downregulation.

Effects of Myomas on Pregnancy. These common tumors are associated with a number of obstetrical complications, including excessive preterm labor, placental abruption, fetal malpresentation, obstructed labor, cesarean delivery, and postpartum hemorrhage (Davis, 1990; Hasan, 1990; Katz, 1989; Lev-Toaff, 1987; Rice, 1989; Sheiner, 2004; Winer-Muram, 1984, and all their colleagues). In a review of pregnancy outcomes in 2065 women with leiomyoma, Coronado and co-workers (2000) reported that placental abruption and breech presentation increased fourfold, first-trimester bleeding and dysfunctional labor increased twofold, and cesarean delivery increased sixfold. In a case-control study, Salvador and associates (2002) reported an eightfold second-trimester abortion risk. They also concluded that genetic amniocentesis did not increase the risk of midpregnancy loss in women with myomas.

The two factors most important in determining morbidity are myoma size and location. Proximity to the placental implantation site is important ([Table 40-5](#)). Specifically, abortion, placental abruption, preterm labor, and postpartum hemorrhage all are increased if the placenta is adjacent to or implanted over a myoma. Tumors in the cervix or lower uterine segment are particularly troublesome, because they may obstruct labor ([Fig. 40-12](#)). Large tumors distort anatomy and push the ureters laterally. A case of complete inferior vena caval obstruction by a large myoma at 17 weeks was described by Greene and colleagues (2002). Hemorrhage is more likely at cesarean delivery, and hysterectomy can be technically difficult ([Fig. 40-13](#)). In some cases, myomas that are contiguous with the birth canal may be carried upward as the uterus enlarges. In many cases, the route of delivery can be decided before the onset of labor.

Management of Myomas During Pregnancy. After the diagnosis is confirmed, expectant management is recommended.

IMAGING OF MYOMAS. Ultrasound is indispensable to correctly identify myomas and to follow their growth during pregnancy (see [Fig. 40-12](#)). There are limitations to sonography in evaluating myomas and other pelvic masses (Exacoustos and Rosati, 1993; Kier and co-workers, 1990; Strobelt and associates, 1994). Specifically, myomas have been confused with ovarian masses — both benign and malignant — as well as with molar pregnancy, ectopic pregnancy, missed abortion, bowel abnormalities, and even the fetal head. In some cases the use of color Doppler may be beneficial (Kessler and colleagues, 1993; Locci and associates, 1993).

MRI serves as an adjunct to ultrasound (Hricak and associates, 1992; Karasick and colleagues, 1992; Kier and co-workers, 1990). Comparisons with ultrasonic imaging have been made in the same women, and MRI was found to be superior (Weinreb and associates, 1990; Zawin and colleagues, 1990). MRI techniques have been described which markedly improve the reliability of identifying uterine myomas (Mayer and Shipilov, 1995; Schwartz and associates, 1998; Torashima and colleagues, 1998).

MYOMECTOMY. Resection of myomas during pregnancy is generally contraindicated. We agree with most other authorities that surgery should be limited to tumors with a discrete pedicle that can be clamped and easily ligated (Burton and associates, 1989). Resection of intramural myomas during pregnancy, or at the time of delivery, may stimulate profuse bleeding. In some cases, unrelenting pain from infarction and degeneration prompts surgical treatment. De Carolis and colleagues (2001) and Celik and associates (2002) have described good outcomes following myomectomy in a total of 23 women. Most of the women were between 14 and 20 weeks, and in almost 50 percent of cases, the surgery was performed because of pain. In some of these cases, an intramural myoma was in contact with the implantation site. Except for one loss immediately following surgery at 19 weeks, most women had cesarean delivery at term. These investigators, as well as Mollica and associates (1996), emphasize that such management is for highly selected cases. Joo and co-workers (2001) described antepartum removal of a 940-g degenerating fundal myoma that caused fetal postural deformity and oligohydramnios at 25 weeks. Postoperatively amniotic fluid volume normalized, and a normal infant was delivered by cesarean at term.

Infection of Myomas Postpartum. Although puerperal pelvic infections and myomas are both fairly common, myomas rarely become infected (Genta and colleagues, 2001). Myomas may become infected postpartum when there is pelvic infection or septic abortion ([Figure 40-14](#)). They are especially likely to do so if the myoma is located immediately adjacent to the placental implantation site, or if an instrument, such as a sound or curette, perforates the myoma.

Figure 40-12. Two uterine myomas (*), one posterior and one anterior, are seen in this 13-week pregnancy. Arrows point to fetal head and body. (B = bladder.) (Courtesy of Dr. R. Santos.)

Figure 40-13. Cesarean hysterectomy specimen from the case shown in [Figure 40-](#)

12. The upper mass is the body of the uterus which was just emptied by cesarean delivery. The lower mass is a huge myoma arising low in the uterus. The infant weighed 3250 g, and the uterus with the myoma weighed 2900 g.

Figure 40-14. Infected myoma with septic shock in a woman 6 days following cesarean delivery. The sagittal T₁-weighted magnetic resonance image shows decreased signal intensity in multiple leiomyomas. The lower myoma marked with arrowheads has heterogeneous signal intensity, which represents pus. (From Lin and colleagues, 2002, with permission.)

ENDOMETRIOSIS AND ADENOMYOSIS. Endometriosis and adenomyosis are rarely symptomatic during pregnancy. Rupture of an endometrioma rarely may cause bizarre and vexing clinical symptoms or labor dystocia. However, there are a number of case reports of symptoms arising from endometrial implants in cesarean delivery incisions or an episiotomy (Bumpers and associates, 2002).

Adenomyosis is common in older women. Its acquisition may be at least partially related to disruption of the endometrial-myometrial border during sharp curettage for abortion (Curtis and co-workers, 2002). Although problems during pregnancy are rare, Azziz (1986) performed an 80 year review and found that adenomyosis has been associated with uterine rupture, ectopic pregnancy, uterine atony, and placenta previa. Successful pregnancy may follow treatment of adenomyosis with gonadotropin-releasing hormone agonists (Hirata and co-workers, 1993; Silva and colleagues, 1994).

OVARIAN ABNORMALITIES. Any type of ovarian mass may complicate pregnancy. The incidence of tumors and cysts varies depending on the age group studied and the frequency with which prenatal sonography is used. From their review, Katz and colleagues (1993) found an average incidence of adnexal masses of 1 in 200 pregnancies. In a prospective population-based Italian study of almost 6650 pregnancies, Zanetta and associates (2003) found at least one mass larger than 3 cm in every 85 women. Whitecar and associates (1999) reported that masses requiring laparotomy complicated 1 in 1300 pregnancies. Koonings and co-workers (1988) reported finding one adnexal neoplasm per 200 cesarean deliveries.

The most common ovarian tumors are cystic. Whitecar and associates (1999) described 130 adnexal masses diagnosed during pregnancy at a number of military hospitals as well as University Hospital in San Antonio, Texas. About 30 percent were cystic teratomas, 28 percent were serous or mucinous cystadenomas, 13 percent were corpus luteal cysts, and 7 percent were other benign cysts. Importantly, 5 percent of all 130 masses were malignant, and 50 percent were serous carcinomas of low-malignant potential. Sherard and co-workers (2003) identified adnexal masses complicating 1 in every 600 pregnancies in Pitt County Memorial Hospital in North Carolina. About 50 percent were benign cystic teratomas, 20 percent were cystadenomas, and 13 percent were corpus luteal cysts. Likely because these cases were referred, 13 percent were malignant tumors; 5 of these 8 were of low-malignant potential. Of the 77 tumors described by Zanetta and colleagues (2003), 50 percent were simple cysts, 10 percent were benign cystic teratomas, and 4 percent were borderline malignant tumors.

Ovarian tumors unique to pregnancy are also found by ultrasound or at cesarean delivery. In addition to corpus luteal cysts, these include luteomas, which may be virilizing (Mazza and colleagues, 2002). Also, *ovarian hyperstimulation syndrome*, although usually caused by ovulation-induction therapy, may be spontaneous (Kaiser, 2003; Vasseur and associates, 2003). These are discussed further in [Chapter 5](#) (see p. 124).

Second to malignancy, the most serious complications of ovarian cysts during pregnancy are torsion or hemorrhage. The incidence of these complications depends on tumor size and whether laparotomy is done preemptively for tumors more likely to undergo torsion. Torsion was identified in 5 percent of women reported by Whitecar (1999) and Zanetta (2003), each with their colleagues.

Management. Early in pregnancy, ovarian enlargement less than 6 cm in diameter usually is the consequence of corpus luteum formation. With the advent of high-resolution sonography, Thornton and Wells (1987) proposed a conservative approach to management based on ultrasonic characteristics. They recommend resection of all cysts suspected of rupture or torsion, those capable of obstructing labor, and measuring more than 10 cm in diameter because of the increased risk of cancer in large cysts. Cysts 5 cm or less could be left alone, and indeed, most undergo spontaneous resolution.

Management of cysts between 5 and 10 cm in diameter is controversial. Some clinicians recommend that these cysts be managed expectantly if they have a simple cystic appearance. Whitecar and co-workers (1999) caution against this approach, but most recent studies support this. Importantly, if cysts contain septae, nodules, papillary excrescences, or solid components, then resection is recommended (Caspi and co-workers, 2000; Fleischer and associates, 1990). Women with these 5- to 10-cm, intermediate-sized cysts who are observed may require emergency exploration for rupture, torsion, or infarction in as many as 50 percent of cases (Hess and colleagues, 1988; Platek and colleagues, 1995).

Laparoscopy is used with increased frequency to evaluate women with these intermediate-sized cysts as well as for surgical resection of ovarian masses (see [Chap. 41](#), p. 975). Soriano and colleagues (1999) described comparable maternal and fetal outcomes in 39 women undergoing laparoscopic adnexal surgery in the first trimester and in 54 who had either first- or second-trimester laparotomy. Akira and associates (1999) compared gasless laparoscopy with laparotomy for ovarian cystectomy in 35 women at 12 to 16 weeks; these investigators reported advantages to the laparoscopic approach. Parker and co-workers (1996) described laparoscopy between 9 and 17 weeks for a benign cystic teratoma in 12 women. All but two of these 5- to 13-cm tumors ruptured intraoperatively, but none of the women developed evidence of peritonitis.

Thus, the major questions to be answered once a pelvic mass is discovered during pregnancy include the following:

1. What is the mass and what is the likelihood that it is malignant?
2. Is there a good possibility that the mass will regress?
3. Will the mass undergo torsion and possible rupture, or will it be an obstruction to delivery?

Only time, serial ultrasonic surveillance, and labor will provide answers to the last two questions. As for the first question, Kier and associates (1990) reported that MRI correctly identified the origin of unknown pelvic masses in 17 of 17 cases versus 12 of 17 cases using sonography. With the high-resolution sonography that is currently available, expectant management is much more common (Sherard and colleagues, 2003; Zanetta and co-workers, 2003). In some cases, transvaginal color Doppler assessment of tumor vascularity can be used for better characterization of adnexal tumors (Kurjak and Zalud, 1990).

RECOMMENDATIONS. It seems reasonable to remove all ovarian masses over 10 cm because of the substantive risk of malignancy. Tumors from 6 to 10 cm should be carefully evaluated for the possibility of neoplastic disease by ultrasound, MRI, or both. If evaluation suggests a neoplasm, then resection is indicated. If the corpus luteum is removed before 10 weeks, then 17 α -OH-progesterone, 250 mg intramuscularly, is given weekly until 10 weeks. Cystic masses that are thought to be benign or are less than 6 cm are observed serially with imaging techniques, and resection is performed if they grow, begin to look suspicious, or become symptomatic. In general, we have performed elective surgery at 16 to 20 weeks. Most masses that will regress will have done so by that time.

TUMOR MARKERS. Measurement of ovarian tumor serum markers is rarely helpful during pregnancy (Zanetta and colleagues, 2003). Routine screening for neural-tube defects led to the diagnosis of an immature ovarian teratoma in two women with elevated alpha-fetoprotein levels (Frederiksen and associates, 1991; Montz and co-workers, 1989). A similar discovery of an ovarian endodermal sinus tumor was described by van der Zee and associates (1991). The role of tumor markers CA54/61, CASA, CA15-3, inhibin, macrophage colony-stimulating factor, and CA125 remains unproven even in the management of nonpregnant women (Devine and associates, 1994; Spitzer and colleagues, 1998).

Ovarian Carcinoma. Malignant ovarian neoplasms are unusual during pregnancy simply because of the young population involved. Ovarian malignancies are discussed in [Chapter 57](#) (see p. 1266).

SECTION VIII - MEDICAL AND SURGICAL COMPLICATIONS

41. General Considerations and Maternal Evaluation

INTRODUCTION

Accurate quantification of the incidence and types of medical and surgical illnesses complicating pregnancy is difficult but can be estimated by various indices of hospitalization. In a managed-care population of over 46,000 pregnant women, Gazmararian and colleagues (2002) reported that the overall rate of antenatal hospitalization was 10.1 per 100 deliveries. About one third of these were for nonobstetrical conditions such as renal, gastrointestinal, pulmonary, and infectious diseases. Care of these women warrants a team effort between obstetricians and maternal-fetal medicine specialists, along with internists, surgeons, anesthesiologists, and others (American College of Obstetricians and Gynecologists, 2003). Obstetricians also must have a working knowledge of medical and surgical diseases common to women of childbearing age. Nonobstetricians who see these women in consultation should be familiar with the effects that various diseases have on pregnancy and vice versa, as well as pregnancy-induced physiological changes that include normal alterations in laboratory values.

A number of generalizations concern the rational approach to management of pregnancy complicated by nonobstetrical disorders. The first tenet is simple: **A woman should never be penalized because she is pregnant.** Stated differently: If a proposed medical or surgical regimen is altered because the woman is pregnant, can the alteration be justified? What therapy would be given if she was not pregnant? Such an approach should allow individualization of care for most medical and surgical disorders. Moreover, it may be especially helpful when dealing with consultants asked to see these women.

MATERNAL PHYSIOLOGY AND ALTERATIONS IN LABORATORY VALUES

Pregnancy induces profound physiological changes in most organ systems, and these may amplify or obfuscate evaluation of certain disorders. A number of standard laboratory evaluations are also altered by pregnancy. Some of these would, in the nonpregnant woman, suggest marked organ dysfunction, or conversely, normalcy, at a time when the woman was actually quite ill. The wide ranges of pregnancy effects on normal physiology and on laboratory values are discussed in [Chapter 5](#) as well as in the chapters that follow.

MEDICATIONS DURING PREGNANCY

Antepartum management of nonobstetrical disorders includes administration of a variety of drugs. Fortunately, the vast majority necessary to treat the most commonly encountered complications can be used with relative safety. However, there are a few notable exceptions, which are considered in detail in [Chapter 14](#), as well as with the discussions of specific disorders for which these drugs are given.

SURGERY DURING PREGNANCY

EFFECT OF SURGERY AND ANESTHESIA ON PREGNANCY OUTCOME. The risk of an adverse pregnancy outcome does not appear to be increased in women who undergo most uncomplicated surgical procedures. However, this risk may be increased when there are complications. For example, perforative appendicitis with feculent peritonitis has significant maternal and perinatal morbidity and mortality even if surgical and anesthetic techniques are flawless. Conversely, procedure-related complications may adversely affect pregnancy outcome. For example, a woman who has uncomplicated removal of an inflamed appendix may suffer aspiration of acidic gastric contents on extubation (see [Chap. 19](#), p. 490).

The most extensive experiences regarding anesthetic and surgical risks to pregnancy are from the Swedish Birth Registry and reported by Mazze and Kallen (1989). These investigators studied the effects of 5405 nonobstetrical surgical procedures performed in 720,000 pregnant women from 1973 to 1981 ([Table 41-1](#)). Surgery was performed in the first trimester in 41 percent of women, 35 percent in the second, and 24 percent in the third. Importantly, 60 percent were abdominal or pelvic procedures — 25 percent were abdominal operations, about 20 percent were gynecological and urological procedures, and about 15 percent were laparoscopic procedures. Laparoscopy was the most commonly performed first-trimester operation, and appendectomy was the most common second-trimester procedure.

The types of anesthesia administered to the 5405 women in the Swedish report are shown in [Table 41-2](#). Over half of these procedures were performed using general anesthesia, and commonly this involved nitrous oxide supplemented by another inhalation agent or intravenous medications.

Perinatal Outcomes. Excessive perinatal morbidity associated with nonobstetrical surgery is attributable to the disease itself rather than to adverse effects of surgery and anesthesia. Mazze and Kallen (1989) compared pregnancy outcomes in 5405 women undergoing surgery with those in 720,000 pregnancies without antepartum surgery. As shown in [Table 41-3](#), rates of stillbirths and congenital malformations were similar in both groups. However, there was a significantly increased incidence of low-birthweight and preterm births as well as neonatal deaths in women who had undergone surgery. In a study from MetroHealth Medical Center in Cleveland, Stepp and associates (2002) analyzed pregnancy outcomes following abdominal surgery. Factors associated with preterm or preterm delivery included first-trimester surgery, peritonitis, procedure length, and surgery after 24 weeks.

As previously stated, the Swedish researchers found that stillbirth and congenital malformation rates were not increased significantly. Czeizel and colleagues (1998) also reported that anesthetic agents are not teratogenic. However, Kallen and Mazze (1990) scrutinized 572 operations performed at 4 to 5 weeks of gestation and found a possible causal relationship with neural-tube defects. Sylvester and co-workers (1994) reported similar observations from the Metropolitan Atlanta Congenital Defects Program. This case-control study documented a significantly increased risk of hydrocephaly in conjunction with other major defects — especially eye anomalies — in women exposed to general anesthesia. Thus, as Rosen (1999) concluded, we cannot state categorically that anesthetic agents are not teratogenic.

LAPAROSCOPIC SURGERY DURING PREGNANCY. Over the past decade, the use of laparoscopic techniques has become common for diagnosis and management of a number of surgical disorders complicating pregnancy. The most obvious application is management of ectopic pregnancy (see [Chap. 10](#), p. 261). With established pregnancy, in most studies laparoscopy has been used for exploration and treatment of adnexal masses (see [Chap. 40](#), p. 965) or for cholecystectomy or appendectomy (see [Chap. 50](#), p. 1136, and [Chap. 49](#), p. 1119). Lachman and colleagues (1999) reviewed 518 laparoscopic procedures performed during pregnancy — 45 percent for cholecystectomy, 34 percent for adnexal surgery, and 15 percent for appendectomy. Fatum and Rojansky (2001) reported similar findings in a later review of 308 reported cases. They also concluded that gestational age of 26 to 28 weeks was the upper gestational age limit for successful laparoscopy. Al-Fozan and Tulandi (2002) have recently reviewed the safety and risks of laparoscopy in pregnancy.

Maternal and Fetal Effects. Hemodynamic changes induced by abdominal insufflation for laparoscopy are similar in pregnant and nonpregnant women. Reedy and colleagues (1995) studied these effects in baboons at the human equivalent gestation of 22 to 26 weeks. Although there were no substantive changes at 10-mm Hg insufflation, 20 mm Hg of pressure caused significant maternal cardiovascular and respiratory changes after 20 minutes. Some of these changes were increased respiratory rate, respiratory acidosis, diminished cardiac output, and increased pulmonary artery pressure with concomitantly increased pulmonary capillary wedge pressure. Steinbrook and Bhavani-Shankar (2001) used noninvasive hemodynamic monitoring in four healthy women at 17 to 24 weeks during scheduled laparoscopic cholecystectomy. Compared with preinduction values, the cardiac index decreased 26 percent by 5 minutes of insufflation and 21 percent by 15 minutes. The mean arterial pressures, systemic vascular resistance, and heart rate did not change significantly. These changes were similar to those reported in nonpregnant women by Wahba and colleagues (1995).

The precise effects of laparoscopy in the human fetus are currently unknown. Studies of pregnant ewes have been reported by Barnard and associates (1995) and Hunter and colleagues (1995). Using carbon dioxide insufflation to establish a pneumoperitoneum, they found that uteroplacental blood flow decreases when intraperitoneal pressure exceeds 15 mm Hg. This was due to decreased perfusion pressure and increased placental vessel resistance.

To study the impact of laparoscopy on perinatal outcomes, Reedy and colleagues (1997b) used the updated Swedish Birth Registry described earlier. Between 1973 and 1993, there were slightly over 2 million deliveries. There were 2181 laparoscopies and 1522 laparotomies performed in these women. As shown in [Figure 41-1](#), laparoscopy was performed primarily during the first trimester. Perinatal outcomes in women undergoing surgery were compared with those of all women in the database. The investigators confirmed their previous studies and found an increased risk of low birthweight, preterm delivery, and fetal growth restriction in the operative group. There were no differences in malformations or perinatal outcome when laparoscopy and laparotomy were compared.

Technique. Preparation for laparoscopy differs little from that commonly used for laparotomy. Bowel cleansing empties the large intestine and may facilitate visualization. Nasogastric or orogastric decompression reduces the risk of injury as well as the risk of aspiration. Aorto-caval compression is avoided by a left-lateral tilt. Using this position at about 16 weeks or more maximizes uterine perfusion (Kinsella and Lohmann, 1994). Positioning of the lower extremities in boot-type stirrups maintains access to the vagina for fetal sonographic assessment or manual displacement of the uterus. Flexion at the hip should be minimal to avoid obstruction of the surgical field by the knees.

Beyond the first trimester, technical modifications of standard pelvic laparoscopic entry are required to avoid puncture or laceration of the uterus. Some clinicians recommend *open* or *gasless* laparoscopic entry techniques (Akira and co-workers, 1999) to avoid perforations of the uterus, pelvic veins, and adnexae. The abdomen is incised at or above the umbilicus. The peritoneum is incised under direct vision, and insertions of the conventional 10-mm cannula and laparoscope are directed upward. Then, under direct visual guidance, they are rotated toward the lower abdomen and pelvis. These techniques avoid the cardiovascular changes with pneumoperitoneum and decrease the risk of uterine perforation with the trocar or Veress needle. The cannula is then connected to the insufflation systems, and a 10-mm Hg pneumoperitoneum is initiated. The initial insufflation should be conducted slowly to allow for prompt assessment and reversal of any untoward pressure-related effects. Gas leakage around the cannula is managed by tightening the surrounding skin with a towel clamp.

Insertion of secondary trocars is most safely performed under direct laparoscopic visual surveillance through the primary port. The skin and fascia are incised with a scalpel, and the trocar-cannula tandem is advanced against the tension of the pneumoperitoneum with a smooth, steady motion. For lower abdominal placement, the dome of the bladder and the inferior epigastric arteries should be identified laparoscopically.

Complications. Risks inherent to laparoscopy are probably not increased during pregnancy. Reported complications are uncommon (Fatum and Rojansky, 2001; Lachman and colleagues, 1999). In a mail survey, Reedy and co-workers (1997a) surveyed 192 laparoscopic surgeons who described complications inherent to laparoscopy as well as one case of intrauterine placement of the Veress needle.

Figure 41-1. Distribution of laparoscopic procedures and laparotomies during pregnancy by weeks of gestation. (From Reedy and colleagues, 1997a, with permission.)

IMAGING TECHNIQUES

A number of imaging modalities are used as an adjunct for both diagnosis and therapy during pregnancy. These include radiography, ultrasound, and magnetic resonance imaging. The use of radiography is most worrisome to both the obstetrician and the patient. Inevitably, some radiographic procedures are performed prior to recognition of early pregnancy, usually because of trauma or life-threatening illness. Fortunately, most diagnostic radiographic procedures are associated with little or no known significant fetal risks. As with drugs and medications, however, radiographic procedures during pregnancy may lead to litigation if there is an adverse pregnancy outcome. Conversely, a needless therapeutic abortion may be performed because of patient or physician anxiety.

IONIZING RADIATION. The term *radiation* is poorly understood, and it often is applied not only to x-rays but also to microwaves, ultrasound, diathermy, and radio waves. Of these, x-rays and gamma rays have short wavelengths with very high energy and are forms of ionizing radiation. The other four energy forms have rather long wavelengths and low energy (Brent, 1999). The biological effects of x-rays are caused by an electrochemical reaction that can result in tissue damage. At high doses, x-rays may cause cell death, mutations, cancer, and developmental defects.

For these reasons, ionizing radiation from x-rays and gamma rays is a primary biological concern. Ionizing radiation refers to waves or particles (photons) of significant energy that can break chemical bonds, such as those in DNA, or that can create free radicals or ions capable of causing tissue damage (Hall, 1991). Methods of measuring the effects of x-rays are summarized in [Table 41-4](#). The standard terms used are exposure (in air), dose (to tissue), and relative effective dose (to tissue). In the range of energies for diagnostic x-rays, the dose, expressed in rad, and the relative effective dose, expressed in rem, can be used interchangeably. For consistency, all doses to follow will be expressed in rad, the traditional unit, or in gray (Gy), the modern unit (1 Gy = 100 rad).

X-ray Dosimetry. When calculating the dose of ionizing radiation such as that from x-rays, several factors are considered (Wagner and colleagues, 1997). These include:

1. Type of study.
2. Type and age of equipment.
3. Distance of target organ from radiation source.
4. Thickness of the body part penetrated.
5. Method or technique used for the study.

Estimates of dose to the uterus and embryo for a variety of commonly used radiographic examinations are summarized in [Table 41-5](#). Studies of maternal body parts farthest from the uterus (e.g., head) result in a very small dose of radiation scatter to the embryo or fetus. Because the size of the woman, radiographic technique, and equipment performance are variable factors, data in the table serve only as a guideline. When the radiation dose for a specific individual is required, a medical physicist may be consulted.

Potential Adverse Fetal Effects. The harmful effects of radiation exposure according to Brent (1999) are direct or indirect:

1. Cell death, which affects embryogenesis.
2. Growth restriction.
3. Congenital malformations.
4. Carcinogenesis (controversial).
5. Microcephaly and mental retardation.
6. Sterility.

The harmful fetal effects of ionizing radiation have been extensively studied for cell damage with resultant dysfunction of embryogenesis. These have been assessed both in animal models as well as in human studies of Japanese atomic bomb survivors.

ANIMAL STUDIES. Adverse radiation effects in animals are somewhat different from those in humans. A number of animal studies have addressed these potential embryopathological effects (Brent, 1971, 1999; Wilson and colleagues, 1953). Several conclusions can be drawn:

1. High-dose ionizing radiation is most likely to be lethal to the preblastocyst during the preimplantation stage; the embryo is very insensitive to teratogenic or other effects of radiation at this time.
2. During the period of organogenesis, high-dose radiation is more likely to cause teratogenic changes, growth restriction, or lethal effects.
3. During the fetal period, the fetus is more likely to manifest growth restriction and central nervous system effects.

In animal studies, various organs manifest teratogenic effects, whereas in humans, growth restriction and central nervous system anomalies are the most common following high-dose ionizing radiation. Most studies involved large doses — 100 to 200 rad (1 to 2 Gy) — and a threshold phenomenon has been demonstrated (Brent, 1999). Thus, it is not always possible to

extrapolate animal data directly to humans.

HUMAN DATA. Possible adverse human fetal effects of high-dose ionizing radiation are principally derived from two sources. The first is from reports of large-dose radiation given to treat women for malignancy, menorrhagia, and uterine myomas (Brent, 1989). Goldstein and Murphy (1929) reported that radiation estimated to be over 100 rad caused microcephaly or hydrocephaly in 19 of 75 exposed embryos. Other adverse effects included mental retardation, abnormal genitalia, growth restriction, microphthalmia, and cataracts. Dekaban (1968) reported 22 infants with microcephaly, mental retardation, or both, following exposure to an estimated 250 rad in the first half of pregnancy. In both studies, other organ malformations were not found unless there was also microcephaly, eye abnormalities, or growth restriction (Brent, 1999).

The second and most often quoted human data of irradiation exposure are from atomic bomb survivors from Hiroshima and Nagasaki (Greskovich and Macklis, 2000; Otake and co-workers, 1987). Adverse fetal effects from exposure to fallout from the atomic bomb include an increased risk of microcephaly and severe mental retardation with high exposure beginning at certain gestational ages ([Fig. 41-2](#)). The risk is greatest at 8 to 15 weeks, and larger doses are necessary at 16 to 25 weeks to cause an equivalent proportion of cases of mental retardation. Another important observation is the suggestion of a nonthreshold linear relationship of radiation dose at 8 to 15 weeks, so that even very low doses cause a slight increase in mental retardation incidence (Hall, 1991). There is no documented increased risk of mental retardation in humans at gestational ages less than 8 weeks or greater than 25 weeks, even with doses exceeding 50 rad (Committee on Biological Effects, 1990).

The effect of ionizing radiation on intelligence quotient (IQ) scores in children who were exposed in utero is also dependent on gestational age as well as radiation dose. The highest risk again is at 8 to 15 weeks, followed by 16 to 25 weeks for doses greater than 50 rad.

The implications of these findings seem straightforward. At 8 to 15 weeks, the embryo is most susceptible to radiation-induced mental retardation. This risk is probably a nonthreshold linear function of dose, with the risk of severe mental retardation being as low as 4 percent for 10 rad and as high as 60 percent for 150 rad (Committee on Biological Effects, 1990). These doses are 10 to 100 times higher than those from diagnostic radiation. However, cumulative doses from multiple procedures may enter that harmful range, especially at 8 to 15 weeks. At 16 to 25 weeks, the risk is less, and there is no proven risk before 8 weeks or after 25 weeks.

Current evidence suggests that there is no increased risk of malformations, growth restriction, or abortion from a radiation dose of less than 5 rad. Indeed, Brent (1999) concluded that gross congenital malformations would not be increased in a human pregnant population exposed to less than 20 rad (0.2 Gy).

Oncogenic Effects of Ionizing Radiation. Whether there is an association between in utero diagnostic radiation exposure and increased risk of childhood cancers is controversial; supporting data are few. In older studies, some investigators reported that these cancers, and especially leukemia, were increased (Diamond and colleagues, 1973; Shu and associates, 1994; Stewart and Kneale, 1970). Conversely, Brent (1999) and others have questioned such an association, and according to the National Radiological Protection Board (1993) of the United Kingdom, the risk barely exceeds threshold for diagnostic studies. Moreover, there were only two cases of childhood cancer detected among 1630 atomic bomb survivors with high exposure (Committee on Biological Effects, 1990). Data concerning whether atomic bomb survivors are at risk for adult cancers are not yet available.

Therapeutic Radiation. According to the Radiation Therapy Committee Task Group of the American Association of Physics in Medicine, about 4000 pregnant women annually undergo cancer therapy in the United States (Stovall and colleagues, 1995). This Task Group emphasizes careful individualization of radiotherapy for the pregnant woman (see [Chap. 57](#), p. 1258). For example, shielding of the fetus and other safeguards can be taken (Fenig and colleagues, 2001; Nuyttens and colleagues, 2002). Even then, the fetus may be exposed to unacceptable doses of radiation, and a carefully designed plan must be considered (Prado and colleagues, 2000). For example, a model to estimate fetal dosage with maternal brain radiotherapy and with tangential breast irradiation has been developed by Mazonakis and colleagues (1999, 2003).

Diagnostic Radiation. As previously discussed, therapeutic abortion is not indicated because of fetal exposure to a single diagnostic radiographic procedure (Brent, 1999). To put fetal risk into perspective, it is important to know the estimated x-ray dosimetry. According to the American College of Radiology (Hall, 1991), **no single diagnostic procedure results in a radiation dose significant enough to threaten the well-being of the developing embryo and fetus.**

Radiographs. Estimated radiation doses for standard radiographs are presented in [Table 41-5](#). In pregnancy, the chest radiograph is the most commonly used study, and fetal exposure is exceptionally small for two views (0.07 mrad). The single abdominal radiograph has a higher dose (100 mrad), because the embryo or fetus is directly in the x-ray beam. The standard intravenous pyelogram may exceed 1 rad because of the number of films taken. For this reason, and as discussed in [Chapter 48](#) (see p. 1099), the one-shot pyelogram may be useful when urolithiasis or other causes of urinary obstruction are suspected but unproven by ultrasound. Most "trauma series," such as radiographs of an extremity, skull, or rib series, deliver low doses because of the fetal distance from the target area.

Fetal indications for radiographic studies are limited. Perhaps the most common is pelvimetry with a breech presentation (see [Chap. 24](#), p. 567). Another indication is for a suspected fetal skeletal anomaly where the ultrasonic diagnosis is unclear, such as with caudal regression syndrome and sirenomelia.

Fluoroscopy and Angiography. Dosimetry calculations for fluoroscopy and angiography are much more difficult because of variations in the number of radiographs obtained, fluoroscopy time, and the amount of fluoroscopy time the fetus is in the radiation field. As shown in [Table 41-6](#), the range is quite variable. Although the Food and Drug Administration limits exposure rate for conventional fluoroscopy such as barium studies, special-purpose systems such as angiography units have potential for much higher exposure.

In nonpregnant patients, commonly performed studies involving routine fluoroscopy are the upper gastrointestinal series and barium enema. Frequently, these are done early in pregnancy, during the period of preimplantation or early organogenesis and most often before the woman realizes that she is pregnant. The upper gastrointestinal series has significantly less fetal exposure than a barium enema. Even so, endoscopy is usually preferred for evaluation during pregnancy (see [Chap. 49](#), p.

1112).

Angiography may occasionally be necessary for serious maternal disorders. As before, the longer the distance from the embryo or fetus, the less the exposure and risk.

Computed Tomography. Imaging using computed tomography (CT) scanning involves multiple exposures of very thin x-ray beams in a 360-degree circle and their computerized interpretations. The result is an axial (occasionally sagittal) image of a body portion, referred to as a *slice*. Multiple slices of the target are obtained.

Newer-generation tomography equipment is increasingly sensitive, however, better resolution may cause higher radiation exposure. Conversely, because there is less scatter with newer equipment, areas not directly scanned have less exposure. For example, skin exposure from a head tomographic scan is typically as high as 5 to 6 rad along the area scanned. In the body, doses typically range from approximately 5 rad at the skin surface to 2 rad in the center of the slice.

Spiral CT allows for continuous acquisition of images in a spiral with image reformatting in multiple planes compared with the conventional axial images. The exposure is dependent on the *pitch*, which is the degree of stretching or tightening of the spiral. The less the pitch, the tighter the spiral, and the greater the exposure. At the present time, a typical pitch ranges from 1.0 to 2.0 and results in radiation exposure similar to or less than that for conventional tomography (Jurik and colleagues, 1996). In a comparative study, Winer-Muram and co-workers (2002) determined body geometry for 23 pregnant women. The estimated fetal dose with helical CT was lower than that from ventilation-perfusion lung scanning during all trimesters. A note of caution — because of the ease and brevity of CT scanning, there is a tendency to increase the number of acquisitions and to increase exposure (Zoetelief and Geleijns, 1998).

Many variables in each tomographic study affect calculation of radiation doses, especially slice thickness and number of cuts obtained. If a study is performed with and without contrast, twice as many images are obtained, and the dose is doubled. Fetal radiation exposure is also dependent on factors such as the size of the mother and the size and position of the fetus (Ragossino and colleagues, 1986). Finally, the closer the target area is to the fetus, the greater the radiation exposure. Estimated fetal doses from some CT scans are summarized in [Table 41-7](#).

Cranial CT scanning is the most commonly requested study in pregnant women. Its use in women with eclampsia is discussed in [Chapter 34](#) (see p. 776). Nonenhanced CT scanning is the preferred imaging technique to detect acute hemorrhage within the epidural, subdural, or subarachnoid spaces. If indicated, abdominal tomography should be performed in the pregnant woman with severe trauma (American College of Obstetricians and Gynecologists, 1998). CT pelvimetry is used in some cases before attempting breech vaginal delivery (see [Chap. 24](#), p. 567). The fetal dose may approach 1.5 rad, but use of a low-exposure technique may reduce this to 250 mrad (see [Table 41-7](#)).

It Multidetector-row CT imaging is a superior technique and allows acquisition of 16 or more slices simultaneously. Advantages are quickness; it acquires the entire thorax in 10 seconds. It results in more radiographic exposure. Goldhaber (2004) cites a detection rate of 90 percent for pulmonary emboli in nonpregnant patients. In pregnant women, Nuthalapaty and colleagues (2005) cite a number of quality concerns.

Nuclear Medicine Studies. These studies are performed by "tagging" a radioactive element to a chemical agent. For example, the radioisotope technetium^{99m} may be tagged to red blood cells, sulphur colloid, or pertechnetate. The method used to tag the agent determines fetal radiation exposure. Placental transfer and renal clearance, whereby fetal proximity to the maternal bladder increases exposure, are important. Measurement of radioactive technetium is based on its decay, and the units used are the curie (Ci) or the becquerel (Bq). Doses usually are expressed in millicuries (mCi).

Depending on the physical and biochemical properties of a radioisotope, an average fetal exposure can be calculated (Wagner and co-workers, 1997; Zanzonico, 2000). Commonly used radiopharmaceuticals and estimated absorbed fetal doses are given in [Table 41-8](#). The dose of radionuclide can be kept as low as possible (Adelstein, 1999). Exposures vary with gestational age and are greatest earlier in pregnancy for most radiopharmaceuticals. One exception is the later effects of iodine¹³¹ on the fetal thyroid (Wagner and associates, 1997). The International Commission on Radiological Protection (2001) has compiled dose coefficients for radionuclides during pregnancy. Stather and colleagues (2002) detailed the biokinetic and dosimetric models used by the International Commission to estimate fetal radiation doses when a pregnant woman is exposed to a radionuclide.

Clinically suspected pulmonary embolism during pregnancy has been studied with *ventilation-perfusion lung* scanning (see [Chap. 47](#), p. 1084). Perfusion is measured with injected ⁹⁹Tc-macroaggregated albumin, and ventilation is measured with inhaled xenon¹²⁷ or xenon¹³³. Fetal exposure with either is negligible (Chan and colleagues, 2002; Mountford, 1997).

Thyroid scanning with iodine¹²³ or iodine¹³¹ seldom is indicated in pregnancy. With trace doses used, however, fetal risk is minimal. Therapeutic radioiodine in doses to treat Graves disease or thyroid cancer may cause fetal thyroid ablation (Green and colleagues, 1971).

The *sentinel lymphoscintigram* for detecting the axillary lymph node most likely to have metastases from breast cancer is a popular preoperative study to replace lymph node dissection (DeAngelis and co-workers, 1999). The calculated dose is approximately 500 mrad (Adelstein, 1999; Schwartz and colleagues, 2003; Steenvoorde and colleagues, 1998; Timins, 2001) and should not preclude its use during pregnancy (see [Table 41-8](#)).

Figure 41-2. Severe mental retardation caused by ionizing radiation in fetuses exposed at various gestational ages to the atomic bomb in Hiroshima and Nagasaki (1 Gy = 100 rad). The bar lines represent 90-percent confidence levels. (Data from Otake and associates, 1987, with permission.)

ULTRASONOGRAPHY. Of all of the major advances in obstetrics, the development of ultrasonography for study of the fetus and mother certainly is one of the greater achievements. The technique has become virtually indispensable in everyday practice. The wide range of clinical uses of ultrasound in pregnancy is further discussed in [Chapter 16](#) and in many other sections of this book.

Safety. Diagnostic ultrasonography uses sound wave transmission at certain frequencies. At very high intensities, there is a potential for human tissue damage from heat and cavitation (Callen, 2000). In the low-intensity range of real-time imaging, however, no fetal risks have been demonstrated in more than 35 years of use (Maulik, 1997; Miller and colleagues, 1998). More recently, Naumburg and associates (2000) performed a case-control study of 578 children with leukemia. When compared with healthy controls, one third of each cohort was found to have been exposed to ultrasound in utero.

Recent advances in technology have introduced Doppler-shift imaging coupled with gray-scale imaging to localize spectral waveforms and superimpose color mapping. Higher energy intensities are used with this duplex Doppler imaging. Again, however, these should have no embryo or fetal effects if low-level pulses are used (Kossoff, 1997).

Ultrasound equipment must have a video display of acoustic output to safeguard against exceeding standards set by a number of organizations (American College of Obstetricians and Gynecologists, 1996). Acoustic outputs are displayed as the *thermal index* and *mechanical index*. The thermal index is an estimate of temperature increases from acoustic output. If the index is below 1.0, then no potential risk is expected (Miller and associates, 1998). Adverse effects reflected in thermal index changes have not been demonstrated with Doppler use in clinical applications (Maulik, 1997). The mechanical index is used to estimate the potential risk of cavitation from heat generated by real-time imaging. As long as sonographic contrast agents are not used, there is no hypothetical fetal risk.

MAGNETIC RESONANCE IMAGING. Magnetic resonance imaging (MRI) has proven extremely useful in obstetrics because it does not use ionizing radiation. Its application is cited throughout this book. Advantages include high soft tissue contrast, ability to characterize tissue, and acquisition of images in any plane — particularly axial, sagittal, and coronal. MRI uses powerful magnets to alter the state of protons temporarily. The hydrogen proton is used for imaging because of its abundance, especially in water and fat. Radio waves are then used to deflect the magnetic vector. When the radiofrequency source is turned off, hydrogen protons return to their normal state. In doing so, they emit radio waves of different frequencies, which are received by radio coils wrapped around the body part. The relative intensity of these signals is plotted on a gray scale. A series of pulse sequences in all planes can be obtained, and each acquisition includes information about the location and characteristics of the sequences. From this, an image is constructed. Technological advances have significantly reduced scan times and improved image quality.

Safety. There are no reported harmful human effects from MRI (American College of Radiology, 1998; Levine, 2000). Chew and colleagues (2001) found no differences in blastocyst formation with 1.5-T MRI use in early murine embryo development. Vadeyar and associates (2000) noted no demonstrable fetal heart rate pattern changes during MRI. Recently, Chung (2002) reviewed safety issues.

The standards of the American College of Radiology (1998) dictate that each request for an MRI of a pregnant woman be approved by the attending radiologist. Indicated imaging should be performed at any gestational age if no other imaging studies can be performed, or if MRI would provide information that would otherwise require radiation exposure. Contraindications to MRI include internal cardiac pacemakers, neurostimulators, implantable defibrillators, implantable electronic infusion pumps, cochlear implants, and some other devices. Certain intracranial aneurysm clips and any metallic foreign body in the globe of the eye contraindicate scanning.

Contrast Agents. A number of elemental *gadolinium chelates* are used to create contrast, including gadopentetate, gadodiamide, gadoteridol, and gadoterate. These cross the placenta and are found in fetal amniotic fluid. In large doses, gadopentetate causes developmental delay in animal fetuses (Briggs and colleagues, 2002). The use of contrast agents currently is not recommended unless overwhelming benefits are perceived.

Maternal Indications. The use of MRI during pregnancy has been extremely helpful. In maternal disorders unrelated to pregnancy, MRI technology has the advantage over CT because of the lack of ionizing radiation. In some cases, MRI may be complementary to CT, and in others, MRI is preferable. Central nervous system abnormalities, such as brain tumors or spinal trauma, are more clearly seen with MRI (Mantello and associates, 1993). As discussed in [Chapter 34](#) (see p. 776), MRI has provided valuable insights into the pathophysiology of eclampsia (Cunningham and Twickler, 2000; Zeeman and associates, 2003). *Magnetic resonance angiography* provides imaging of the cerebral vasculature and can also be used to calculate flow of the middle and posterior cerebral arteries (Zeeman and colleagues, 2003).

MRI is a superb technique to evaluate the abdomen and retroperitoneal space in a pregnant woman. All things being equal, MRI is preferable to CT, which involves fetal radiation. MRI has been used for detection and localization of adrenal tumors, gastrointestinal lesions, intra-abdominal malignancies, and uterine and ovarian masses in pregnancy. Either CT or MRI is useful for evaluation of puerperal infections, but MRI provides better visualization of the bladder flap area following cesarean delivery (Brown and associates, 1999; Twickler and colleagues, 1997). MRI may be used to diagnose venous thrombosis of the pelvic vessels and vena cava in a pregnant woman — a decided advantage over CT. A computerized reconstructed venogram of a large ovarian vein thrombosis without extremity involvement is shown in [Figure 41-3](#).

Fetal Indications. Specific uses of fetal MRI as a complement to ultrasonography have emerged (De Wilde and colleagues, 2005). Zaretsky and associates (2002) showed that MRI can be used to image almost all elements of the standard anatomical survey. Reichel and colleagues (2003) have validated its use for fetal central nervous system biometry. Zaretsky and co-workers (2003) also showed that fetal weight estimation was more accurate using MRI than with ultrasonography. Fast acquisition sequencing has solved problems with fetal movement to improve imaging; the technique is referred to as *HASTE* — Half-Fourier Acquisition Single slow Turbo spin Echo. Levine and colleagues (2001) studied pregnant pigs and reported that HASTE protocols do not generate significant heat in the uterus or fetus.

The most common fetal indication for MRI has been with suspected brain anomalies. Levine and co-workers (1999) found that use of fast-acquisition technology altered the diagnosis in 20 of 66 (30 percent) fetuses with central nervous system

abnormalities. Twickler and associates (2003) reported that fetal imaging with *single-shot fast spin echo (SSFSE)* provided additional information in 46 of 72 (64 percent) fetuses with abnormal intracranial findings by ultrasonography. Sharma and colleagues (2003) also found it helpful in further evaluating brain anomalies in fetuses aborted by dilatation and evacuation (D & E), which distorted or destroyed the anatomy. Righini and co-workers (2004) found MRI superior to ultrasound in detecting brain infarction in the surviving monozygotic twin after one fetus died from twin-to-twin transfusion syndrome. Merzoug and associates (2002) have provided a detailed review of normal and abnormal brain images. Some examples are shown in [Figure 41-4](#).

In addition, MRI may be used to obtain very specific details of fetal anatomy and complex dysmorphology (Coakley and co-workers, 1999; Zaretsky and colleagues, 2002). In another study, Caire and co-workers (2003) showed excellent detail with MRI in fetuses with suspected genitourinary anomalies despite a high incidence of oligohydramnios, which is common in these cases. Brody (2004) suggested using MRI to monitor fetal lung volume. Zaretsky and Twickler (2003) have provided a scholarly review of normal and abnormal fetal anatomy viewed with MRI.

Finally, Fenton and associates (2000) used *magnetic resonance spectroscopy* to analyze a lecithin peak in three term fetuses. This raises the possibility of in vivo analysis of lung maturity.

Figure 41-3. Reconstructed magnetic resonance venogram demonstrates normal flow in the left ovarian vein (*small arrows*). The thrombosed right ovarian vein (*large arrows*) has no flow, and the clot produces a mass effect at its confluence with the inferior vena cava (*arrowheads*). (From Nurenberg and Twickler, 1995, with permission.)

Figure 41-4. Magnetic resonance imaging of the fetal cranium. **A.** Cursors show atrial measurement in a 28-week normal fetus. **B.** Cursors show measurements of abnormally enlarged cisterna magna in a 29-week fetus. (From Twickler and colleagues, 2002, with permission.)

GUIDELINES FOR DIAGNOSTIC IMAGING DURING PREGNANCY.

The American College of Obstetricians and Gynecologists (2004) has reviewed the effects of radiographic, ultrasonographic, and magnetic resonance exposure during pregnancy. Its suggested guidelines are shown in [Table 41-9](#).

42. Critical Care and Trauma

INTRODUCTION

Women with a broad spectrum of pathophysiological conditions, some of which may have previously precluded pregnancy, may benefit from technology and expertise in *critical care obstetrics*. Examples are women with serious heart disease, acute or chronic pulmonary disorders, or trauma, or those with complications of severe preeclampsia or sepsis syndrome. Pregnancy poses unique considerations for critical care, and it is imperative that obstetricians and other members of the health care team have a working knowledge of these factors. Pregnant women are usually young and in good health, and their prognosis should be better than that of many other patients admitted to an intensive care unit (ICU). Indeed, obstetrical patients had an *actual mortality ratio* (ratio between actual and predicted mortality rate) of 0.25 to 0.42, significantly lower than the expected 1.0 ratio (Lewinsohn and colleagues, 1994; Mahutte and associates, 1999).

OBSTETRICAL INTENSIVE CARE

In most cases, obstetrical patients who need intensive care are those with complications specifically related to pregnancy. As shown in [Table 42-1](#), Zeeman and colleagues (2003) reported that two thirds of women admitted to an obstetrical critical care unit had pregnancy-specific complications. Severe gestational hypertension and obstetrical hemorrhage were the most common reasons for admission. In some cases of life-threatening hemorrhage, such as with uterine atony or genital tract lacerations, surgical procedures are necessary to stop bleeding. In these cases, close proximity to a delivery-operating room is most advantageous. Finally, for the one third of pregnant women who have serious medical or surgical disorders, there frequently is concern for fetal well-being. Here again, proximity to a delivery-operating room provides personnel and equipment for appropriate fetal surveillance.

Critically ill women may be managed in the obstetrical unit, and some institutions have specialized rooms with necessary equipment and experienced personnel available. Triage to a medical or surgical ICU depends on the acuity of care needed and the ability of that facility to provide it. For example, in most obstetrical units, women who require ventilatory support, invasive monitoring, or pharmacological support of circulation are transferred to a specialized ICU.

SYSTEMS FOR OBSTETRICAL CRITICAL CARE. A number of reports describe systems designed to care for critically ill pregnant women. In all, each institution has its own protocol for triage. They can be described in three categories.

1. A "full-service" obstetrical ICU, which provides all aspects of critical care that is usually given in medical or surgical ICUs (Jenkins and colleagues, 2003; Mabie and Sibai, 1990). Almost 1 percent of women delivered at the University of Tennessee were admitted to such an obstetrical ICU.
2. In most large institutions, severely ill women are transferred to a medical or surgical ICU that is operated by "intensivists." These tertiary care referral institutions show a remarkably similar proportion of obstetrical patients admitted to these ICUs: 0.4 percent at the University of California, San Francisco; 0.5 percent at the University of North Carolina; 0.3 percent at McGill University in Montreal; and 0.4 percent at Good Samaritan in Phoenix (Harris and Foley, 2002; Kilpatrick and Matthay, 1992; Mahutte and associates, 1999; Monaco and colleagues, 1993).
3. Intermediate care unit. We have developed such a unit both at Parkland Hospital as well as at the University of Alabama at Birmingham Hospital. Organization of these units is presented below, but briefly, their design permits care of most critically ill pregnant women in or near the obstetrical suite. As shown in [Table 42-1](#), 1.7 percent of over 28,000 women delivered at Parkland Hospital over a 2-year period were admitted to this obstetrical intermediate care unit. Of these, 483 women (15 percent) were transferred to a medical or surgical ICU, usually for ventilatory support.

ORGANIZATION OF OBSTETRICAL CRITICAL CARE. The concept and development of critical care began in the 1960s. In 1983, the National Institutes of Health held the first Consensus Conference pertaining to critical care. In 1988, the Society for Critical Care Medicine promulgated definitions and established guidelines for design and staffing of ICUs. These continue to be refined by certifying organizations (Manthous, 2004). Although the evolution of critical care for obstetrical patients has generally followed these developments, there are no specific guidelines for pregnant women. Thus, the tertiary care centers discussed above describe variations in ICU design, utilization rates, management, and outcomes.

Because of high costs incurred by ICUs, a step-down *intermediate care unit* was developed. This type of unit was designed to include patients who did not require intensive care per se but who needed a higher level of care than that provided on a general ward. In 1998, the American College of Critical Care Medicine and the Society of Critical Care Medicine published guidelines for care of critically ill patients in intermediate care units ([Table 42-2](#)). By that time, most referral centers had already incorporated these concepts of a "step-down unit," although this was not formally assessed for obstetrical patients.

At Parkland Hospital, the present system of an intermediate care unit for critically ill pregnant women has evolved over the past three decades. The two-tiered system incorporates the guidelines for intermediate and intensive care described for nonobstetrical patients. The results of an audit of this unit for 1998 to 1999 were described by Zeeman and colleagues (2003). The reasons for admission to the unit during these 2 years are listed in [Table 42-1](#). Of these women, about 20 percent were undelivered. Because they remain in the obstetrical suite, their care is provided by specially trained obstetricians and obstetrical nurses with experience in critical care medicine. If not available, a team of physicians and nurses should be assembled that includes clinicians with special expertise sufficient to deal with all problem areas. Team members typically include obstetricians, anesthesiologists, pulmonologists, cardiologists, and other intensivists.

Institutional capabilities as well as frequency and acuity of obstetrical complications determine the need for critical care. Only a few institutions can satisfy requirements for a full-service obstetrical ICU. Most tertiary care centers have instead developed

intermediate care units with selected triage to other ICUs. The vast majority of smaller hospitals are not able to fulfill the requirements for an obstetrical intermediate care unit. In these instances, transfer to a medical or surgical ICU is preferable, but there must be close collaboration between obstetricians and intensivists with other specialists.

PULMONARY ARTERY CATHETER USE. In our extensive experience, invasive hemodynamic monitoring is seldom necessary for critically ill obstetrical patients. A few women who have multiple and complex problems may sometimes be better managed with such monitoring. An example is sepsis complicated by pulmonary edema and persistent hypotension. Use of pulmonary catheter monitoring is controversial. Some studies have shown excess morbidity and mortality because of its use. Two recent randomized trials of 2670 medical and surgical patients described no benefits but no excessive morbidity (Richard and co-workers, 2003; Sandham and colleagues, 2003). Some of its uses in obstetrics and its methodology are described in detail by Clark and colleagues (1997).

Pulmonary artery catheterization has been used in a number of cardiac or pulmonary conditions complicating pregnancy. Information from these has contributed immensely to understanding of some common obstetrical conditions. These include myocardial infarction, cardiomyopathy, and mitral stenosis; acute respiratory distress syndrome (ARDS); amniotic fluid embolism; and severe preeclampsia-eclampsia (Clark, 1988, 1995, 1997; Cunningham, 1986, 1987; Hankins, 1984, 1985, and all their co-workers). The most enthusiastically perceived needs for invasive monitoring are for women with severe preeclampsia-eclampsia (Gilbert and associates, 2000). We remain unconvinced that this is justified for most cases. Ironically, with better understanding of underlying pathophysiology that has been provided by invasive monitoring, the need for its use has declined.

Measurement. The use of a pulmonary artery catheter allows measurement of pulmonary arterial pressures and filling pressures, including central venous and pulmonary capillary wedge pressures. Formulas for deriving various cardiopulmonary parameters are shown in [Table 42-3](#). Cardiac output, stroke volume, and systemic and pulmonary vascular resistance can be corrected for body size by dividing by body surface area to obtain *index values*. Nomograms for nonpregnant adults are used.

In a landmark investigation, Clark and colleagues (1989) obtained cardiovascular measurements in healthy pregnant women and again in these same women when they were not pregnant, so that they served as their own controls ([Table 42-4](#)). These investigators showed that ventricular performance remains unchanged during pregnancy from the nonpregnant state because increased blood volume and cardiac output are compensated by decreased vascular resistance and increased pulse rate ([Fig. 42-1](#)). A working knowledge of these changes is paramount to understanding the pathophysiology of pregnancy complications discussed throughout this book.

One important caveat regarding pulmonary artery monitoring emphasized by Van Hook and Hankins (1997): The information does not always reflect uteroplacental perfusion. Assessment of fetal status using sonography, biophysical testing, and heart rate patterns is used instead.

Figure 42-1. Ventricular function in 10 healthy pregnant women at term. Individual values are plotted and all but one fall between the lines that define normal function. (LVSWI = left ventricular stroke work index; PCWP = pulmonary capillary wedge pressure.) (Plotted data points from Clark and colleagues, 1989.)

ACUTE PULMONARY EDEMA

The incidence of pulmonary edema complicating pregnancy averages about 1 in 500 to 1000 deliveries at tertiary referral centers. In obstetrics, the three general causes of acute pulmonary edema include:

1. Ventricular dysfunction (heart failure).
2. Permeability edema from alveolar-capillary injury or beta-mimetic tocolytic therapy.
3. Combination of these two problems.

Taken in toto, studies in pregnant women indicate that more than half who develop pulmonary edema have some degree of sepsis syndrome in conjunction with either tocolysis or vigorous fluid therapy. Cardiogenic pulmonary edema is identified in about half. In many women, obstetrical hemorrhage with resuscitation or vigorous treatment for preterm labor are common precipitating causes.

Sciscione and colleagues (2003) reported that among 51 cases of pulmonary edema, about 25 percent each were due to cardiac failure, tocolytic therapy, iatrogenic fluid overload, or preeclampsia. DiFederico and associates (1998) reported that 40 percent of 84 cases from the University of California, San Francisco, were associated with tocolytic therapy for preterm labor or fetal surgery. The importance of tocolytic therapy cannot be understated. It caused 15 percent of cases of pulmonary edema and one maternal death in 51 women who required tracheal intubation and assisted ventilation (Jenkins and colleagues, 2003).

HEART FAILURE. Most cases of cardiogenic pulmonary edema during pregnancy are due to diastolic heart failure caused by chronic hypertension and obesity leading to left ventricular hypertrophy (Jessup and Brozena, 2003; Kenchaiah and colleagues, 2002). Other cases are caused by congenital or acquired anatomical defects as discussed in [Chapter 44](#). In many instances, heart failure is precipitated acutely by superimposed preeclampsia, excessive blood loss, anemia, and puerperal sepsis (Cunningham and associates, 1986; Sibai and colleagues, 1987).

ACUTE RESPIRATORY DISTRESS SYNDROME. The most common cause of respiratory failure in pregnancy is ARDS. This pathophysiological manifestation of acute lung injury is a continuum from mild pulmonary insufficiency to dependence on mechanical ventilation. Because there are no uniform criteria for diagnosis of ARDS, its incidence is variably reported. In a review, Catanzarite and associates (2001) computed it to be about 1 in 3000 to 6000 deliveries. Severe disease requiring ventilatory support has a mortality rate of about 50 percent for all persons. It is as high as 90 percent if caused or complicated by sepsis. Although they are younger and healthier than the overall population, pregnant women still have mortality of 25 to 40 percent (Catanzarite and co-workers, 2001; Perry and colleagues, 1996).

Definitions. Physiological criteria required for diagnosis of ARDS differ, but clinically it is important to remember that the spectrum is wide. For research purposes, most investigators define ARDS as radiographic pulmonary infiltrates, a ratio of arterial oxygen tension to the fraction of inspired oxygen ($P_{aO_2}:F_{iO_2}$) of less than 200 mm Hg, and no evidence of heart failure (Ware and Matthay, 2000; Weg and colleagues, 1998). For clinical purposes, however, a working diagnosis is used when the $P_{aO_2}:F_{iO_2}$ ratio is higher in the face of pulmonary infiltrates seen on radiograph.

Pathophysiology. Again, ARDS is a pathophysiological diagnosis. With acute lung injury from a variety of causes, there is recruitment of neutrophils to the site of inflammation by chemokines. As neutrophils accumulate, they initiate further tissue injury by their cytokine secretion. Although there is widespread injury to microvascular endothelium, including the pulmonary vasculature, there is also alveolar epithelial injury. These result in increased pulmonary capillary permeability, surfactant loss or inactivation, diminished lung volume, and vascular shunting with resultant arterial hypoxemia. The second phase of the syndrome usually begins 3 to 4 days later. It involves development of *fibrosing alveolitis* and subsequent repair. The long-term prognosis for pulmonary function is surprisingly good (Herridge and colleagues, 2003). The subject was reviewed by Ware and Matthay (2000).

Etiology. A number of disorders have been associated with acute pulmonary injury and permeability edema during pregnancy (Table 42-5). Although many are coincidental, some are unique to pregnancy. For all patients, sepsis and diffuse infectious pneumonia are the two most common single-agent causes. In combination, they account for 60 percent of cases. Antepartum pyelonephritis, intrapartum chorioamnionitis, and puerperal pelvic infection are frequent causes of obstetrical sepsis. Severe preeclampsia, aspiration, and obstetrical hemorrhage are also commonly found (see Table 42-5). Importantly, more than half of these women have some combination of sepsis, shock, trauma, and fluid overload. The latter is exacerbated by tocolytic therapy, which Amon and associates (2000) reported to have a 5-percent incidence of pulmonary edema. Thus, multiplicity of causes is the rule with acute and severe lung injury. The contribution, if any, of *transfusion-related acute lung injury (TRALI)* as described by Kopko and colleagues (2002), is not known at this time (see Chap. 35, p. 842).

Clinical Course. With pulmonary injury, the clinical condition depends largely on the magnitude of the insult, the ability to compensate for it, and the stage of the disease. For example, if the woman presents soon after the initial injury, there commonly are no physical findings except perhaps hyperventilation. In addition, arterial oxygenation usually is adequate. Pregnancy-induced mild metabolic alkalosis may be accentuated by hyperventilation. With continuing insult, clinical and radiological evidence for pulmonary pathology becomes more obvious. Decreased lung compliance and increased intrapulmonary blood shunting are now apparent. Progressive alveolar and interstitial edema develop along with extravasation of inflammatory cells and erythrocytes.

Ideally, pulmonary injury is identified at this early stage, with specific therapy directed at the insult if possible. Further progression may result in acute respiratory failure characterized by marked dyspnea, tachypnea, and hypoxemia. Further loss of lung volume results in worsening of pulmonary compliance and increased intrapulmonary shunting. There are now diffuse abnormalities by auscultation and the chest radiograph characteristically demonstrates bilateral lung involvement (Fig. 42-2). At this phase, injury has progressed to a point that ordinarily is lethal in the absence of high inspired-oxygen concentrations. Positive airway pressure, whether by mask or by intubation, may now also be necessary at this stage for airspace recruitment. When shunting exceeds 30 percent, severe refractory hypoxemia develops along with metabolic and respiratory acidosis that can result in myocardial irritability, dysfunction, and cardiac arrest.

Management. In acute and severe lung injury, attempts are made to provide adequate oxygenation of peripheral tissues while ensuring that therapeutic maneuvers do not further aggravate lung injury. At least intuitively, increasing oxygen delivery should produce a corresponding increase in tissue uptake, but this is difficult to measure (Evans and Smithies, 1999). Support of systemic perfusion with intravenous crystalloid and blood is imperative (see Chap. 35, p. 839). Sepsis is commonplace in lung injury, and vigorous antimicrobial therapy is given for infection. Three critical points merit emphasis:

1. Oxygen delivery is directly proportional to cardiac output.
2. The overwhelming majority of transported oxygen is bound to hemoglobin. Accordingly, oxygen delivery can be greatly improved by correction of anemia because each gram of hemoglobin carries 1.25 mL of oxygen when 90 percent saturated.
3. Increasing the arterial P_{O_2} from 100 to 200 mm Hg results in the transport of only 0.1 mL of additional oxygen for each 100 mL of blood.

Reasonable goals in caring for the woman with severe lung injury are to obtain a P_{aO_2} of 60 mm Hg or 90-percent saturation at an inspired oxygen content of less than 50 percent, along with positive end-expiratory pressures less than 15 mm Hg. It remains controversial whether delivery will improve maternal oxygenation (Jenkins and co-workers, 2003; Tomlinson and colleagues, 1998).

OXYHEMOGLOBIN DISSOCIATION CURVE. The propensity of the hemoglobin molecule to release oxygen is described by the oxyhemoglobin dissociation curve. Simplistically, the curve can be divided into an upper oxygen association curve representing the alveolar-capillary environment and a lower oxygen dissociation portion representing the tissue capillary environment (Fig. 42-3). Shifts of the curve have their greatest impact at the steep portion because they affect oxygen delivery. A rightward shift is associated with decreased hemoglobin affinity for oxygen and hence increased tissue-capillary oxygen interchange. Rightward shifts are produced by hypercapnia, metabolic acidosis, fever, and increased 2,3-diphosphoglycerate levels. During pregnancy, the erythrocyte concentration of 2,3-diphosphoglycerate is increased by

approximately 30 percent. This favors oxygen delivery to both the fetus and peripheral maternal tissues (Rorth and Bille-Brahe, 1971).

Fetal hemoglobin has a higher oxygen affinity than adult hemoglobin, and its curve is positioned to the left of the adult curve (see Fig. 42-3). To achieve 50-percent hemoglobin saturation in the mother, the P_{aO_2} must be 27 mm Hg compared with only 19 mm Hg in the fetus. Under normal physiological conditions, the fetus is constantly on the dissociation, or tissue, portion of the curve. Even with severe maternal lung disease and very low P_{aO_2} levels, oxygen displacement to fetal tissues is favored. This has been confirmed by studies of pregnant women and their fetuses at high altitude, where despite a maternal P_{aO_2} of only 60 mm Hg, the fetal P_{aO_2} as is equivalent to that at sea level (Subrevilla and colleagues, 1971).

MECHANICAL VENTILATION. In some patients, positive pressure ventilation by face mask may be effective in early stages of pulmonary insufficiency (Wyncoll and Evans, 1999). In an attempt to maximize fetal environment, early intubation is preferred in the pregnant woman if respiratory failure appears to be imminent. Mechanical ventilation is adjusted to obtain a P_{aO_2} greater than 60 mm Hg, or a hemoglobin saturation of 90 percent and a P_{aCO_2} of 35 to 45 mm Hg. Lower levels for P_{aO_2} should be avoided, because placental perfusion may be impaired (Levinson and co-workers, 1974).

Jenkins and associates (2003) reported their experiences with 51 women who required mechanical ventilation. Almost half had severe preeclampsia. Most were intubated postpartum, but 11 were delivered while being ventilated. Another six improved and were discharged undelivered. Of these 51 pregnancies, there were seven maternal deaths (14 percent). Importantly, one woman died as a complication of tocolytic treatment. Schneider and colleagues (2003) described 53 women who were delivered while receiving ventilatory support. The maternal mortality rate was 17 percent. In another report, Chen and co-workers (2003) reported four maternal deaths among 16 pregnant women who required mechanical ventilation. None of these investigators concluded that delivery improved maternal outcome.

POSITIVE END-EXPIRATORY PRESSURE. With severe lung injury and high intrapulmonary shunt fractions, it may not be possible to provide adequate oxygenation with usual ventilatory pressures, even with 100-percent oxygen. Positive end-expiratory pressure is usually successful in decreasing the shunt by recruiting collapsed alveoli. At low levels (e.g., 5 to 15 mm Hg), positive pressure can usually be used safely. At the higher levels, right-sided venous return can be impaired, resulting in decreased cardiac output and decreased uteroplacental circulation. High levels can also result in overdistention of alveoli, falling compliance, and barotrauma.

FLUID THERAPY. Treatment requires detailed attention to fluid balance, because fluid overload further compromises pulmonary status (Wyncoll and Evans, 1999). Intake and output records should be supplemented with daily weights. Mechanically ventilated patients retain an extra liter of fluid daily. Because respiratory distress syndrome is characterized by a pulmonary permeability defect, fluid leaks into the interstitium, even at normal pressures. Thus, it is best to maintain the lowest pulmonary capillary wedge pressure possible while avoiding decreased cardiac output.

Some pregnancy-induced physiological changes may predispose the woman to greater risk of permeability edema from fluid therapy. Colloid oncotic pressure (COP) is determined by serum albumin concentration, and 1 g/dL exerts about 6 mm Hg pressure. As discussed in Chapter 5 (see p. 140), serum albumin concentrations normally decrease in pregnancy. This results in a continuous decline in COP across normal pregnancy — from 28 mm Hg in the nonpregnant woman to 23 mm Hg at term (Robertson, 1969). There is a further decline to 17 mm Hg in the puerperium (Benedetti and Carlson, 1979). In women with preeclampsia, endothelial leakage causes extravascular albumin loss, and oncotic pressure is only 16 mm Hg antepartum and 14 mm Hg postpartum (Zinaman and co-workers, 1985). These changes have a significant clinical impact on the *colloid oncotic pressure/wedge pressure gradient*. Normally, this gradient exceeds 8 mm Hg, however, when it is 4 mm Hg or less, there is an increased risk for pulmonary edema.

OTHER THERAPY. After promising preliminary data on *artificial or replacement surfactant therapy*, Anzueto and colleagues (1996) found no benefits in 725 patients with sepsis-induced lung failure. In two subsequent studies, inhalation of *nitric oxide* caused early improvement, but mortality was unchanged (Taylor and co-workers, 2004; Wyncoll and Evans, 1999). In a small preliminary study, *prolonged methylprednisolone* therapy begun in patients with no improvement by day 7 demonstrated improved lung function and reduced mortality (Meduri and associates, 1998). Using an animal model, Imai and co-workers (2003) reported that a "protective" strategy using low tidal volumes and high end-expiratory pressure protected against end-organ epithelial apoptosis in the kidney and small intestine.

Other specific therapies under current investigation include *immunotherapy* with anti-CD blocking antibodies, *lipid mediator antagonists* to arachidonic acid, and *antioxidants* (Clark and colleagues, 1997).

Figure 42-2. Severe acute respiratory distress syndrome with diffuse infiltrates. (Courtesy of Dr. Michael Landay.)

Figure 42-3. Oxyhemoglobin dissociation curve. With higher oxygen tension (P_{aO_2}) in the pulmonary alveoli, adult hemoglobin is maximally saturated compared with that at the lower oxygen tension at the tissue capillary level. At any given oxygen tension, fetal hemoglobin carries more oxygen than adult hemoglobin, as indicated by percent saturation.

The sepsis syndrome is induced by a systemic inflammatory response to bacteria or their by-products such as endotoxins or exotoxins (Fig. 42-4). Infections that most commonly cause the sepsis syndrome in obstetrics are antepartum pyelonephritis (see Chap. 48, p. 1096), chorioamnionitis and puerperal sepsis (see Chap. 31, 712), septic abortion (see Chap. 9, p. 247), and necrotizing fasciitis (see Chap. 31, p. 720). In over 4000 nonpregnant patients, the mortality rate at 28 days was 30 to 40 percent with severe sepsis (Abraham and colleagues, 1997, 1998; Bernard and associates, 2001). When there is septic shock, mortality is greater regardless of the etiology. Mabie and associates (1997) reported 28-percent maternal mortality in 18 women.

Figure 42-4. The sepsis syndrome begins with a systemic inflammatory response syndrome (SIRS) in response to infection that may progress to septic shock. (Courtesy Dr. Robert S. Munford.)

ETIOPATHOGENESIS. The sepsis syndrome in obstetrics may be caused by any of a number of pathogens. Although pelvic infections are usually polymicrobial, bacteria that cause severe sepsis syndrome are frequently endotoxin-producing Enterobacteriaceae, most commonly *Escherichia coli*. Other pathogens are aerobic and anaerobic streptococci, *Bacteroides* species, and *Clostridium* species. Some group A β -hemolytic streptococci and *Staphylococcus aureus* produce virulent exotoxins that can rapidly cause all features of the sepsis syndrome (see Chap. 31, p. 713). Some virulent streptococci produce proteases that degrade IL-8 (Hidalgo-Grass and associates, 2004). In pyelonephritis, *E coli* and *Klebsiella* species commonly cause bacteremia and sepsis syndrome (Cunningham and associates, 1987; Mabie and colleagues, 1997).

Endotoxin is a lipopolysaccharide released on lysis of the cell wall of gram-negative bacteria. A number of potent bacterial exotoxins can also cause severe sepsis syndrome. Examples include exotoxins from *Clostridium perfringens*, toxic shock syndrome toxin from *S aureus*, and toxic shock-like exotoxin from group A β -hemolytic streptococci (Hoadley, 2002). As described by Nathan and colleagues (1993), these exotoxins cause rapid and extensive tissue necrosis and gangrene, especially of the postpartum uterus, and may cause profound cardiovascular collapse with maternal death (see Chap. 31, p. 721).

Sequelae of the sepsis syndrome begin with an inflammatory response that is directed against microbial endotoxins and exotoxins. Simply put, these and other toxins stimulate CD4 T cells to produce proinflammatory cytokines that include tumor necrosis factor- α (TNF- α) and interleukin-1(IL-1) and IL-8. Neutrophils then adhere to endothelium and secrete a number of toxic substances such as proteases, oxidants, and cytokines. A myriad of cellular reactions follow that include stimulation of pro- and anti-inflammatory compounds, procoagulant activity, gene activation, receptor regulation, and immune suppression (Hotchkiss and Karl, 2003; Wheeler and Bernard, 1999). It is likely that IL-6 mediates myocardial suppression (Pathan and associates, 2004).

The pathophysiological response to this cascade is selective vasodilation with maldistribution of blood flow and volume. Leukocyte and platelet aggregation cause capillary plugging. Vascular endothelial injury causes profound capillary leakage and interstitial fluid accumulation. Depending on the injury and inflammatory response, which are likely related to the virulence and dose of toxin, there is a spectrum of clinical response (see Fig. 42-4). Thus, sepsis syndrome is a clinical as well as pathophysiological continuum, the most severe result of which is *septic shock*. In its early stages, clinical shock results primarily from decreased systemic vascular resistance that is not compensated fully by increased cardiac output. Hypoperfusion results in lactic acidosis, decreased tissue oxygen extraction, and end-organ dysfunction. According to Schrier and Wang (2004), renal failure is common, and sepsis may cause *multiple organ failure* (Table 42-6).

HEMODYNAMIC CHANGES WITH SEPSIS. The pathophysiology of the sepsis syndrome has been elucidated by Parker (1987) and Parrillo (1990) and their colleagues from the National Institutes of Health. They observed that capillary leakage initially causes hypovolemia. If circulating volume is restored with intravenous crystalloid at this point, sepsis is a high cardiac output, low systemic vascular resistance condition. Concomitantly, pulmonary hypertension develops. This is often referred to as the *warm phase* of septic shock. These findings are the most common cardiovascular manifestations of early sepsis, and they often have prognostic significance. Paradoxically, despite the high cardiac output, patients with severe sepsis likely have myocardial depression (Ognibene and co-workers, 1988).

Most previously healthy pregnant women with sepsis at this stage respond well to fluid resuscitation, intensive antimicrobial therapy, and if indicated, removal of infected tissue. Conversely, if hypotension is not corrected following vigorous fluid infusion, then the prognosis is more guarded. At this juncture, if there also is no response to β -adrenergic inotropic agents, this indicates severe and unresponsive extracellular fluid extravasation with vascular insufficiency, overwhelming myocardial depression, or both. Oliguria and continued peripheral vasoconstriction characterize a secondary, *cold phase* of septic shock, from which survival is uncommon. Another poor prognostic sign is continued renal, pulmonary, and cerebral dysfunction once hypotension has been corrected. The average risk of death increases by 15 to 20 percent with failure of each organ system (Wheeler and Bernard, 1999). If three systems are involved, mortality is 70 percent (Martin and colleagues, 2003).

DIAGNOSIS AND TREATMENT. Whenever serious bacterial infection is suspected, blood pressure and urine flow should be monitored closely. In obstetrics, whenever there is evidence of hypotension or oliguria, septicemia or hemorrhage should be immediately considered. When there is hypotension with sepsis syndrome, prompt and aggressive treatment is initiated. One treatment scheme is shown in Table 42-7. Rapid infusion with 2 L and sometimes as many as 4 to 6 L of crystalloid fluids may be required to restore renal perfusion in severely affected women. Because of the vascular leak, there is hemoconcentration. To combat this, blood is given along with crystalloid to maintain the hematocrit at about 30 percent (Rivers and colleagues, 2001). The use of colloid solution such as 5-percent human albumin is controversial (Clark and colleagues, 1997; Ware and Matthay, 2000). We do not recommend its use.

If aggressive volume replacement is not promptly followed by urinary output of at least 30 and preferably 50 mL/hr, as well as other indicators of improved perfusion, then consideration is given for vasoactive drug therapy. At this point, some clinicians

opt for insertion of a pulmonary artery catheter. Mortality is high when sepsis is further complicated by respiratory or renal failure. With severe sepsis, damage to pulmonary capillary endothelium and alveolar epithelium causes alveolar flooding and pulmonary edema. This may occur even with low or normal pulmonary capillary wedge pressures. Management of *acute respiratory distress syndrome* is described on page 991.

Broad-spectrum antimicrobials are administered in maximal doses after appropriate cultures are taken. Appropriate empirical coverage results in better survival in severe sepsis (MacArthur and colleagues, 2004). Cultures of blood along with exudates that are not contaminated by normal flora are taken. For women with an infected abortion or deep fascial infections, a Gram-stained smear may be helpful in identifying *Clostridium perfringens* or group A streptococcal organisms. Generally, empirical coverage with regimens such as ampicillin plus gentamicin plus clindamycin suffices for pelvic infections (see [Chap. 31](#), p. 714).

Surgical Treatment. Continuing sepsis may prove fatal, and debridement of necrotic tissue or drainage of purulent material is crucial. Of 18 pregnant women with septic shock, Mabie and colleagues (1997) reported that eight required surgical therapy to control the source of infection. A meticulous search is made for such foci. For women with an infected abortion, the uterine contents must be removed promptly by curettage. Hysterectomy is seldom indicated unless gangrene has resulted.

For women with pyelonephritis, continuing sepsis often is from urinary obstruction caused by calculi or a perinephric or intrarenal phlegmon or abscess. Renal sonography or "one-shot" pyelography may be used to diagnose obstruction and calculi, whereas computed tomography (CT) may be helpful to diagnose a phlegmon or abscess. With obstruction, ureteral catheterization, percutaneous nephrostomy, or flank exploration may be lifesaving (see [Chap. 48](#), p. 1098).

Most cases of puerperal sepsis are clinically manifested in the first several days postpartum, and tissue debridement is not usually indicated this early. There are several exceptions to this:

1. Necrotizing fasciitis of the episiotomy site or abdominal surgical incision. As described by Gallup and colleagues (2002), this is a surgical emergency, and aggressive management is discussed in [Chap. 31](#) (see p. 720).
2. Massive uterine myonecrosis caused by group A β -hemolytic streptococcal infections. The mortality rate in these women is high, and prompt hysterectomy may be lifesaving (Mabie and co-workers, 1997; Nathan and colleagues, 1993). Other virulent organisms can produce similar findings (Clad and associates, 2003).
3. Persistent or aggressive uterine infection with necrosis and dehiscence of the uterine incision with severe peritonitis. **Any woman with infection following cesarean delivery who is suspected of having peritonitis should be carefully evaluated for uterine incisional necrosis or bowel perforation.** Prompt surgical exploration, and frequently hysterectomy, must be done. CT of the pelvis is useful to characterize these infections. Overwhelming chorioamnionitis and sepsis caused by a gas-forming *E coli* and which required hysterectomy has been reported (Catanzarite and associates, 1994).
4. Peritonitis and sepsis much less commonly may result from a ruptured parametrial, intra-abdominal, or ovarian abscess (see [Chap. 31](#), p. 718).

Adjunctive Therapy

PRESSOR AGENTS. Vasoactive drugs are not given unless aggressive fluid treatment fails to correct hypotension and perfusion abnormalities. One commonly used agent is dopamine hydrochloride, which when given in doses of 2 to 10 $\mu\text{g}/\text{kg}/\text{min}$ stimulates cardiac α -receptors to increase cardiac output. Doses of 10 to 20 $\mu\text{g}/\text{kg}/\text{min}$ cause β -receptor stimulation, an increase in systemic vascular resistance, and an increase in blood pressure. At doses of more than 20 $\mu\text{g}/\text{kg}/\text{min}$, α -receptor stimulation predominates, but dopamine is seldom needed at these higher doses. If there is no response to dopamine, then dobutamine, 5 to 15 $\mu\text{g}/\text{kg}/\text{min}$, or norepinephrine, 5 to 20 $\mu\text{g}/\text{min}$, may be of benefit (Wheeler and Bernard, 1999).

OXYGENATION AND VENTILATION. Oxygen is administered in an attempt to improve tissue oxygenation. As the septic shock syndrome progresses and intravascular volume is restored, there may be substantive pulmonary capillary endothelial damage with leakage into alveoli. Resultant pulmonary edema causes hypoxemia, which worsens tissue hypoxia and acidosis. When this is severe and adequate oxygenation cannot be maintained by increased oxygen delivered via a nonbreathing mask or by a continuous positive airway pressure mask, then tracheal intubation and mechanical ventilation that delivers positive pressure may prove to be lifesaving (see p. 993).

ANTI-INFLAMMATORY AGENTS. Serum cortisol levels are typically elevated in sepsis and higher levels are associated with increased mortality (Sam and associates, 2004). Either high-dose *methylprednisolone* nor intravenous *ibuprofen* improved morbidity or mortality rates (Bernard and co-workers, 1997; Cronin and colleagues, 1995). Clinical studies of the nitric oxide synthase inhibitor, NG-methyl-L-arginine hydrochloride (546C88), indicated increased mortality rates over placebo despite improved cardiovascular status (Bakker, 2004; Lopez, 2004; Watson 2004, and all their colleagues).

ANTICOAGULANT THERAPY. Sepsis activates procoagulant production and causes microcirculatory obstruction; thus, a number of agents that block coagulation have been used for treatment. Both *antithrombin III* and *tissue factor pathway inhibitor* have been ineffective (Abraham and co-workers, 2003; Warren and colleagues, 2001). In a landmark study by Bernard and associates (2001), recombinant activated protein C was shown to improve 28-day mortality rates from sepsis. A major drawback is hemorrhage during infusion. Currently, the use of these anticoagulants seems justified with sepsis-related purpura fulminans (Dempfle, 2004).

IMMUNOTHERAPY. In general, immunotherapy for sepsis has been disappointing. Infusion of *antiendotoxin antibody* was found to have no benefits (French National Registry of HA-1A in Septic Shock, 1994). Similarly, *E5 murine monoclonal IgM antiendotoxin antibody* did not improve mortality (Angus and associates, 2000). *Anticytokine antibodies* and *competitive blockers of TNF- α binding* have also been used without benefit (Abraham and colleagues, 1997, 1998).

TRAUMA IN PREGNANCY

Trauma, homicide, and similar violent events are a leading cause of death in young women. As many as 10 to 20 percent of pregnant women suffer physical trauma (American College of Obstetricians and Gynecologists, 1998; Rickert and associates, 2003). Injury-related deaths are the most commonly identified cause of maternal morbidity in Cook County, Illinois; New York City; Maryland; Utah; and North Carolina (Dannenbergh, 1995; Fildes, 1992; Harper and Parsons, 1997; Horon and Cheng, 2001; Jacob, 1998; and all their colleagues). In addition, in a California study of 4.8 million pregnancies by El Kady and co-workers (2003), almost 1 in 350 women were hospitalized for trauma.

Homicide of pregnant women is prevalent also. In a review of pregnancy-associated deaths, Frye (2001) concluded that 20 percent of maternal deaths were the result of murder. In a 10-city case-control study, McFarlane and associates (2002) found that 5 percent of female homicide victims were pregnant. By far, the most frequent form of trauma in pregnancy is from physical or sexual abuse, which commonly occurs because of domestic abuse or battering (Eisenstat and Bancroft, 1999).

BLUNT TRAUMA. Many forms of blunt trauma are encountered in pregnancy. Their common theme concerns immediate assessment of maternal effects of trauma, emergency treatment, and then evaluation of collateral effects on the fetus.

Physical Abuse. According to the U.S. Department of Justice, women who are 16 to 24 years of age have the highest per capita rates of intimate partner violence — 19.4 per 1000 (Rennison and Welchans, 2000). It is estimated that 5 million women each year are physically assaulted by their male partners (American College of Obstetricians and Gynecologists, 1999). One goal in violence prevention for Healthy People 2010 is reduction of physical abuse directed at women by male partners.

Even more appalling is that pregnant women are not immune to this physical violence. Most supporting data have been accrued by public institutions. One third of injuries to pregnant women cared for at the University of Mississippi Medical Center were intentionally inflicted (Poole and colleagues, 1996). McFarlane and colleagues (1992) and Berenson and co-workers (1991) reported that almost a fourth of women attending public clinics had been physically or sexually abused during pregnancy. Cokkinides and colleagues (1999) found that 11 percent of 6000 pregnant women reported physical violence. This was linked to poverty, poor education, and use of tobacco and alcohol. Drug use is associated with half of instances in all battered women (Kyriacou and associates, 1999). Abuse during pregnancy places the woman at high risk for homicide during or after pregnancy (McFarlane and collaborators, 2002). Unfortunately, abused pregnant women tend to remain with their abusers, and 60 percent reported two or more episodes of physical assault during pregnancy (McFarlane and colleagues, 1992).

The woman who is physically abused tends to present late, if at all, for prenatal care. Occurrence of preterm labor and chorioamnionitis is increased twofold (Berenson and co-workers, 1994). There is also increased risk of low birthweight and cesarean delivery (Covington, 2001; Curry, 1998; Murphy, 2001, and all their associates). Another risk factor for adverse pregnancy outcomes is police-reported partner violence (Lipsky and colleagues, 2003).

SCREENING AND PREVENTION. Universal screening for *intimate partner violence* is not currently recommended by most researchers because its effectiveness is unknown (Wathen and MacMillan, 2003). Instead, a case-finding approach based on clinical suspicion is used. As discussed in [Chapter 8](#) (see p. 210), the American College of Obstetricians and Gynecologists (1999) has provided screening methods for domestic violence and recommends their use at the initial prenatal visit, during each trimester, and at the time of postpartum follow-up.

Sexual Assault. According to the U.S. Department of Justice (2000), 17 percent of adult women will be sexually assaulted sometime during their lives. It is generally thought that only 10 to 20 percent of sexual assaults are reported. Satin and co-workers (1991), who reviewed over 5700 sexual assaults against women reported in Dallas County over 6 years, found that 2 percent of the victims were pregnant. Associated physical trauma occurs in about half of all women (Sugar and colleagues, 2004). In the Dallas Study, trauma was less common during pregnancy, and only one third of assaults took place after 20 weeks. From a forensic standpoint, evidence collection was not altered.

Satin and co-workers (1992) also interviewed 2404 women postpartum and found that the lifetime prevalence of forced sexual contact was 5 percent. Compared with nonvictims, rape victims had a higher incidence of sexually transmitted diseases, urinary infections, vaginitis, drug use, and multiple hospitalizations. Berenson and colleagues (1992) reported that 8 percent of pregnant adolescents had been sexually assaulted. In 46 percent of cases, the perpetrator was a member of the family and in 33 percent of cases, a spouse or boyfriend.

The importance of psychological counseling for the rape victim and her family cannot be overemphasized. In addition to attention to physical and psychological injuries, exposure to sexually transmitted diseases must be considered. The current recommendations for prophylaxis are shown in [Table 42-8](#). If the woman is not pregnant, another very important aspect is emergency contraception as recommended by the American College of Obstetricians and Gynecologists (2001). This was recently reviewed by Westhoff (2003) and is discussed in detail in [Chapter 32](#) (see p. 744).

Automobile Accidents. Between 1 and 3 percent of pregnant women are involved in motor vehicle accidents (Hyde and associates, 2003; Weiss and colleagues, 2002). Vehicular crashes are the most common causes of serious, life-threatening, or fatal blunt trauma during pregnancy (Connolly and co-workers, 1997; Pak and colleagues, 1998). They are also the leading cause of traumatic fetal deaths (Weiss, 2001). Many of these deaths might be prevented with use of three-point restraints. Pearlman and associates (2000) found that proper seat belt use and crash severity were the best predictors of maternal-fetal outcome. Hyde and colleagues (2003) reported that fetal mortality was three times as great in women who were not wearing a seat belt. Importantly, Tyroch and associates (1999) reported that although 86 percent of pregnant women used restraints, almost 50 percent used them incorrectly.

Effects of deployment of airbags in pregnant drivers or passengers have not been widely studied. Sims and associates (1996) reported three third-trimester women whose driver-side airbag deployed in 10- to 25-mph collisions. They reported no injuries. Schultze and colleagues (1998) reported a 20-percent placental abruption that caused a stillborn 28-week fetus in a woman whose airbag deployed in a 40-mph collision. Even less is known about passenger-side bags or door bags (Moorcroft and co-workers, 2003).

Other Blunt Trauma. Some other common causes of blunt trauma are falls and aggravated assaults (Schiff and associates, 2002). In the California study by El Kady and co-workers (2004), intentionally afflicted injuries were present in about a third of pregnant women who were hospitalized for trauma. Less common are blast or crush injury (Awwad and co-workers, 1994a; Schoenfeld and colleagues, 1995). Serious intra-abdominal injuries are of particular concern. Probably related to the markedly increased pelvic and abdominal vascularity, retroperitoneal hemorrhage is encountered more commonly compared with that of nonpregnant women. Leggon and associates (2002) reviewed 101 pelvic fractures during pregnancy and found a 9-percent maternal and 35-percent fetal mortality rate. Conversely, bowel injuries are less frequent because of the protective effect of the large uterus. Diaphragmatic, splenic, liver, and kidney injuries may also be sustained (Flick and colleagues, 1999; Icery and Chez, 1999).

Fetal Injury and Death. According to Kissinger and co-workers (1991), the risk of fetal death with trauma is significant when there is direct fetoplacental injury, maternal shock, pelvic fracture, maternal head injury, or hypoxia. In a 16-state review of fetal deaths due to trauma from 1995 through 1997, Weiss and associates (2001) found that motor vehicle crashes caused 82 percent. There was placental injury in almost 50 percent of cases and uterine rupture in 4 percent.

Although fetal injury and death are uncommon, there are many interesting case reports. Fetal skull and brain injury are most common. These injuries are more likely if the head is engaged and the maternal pelvis is fractured on impact (Palmer and Sparrow, 1994). Conversely, fetal head injuries, presumably from a *contrecoup* effect, may be sustained in unengaged vertex or nonvertex presentations. Weyerts and colleagues (1992) described a newborn with paraplegia and contractures associated with a motor vehicle accident sustained several months before birth.

Placental Abruption and Uterine Rupture. Two uniquely catastrophic events can occur with blunt trauma during pregnancy — placenta abruption and uterine rupture. These two conditions often are life-threatening to both mother and fetus. A third catastrophic event is a placental tear or "fracture" that can result in fetal hemorrhage and exsanguination, either into the amniotic sac or as fetomaternal hemorrhage.

TRAUMATIC PLACENTAL ABRUPTION. Placental separation is likely caused by deformation of the elastic myometrium around the relatively inelastic placenta (Crosby and associates, 1968). Some degree of abruption complicates 1 to 6 percent of "minor" injuries and up to 50 percent of "major" injuries (Goodwin and Breen, 1990; Pearlman and co-workers, 1990; Schiff and associates, 2002). In one study, Reis and colleagues (2000) reported that abruption was more likely if the car was exceeding 30 mph.

Findings with traumatic abruption may be similar to those for spontaneous placental abruption discussed in [Chapter 35](#) (see p. 811), although the causes of the two conditions are dissimilar. This is not universal, however, and Kettel and co-workers (1988) emphasized that traumatic abruption may be occult and not associated with uterine pain, tenderness, and bleeding. Stettler and associates (1992) reviewed our experiences with 13 such women at Parkland Hospital and reported that although 11 had uterine tenderness, only five had vaginal bleeding. Thus, because traumatic abruption is more likely to be concealed, the incidence of associated coagulopathy is higher than with spontaneously occurring abruption. Other common findings are uterine contractions; evidence of fetal compromise such as fetal tachycardia, late decelerations, and acidosis; and fetal death.

In women with partial separation, abruption may not be so obvious. According to Pearlman and associates (1990), detection of uterine contractile activity using electronic monitoring was suggestive of abruption. If contractions are fewer than every 10 minutes during 4 hours of monitoring, an abruption is most unlikely. Women with contractions of greater frequency, however, have a 20 percent chance of an abruption. If tocolytics are used, they may obfuscate these findings.

UTERINE RUPTURE. Blunt trauma results in uterine rupture in less than 1 percent of severe cases (American College of Obstetricians and Gynecologists, 1998). Rupture is more likely in a previously scarred uterus and is usually associated with a direct impact of substantive force. Decelerative forces following a 25-mph collision can generate up to 500 mm Hg of intrauterine pressure in a properly restrained woman (Crosby and associates, 1968). Findings may be identical to those for placental abruption with an intact uterus, and maternal and fetal deterioration are soon inevitable. Pearlman and Cunningham (1996) described uterine fundal "blow out" with fetal decapitation in a 20-week pregnancy following a high-speed collision. If the fetus is dead, it may be particularly difficult to diagnose uterine rupture, although Dash and Lupetin (1991) were able to do so in a 24-week pregnancy by using CT. In a case without rupture, Duplantier and colleagues (2002) described 180-degree uterine torsion at term.

Fetal-Maternal Hemorrhage. If there is considerable abdominal force associated with trauma, and especially if the placenta is lacerated, or "fractured," then life-threatening fetal-maternal hemorrhage may be encountered (Pritchard and associates, 1991). A small amount of fetal-maternal bleeding (less than 15 mL in 90 percent of cases) has been described in up to a third of trauma cases (Goodwin and Breen, 1990; Pearlman and associates, 1990). Massive fetal-maternal hemorrhage may coexist with traumatic abruption (Stettler and associates, 1992). Importantly, placental abruption per se is seldom associated with fetal-maternal hemorrhage because there is no fetal bleeding into the intervillous space. Instead, fetal-maternal hemorrhage associated with trauma is caused by a placental tear or "fracture" caused by stretching of the inelastic placenta ([Fig. 42-5](#)).

Figure 42-5. A. Partial placental abruption with adherent blood clot. The fetus died from massive hemorrhage, chiefly into the maternal circulation. **B.** The adherent blood clot has been removed. Note the laceration of the placenta. **C.** Kleihauer-Betke stain of a smear of maternal blood after fetal death. The dark cells that constituted 4.5 percent of peripheral cells are fetal in origin, whereas the empty cells are of maternal origin.

PENETRATING TRAUMA. Knife and gunshot wounds are the most common penetrating injuries and may be associated with aggravated assaults, suicide attempts, or attempts to cause abortion. The incidence of maternal visceral injury with penetrating trauma is only 15 to 40 percent compared with 80 to 90 percent in nonpregnant individuals (Stone, 1999).

When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be seriously injured. Indeed, although the fetus sustains injury in two thirds of such cases, visceral injuries to the mother are seen in only 20 percent.

Awwad and colleagues (1994b) reported unique experiences with high-velocity penetrating wounds of the pregnant uterus collected during 16 years of civil war in Lebanon. Among 14 women, two died, but neither death was as a direct result of intra-abdominal injury. Three observations were made:

1. There were visceral injuries when the entrance wound was in either the upper abdomen or back.
2. When the entry wound site was anterior and below the uterine fundus, there were no visceral injuries in all six women.
3. Half the women had perinatal deaths due to either maternal shock, uteroplacental injury, or direct fetal injury.

MANAGEMENT OF TRAUMA. In general, the severity of injury is directly related to maternal and fetal outcomes (Schiff and colleagues, 2002). That said, severity scoring does not accurately predict significant morbidity and mortality related to placental abruption. Schiff and Holt (2002) evaluated 294 pregnant women hospitalized for injuries in Washington State from 1989 through 1997. The *injury severity score* was not accurate to predict adverse pregnancy outcomes, as relatively minor injuries were associated with placental abruption. Similarly, Biester and co-workers (1997) reported that the revised trauma score was not predictive of adverse pregnancy outcome.

With few exceptions, treatment priorities in injured pregnant women are directed as they would be in nonpregnant patients (Warner and colleagues, 2004). Primary goals are evaluation and stabilization of maternal injuries. Attention to fetal assessment during the acute evaluation may divert attention from life-threatening maternal injuries (American College of Obstetricians and Gynecologists, 1998). Basic rules are applied to resuscitation, including establishing ventilation and arrest of hemorrhage along with treatment for hypovolemia with crystalloid and blood products. **An important aspect of management is repositioning of the large uterus away from the great vessels to diminish its effect on decreased cardiac output.**

Following emergency resuscitation, evaluation is continued for fractures, internal injuries, bleeding sites, as well as placental, uterine, and fetal injuries. If indicated, open peritoneal lavage should be performed (Scorpio and colleagues, 1992). Penetrating injuries in most cases must be evaluated using radiography (see [Chap. 41](#), p. 977). Because clinical response to peritoneal irritation is blunted during pregnancy, an aggressive approach to exploratory laparotomy is pursued for abdominal trauma. Whereas exploration is mandatory for abdominal gunshot wounds, some clinicians advocate close observation for selected stab wounds (Grubb, 1992).

Associated and sometimes delayed injuries can be bizarre. Hnat and colleagues (2003) described a woman who remained comatose throughout pregnancy from a closed-head injury in early gestation. Raymond and associates (2002) described a mother-fetus pair with chronic lead poisoning from an unremoved bullet lodged 15 years earlier!

Cesarean Delivery. The necessity for cesarean delivery of a live fetus depends on several factors. Laparotomy itself is not an indication for hysterectomy. Some considerations include gestational age, fetal condition, extent of uterine injury, and whether the large uterus hinders adequate treatment or evaluation of other intraabdominal injuries (Awwad and colleagues, 1994a).

Electronic Monitoring. As for many other acute or chronic maternal conditions, fetal well-being may reflect the status of the mother, and thus fetal monitoring is another "vital sign" that helps evaluate the extent of maternal injuries. Even if the mother is stable, electronic monitoring may be predictive of placental abruption. In the study cited on page 999, Pearlman and associates (1990) reported no abruptions if uterine contractions were less often than every 10 minutes within 4 hours after trauma was sustained. **Almost 20 percent of women who had contractions more frequently than every 10 minutes in the first 4 hours had an associated placental abruption.** In these cases, abnormal tracings were common and included fetal tachycardia and late decelerations. Connolly and co-workers (1997) reported no adverse outcomes in women who had normal monitor tracings.

Because placental abruption usually develops early following trauma, fetal monitoring is begun as soon as the mother is stabilized. The duration that post-trauma monitoring should be performed is not precisely known. According to Goodwin and Breen (1990), an observation period of 2 to 6 hours is sufficient if there are no other ominous signs such as contractions, uterine tenderness, or bleeding. Monitoring is continued as long as there are uterine contractions, a nonreassuring fetal heart pattern, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes (American College of Obstetricians and Gynecologists, 1998). In very rare cases, abruption placenta has developed days after trauma (Higgins and Garite, 1984).

Fetal-Maternal Hemorrhage. Routine use of the Kleihauer-Betke or an equivalent test in pregnant trauma victims is controversial (Pak and associates, 1998). It is unclear if their routine use will modify adverse outcomes associated with fetal anemia, cardiac arrhythmias, and death. In a retrospective review of 125 pregnant women with blunt injuries admitted to a level I trauma center, Towery and co-workers (1993) reported that the Kleihauer-Betke test had a sensitivity of 56 percent, a specificity of 71 percent, and an accuracy of 27 percent. The investigators concluded that the test was of little use with acute trauma management, and that electronic fetal monitoring or ultrasound, or both, are more useful in detecting fetal or pregnancy-associated complications. Dupre and associates (1993) reached similar conclusions, and although they found evidence for fetal-maternal hemorrhage in 22 percent of women studied, it was of no prognostic significance. Connolly and co-workers (1997) reached similar conclusions. In another study, however, Muench and colleagues (2003) reported that a Kleihauer-Betke test showing fetal cells of 0.1 percent or greater was predictive of preterm labor in women with blunt trauma.

For the woman who is D-negative, administration of anti-D immunoglobulin should be considered. This may be omitted if the test for fetal bleeding is negative. Isoimmunization may still develop if the fetal-maternal hemorrhage exceeds 15 mL of fetal cells.

Another important aspect of care for the pregnant trauma patient is to ensure that her tetanus immunization is current.

THERMAL INJURY. Although Parkland Hospital is a major burn center for the United States, we have not seen a large number of pregnant women with severe burns. Fetal prognosis is poor with severe burns. Usually the woman enters labor spontaneously within a few days to a week, and often delivers a stillborn infant. Contributory factors are hypovolemia, pulmonary injury, septicemia, and the intensely catabolic state associated with burns.

Prognosis. In their review, Polko and McMahon (1998) concluded that pregnancy does not alter maternal outcome compared with that of nonpregnant women of similar age. A number of investigators have reported that maternal and fetal survival parallels the percentage of burned surface area. In the 162 pregnant burned women shown in [Figure 42-6](#), as the burn area reaches or exceeds 50 percent, both maternal and fetal morbidity become formidable.

Skin Contractures. Following serious abdominal burns, skin contractures that develop may be painful during a subsequent pregnancy and may even necessitate surgical decompression and split skin autografts (Matthews, 1982). Widgerow and colleagues (1991) described two women in whom surgical release of contractures without covering the resulting defect was sufficient. McCauley and colleagues (1991) followed seven women with severe circumferential truncal burns sustained at a mean age of 7.7 years. All of 14 subsequent pregnancies were delivered at term without major complications. Loss or distortion of nipples may cause problems in breast feeding. Interestingly, normal abdominal tissue expansion due to pregnancy appears to be an excellent source for obtaining skin grafts postpartum to correct scar deformities at other body sites (Del Frari and colleagues, 2004).

Figure 42-6. Maternal and fetal morbidity by burn severity in 162 women. (Data from Akhtar, 1994; Amy, 1985; Mabrouk and el-Feky, 1997; Rayburn, 1984; Rode, 1990, and all their colleagues.)

ELECTRICAL SHOCK. Earlier case reports were suggestive of a high fetal mortality with electric shock (Fatovich, 1993). In a prospective cohort study, however, Einerson and colleagues (1997) showed similar perinatal outcomes in 31 exposed women compared with those of pregnant controls. They concluded that traditional 110-volt North American electrical current likely is less dangerous than 220-volt currents available in Europe. Sozen and Nesin (2004) described a woman with iliofemoral thrombosis at 29 weeks that *may* have been related to a mild electrical shock at 22 weeks. Koumbourlis (2002) has described the pathophysiological effects of electrical current and lightning injuries.

CARDIOPULMONARY RESUSCITATION

Cardiac arrest fortunately is rare during pregnancy. There are special considerations for cardiopulmonary resuscitation (CPR) conducted in the second half of pregnancy. In nonpregnant women, external chest compression results in a cardiac output of only 30 percent of normal (Clark and colleagues, 1997). Cardiac output may be even less in late pregnancy when uterine aortocaval compression may impede resuscitative efforts by diminishing forward flow as well as venous return. **Thus, uterine displacement is paramount to accompany other resuscitative efforts.** Left lateral displacement can be accomplished manually by a member of the team, by tilting the operating table laterally, by placing a wedge under the right hip, or by using the Cardiff resuscitation wedge. Rees and Willis (1988) showed with a manikin that resuscitation with the Cardiff wedge was as efficient as resuscitation in the supine position. If no equipment is available (e.g., in an out-of-hospital arrest), an individual kneels on the floor with the woman's back on the thighs to form a "human wedge" (Whitty, 2002).

Over the past few years, the recommendation by many authors is to perform cesarean delivery within 4 to 5 minutes of beginning CPR if the fetus is viable (Moise and Belfort, 1997). Certainly there is an inverse correlation between neurologically intact neonatal survival and the cardiac arrest-to-delivery interval in women delivered by perimortem cesarean. According to Clark and co-workers (1997), 98 percent of infants delivered within 5 minutes of arrest are neurologically intact. From 6 to 15 minutes it is 83 percent; from 16 to 25 minutes, 33 percent; and from 26 to 35 minutes, 25 percent. Based on theory and a few anecdotal case reports, delivery may also enhance maternal resuscitative efforts, which obviously must be continued throughout surgery and delivery (Finegold and colleagues, 2002). For all these reasons, the American College of Obstetricians and Gynecologists (1998) advises consideration for cesarean delivery in third-trimester pregnancy within 4 minutes of cardiac arrest. Unfortunately, as emphasized by Clark and associates (1997), and in our experiences, these goals rarely can be met in actual practice. Whitten and Irvine (2000) and Whitty (2002) have reviewed indications for postmortem and perimortem cesarean delivery.

43. Obesity

INTRODUCTION

Excessive weight has become one of the major health problems in the United States as well as in other affluent societies. Because of its medical importance and its multifaceted effects on pregnancy, it is discussed separately in this chapter. The prevalence of obesity in the United States has increased steadily as economic prosperity has increased. For a number of years, obesity has been termed *epidemic*. Strictly defined, the word *epidemic* implies a *temporary* widespread outbreak of greatly increased frequency and severity. Therefore, and unfortunately, obesity more correctly is *endemic* — a condition that is habitually present. Its prevalence continues to increase. From 1960 to 1991, the National Health and Nutrition Examination Survey (NHANES) documented an alarming increase among adults over the past decade (Kuczmarski and colleagues, 1994). By 1991, approximately one third of adults in the United States were overweight. That same year, Allison and co-workers (1999) attributed almost 300,000 deaths to obesity. Sadly, the problem is not limited to adults. Ogden and associates (2002) reported that 15 percent of children 6 through 11 years of age were overweight. The prevalence in adolescents is similar.

Public health authorities began to address the problem of obesity in the late 1980s. A stated goal of *Healthy People 2000* was to reduce the prevalence of overweight people to 20 percent or less by the end of the 20th century (Public Health Service, 1990). Unfortunately, this goal was not achieved, and in fact, more than 50 percent of the population was overweight at the beginning of 2000.

As evidence accrues, the nature and scope of morbidity due to obesity have become better elucidated. Diabetes mellitus, heart disease, hypertension, stroke, and osteoarthritis are among the many obesity-related diseases. These obesity-related diseases together result in a decreased life span. Bray (2003) aptly concluded that the worldwide obesity epidemic will be followed by a worldwide diabetes epidemic. Obese women who become pregnant — and their fetuses — are predisposed to a variety of serious pregnancy-related complications. Long-term maternal effects include significant and increased morbidity and mortality. Moreover, recent studies have suggested that the offspring of obese parents may suffer long-term morbidity. Ironically, severely growth-restricted female infants who become obese as adults are at high risk for preeclampsia (Dempsey and colleagues, 2003).

DEFINITIONS

A number of systems have been used to define and classify obesity. The *body mass index* (BMI), which is also known as the *Quetelet index*, is currently in use. The BMI is calculated as weight in kilograms divided by height in meters squared (kg/m^2). Calculated BMI values are available in various chart and graphic forms, such as the one shown in [Figure 43-1](#). According to the National Heart, Lung, and Blood Institute (1998), a *normal* BMI is 18.5 to 24.9 kg/m^2 ; *overweight* is a BMI of 25 to 29.9 kg/m^2 ; and *obesity* is a BMI of 30 kg/m^2 or greater. According to Freedman and colleagues (2002), obesity is further categorized as class I (BMI: 30 to 34.9 kg/m^2), class II (BMI: 35 to 39.9 kg/m^2), and class III (BMI: 40-plus kg/m^2).

Figure 43-1. Chart for estimating body mass index (BMI). To find the BMI category (e.g., obese) for a particular subject, locate the point at which the height and weight intersect. The BMI is the bold number on the dashed line closest to this point. The "High" category is now termed "Overweight."

PREVALENCE. By the end of 2000, Pleis and colleagues (2003) reported that 34 percent of adult American individuals were overweight. Another 27 percent were obese, an increase of 75 percent compared with 1980 statistics. **Thus, at the end of 2000, more than 50 percent of adults in the United States were either overweight or obese.** Prevalence data for women are shown in [Figure 43-2](#). Mokdad and associates (2003) reported that 2.8 percent of women and 1.7 percent of men were extremely obese (class III), with a BMI of 40 kg/m^2 or more. There is a disparate prevalence of obesity in indigent individuals in this country (Drewnowski and Specter, 2004).

As previously stated, childhood obesity is also a serious problem. Using the definition of overweight as at or above the 95 percentile for age and ethnicity, the prevalence of obesity in children has increased two- to threefold in the United States from 1971 to 1999 (National Center for Health Statistics, 1999; Ogden and co-workers, 2002). Moreover, the problem is worldwide, even in third-world countries (Ebbeling, 2002). In adolescents, the increasing prevalence of obesity is associated with declining physical activity (Kimm and associates, 2002).

Figure 43-2. National Center for Health Statistics: Prevalence of overweight (BMI $\geq 25 \text{ kg}/\text{m}^2$) or obese (BMI $\geq 30 \text{ kg}/\text{m}^2$) women by race/ethnicity and age in the United States for 1997-1998. (BMI = body mass index.) (Data from Schoenborn and colleagues, 2002.)

METABOLIC SYNDROME. In some people, obesity interacts with inherited factors and leads to the onset of *insulin resistance*. This metabolic abnormality in turn is responsible for altered glucose metabolism and a predisposition to type 2 diabetes mellitus. In addition, it causes a number of subclinical abnormalities that predispose to cardiovascular disease and accelerate its onset. The most important among these are type 2 diabetes, dyslipidemia, and hypertension. These conditions, when clustered together with other insulin resistance-related subclinical abnormalities, are referred to as the *metabolic syndrome* (Abate, 2000). Virtually all obese women with hypertension demonstrate elevated insulin levels. The levels are even higher in women with excessive fat in the abdomen — an apple shape, compared with fat in the hips and thighs — a pear

shape (American College of Obstetricians and Gynecologists, 2003). In fact, Gus and associates (2004) recently reported that for women, a waist circumference over 88 cm was more predictive of hypertension than a BMI greater than 30 kg/m².

The criteria used by the National Institutes of Health (2001) to define the metabolic syndrome are shown in [Table 43-1](#). Drugs that increase sensitivity to insulin, such as metformin and glitazones, also cause a decrease in blood pressure levels (Chen and colleagues, 1996).

Prevalence. Because metabolic syndrome is newly defined, prevalence data have been calculated from a study in progress. Ford and colleagues (2002) did a follow-up study between 1988 and 1994 of 8814 men and women enrolled in the Third National Health and Nutrition Survey (NHANES III). Using the criteria shown in [Table 43-1](#), there was an overall prevalence of the metabolic syndrome in 24 percent of women and 22 percent of men. As expected, prevalence increased with age. For 4549 women, prevalence was about 6 percent in those 20 to 29 years of age; 14 percent in those 30 to 39 years of age; 20 percent in those 40 to 49 years of age; and greater than 30 percent for women older than 50 years of age.

MORBIDITY AND MORTALITY ASSOCIATED WITH OBESITY

Obesity continues to be very costly, not only in morbidity and mortality, but also in health care dollars. Colditz (1999) estimated that 300,000 adults die each year from obesity-related causes. He estimated direct costs of obesity and physical inactivity to be 9.4 percent of annual health care expenditures in the United States.

Individuals who are overweight are at increased risk for an imposing number of complications ([Table 43-2](#)). The direct link between obesity and type 2 diabetes mellitus is well known (Mokdad and associates, 2001, 2003). In one study by Hu and co-workers (2001), 16-year follow-up data were reported from the Nurses' Health Study which began in 1974. In more than 1.3 million person-years, 3300 women developed type 2 diabetes, and the most important factor in its development was obesity.

Heart disease due to obesity (*adipositas cordis*) is caused by hypertension, hypervolemia, and dyslipidemia. Even before hypertension developed, Chinali and co-workers (2004) found evidence of abnormal left ventricular geometry and function in patients with the metabolic syndrome. Kenchaiah and colleagues (2002) reported a twofold risk for heart failure for women from the Framingham Heart Study who were either overweight or obese. Indeed, 14 percent of cases of heart failure were due to obesity alone. Ninomiya and co-workers (2004) found a twofold risk with the metabolic syndrome for myocardial infarction and stroke in the cohort from NHANES III.

Other common conditions that are increased in obesity are osteoarthritis and asthma.

Excessive weight is associated with increased early mortality, as shown by Peeters (2003) and Fontaine (2003) and their colleagues in follow-up studies from both the Framingham Heart Study and the NHANES III cohort. Results from a prospective study by Calle and associates (1999) are shown in [Figure 43-3](#). The mortality risk from cardiovascular disease and cancer increased directly with increasing BMI. A subsequent study by Calle and co-workers (2003) confirmed that mortality from all causes combined, as well as from cancer, was increased in obese and overweight persons.

Figure 43-3. Body mass index (BMI) and multivariate relative risk of death from various causes among nonsmoking women with no history of disease at enrollment. The reference category was made up of subjects with a BMI of 23.5 to 24.9 kg/m². The relative risk of death is plotted versus incremental BMI for cardiovascular disease (....), cancer (---), and all other causes (___). (From Calle and associates, 1999, with permission.)

TREATMENT OF OBESITY

Weight loss is tremendously difficult for obese individuals to accomplish. If achieved, long-term maintenance poses equivalent or even more daunting difficulties. There are innumerable methods espoused to help or even directly cause weight loss. The vast majority of these are patently dishonest charlatan schemes designed to extract money from overweight individuals, and even the most legitimate methods are fraught with frequent failure. If they are successful, slow and inexorable return to preintervention weight usually follows (National Institutes of Health Technology Assessment Conference Panel, 1993). Legitimate weight loss approaches include behavioral, pharmacological, and surgical techniques, or a combination of these methods (Yanovski and Yanovski, 2002).

PREGNANCY AND OBESITY

Obesity has been associated with subfertility due to increased insulin resistance (see [Table 43-2](#)). In their review, Neill and Nelson-Piercy (2001) linked impaired fecundity in women with a BMI in excess of 30 kg/m². In the many overweight and obese women who achieve pregnancy, there are a number of increased and interrelated adverse perinatal outcomes. **Marked obesity is unequivocally hazardous to the pregnant woman and her fetus.**

PREVALENCE. Because the overall prevalence of obesity has increased over the past several decades, the prevalence of obesity complicating pregnancy has also increased. Before adoption of the BMI, investigators used a variety of definitions of obesity to assess risks during pregnancy. For example, in the study shown in [Figure 43-4](#), four definitions were used. Regardless of how obesity was defined, all groups showed substantive increases in prevalence over the 20-year study. Ehrenberg and colleagues (2002) reported similar findings in a 15-year study in Cleveland.

Figure 43-4. Increasing prevalence of obesity during 20 years in pregnant women

classified at the time of their first prenatal visit at the University of Alabama at Birmingham. All women were classified into the first three categories shown on the graph. In approximately half of the women, height was available and they were classified by body mass index. (From Lu and colleagues, 2001, with permission.)

WEIGHT LOSS DURING PREGNANCY. Because maternal catabolism is, intuitively, not good for fetal growth and development, the Institute of Medicine (1992) recommends that even women who are obese (BMI of 30 kg/m² or higher) should not attempt weight loss during pregnancy. These women should, however, limit weight gain to less than 15 pounds. This aspect of prenatal care is discussed in [Chapter 8](#) (see p. 213).

MATERNAL MORBIDITY. Increased maternal morbidity results from obesity, defined variably as more than 150 percent of ideal body weight, BMI greater than 35 kg/m², BMI greater than 40 kg/m², and 150 pounds or more greater than ideal body weight (Bianco, 1998; Cedergren, 2004; Garbaciak, 1985; Isaacs, 1994; Kabiru and Raynor, 2004; Kumari, 2001, and all their colleagues). These investigators chronicled significantly increased incidences of a number of disorders including chronic hypertension, gestational diabetes, preeclampsia, fetal macrosomia, as well as higher rates of cesarean delivery and postpartum complications.

In a nurse-midwife practice, women whose BMI exceeded 29 kg/m² had a two- to fourfold increased cesarean delivery rate (Kaiser and Kirby, 2001). Similarly, in a physician private practice, the cesarean delivery rate for dystocia was increased sixfold in obese nulliparas (Young and Woodmansee, 2002). In another study, only 15 percent of obese women with a previous cesarean delivery succeeded in having a subsequent vaginal delivery (Chauhan and colleagues, 2001). These same investigators stratified women by BMI category and reported a successful trial of labor in 82 percent of women who weighed less than 200 lb, in 57 percent of those weighing 200 to 299 lb, and in only 13 percent of those weighing more than 300 lb (Carroll and collaborators, 2003). Although Edwards and co-workers (2003) reported a success rate of greater than 50 percent, they showed that costs for a planned trial of labor and elective cesarean delivery were equivalent.

Second-trimester dilatation and evacuation was reported to take longer and be more difficult in women whose BMI was 30 kg/m² or greater (Dark and co-workers, 2002).

In addition, there are reports of increased adverse pregnancy outcomes in overweight women with a BMI of 25 to 29.9 kg/m². Sebire and collaborators (2001) studied 287,213 singleton pregnancies delivered in the North West Thames Region of London. Their results are shown in [Table 43-3](#) according to BMI category. Cunningham and associates (1986) reported that obesity (weight greater than 200 pounds) and hypertension were common co-factors in causing peripartum heart failure. Myles and co-workers (2002) found that obesity was an independent risk factor for postcesarean infection morbidity. Finally, obese women are less likely to breast feed (Li and colleagues, 2003).

Preeclampsia. Obesity is a consistent risk factor for preeclampsia (Cedergren, 2004; Jensen and associates, 2003; Sebire and colleagues, 2001). In a review of studies that included over 1.4 million women, O'Brien and collaborators (2003) found that the preeclampsia risk doubled with each 5 to 7 kg/m² increase in prepregnancy BMI. In obese, nonpregnant individuals, at least some of the long-term cardiovascular morbidity was thought to be due to obesity-mediated systemic inflammation and endothelial dysfunction (Brook and associates, 2001). According to Davi and colleagues (2002), this phenomenon was associated more with android obesity (apple shape) than gynoid obesity (pear shape) — one characteristic of the metabolic syndrome discussed on page 1009. It has become apparent that endothelial activation plays an integral role in preeclampsia (see [Chap. 34](#), p. 769). Obesity is associated with low-grade inflammation, and Wolf and co-workers (2001) linked these two conditions by providing intriguing evidence that inflammation may explain, at least partly, the association of obesity with preeclampsia. More recently, Ramsay and collaborators (2002) confirmed that obese pregnant women had significantly elevated levels of serum interleukin-6 and C-reactive protein as well as evidence of impaired endothelial function. Specifically, 23 pregnant women with a median BMI of 31 kg/m² were compared with 24 with a median BMI of 22 kg/m². Obese women had significantly higher levels of triglycerides, very-low-density lipoprotein cholesterol, insulin, and leptin.

Long-Term Consequences. It is intuitive that excessive prepregnancy weight can be used to predict long-term obesity with its attendant morbidity and mortality. Rooney and Schauburger (2002), however, reported that excess weight gain during pregnancy — but not prepregnancy weight — is a predictor of long-term obesity. They followed 540 women postpartum for a mean duration of 8.5 years. During this period, the average weight gain was 6.3 kg. Women who had gained less than the recommended amount of weight during pregnancy were on average 4.1 kg heavier at the end of the follow-up period. Women who gained the recommended amount were 6.5 kg heavier. Finally, women who gained more than the recommended amount were 8.4 kg heavier.

Contraception. Oral contraceptive failure is more likely in overweight women. In reviewing studies on hormonal contraceptive efficacy, it is apparent that the typical study subject is not representative of the average American woman. As discussed earlier, at least 50 percent of American women have a BMI greater than 25 kg/m² and thus are considered to be overweight (see [Table 43-2](#)). In contraceptive studies, however, the majority of subjects have a BMI between 18 and 28 kg/m² (Holt and co-workers, 2002; Ziemann and collaborators, 2002). In one study, the mean serum medroxyprogesterone acetate concentration was lower in the women with a BMI greater than 28 kg/m² compared with that of those with a lower BMI (Rahimy and associates, 1999). Efficacy of the Ortho-Evra patch was studied by Ziemann and colleagues (2002). In their analysis of the pooled data from three multicenter studies, they found a significant association between increasing body weight and contraceptive failure. Holt and colleagues (2002) studied 755 women with 2822 person-years of pill use and found that those in the highest weight quartile (70.5 kg or more) had a 1.6-fold increased risk of pregnancy. Importantly, women in this quartile who used very-low-dose oral contraceptives had a four- to fivefold increased pregnancy rate (see [Chap. 32](#), p. 727).

PERINATAL MORBIDITY AND MORTALITY. Both fetal and neonatal complications are

increased in obese women. For example, obese women, variably defined, have a two- to threefold risk for a fetus with a neural-tube defect or other anomalies (Mikhail, 1996; Waller, 1994; Werler, 1996, and all their collaborators). In another study, Shaw and colleagues (1996, 2000) reported that women with a BMI of 30 kg/m² or more had a twofold increased incidence of neural-tube defects compared with that of control women. In a case-control study from the Atlantic Birth Defects Risk Factor Surveillance Study, Watkins and associates (2003) reported a 3.5-fold increase in neural-tube defects in obese women. They also found a two- to threefold increased incidence in omphalocele, heart defects, and multiple anomalies. The last two were also increased twofold in overweight women whose BMI was 25 to 29.9 kg/m².

Two important and interrelated co-factors that contribute to excessive perinatal morbidity and mortality are chronic hypertension and diabetes mellitus, both of which are associated with obesity (Stephansson and colleagues, 2001). Chronic hypertension is a well-known cause of fetal growth restriction (see [Chap. 45](#), p. 1047). Pregestational diabetes increases the rate of birth defects. Gestational diabetes is complicated by excessive numbers of large-for-gestational age and macrosomic infants (see [Chap. 38](#), p. 905). Whatever the cause(s), the prevalence of macrosomic infants is increased in obese women (Bianco and co-workers, 1998; Cedergren, 2004; Isaacs and associates, 1994). There are also long-term sequelae for macrosomic infants born to these mothers. Low-birthweight infants have lower subsequent risks of type 2 diabetes, insulin resistance, and metabolic syndrome, whereas infants who weigh more than 4000 g have increased risks (Innes and colleagues, 2002). From preliminary observations, Armstrong and colleagues (2002) reported that breast feeding decreases the risk of childhood obesity in these large infants. Alternatively, Ruowei and co-workers (2003) reported that obese women were less likely to breast feed.

An increased incidence of otherwise inexplicable late-pregnancy stillbirths has been associated with obesity. Cnattingius and colleagues (1998) found a significant 1.6-fold increase in the stillbirth rate in women with a BMI of 25 to 29.9 kg/m². The rate was increased 2.6-fold for women with a BMI of 30 kg/m² or more. In addition, early neonatal death was nearly doubled in nulliparous women with a BMI of 30 kg/m² or higher. Stephansson and associates (2001) used the same database for a case-control study of 649 nulliparas who had stillbirths. They confirmed an almost threefold late-stillbirth rate in women with a BMI of greater than 25 kg/m². They attributed the increase to socioeconomic deprivation and pregnancy complications, particularly preeclampsia and diabetes. Baydock and Chari (2002) found that a prepregnancy BMI of greater than 30 kg/m² was an independent risk factor for stillbirth.

MANAGEMENT. A program of weight reduction is probably unrealistic during pregnancy. If such a regimen is chosen, however, it is mandatory that the quality of the diet be monitored closely and that ketosis be avoided (Rizzo and associates, 1991). Close prenatal surveillance detects most early signs of diabetes or hypertension. Standard screening tests for fetal anomalies are sufficient. Accurate assessment of fetal growth usually requires serial sonography. Wolfe and colleagues (1990) have highlighted the technical difficulties with ultrasonic fetal visualization in women with a BMI above the 90th percentile. Antepartum and intrapartum fetal heart rate monitoring are likewise made more difficult, and sometimes these are even impossible.

Evaluation by anesthesia personnel is performed at a prenatal visit or on arrival at the labor unit (American College of Obstetricians and Gynecologists, 2002). Anesthetic risks and complications faced by obese women are discussed in [Chapter 19](#) (see p. 489). Special attention to complications that might arise during labor and delivery is mandatory. For cesarean delivery, forethought is given to optimal placement and type of abdominal incision to access the fetus and to the intervening tissue thickness. Individual differences in maternal body habitus preclude any one approach as superior (Gilstrap and colleagues, 2002). Meticulous attention to achieving a structurally secure closure is mandatory.

PREGNANCY FOLLOWING SURGICAL PROCEDURES FOR OBESITY. A

number of surgical procedures have been designed to treat morbid obesity by either decreasing gastric volume or bypassing gastrointestinal absorption (Brolin, 2002; Yanovski and Yanovski, 1999). Buchwald and associates (2004) in a meta-analysis found these procedures to improve or resolve diabetes, hyperlipidemia, hypertension, and obstruction sleep apnea. Although none are recommended during pregnancy, invariably more women will become pregnant subsequent to these procedures as their popularity grows (Sheiner and associates, 2004). According to the American Society for Bariatric Surgery (2003), there were 47,000 surgeries for obesity in 2001, 63,000 in 2002, and over 100,000 for 2003 (Mitka, 2003; Steinbrook, 2004).

Jejunioileal Bypass. This was one of the earliest surgical methods that was successful for weight loss. In this procedure, the duodenum is divided and anastomosed to the terminal jejunum very near the ileocecal junction. Thus, the vast majority of the small bowel is bypassed with resultant diminished food absorption. This procedure was followed by significant long-term morbidity and mortality, and it has been abandoned by most surgeons. Older reports chronicled shorter gestations, lower mean birthweight, and more small-for-gestational-age infants after weight reduction (Knudsen and Kallen, 1986).

Gastric Bypass. This older procedure excludes the lower 90 percent of the stomach by creating an upper gastrojejunostomy. Printen and Scott (1982) described 51 pregnancies in 45 morbidly obese women who had antenatal gastric bypass surgery. Complications were uncommon, and fetal growth restriction was not increased in the 46 infants delivered. Richards and colleagues (1987) reported similar experiences with 57 pregnancies at the University of Utah. These women weighed an average of 194 pounds before and 147 pounds after surgery. Compared with preprocedure pregnancies, mean birthweight decreased from 3600 to 3200 g, and the incidence of large-for-gestational-age infants decreased from 37 to 16 percent. Impressively, the incidence of pregnancy-associated hypertension fell from 46 to 9 percent.

Gastroplasty. There are several variations of surgical gastroplasty in which a narrow channel is created through the stomach by using stapling devices. The *vertical-banded gastroplasty* is the most popular bariatric procedure performed currently (Brunicardi and associates, 2001). Subsequent pregnancy outcomes have been chronicled. Bilenka and colleagues (1995) described 14 pregnancies in nine women who had undergone the procedure. The mean weight loss was 80 pounds, and the women had fewer complications compared with their preprocedure pregnancies. Martin and co-workers (2000) described 23 pregnancies in women after *adjustable gastric banding*. For three women with excessive nausea and vomiting, band adjustment to decrease obstruction was successful. Dixon and associates (2001) described 22 pregnancies in 20 women who were using the Lap-Band System. In this method, the gastric band is laparoscopically placed 2 cm below the gastroesophageal junction. An internal balloon reservoir is adjusted by saline instillation into percutaneously placed tubing. The mean weight loss

before pregnancy was 30 kg. Weight gain during pregnancy averaged 8.3 kg, and there were few complications. Mean birthweights of infants were similar before and after maternal banding.

Roux-en-Y Bypass. This type of bypass is the most effective bariatric procedure currently in use (Brunicardi and associates, 2001). It most often is performed laparoscopically. The procedure is depicted in [Figure 43-5](#). The proximal stomach is transected to leave a 30-mL pouch. A gastroenterotomy is made by connecting the proximal end of the distal jejunum which was divided 60 cm distal to the ligament of Treitz. The Roux-en-Y enteroenterostomy is completed 60 cm distal to the gastrojejunostomy. Brunicardi and colleagues (2001) summarized four series totaling almost 400 men and nonpregnant women. Mean weight loss at 1 year in the four series ranged from 21 to 43 kg. In the largest study, at 1 year, 300 patients had lost a mean of 80 percent of their excessive weight. At 5 years, 50 to 75 percent of the weight loss had been maintained, and at 14 years maintenance of lost weight still exceeded 50 percent (American Society of Bariatric Surgery, 2003). Current costs are \$20,000 to \$50,000 (Steinbrook, 2004).

Wittgrove and associates (1998) described 49 pregnancies in 36 women after a Roux-en-Y bypass. There were 17 who had delivered at least one child prior to surgery. When prior pregnancy outcomes were compared with those after bypass, there was a dramatic reduction in hypertension (40 versus 0 percent), diabetes (24 versus 0 percent), and infant weight greater than 4000 g (30 versus 5 percent). At least one maternal death from herniation and obstruction has been reported (Moore and colleagues, 2004).

Figure 43-5. Roux-en-Y gastric bypass. A stapler fired across the cardia of the stomach creates a 20- to 30-mL pouch. The jejunum is divided distal to the ligament of Treitz with the distal end anastomosed to the upper stomach. (From Brolin, 2002, with permission.)

or oncogenic effect (see [Chap. 41](#), p. 981). Thallium²⁰¹ is used to evaluate regional coronary perfusion. A standard dose yields a fetal exposure of 300 to 1100 mrad and depends on the stage of gestation. If indicated, right-sided heart catheterization can be performed with limited fluoroscopy. On rare occasions, it may be necessary to perform left-sided heart catheterization. In women with clear indications, any minimal theoretical risk is outweighed by maternal benefits.

Electrocardiography. As the diaphragm is elevated in advancing pregnancy, there is an average 15-degree left-axis deviation in the electrocardiogram (ECG), and mild ST changes may be seen in the inferior leads. Atrial and ventricular premature contractions are relatively frequent (Carruth and colleagues, 1981). Pregnancy does not alter voltage findings.

Chest Radiography. Anteroposterior and lateral chest radiographs may be useful when heart disease is suspected clinically. When used with a lead apron shield, fetal radiation exposure is minimized (see [Chap. 41](#), p. 979). Slight heart enlargement cannot be detected accurately by radiography because the heart silhouette normally is larger in pregnancy. That said, gross cardiomegaly can usually be excluded.

Echocardiography. The widespread use of echocardiography has allowed accurate diagnosis of most heart diseases during pregnancy. It allows noninvasive evaluation of structural and functional cardiac factors. Some normal pregnancy-induced changes include tricuspid regurgitation as well as significantly increased left atrial size and left ventricular outflow cross-sectional area (Limacher and co-workers, 1985).

CLINICAL CLASSIFICATION. There is no clinically applicable test for accurately measuring functional cardiac capacity. A helpful clinical classification was first published in 1928 by the New York Heart Association (NYHA) and was revised for the eighth time in 1979. This classification is based on past and present disability and is uninfluenced by physical signs.

- **Class I.** *Uncompromised (no limitation of physical activity):* These women do not have symptoms of cardiac insufficiency or experience anginal pain.
- **Class II.** *Slight limitation of physical activity:* These women are comfortable at rest, but if ordinary physical activity is undertaken, discomfort results in the form of excessive fatigue, palpitation, dyspnea, or anginal pain.
- **Class III.** *Marked limitation of physical activity:* These women are comfortable at rest, but less than ordinary activity causes excessive fatigue, palpitation, dyspnea, or anginal pain.
- **Class IV.** *Severely compromised (inability to perform any physical activity without discomfort):* Symptoms of cardiac insufficiency or angina may develop even at rest, and if any physical activity is undertaken, discomfort is increased.

Siu and associates (2001) expanded on the NYHA classification and developed a scoring system for predicting cardiac complications during pregnancy based on their prospective analysis of 562 consecutive pregnant women with heart disease in 13 Canadian teaching hospitals. Predictors of cardiac complications included the following:

1. Prior heart failure, transient ischemic attack, arrhythmia, or stroke.
2. Baseline NYHA class III or greater or cyanosis.
3. Left-sided heart obstruction defined as mitral valve area below 2 cm², aortic valve area below 1.5 cm², or peak left ventricular outflow tract gradient above 30 mm Hg by echocardiography.
4. Ejection fraction less than 40 percent.

The risk of pulmonary edema, sustained arrhythmia, stroke, cardiac arrest, or cardiac death was substantively increased with one of these factors and even more so with two or more factors.

In another study of 1000 pregnant women with heart disease from Brazil, Avila and co-workers (2003) reported that 25 percent had cardiovascular complications during pregnancy. These included heart failure (12 percent), arrhythmias (6 percent), thromboembolism, angina, hypoxemia, and infective endocarditis. Maternal mortality was 2.7 percent.

PRECONCEPTIONAL COUNSELING. Women with heart disease may benefit from counseling before deciding to become pregnant (see [Chap. 7](#), p. 192). Maternal mortality generally varies directly with functional classification at pregnancy onset, however, this relationship may change as pregnancy progresses. In the study cited earlier, Siu and colleagues (2001) observed a 6-percent incidence of heart failure in nearly 600 women with NYHA class I or II disease. Their experiences, as well as those of McFaul and co-workers (1988), were that there were no maternal deaths in 1041 of women with class I or II disease.

In some women, life-threatening cardiac abnormalities can be reversed by corrective surgery, and subsequent pregnancy is less dangerous. In other cases, such as women with mechanical valves and those who are taking warfarin, fetal considerations predominate. The classification scheme shown in [Table 44-3](#) stratifies the mortality risk to aid in counseling.

Congenital Heart Disease in Offspring. Many congenital heart lesions appear to be inherited as polygenic characteristics (see [Chap. 12](#), p. 302). Thus, it might be expected that some women with congenital lesions would give birth to similarly affected infants. In general, the risk of congenital heart disease in the offspring of a woman with a particular condition is approximately 3 to 4 percent (Lupton and colleagues, 2002). More specific estimates are presented in [Table 44-4](#).

GENERAL MANAGEMENT

In most instances, management involves a team approach, including an obstetrician, cardiologist, anesthesiologist, and other specialists as needed. Cardiovascular changes likely to be poorly tolerated by an individual woman are identified, and a plan is

formulated to minimize these. Four changes that affect management are emphasized by the American College of Obstetricians and Gynecologists (1992):

1. The 50-percent increase in blood volume and cardiac output by the early third trimester.
2. Further fluctuations in volume and cardiac output in the peripartum period.
3. A decline in systemic vascular resistance, reaching a nadir in the second trimester, and then rising to 20 percent below normal by late pregnancy.
4. Hypercoagulability, of special importance in women requiring anticoagulation before pregnancy with coumarin derivatives.

Within this framework, both prognosis and management are influenced by the nature and severity of the specific lesion, in addition to the functional classification.

MANAGEMENT OF CLASS I AND II DISEASE. With rare exceptions, women in NYHA class I and most in class II go through pregnancy without morbidity. Special attention should be directed toward both prevention and early recognition of heart failure. As discussed in a scholarly review by Jessup and Brozena (2003), the onset of congestive heart failure is generally gradual. The first warning sign is likely to be persistent basilar rales, frequently accompanied by a nocturnal cough. A sudden diminution in ability to carry out usual duties, increasing dyspnea on exertion, or attacks of smothering with cough are symptoms of serious heart failure. Clinical findings may include hemoptysis, progressive edema, and tachycardia.

Infection with sepsis syndrome is an important factor in precipitating cardiac failure. Moreover, bacterial endocarditis is a deadly complication of valvular heart disease. Each woman should receive instructions to avoid contact with persons who have respiratory infections, including the common cold, and to report at once any evidence for infection. Pneumococcal and influenza vaccines are recommended.

Cigarette smoking is prohibited, both because of its cardiac effects as well as the propensity to cause upper respiratory infections. Illicit drug use may be particularly harmful, given the cardiovascular effects of cocaine or amphetamines, in addition to the propensity for intravenous use of any illegal substance to cause infective endocarditis.

Labor and Delivery. In general, delivery should be accomplished vaginally unless there are obstetrical indications for cesarean delivery. Induction is generally safe (Oron and colleagues, 2004). As discussed in [Chapter 42](#) (see p. 989), *pulmonary artery catheterization* may be indicated for continuous hemodynamic monitoring in some women with heart disease. In our experience, such monitoring is rarely indicated, especially in women who have remained in functional NYHA class I or II.

Relief from pain and apprehension is especially important. Although intravenous analgesics provide satisfactory pain relief for some women, continuous epidural analgesia is recommended in most cases. The major problem with conduction analgesia is maternal hypotension (see [Chap. 19](#), p. 484). This is especially dangerous in women with intracardiac shunts, in whom flow may be reversed, with blood passing from right to left within the heart or aorta, thereby bypassing the lungs. Hypotension can be life-threatening with pulmonary hypertension or aortic stenosis because ventricular output is dependent on adequate preload. In women with these conditions, narcotic conduction analgesia or general anesthesia may be preferable.

During labor, the mother with significant heart disease should be kept in a semirecumbent position with lateral tilt. Vital signs should be taken frequently between contractions. Increases in pulse rate much above 100 per minute or in the respiratory rate above 24 per minute, particularly when associated with dyspnea, may suggest impending ventricular failure. If there is any evidence of cardiac decompensation, intensive medical management must be instituted immediately. It is essential to remember that delivery itself does not necessarily improve the maternal condition. Moreover, emergency operative delivery may be particularly hazardous. Clearly, both maternal and fetal conditions must be considered in the decision to hasten delivery under these circumstances.

For vaginal delivery in women with only mild cardiovascular compromise, epidural analgesia given along with intravenous sedation often suffices. This has been shown to minimize intrapartum cardiac output fluctuations and allows forceps or vacuum-assisted delivery. Subarachnoid blockade is not generally recommended in women with significant heart disease. For cesarean delivery, epidural analgesia is preferred by most clinicians with caveats for its use with pulmonary hypertension. Finally, general endotracheal anesthesia with thiopental, succinylcholine, nitrous oxide, and at least 30-percent oxygen has also proved satisfactory (see [Chap. 19](#), p. 488).

INTRAPARTUM HEART FAILURE. Cardiovascular decompensation during labor may manifest as pulmonary edema and hypoxia, hypotension, or both. The proper therapeutic approach depends on the specific hemodynamic status and the underlying cardiac lesion. For example, decompensated mitral stenosis with pulmonary edema due to fluid overload is often best approached with aggressive diuresis, or if precipitated by tachycardia, by heart rate control with β -blocking agents. On the other hand, the same treatment in a woman suffering decompensation and hypotension due to aortic stenosis could prove fatal. **Unless the underlying pathophysiology is understood and the cause of the decompensation clear, empirical therapy is hazardous.**

Puerperium. Women who have shown little or no evidence of cardiac distress during pregnancy, labor, or delivery may still decompensate postpartum. Therefore, it is important that meticulous care be continued into the puerperium. Postpartum hemorrhage, anemia, infection, and thromboembolism are much more serious complications with heart disease. Indeed, these factors often act in concert to precipitate postpartum heart failure in women with underlying disease (Cunningham and associates, 1986).

If tubal sterilization is to be performed after vaginal delivery, it may be best to delay the procedure until it is obvious that the mother is afebrile, not anemic, and has demonstrated that she can ambulate without evidence of distress. Women who do not undergo tubal sterilization should be given detailed contraceptive advice. Special considerations for contraception in women

with various cardiac disorders are discussed in some of the following sections and throughout [Chapter 32](#).

MANAGEMENT OF CLASS III AND IV DISEASE. These severe cases are uncommon today. In the Canadian study by Siu and associates (2001) cited earlier, only 3 percent of the women had NYHA class III heart disease, and none had class IV when first seen. The important question in these women is whether pregnancy should be undertaken. If women choose to become pregnant, they must understand the risks and cooperate fully with planned care. If seen early enough, women with some types of severe cardiac disease should consider pregnancy interruption. If the pregnancy is continued, prolonged hospitalization or bed rest is often necessary.

Epidural analgesia for labor and delivery is usually recommended. Vaginal delivery is preferred in most cases, and labor induction can usually be done safely (Oron and associates, 2004). Cesarean delivery is limited to obstetrical indications. The decision for cesarean delivery must take into account the specific cardiac lesion, overall maternal condition, availability and experience of anesthetic support, as well as physical facilities. These women often tolerate major surgical procedures poorly and should be delivered in a facility with experience with complicated cardiac disease.

SURGICALLY CORRECTED HEART DISEASE

The majority of clinically significant lesions are repaired during childhood. Examples of defects not diagnosed until adulthood include atrial septal defects, pulmonic stenosis, bicuspid aortic valve, and aortic coarctation (Brickner and colleagues, 2000). In some cases, the defect is mild and surgery is not required. In others, a significant structural anomaly is amenable to surgical correction. With successful repair, many women attempt pregnancy. In some instances, surgical corrections have been performed during pregnancy.

VALVE REPLACEMENT BEFORE PREGNANCY. A number of reproductive-aged women have had a prosthesis implanted to replace a severely damaged mitral or aortic valve. Reports of subsequent pregnancy outcomes are now quite numerous, and indeed, successful pregnancies have followed prosthetic replacement of even three heart valves (Nagorney and Field, 1981).

Effects on Pregnancy. Pregnancy is to be undertaken in these women only after serious consideration. Women with a *mechanical valve prosthesis* must be anticoagulated, and when not pregnant, warfarin is recommended. As shown in [Table 44-5](#), a number of serious complications can develop, especially with mechanical valves. Thromboembolism involving the prosthesis and hemorrhage from anticoagulation are of extreme concern (Nassar and co-workers, 2004). There also may be deterioration in cardiac function. Overall, maternal mortality is 3 to 4 percent with mechanical valves, and fetal loss is common.

The critical issue is anticoagulation, and there is a suggestion that heparin may be less effective than warfarin in preventing thromboembolic events. Unfortunately, spontaneous abortions, stillbirths, and malformed fetuses are more common if warfarin is used (see [Chap. 14](#), p. 349). The results shown in [Table 44-5](#) are similar to those reported by Chan and colleagues (2000) in their review. They concluded that better maternal outcomes were achieved with continuation of warfarin throughout pregnancy, however, the embryopathy rate was 6.4 percent. Heparin substitution from 6 to 12 weeks eliminated embryopathy, but thromboembolic complications significantly increased. Cotrufo and colleagues (2002) described the outcomes of 71 pregnancies in women with mechanical valve prostheses who were anticoagulated with warfarin for the entire duration of pregnancy. Although there were no maternal deaths or thromboembolic or hemorrhagic complications, the rates of miscarriage (32 percent), stillbirth (7 percent), and embryopathy (6 percent) were all increased. The risk of complications was higher when the mean daily dose of warfarin exceeded 5 mg.

Low-dose unfractionated heparin is definitely inadequate. Iturbe-Alessio and colleagues (1986) reported that 3 of 35 women on such therapy suffered massive thrombosis of a mitral prosthesis — two of these died. Similarly, Chan and co-workers (2000) found in their review that two of five women treated solely with low-dose heparin during pregnancy died. Low-molecular-weight heparin also is problematic because of reports of valvular thrombosis in patients, especially pregnant women, who were apparently adequately anticoagulated (Leyh and colleagues, 2002, 2003; Rowan and associates, 2001). Following such reports and a warning issued by Aventis Pharmaceuticals, the American College of Obstetricians and Gynecologists (2002) advises against use of low-molecular-weight heparins in pregnant women with prosthetic heart valves. Potential alternatives that need further evaluation include antiplatelet therapy with dipyridamole, ticlopidine, and aspirin (Ueno and collaborators, 2001). Nassar and co-workers (2003) have described the use of thrombolytic agents for a thrombosed mitral valve prosthesis during pregnancy.

Porcine tissue valves are much safer during pregnancy (see [Table 44-5](#)), primarily because anticoagulation is not required. Deviri and colleagues (1985) reported no thromboses during 22 pregnancies in 11 unanticoagulated women with a porcine xenograft. Lee and associates (1994) described generally good outcomes in 95 pregnancies in 57 women with a porcine graft. That said, valvular dysfunction with heart failure has been common (see [Table 44-5](#)). Additionally, although such bioprostheses are less thrombogenic, they are not as durable as mechanical prostheses. Their use necessitates the acceptance of another valve replacement in 10 to 15 years. Fortunately, pregnancy does not appear to shorten this interval (North and colleagues, 1999; Salazar and co-workers, 1999).

Management. For women with a mechanical heart valve, most clinicians recommend full anticoagulation throughout pregnancy (American College of Obstetricians and Gynecologists, 2000). This may be accomplished with adjusted-dose heparin to prolong the partial thromboplastin time by 1.5 to 2.5 times baseline values (see [Chap. 47](#), p. 1082). The American Heart Association and American College of Cardiology Foundation recommend that if unfractionated heparin is used, it should be given subcutaneously twice daily, starting at a total dose of 35,000 U. Laboratory monitoring should be performed at least twice weekly (Hirsh and colleagues, 2003). Alternatively, Reimold and Rutherford (2003) recommend the use of warfarin to achieve a target international normalized ratio of 2.0 to 3.0 throughout most of pregnancy. Between 6 and 12 weeks and again after 36 weeks, they use unfractionated heparin.

Heparin is stopped just before delivery. If delivery supervenes while the anticoagulant is still effective, and extensive bleeding is encountered, *protamine sulfate* is given intravenously. Anticoagulant therapy with warfarin or heparin may be restarted 6

hours following vaginal delivery, usually with no problems. Following cesarean delivery, however, full anticoagulation should be withheld for at least 24 hours. Clark and colleagues (2000) reviewed the use of coumarin derivatives in breast feeding women and concluded that warfarin can be safely give, because transfer to milk is minimal.

CONTRACEPTION. Because of their possible thrombogenic action, estrogen-progestin oral contraceptives are relatively contraindicated in women with prosthetic valves (see [Chap. 32](#), p. 732). Because such women are generally fully anticoagulated, however, any increased risk is speculative. Sterilization should be considered because of serious problems during pregnancy.

VALVE REPLACEMENT DURING PREGNANCY. Although usually postponed until after delivery, valve replacement during pregnancy may be lifesaving. A number of reviews all confirm that surgery on the heart or great vessels is associated with major maternal and fetal morbidity and mortality. Weiss and colleagues (1998a) reviewed cases between 1984 and 1996. In 70 women, 59 of whom had cardiopulmonary bypass, maternal mortality was 6 percent and perinatal mortality was 30 percent. With valvular surgery, maternal mortality was 9 percent. More recently, Arnoni and associates (2003) reviewed the outcomes of 58 such women from Brazil. The maternal mortality rate was 8 percent, and 18 percent of the fetuses died as a direct result of the surgery. They concluded that mortality might be reduced by performing procedures earlier in gestation, avoiding emergency operations, and minimizing bypass time.

Strickland and colleagues (1991) reported the Mayo Clinic experience in 10 women undergoing cardiopulmonary bypass with pump times ranging from 18 to 154 minutes. The fetal response to bypass was usually bradycardia, and the investigators recommended that high-flow, normothermic perfusion be used if possible. Khandelwal and associates (1996) meticulously recorded fetal and uterine blood flow velocity patterns during a 74-minute bypass procedure at 19 weeks for aortic valve replacement. Despite high peak flow rates and sustained mean arterial pressures, uterine and umbilical artery resistances increased greatly, and fetal hydrocephalus and ascites developed within 2 days.

MITRAL VALVOTOMY DURING PREGNANCY. This operation is less commonly performed because the incidence of rheumatic mitral stenosis has declined. Schenker and Polishuk (1968) described 325 pregnancies in 182 women who previously had undergone mitral valvotomy. Heart failure developed in 42 percent of these women at some point during their first pregnancy following valvular surgery. This percentage increased with successive pregnancies, and women suffering heart failure in one pregnancy inevitably had recurrence in subsequent pregnancies. Coexisting atrial fibrillation was especially ominous and commonly was associated with heart failure, thromboembolic disease, and death.

In the past, tight mitral stenosis that required intervention during pregnancy usually was treated surgically by closed mitral valvotomy (Pavankumar and associates, 1988). In the past 25 years, percutaneous transcatheter balloon dilatation of the mitral valve has largely replaced surgical valvotomy during pregnancy (Abouzieed, 2001; Gupta, 1998; Malhotra, 2003, and all their associates). In one series, de Souza and colleagues (2001a) described 24 consecutive pregnant women who underwent open mitral commissurotomy between 1985 and 1990 and compared them with 21 consecutive pregnant women who underwent percutaneous balloon mitral valvuloplasty between 1990 and 1995. The one maternal death occurred in the open-repair group. The balloon procedure was over 90-percent successful, and functional outcomes between the two groups were similar. Perinatal mortality was sixfold higher in the open repair group (33 versus 5 percent). The investigators rightfully concluded that balloon valvuloplasty is the treatment of choice for refractory congestive heart failure in pregnant women.

HEART TRANSPLANTATION. By 1994, the registry of the International Society for Heart and Lung Transplantation had compiled data from more than 30,000 heart and heart-lung transplant operations (Hosenpud and associates, 1994). The procedure increasingly has become more successful, especially since more efficacious medications to prevent vasculopathy and rejection of the allograft have become available (Eisen and co-workers, 2003). It is now estimated that at least two thirds of recipients are fully functional following heart transplantation (Kapp, 2003). In a remarkable example, a 42-year-old female heart transplant recipient climbed Mount Whitney with two different hearts, and subsequently, she scaled Mount Kilimanjaro and the Matterhorn (Kapp, 2003)!

In 1988, Lowenstein and associates reported the first successful pregnancy in a heart transplant recipient. Key and associates (1989) as well as Kim and colleagues (1996) provided detailed data to show that the transplanted heart responded normally to pregnancy-induced changes. Complications are common during pregnancy. Armenti and associates (2001) analyzed 48 pregnancies in 27 heart transplant recipients entered into the National Transplantation Pregnancy Registry. Fifty percent developed hypertension, 22 percent suffered at least one rejection episode during pregnancy, and almost 50 percent delivered preterm. At follow-up, five women had died, all at more than 2 years postpartum. Similar results were reported by Dashe and associates (1998) in their review.

VALVULAR HEART DISEASE

Rheumatic fever is uncommon in the United States because of less crowded living conditions, availability of penicillin, and evolution of nonrheumatogenic streptococcal strains. Still, it remains the chief cause of serious mitral valvular disease.

MITRAL STENOSIS. Rheumatic endocarditis causes three fourths of cases of mitral stenosis. The contracted valve impedes blood flow from the left atrium to the ventricle. As shown in [Table 44-6](#), with tight stenosis, the left atrium is dilated, left atrial pressure is chronically elevated, and significant passive pulmonary hypertension may develop. The increased preload of normal pregnancy, as well as other factors that require increased cardiac output, may cause ventricular failure with pulmonary edema in these women with relatively fixed cardiac output. Indeed, 25 percent of women with mitral stenosis have cardiac failure for the first time during pregnancy (Caulin-Glaser and Setaro, 1999). In some women, this may be confused with idiopathic peripartum cardiomyopathy (Cunningham and colleagues, 1986).

The normal mitral valve surface area is 4.0 cm². When stenosis narrows this to less than 2.5 cm², symptoms usually develop (Desai and colleagues, 2000). The most prominent complaint is dyspnea due to pulmonary venous hypertension and pulmonary edema. Other common symptoms are fatigue, palpitations, cough, and hemoptysis.

With significant mitral stenosis, tachycardia shortens ventricular diastolic filling time and increases the mitral gradient, which raises left atrial and pulmonary venous and capillary pressures and may result in pulmonary edema. Thus, sinus tachycardia is often treated prophylactically with β -blocking agents. Atrial tachyarrhythmias, including fibrillation, are common in mitral stenosis and are treated aggressively with cardioversion if necessary. Atrial fibrillation also predisposes to mural thrombus formation and cerebrovascular embolization, causing stroke (see [Chap. 55](#), p. 1234).

Hameed and associates (2001) described the outcomes of 66 pregnancies in 64 women with valvular heart disease managed at the University of Southern California Medical Center between 1979 and 1998. Of the 46 women with mitral stenosis, heart failure (43 percent) and arrhythmias (20 percent) were frequent complications. Fetal growth restriction was more common in those women with severe stenosis defined as a valvular area less than 1.0 cm^2 . Maternal prognosis is also related to functional capacity. Among 486 pregnancies complicated by rheumatic heart disease, predominantly mitral stenosis, Sawhney and associates (2003) reported that 8 of 10 maternal deaths were in women in NYHA classes III or IV.

Management. Limited physical activity is generally recommended. If symptoms of pulmonary congestion develop, activity is further reduced, dietary sodium is restricted, and diuretic therapy is started (Siva and Shah, 2005). A β -blocker drug can be given to slow heart rate response to activity and anxiety (Al Kasab and associates, 1990). If new-onset atrial fibrillation develops, intravenous verapamil, 5 to 10 mg, is given, or electrocardioversion is performed. For chronic fibrillation, digoxin or a β -blocker or calcium channel blocker is given to slow ventricular response. Anticoagulation with heparin is also indicated.

Labor and delivery are particularly stressful for women with tight mitral stenosis. Pain, exertion, and anxiety cause tachycardia, with possible rate-related heart failure. Epidural analgesia for labor, with strict attention to avoid intravenous fluid overload, is ideal. Abrupt increases in preload may lead to increased pulmonary capillary pressure and pulmonary edema. Thus, care must be taken to avoid fluid overload (Ramin and Gilstrap, 1999). As shown in [Figure 44-2](#), pulmonary capillary wedge pressures increase even more immediately postpartum. Clark and colleagues (1985) hypothesize that this is likely due to loss of the low-resistance placental circulation as well as "autotransfusion" from the lower extremities, pelvis, and the now empty uterus.

Vaginal delivery is preferable, and some authors recommend elective induction so that labor and delivery can be monitored and attended by the most knowledgeable team. In women with severe stenosis with chronic heart failure, insertion of a pulmonary artery catheter may help guide management decisions. Intrapartum endocarditis prophylaxis, as discussed on p. 1033, may be required.

Figure 44-2. Intrapartum alterations in pulmonary capillary wedge pressure in eight women with mitral valve stenosis. **A.** First-stage labor. **B.** Second-stage labor, 15 to 30 minutes before delivery. **C.** Postpartum 5 to 15 minutes. **D.** Postpartum 4 to 6 hours. **E.** Postpartum 18 to 24 hours. (From Clark and colleagues, 1985, with permission.)

MITRAL INSUFFICIENCY. Mitral regurgitation develops when there is improper coaptation of mitral valve leaflets during systole. This is eventually followed by left ventricular dilatation and eccentric hypertrophy (see [Table 44-6](#)). Chronic mitral regurgitation may have a number of causes, including rheumatic fever, mitral valve prolapse, or left ventricular dilatation of any etiology (e.g., dilated cardiomyopathy). Less common causes include a calcified mitral annulus, possibly some appetite suppressants, and in older women, ischemic heart disease. Mitral valve vegetations, known as *Libman-Sacks endocarditis*, are relatively common in women with antiphospholipid antibodies (Roldan and colleagues, 1996). These may or may not coexist with systemic lupus erythematosus (see [Chap. 54](#), p. 1217). Acute mitral insufficiency is caused by rupture of a chorda tendineae, infarction of papillary muscle, or leaflet perforation from infective endocarditis.

In nonpregnant patients, symptoms from mitral valve incompetence are rare, and valve replacement is seldom indicated, except for infective endocarditis. Likewise, mitral regurgitation is well tolerated during pregnancy, probably because of decreased systemic vascular resistance, which actually results in less regurgitation. Heart failure only rarely develops during pregnancy, and occasionally tachyarrhythmias need to be treated. Intrapartum prophylaxis against bacterial endocarditis may be indicated (see p. 1033).

AORTIC STENOSIS. Stenosis of the aortic valve is a disease of aging, and in a woman younger than 30 years of age, it is most likely due to a congenital lesion. The lesion is less common since the decline in incidence of rheumatic diseases. In the United States, the most common stenotic lesion is a bicuspid valve. Stenosis reduces the normal 2- to 3- cm^2 aortic orifice and creates resistance to ejection. Reduction in the valve area to a fourth its normal size produces severe obstruction to flow and a progressive pressure overload on the left ventricle (Carabello, 2002). Concentric left ventricular hypertrophy follows, and if severe, end-diastolic pressures become elevated, ejection fraction declines, and cardiac output is reduced (see [Table 44-6](#)). Characteristic clinical manifestations develop late and include chest pain, syncope, heart failure, and sudden death from arrhythmias. Life expectancy averages only 5 years after exertional chest pain develops, and valve replacement is indicated for symptomatic patients.

Clinically significant aortic stenosis is uncommonly encountered during pregnancy. Although mild to moderate degrees of stenosis are well tolerated, severe disease is life threatening. The principal underlying hemodynamic problem is the fixed cardiac output associated with severe stenosis. During pregnancy, a number of factors commonly decrease preload further and thus aggravate the fixed cardiac output. Some examples include blood loss, regional analgesia, and vena caval occlusion. Importantly, all of these factors decrease cardiac, cerebral, and uterine perfusion. Because of these considerations, severe aortic stenosis may be extremely dangerous during pregnancy. Indeed, reports after 1975 describe a collective mortality of 7 percent (Lao and colleagues, 1993b). In the report described earlier by Hameed and associates (2001) from Los Angeles County Medical Center, the maternal mortality rate in women with aortic stenosis was 8 percent. Patients with valve gradients exceeding 100 mm Hg appear to be at greatest risk.

Management in Pregnancy. For the asymptomatic pregnant woman, no treatment except close observation is required.

Management of the symptomatic woman includes strict limitation of activity and prompt treatment of infections. If symptoms persist despite bed rest, valve replacement or valvotomy using cardiopulmonary bypass must be considered. In general, balloon valvotomy for aortic valve disease is avoided because of a serious complication rate of more than 10 percent. These complications include stroke, aortic rupture, aortic valve insufficiency, and death (Carabello and Crawford, 1997; Reich and co-workers, 2004). In rare cases, it may be preferable to perform valve replacement during pregnancy (Angel and colleagues, 1988; Lao and associates, 1993a).

For women with critical aortic stenosis, intensive monitoring during labor is important. Pulmonary artery catheterization may be helpful because of the narrow margin separating fluid overload from hypovolemia. Women with aortic stenosis are dependent on adequate end-diastolic ventricular filling pressures to maintain cardiac output and systemic perfusion. Abrupt decreases in end-diastolic volume may result in hypotension, syncope, myocardial infarction, and sudden death. Thus the key to the management of these women is the avoidance of decreased ventricular preload and maintenance of cardiac output. During labor and delivery, such women should be managed on the "wet" side, maintaining a margin of safety in intravascular volume in anticipation of possible hemorrhage. In women with a competent mitral valve, pulmonary edema is rare, even with moderate volume overload.

During labor, narcotic epidural analgesia seems ideal, thus avoiding potentially hazardous hypotension, which may be encountered with standard conduction analgesia techniques. Easterling and colleagues (1988) studied the effects of epidural analgesia for five women with severe stenosis and demonstrated immediate and profound effects of decreased filling pressures. Thus, as emphasized by Camann and Thornhill (1999), slow administration of dilute local anesthetics into the epidural space allows for a safer block. Forceps or vacuum delivery is used for standard obstetrical indications in hemodynamically stable women. Intrapartum bacterial endocarditis prophylaxis is given if bacteremia is suspected (see p. 1033).

AORTIC INSUFFICIENCY. Aortic regurgitation is the diastolic flow of blood from the aorta into the left ventricle. Common causes of aortic valvular incompetence are rheumatic fever, connective tissue abnormalities, and congenitally acquired lesions. With Marfan syndrome, the aortic root may dilate, resulting in regurgitation (see p. 1035). Acute insufficiency may develop with bacterial endocarditis or aortic dissection. Aortic as well as mitral valve insufficiency have been linked to the appetite suppressants fenfluramine and dexfenfluramine (Gardin, 2000; Jick, 2000; Khan, 1998, and all of their associates).

With chronic disease, left ventricular hypertrophy and dilatation develop (see [Table 44-6](#)). This is followed by slow-onset fatigue, dyspnea, and edema, although rapid deterioration usually follows. Aortic insufficiency is generally well tolerated during pregnancy. Like mitral valve incompetence, diminished vascular resistance is thought to improve the lesion. Symptoms necessitate therapy for heart failure, including bed rest, sodium restriction, and diuretics. Epidural analgesia is used for labor and delivery. Bacterial endocarditis prophylaxis may be required at delivery (see p. 1033).

PULMONIC STENOSIS. The pulmonic valve is affected by rheumatic fever far less often than the other valves. Instead, the lesion is usually congenital and also may be associated with Fallot tetralogy or Noonan syndrome. The clinical diagnosis is typically made by auscultating a systolic ejection murmur over the pulmonary area that is louder during inspiration. Pregnancy is usually well tolerated (Prasad and Ventura, 2001). Indeed, of the eight women with pulmonic stenosis described by Hameed and associates (2001), all had uncomplicated courses. Increased hemodynamic burdens of pregnancy can precipitate right-sided heart failure or atrial arrhythmias in women with severe stenosis. Siu and Colman (2001) recommend consideration for surgical correction before or during pregnancy if symptoms progress.

CONGENITAL HEART DISEASE

The incidence of congenital heart disease in the United States is approximately 8 per 1000 liveborn infants. About a third of these have critical disease that requires cardiac catheterization or surgery, or they die within the first year. Others require surgery in childhood, and 85 percent survive to adulthood (Moodie, 1994). With the relative decline in rheumatic heart disease, this group now represents the majority of women with heart disease during pregnancy (Iserin, 2001).

SEPTAL DEFECTS

Atrial Septal Defects. After bicuspid aortic valve, these are the most commonly encountered congenital cardiac lesions in adults, comprising a third of cases (Brickner and colleagues, 2000). Most are asymptomatic until the third or fourth decade. The secundum-type defect accounts for 70 percent of all cases, and associated mitral valve myxomatous abnormalities with prolapse are common. Most clinicians recommend repair if discovered in adulthood. Pregnancy is well tolerated unless pulmonary hypertension has developed, but this is rare because pulmonary artery pressures are usually low (Zuber and associates, 1999). If congestive heart failure or an arrhythmia develops, treatment is given. Bacterial endocarditis prophylaxis has been recommended in certain circumstances with unrepaired defects (see p. 1033). Based on their review, Aliaga and associates (2003) concluded that the risk of endocarditis with an atrial septal defect is negligible.

Ventricular Septal Defects. These defects spontaneously close in 90 percent of patients during childhood. Almost 75 percent of defects are paramembranous, and physiological derangements are related to the size of the defect. In general, if the defect is less than 1.25 cm², pulmonary hypertension and heart failure do not develop. When the effective size of the defect is greater than the aortic valve orifice, symptoms rapidly develop. For these reasons, most children undergo surgical repair before pulmonary hypertension develops. Adults with unrepaired large defects develop left ventricular failure and pulmonary hypertension, as well as a high incidence of bacterial endocarditis (Brickner and colleagues, 2000).

Pregnancy is well tolerated with small to moderate left-to-right shunts. When pulmonary arterial pressures reach systemic levels, however, there is reversal or bidirectional flow or *Eisenmenger syndrome* (see p. 1028). When this develops, maternal mortality is 30 to 50 percent. Thus, pregnancy is contraindicated, and therapeutic abortion is advised if contraception fails. Bacterial endocarditis is more common with unrepaired defects, and antimicrobial prophylaxis is often required (see p. 1033). Unless repair is associated with a residual septal defect, the risk of endocarditis is low. About 10 to 15 percent of offspring born

to these women have a ventricular septal defect (see [Table 44-4](#)).

PERSISTENT DUCTUS ARTERIOSUS. Like other shunts, the physiological consequences of this lesion are related to its size. Most significant lesions are repaired in childhood. In individuals who do not undergo repair, mortality is high beginning in the fifth decade (Brickner and colleagues, 2000). Pulmonary hypertension develops in some women with an unrepaired persistent ductus. Heart failure may develop in these women, and if systemic blood pressure falls, reversal of blood flow from the pulmonary artery into the aorta causes cyanosis. Sudden drops in blood pressure at delivery, as with conduction analgesia or hemorrhage, may lead to fatal collapse. Therefore, hypotension should be avoided whenever possible and treated vigorously if it develops. Prophylaxis for bacterial endocarditis may be indicated at delivery for unrepaired defects (see p. 1033). The incidence of inheritance is about 4 percent (see [Table 44-4](#)).

CYANOTIC HEART DISEASE. When congenital heart lesions are associated with right-to-left shunting of blood past the pulmonary capillary bed, cyanosis develops. The classical and most commonly encountered lesion in pregnancy is the *Fallot tetralogy*. This is characterized by a large ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta that receives blood from both the right and left ventricles. The magnitude of the shunt varies inversely with systemic vascular resistance. Hence, during pregnancy, when peripheral resistance decreases, the shunt increases and cyanosis worsens. Women who have undergone repair, and in whom cyanosis did not reappear, do well in pregnancy.

Some women with *Ebstein anomaly* of the tricuspid valve may reach reproductive age. Right ventricular failure from volume overload and appearance or worsening of cyanosis are common during pregnancy. In the absence of cyanosis, these women usually tolerate pregnancy well.

Effects on Pregnancy. Pregnant women with cyanotic heart disease generally do poorly. With uncorrected Fallot tetralogy, for example, maternal mortality approaches 10 percent. Any disease complicated by severe maternal hypoxemia is likely to lead to miscarriage, preterm delivery, or fetal death. There is a relationship between chronic hypoxemia and the polycythemia it causes and the outcome of pregnancy. When hypoxemia is intense enough to stimulate a rise in hematocrit above 65 percent, pregnancy wastage is virtually 100 percent.

Sawhney and colleagues (1998) reported stillborn infants in 14 percent and fetal growth restriction in 36 percent of 24 pregnancies in women with cyanotic heart disease. Shime and associates (1987) reported that 13 of 23 women with cyanotic heart disease developed functional deterioration during pregnancy, and seven had cardiac failure. Three of these 23 infants died, and low birthweight was common. Zuber and co-workers (1999) reported good outcomes in 19 women with Fallot tetralogy, but they emphasized that prepregnancy functional class and systolic ventricular function were good in all the women.

PREGNANCY AFTER SURGICAL REPAIR. With satisfactory surgical correction before pregnancy, maternal risks are decreased dramatically and fetal environment is improved. Singh and associates (1982) described 40 pregnancies in 27 women with surgically corrected tetralogy. They concluded that pregnancy is usually well tolerated in women with no major residual defects after surgery. Lao (1994), Lynch-Salamon (1993), Megerian (1994), and their colleagues described 14 pregnancies in 10 women following successful *Mustard repair for transposition of the great vessels*. Two women developed cardiac failure during pregnancy and two others developed worrisome arrhythmias. Connolly and co-workers (1999) reported 60 pregnancies in 22 women who had transposition corrected in childhood. Maternal complications were uncommon, however, two women developed heart failure, another had endocarditis, and a woman with a single coronary artery had a myocardial infarction. All 50 liveborn infants survived.

Hoare and Radford (2001) described four pregnancies in three women who had previously undergone a *Fontan repair* for congenital heart disease characterized by a *single functional ventricle*. Although no maternal deaths occurred, complications were frequent and included preterm birth in all pregnancies, supraventricular arrhythmias in half, and ventricular failure in half.

LABOR AND DELIVERY. Vaginal delivery is preferred unless there is an obstetrical indication for cesarean delivery.

Pulmonary artery catheter monitoring has limitations because of the sometimes bizarre anatomical abnormalities. Care must be taken to avoid sudden blood pressure decreases. For labor pain, epidural opiates may suffice. There is controversy regarding epidural analgesia versus general anesthesia for cesarean delivery (Camann and Thornhill, 1999).

EISENMENGER SYNDROME. This is secondary pulmonary hypertension that develops with any cardiac lesion. The syndrome develops when pulmonary vascular resistance becomes greater than systemic vascular resistance and in which there is some right-to-left shunting. The most common underlying defects are atrial or ventricular septal defects and persistent ductus arteriosus. Patients are asymptomatic for years, but eventually pulmonary hypertension is severe enough to cause right-to-left shunting.

The prognosis for pregnancy depends on the severity of pulmonary hypertension. In a review of 44 cases through 1978, Gleicher and associates (1979) reported maternal and perinatal mortality rates to be about 50 percent. There has been little improvement since then. Weiss and co-workers (1998b) cited a 36-percent maternal death rate in a review of 73 pregnancies. Three of the 26 deaths were antepartum, and the remainder occurred intrapartum or within a month of delivery. Women with Eisenmenger syndrome tolerate hypotension poorly, and the cause of death usually is right ventricular failure with cardiogenic shock. Management is discussed subsequently.

OTHER CARDIOVASCULAR CONDITIONS

PULMONARY HYPERTENSION. High pulmonary blood pressure is generally secondary to cardiac or pulmonary disease, and common causes are persistent and prolonged left-to-right shunting with development of Eisenmenger syndrome. *Primary pulmonary hypertension* is a rare, usually idiopathic, condition that occurs in the absence of an intracardiac or aortopulmonary shunt. Thirty suspected risk factors include certain appetite suppressants, human immunodeficiency virus

and human herpesvirus 8 infections, and sickle cell disease (Cool, 2003; Gladwin, 2004; Humbert, 2001, and all their colleagues). Pengo and associates (2004) found chronic pulmonary hypertension in 3.8 percent of nonpregnant patients 2 years after a pulmonary embolism. Some previously unexplained cases are now thought to be due to antiphospholipid antibodies (see [Chap. 54](#), p. 1215).

The criteria for diagnosis established by a National Institutes of Health registry include a mean pulmonary artery pressure of more than 25 mm Hg at rest, or 30 mm Hg with exertion, in the absence of heart disease, chronic thromboembolic disease, underlying pulmonary disorder, or other secondary causes (Runo and Loyd, 2003). Although cardiac catheterization remains the standard criterion for the measurement of pulmonary artery pressures, noninvasive echocardiography is often used to provide an estimate. In their review of 33 pregnant women who underwent both echocardiography and cardiac catheterization, Penning and colleagues (2001) cautioned that pulmonary artery pressures were significantly overestimated by echocardiography in a third of cases.

The prognosis is poor, and the mean survival from diagnosis is about 2 years. Long-term therapy with intravenous epoprostenol (prostacyclin) or with subcutaneous treprostinil, a prostacyclin analogue, significantly lowers pulmonary vascular resistance (Humbert and colleagues, 2004; Roeleveld and co-workers, 2004). Preconceptional counseling is imperative, and Easterling and associates (1999) recommend that response to nifedipine and prostacyclin be documented for at least 1 year before pregnancy.

Effects on Pregnancy. Maternal mortality is appreciable, especially with primary pulmonary hypertension. In their review, Kiss and colleagues (1995) reported maternal mortality in 7 of 11 (65 percent) women with primary disease. Weiss and associates (1998b) reviewed 27 cases reported from 1978 through 1996 and found a 30-percent mortality rate.

Although pregnancy is contraindicated with severe disease, milder degrees of secondary pulmonary hypertension probably go unnoticed. For example, with the more common use of pulmonary artery catheterization in women with heart disease, we have identified women with mild to moderate pulmonary hypertension who tolerated pregnancy, labor, and delivery quite well. Sheffield and Cunningham (2004) described an example of pulmonary hypertension that occurs with relatively long-standing thyrotoxicosis (see [Chap. 53](#), p. 1192). Boggess and colleagues (1995) described nine women with interstitial and restrictive lung disease who ostensibly had varying degrees of pulmonary hypertension. Three women had severe disease, and all nine tolerated pregnancy reasonably well.

Treatment of symptomatic pregnant women includes limitation of activity and avoidance of the supine position in late pregnancy. Diuretics, supplemental oxygen, and vasodilator drugs are standard therapy for symptoms. Easterling and associates (1999) successfully used nifedipine and prostacyclin during pregnancy, and Badalian and co-workers (2000) described continued epoprostenol (prostacyclin) infusion throughout a twin pregnancy.

Management of labor and delivery is particularly problematic. **These women are at greatest risk when there is diminished venous return and right ventricular filling, which is associated with most maternal deaths.** To avert hypotension, careful attention is given to blood loss at delivery and avoidance of standard epidural analgesia. Pollack and colleagues (1990), as well as others, have reported successful labor analgesia without significant cardiovascular effects from morphine administered intrathecally. Camann and Thornhill (1999) argue against the use of pulmonary artery catheterization for a number of technical and safety issues, not the least of which is that data are usually not clinically useful. Lam and colleagues (2001) have described the use of intubation and inhaled nitric oxide during the labor and forceps delivery of a nullipara with severe primary pulmonary hypertension. Weiss and co-workers (2000) described a woman with severe primary pulmonary hypertension who had a successful cesarean delivery with epidural analgesia and while inhaling 20 mg of aerosolized iloprost, an analogue of prostacyclin. Successful intrapartum use of inhaled epoprostenol has also been described (Bildirici and Shumway, 2004).

MITRAL VALVE PROLAPSE. This diagnosis implies the presence of a pathological connective tissue disorder — often termed *myxomatous degeneration* — which may involve the valve leaflets themselves, the annulus, or the chordae tendineae. Until recently, this condition was thought to have a prevalence as high as 15 percent in otherwise normal young women. Community-based studies, however, indicate the incidence to be only 2 to 3 percent (Freed and colleagues, 1999). For referred cases, it is commonly associated with a wide variety of other cardiac disorders, including atrial septal defect, Marfan syndrome, Ebstein anomaly, and hypertrophic cardiomyopathy.

Most women with mitral valve prolapse are asymptomatic and are diagnosed by routine physical examination or as an incidental finding at echocardiography. The small percentage of women with symptoms have anxiety, palpitations, atypical chest pain, and syncope. Nishimura and colleagues (1985) identified only those patients with redundant mitral valve leaflets to be at increased risk of sudden death, infective endocarditis, or cerebral embolism. Looking at this another way, of 213 young women with documented ischemic strokes, only 1.9 percent had mitral valve prolapse compared with 2.7 percent of controls (Gilon and co-workers, 1999).

Diagnosis. Mitral valve prolapse implies the presence of a pathological condition and should be diagnosed with caution and precision. Reliance on strict diagnostic criteria is essential before assigning a pathological diagnosis or administration of endocarditis prophylaxis (Nishimura and McGoon, 1999).

Effects on Pregnancy. Pregnant women with mitral valve prolapse rarely have cardiac complications. In fact, pregnancy-induced hypervolemia may improve alignment of the mitral valve (Rayburn and colleagues, 1987). For women who are symptomatic, β -blocking drugs are given to decrease sympathetic tone, relieve chest pain and palpitations, and reduce the risk of life-threatening arrhythmias. In general, mitral valve prolapse is not deleterious to pregnancy. We manage these women as if not pregnant and prescribe β -blocker drugs for symptoms. Mitral valve prolapse with regurgitation or valvular damage is considered to be a significant risk factor for development of bacterial endocarditis, and antimicrobial prophylaxis should be given if bacteremia is suspected. Women without evidence of pathological myxomatous change may in general expect excellent pregnancy outcome (Chia and associates, 1994).

PERIPARTUM CARDIOMYOPATHY. This is a diagnosis of exclusion and is similar to idiopathic dilated cardiomyopathy that occurs in nonpregnant adults. Although the term peripartum cardiomyopathy has been used widely to

describe women with peripartum heart failure with no readily apparent etiology, it is doubtful that there is a pregnancy-induced cardiomyopathy. In 1997, the National Heart, Lung, and Blood Institute and the Office of Rare Diseases convened a workshop that established the following diagnostic criteria (Pearson and associates, 2000):

1. Development of cardiac failure in the last month of pregnancy or within 5 months after delivery.
2. Absence of an identifiable cause for the cardiac failure.
3. Absence of recognizable heart disease prior to the last month of pregnancy.
4. Left ventricular systolic dysfunction demonstrated by classic echocardiographic criteria such as depressed shortening fraction or ejection fraction.

Although the workshop panel concluded that the disease is acute, rather than a preexisting one preceding pregnancy, our experiences do not reflect this.

Other causes of new-onset ventricular dysfunction must be excluded. Felker and colleagues (2000) performed endomyocardial biopsy in 1230 nonpregnant patients who had unexplained cardiomyopathy. In exactly half of these, a cause for cardiomyopathy was found, and the most common was myocarditis. Indeed, 26 of 51 women with peripartum cardiomyopathy had histological evidence for myocarditis. Dilated cardiomyopathy is also found in HIV infection (Barbaro and associates, 1998). We carefully evaluated 28 women at Parkland Hospital with peripartum heart failure of obscure etiology who were initially thought to have idiopathic cardiomyopathy. In 21 of these, heart failure was ultimately attributed to hypertensive heart disease, clinically silent mitral stenosis, obesity, or viral myocarditis (Cunningham and associates, 1986).

Chronic hypertension with superimposed preeclampsia is a common cause of heart failure during pregnancy (see [Chap. 45](#), p. 1052). In some cases, mild antecedent hypertension is undiagnosed, and when superimposed preeclampsia develops, it may cause otherwise inexplicable peripartum heart failure. As discussed in [Chapter 43](#), obesity is a common cofactor with chronic hypertension, and it can cause or contribute to underlying ventricular hypertrophy. In the Framingham Heart Study, obesity alone was associated with a doubling of the risk of heart failure in nonpregnant individuals (Kenchaiah and colleagues, 2002).

Regardless of the underlying condition that causes cardiac dysfunction, women who develop peripartum heart failure often have obstetrical complications that either contribute to or precipitate heart failure. For example, preeclampsia is common and may precipitate afterload failure. Acute anemia from blood loss magnifies the physiological effects of compromised ventricular function. Similarly, infection and accompanying fever increase cardiac output and oxygen utilization.

Idiopathic Cardiomyopathy in Pregnancy. After exclusion of an underlying cause for heart failure, idiopathic cardiomyopathy may be considered (Brown and Bertolet, 1998; Hibbard and associates, 1999). We identified this in about 1 in 15,000 deliveries, and this incidence is not different from that of idiopathic cardiomyopathy in young nonpregnant women (Cunningham and colleagues, 1986). Lampert (1993) and Mabie (1993) and their associates have implicated prolonged beta-mimetic tocolysis with terbutaline as provoking cardiomyopathy. As previously discussed, clinically undetected myocarditis is found in up to half of these women if biopsy is done. O'Connell and colleagues (1986) found that a third of pregnant women with idiopathic cardiomyopathy had biopsy evidence of myocarditis compared with only 10 percent of nonpregnant patients.

Women with cardiomyopathy present with signs and symptoms of congestive heart failure. Dyspnea is universal, and other symptoms include orthopnea, cough, palpitations, and chest pain (Sheffield and Cunningham, 1999). The hallmark finding usually is impressive cardiomegaly ([Fig. 44-3](#)). Echocardiographic findings include an ejection fraction less than 45 percent or a fractional shortening less than 30 percent, or both, and an end-diastolic dimension greater than 2.7 cm/m² (Hibbard and colleagues, 1999).

Therapy consists of treatment for heart failure. Sodium intake is limited and diuretics are given to reduce preload. Afterload reduction with hydralazine or another vasodilator is accomplished. Because of marked fetal effects discussed in [Chapter 14](#) (see p. 349), angiotensin-converting enzyme inhibitors are avoided if the woman is undelivered. However, they are given postpartum. Digoxin is given for its inotropic effects unless complex arrhythmias are identified. Because there is a high incidence of associated thromboembolism, prophylactic heparin is often recommended.

PROGNOSIS. The distinction between peripartum heart failure from an identifiable cause versus idiopathic cardiomyopathy is important. This distinction is somewhat artificial, recall that if biopsy is done, at least half of women with peripartum cardiomyopathy have histological myocarditis. As shown in [Figure 44-4](#), the 5- and 10-year survival rates are substantially lower with idiopathic disease (Felker and co-workers, 2000; Pulerwitz and associates, 2004).

According to Lampert and associates (1997), half of all women with peripartum cardiomyopathy regain left ventricular function within 6 months, and they have a good prognosis. Conversely, the other half have high morbidity and mortality rates. With a mean follow-up of 39 months, de Souza and colleagues (2001b) studied the longer-term outcomes of 44 such women. Eight of these (18 percent) died from end-stage heart failure. In addition, two women suffered a nonfatal pulmonary embolism, one had a cerebral ischemic stroke, and another underwent heart transplantation 14 months after the diagnosis. Of eight women with functional NYHA class IV heart failure, one woman improved to class I, four to class II, two to class III, and one remained in class IV. Seven women had a subsequent pregnancy, and all gave birth to healthy term newborns. Elkayam and co-workers (2001) surveyed members of the American College of Cardiology and obtained outcomes of 60 subsequent pregnancies in 44 women who had peripartum cardiomyopathy. Of the 28 women in whom left ventricular function had returned to normal, there were no maternal deaths. However, 20 percent developed symptoms of heart failure during pregnancy. In the remaining 16 with persistent left ventricular dysfunction, 44 percent developed heart failure and three women died between 2 and 24 months postpartum. In a prospective study, Sliwa and co-workers (2004) confirmed these findings. These studies suggest that subsequent pregnancy is inadvisable for women with an ejection fraction persistently less than 50 percent.

Figure 44-3. Idiopathic peripartum cardiomyopathy in patient L.E.S. Peripartum heart failure developed without any identifiable underlying cardiac disease. Despite

an initially good symptomatic response and clearing of pulmonary edema, mild cardiomegaly persisted 3 months postpartum (**A**). Over the ensuing 5 years (**B-D**) cardiomegaly worsened, and she died of end-stage heart failure at age 23. (From Cunningham and colleagues, 1986, with permission.)

Figure 44-4. Survival according to underlying cause of cardiomyopathy. (HIV = human immunodeficiency virus.) (Data from Felker and colleagues, 2000.)

INFECTIVE ENDOCARDITIS. This infection involves cardiac endothelium and produces vegetations that usually deposit on a valve. Infective endocarditis can involve a native or a prosthetic valve, and it may be associated with intravenous drug abuse. Children and adults who have had corrective surgery for congenital heart disease are at greatest risk (Morris and co-workers, 1998). About half of affected adults have a known preexisting heart lesion (Hoen and colleagues, 2002).

Subacute bacterial endocarditis usually is due to a low-virulence bacterial infection superimposed on an underlying lesion. These are usually native valve infections. Organisms that cause indolent endocarditis are most commonly viridans group streptococci or *Enterococcus* species. Historically, *acute endocarditis* was usually caused by coagulase-positive staphylococci. Two large and more recent epidemiological studies, however, indicate that the most common causative organisms are streptococci — especially viridans — followed by *Staphylococcus aureus* and *Enterococcus* species (Hasbun and associates, 2003; Hoen and colleagues, 2002). *S aureus* is the predominant organism among intravenous drug abusers (Karchmer, 2001). *Staphylococcus epidermidis* commonly causes prosthetic valve infections. *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* may cause acute, fulminating disease (Bataskov and colleagues, 1991). Antepartum endocarditis has been described with *Neisseria sicca* and *Neisseria mucosa*, the latter causing maternal death (Cox and associates, 1988; Deger and Ludmir, 1992). Surprisingly, few cases of group B streptococcal endocarditis have been described (Kangavari and co-workers, 2000).

Symptoms of endocarditis are variable and often develop insidiously. Fever is virtually universal, and a murmur is heard in 80 to 85 percent of cases (Karchmer, 2001). Anorexia, fatigue, and other constitutional symptoms are common, and the illness is frequently described as "flu-like." Other findings are anemia, proteinuria, and manifestations of embolic lesions, including petechiae, focal neurological manifestations, chest or abdominal pain, and ischemia in an extremity. In some cases, heart failure develops. Symptoms may persist for several weeks before the diagnosis is made, and a high index of suspicion is necessary. Diagnosis is made using the *Duke criteria*, which include positive blood cultures for typical organisms and evidence of endocardial involvement (Karchmer, 2001). Echocardiography and two-dimensional sector scanning are useful, but lesions only 3 to 4 mm in size or those on the tricuspid valve may be missed. **A negative echocardiographic study does not exclude endocarditis.**

Treatment is primarily medical with appropriate timing of surgical intervention if necessary. Knowledge of the infecting organism is imperative for sensible antimicrobial selection. Most viridans streptococci are sensitive to penicillin G given intravenously along with gentamicin for 2 weeks (Karchmer, 2001). Complicated infections are treated longer, and women allergic to penicillin are either desensitized or given intravenous ceftriaxone or vancomycin for 4 weeks. Staphylococci, enterococci, and other organisms are treated according to microbial sensitivity for 4 to 6 weeks (Darouiche, 2004). Prosthetic valve infections are treated for 6 to 8 weeks. Persistent native valve infection may require replacement, and this is even more commonly indicated with an infected prosthetic valve.

Endocarditis in Pregnancy. Infective endocarditis is uncommon during pregnancy and the puerperium. Over a 7-year period, the incidence of endocarditis at Parkland Hospital was about 1 in 16,000 deliveries (Cox and associates, 1988). Two of seven women died. Treatment is the same as that described earlier. From their reviews, Seaworth and Durack (1986) and Cox and Leveno (1989) cited maternal mortality of about 25 to 35 percent.

Antimicrobial Prophylaxis. The efficacy of antimicrobial prophylaxis to prevent bacterial endocarditis is questionable. Only 13 percent of cases arising in patients with high-risk cardiac lesions do so after a procedure (Van der Meer and associates, 1992). The American Heart Association recommends prophylaxis based on risk stratification ([Table 44-7](#)). These recommendations have been endorsed by the American College of Obstetricians and Gynecologists (2003).

OBSTETRICAL PROCEDURES. The current recommendations of the American College of Cardiology and the American Heart Association suggest that prophylaxis for bacterial endocarditis be administered intrapartum to women at risk only in the presence of suspected bacteremia or active infection (see [Table 44-7](#)). They estimate that the incidence of transient bacteremia at delivery is 1 to 5 percent. Antimicrobial prophylaxis is considered optional for women undergoing an uncomplicated delivery who are at high risk for endocarditis (American College of Obstetricians and Gynecologists, 2003). Although there is meager evidence that a significant number of cases of bacterial endocarditis have been prevented with antimicrobial prophylaxis given for uncomplicated delivery, its risk and costs are not great (McFaul and associates, 1988; Seaworth and Durack, 1986). Individualization seems appropriate.

In the guidelines shown in [Table 44-7](#), the recommended prophylaxis regimens include intravenous or intramuscular administration of 2 g of ampicillin plus 1.5 mg/kg of intravenous gentamicin (to a maximum of 120 mg), followed by 1 g of parenteral ampicillin or oral amoxicillin 6 hours later. In women who are allergic to penicillin, vancomycin, 1 g intravenously over 1 to 2 hours, is substituted for ampicillin. Ideally, prophylaxis should be completed within 30 minutes before the procedure is begun (American College of Obstetricians and Gynecologists, 2003). Obviously, accurate prediction of delivery time is problematic regarding timely administration of the first dose. In women who are at moderate risk for endocarditis, the gentamicin and the second dose of ampicillin may be eliminated.

ARRHYTHMIAS. Cardiac arrhythmias are commonly encountered during pregnancy, labor and delivery, and the puerperium. It is debated whether arrhythmias are more common during pregnancy, but in our experience, their detection is probably increased because of more frequent visits during prenatal care. Perhaps the normal but mild hypokalemia of pregnancy induces arrhythmias (see [Chap. 5](#), p. 129). Most often, treatment is not different from that for nonpregnant patients.

Bradycardias, including complete heart block, are compatible with a successful pregnancy outcome. Some women with complete heart block have syncope during labor and delivery, and occasionally temporary cardiac pacing is necessary. Women with permanent artificial pacemakers usually tolerate pregnancy well (Jaffe and associates, 1987). With fixed-rate devices, cardiac output apparently is increased by augmented stroke volume.

Tachycardias are relatively common and should prompt consideration of underlying cardiac disease. *Wolff-Parkinson-White syndrome* may first appear during pregnancy, but some women with previously diagnosed arrhythmias have an increased incidence of tachycardia during pregnancy (Widerhorn and co-workers, 1992). *Paroxysmal supraventricular tachycardia* is encountered most frequently. Siu and associates (1997) followed 25 women who had supraventricular tachycardia diagnosed before pregnancy. Half of these women had Wolff-Parkinson-White syndrome. Three of 12 women with Wolff-Parkinson-White syndrome and 6 of 13 without the condition had supraventricular tachycardia during pregnancy. If vagal maneuvers do not stimulate conversion, treatment consists of digoxin, adenosine, or calcium-channel blocking drugs. Experience is accruing that adenosine is effective for cardioversion in hemodynamically stable pregnant women (Chakhtoura and co-workers, 1998; Robins and Lyons, 2004). Most of these drugs do not appear to do fetal harm, however, reported fetal bradycardia in response to intravenous adenosine has been described (Dunn and Brost, 2000).

Electrical cardioversion is not contraindicated in pregnancy, but vigilance is important. Barnes and associates (2002) described a case in which direct current cardioversion led directly to a sustained uterine contraction and fetal bradycardia. In some patients, accessory pathway ablation may be indicated (Pappone and colleagues, 2003). Damilakis and associates (2001) calculated that the typical fetal procedure-related radiation dose is less than 1 cGy.

Atrial flutter or fibrillation are more likely associated with underlying disease, such as thyrotoxicosis. Major complications include stroke (Ezekowitz and Levine, 1999). Thus, heparin is recommended by some if fibrillation is chronic and persists during pregnancy. If atrial fibrillation is associated with mitral stenosis, pulmonary edema may develop in late pregnancy if the ventricular rate is increased.

Ventricular tachycardia is uncommon in healthy young women without underlying heart disease. Brodsky and associates (1992) described seven pregnant women with new-onset ventricular tachycardia and reviewed 23 previously published reports. Most of these women were not found to have structural heart disease, and in 60 percent, arrhythmias were stimulated by physical exercise or psychological stress. Of those remaining, two had myocardial infarction, two had a prolonged QT interval, and anesthesia provoked tachycardia in another. In 6 of 26, no precipitating event was found. The investigators concluded that pregnancy events probably precipitated tachycardia and recommended β -blocker therapy for control. For women requiring defibrillation for ventricular arrhythmias, Nanson and associates (2001) found that standard adult energy requirements do not need to be altered solely because of pregnancy.

QT interval prolongation on the ECG may predispose individuals to a potentially fatal ventricular arrhythmia known as *torsades de pointes*. Based on their analysis of 111 pregnant women with long QT syndrome in which a significant increase in cardiac events was noted postpartum but not during pregnancy, Rashba and colleagues (1998) hypothesized that the normal increase in heart rate during pregnancy may bear a partially protective effect. Paradoxically, β -blocker therapy has been shown to decrease the risk of torsades de pointes in patients with long QT syndrome and should be continued during pregnancy and the postpartum period (Gowda and colleagues, 2003). Importantly, many medications, including some used during pregnancy such as erythromycin and clarithromycin, may predispose to QT prolongation (Al-Khatib and associates, 2003; Roden, 2004).

DISEASES OF THE AORTA. Marfan syndrome and coarctation of the aorta are two aortic diseases that place the pregnant woman at increased risk for *aortic dissection*. Half of cases of dissection in young women are related to pregnancy (O'Gara and associates, 2004). Other risk factors are bicuspid aortic valve and Turner or Noonan syndrome. Pepin and colleagues (2000) reported a high rate of aortic dissection or rupture in patients with *Ehlers-Danlos syndrome* (see [Chap. 54](#), p. 1223). Although the mechanism(s) involved are unclear, the initiating event is an aortic intimal tear, and following medial hemorrhage, rupture may occur.

In most cases, aortic dissection presents with severe chest pain described as ripping, tearing, or stabbing in nature. Diminution or loss of peripheral pulses in conjunction with a recently acquired murmur of aortic insufficiency are important physical findings. The differential diagnosis of aortic dissection includes myocardial infarction, pulmonary embolism, pneumothorax, and aortic valve rupture. Lang and Borow (1991) rightfully add obstetrical catastrophes to the list, especially placental abruption and uterine rupture.

More than 90 percent of affected patients have an abnormal chest radiograph. Aortic angiography is the most definitive method for confirming the diagnosis, however, noninvasive imaging with sonography, computed tomography, and magnetic resonance imaging (MRI) are used more frequently. The urgency of the clinical situation frequently dictates which procedure is best. Easterling and colleagues (1991) found that aortic diameter increased significantly in normal women over the course of pregnancy. This increase was even greater for women who developed preeclampsia.

Initial medical treatment is given to lower blood pressure. Proximal dissections most often need to be resected, along with aortic valve replacement if indicated. Distal dissections are more complex, and many may be treated medically. Lederle and colleagues (2002) have shown that survival in nonpregnant patients is not improved by elective repair of abdominal aortic aneurysms smaller than 5.5 cm. Lee and associates (2001) described a successful vaginal delivery in a woman with a 4.5-cm thoracic aortic aneurysm.

Marfan Syndrome. This syndrome is usually inherited as an autosomal dominant trait with a high degree of penetrance. Prenatal diagnosis is usually possible using linkage analysis (see [Chap. 12](#), p. 308). The syndrome is caused by abnormal *fibrillin* produced by any of nearly 50 different mutations in the *FBN1* gene, which is located on chromosome 15q21 (Biggin and

co-workers, 2004). Fibrillin is a constituent of elastin. Thus, Marfan syndrome is a systemic connective tissue disorder characterized by generalized weakness that can result in dangerous cardiovascular complications. Because all tissues are involved, other defects are frequent and include joint laxity and scoliosis. Progressive aortic dilatation causes aortic valve insufficiency, and there may be infective endocarditis and mitral valve prolapse with insufficiency. Aortic dilatation and dissecting aneurysm are the most serious abnormalities. Early death is due either to valvular insufficiency and heart failure or to a dissecting aneurysm. Long-term benefits from β -blocker therapy have been described for nonpregnant adults (Shores and colleagues, 1994).

Effect of Pregnancy. In a review of published cases, Elkayam and associates (1995) found that 20 of 32 women had aortic dissection or rupture and 16 of these died. The actual mortality risk is probably lower, because these case reports likely reflect a publication bias of more severely affected pregnancies. Indeed, in a prospective longitudinal evaluation of 21 women during 45 pregnancies from the Johns Hopkins Hospital, only two had dissection and one died postpartum from graft infection (Rossiter and colleagues, 1995). Similarly, there were no maternal deaths among 14 women with Marfan syndrome followed prospectively by Rahman and co-workers (2003). Importantly, two of these women required surgical correction of an aortic aneurysm and aortic valve replacement. Both groups of investigators concluded that aortic dilatation of more than 40 mm or mitral valve dysfunction are high-risk factors for life-threatening cardiovascular complications during pregnancy. Conversely, women with minimal or no dilatation, and those with normal cardiac function by echocardiography, are counseled regarding the small but serious potential risk of aortic dissection. Elkayam and colleagues (1995) also concluded that pregnancy was safer in women with Marfan syndrome who had no cardiovascular manifestations or aortic arch dilatation. They recommended β -blocker prophylactic therapy during pregnancy.

The aortic root usually measures about 20 mm, and if dilatation reaches 40 mm, then dissection is more likely (Simpson and D'Alton, 1997). If it reaches 50 to 60 mm, then elective surgery should be considered before pregnancy (Gott and collaborators, 1999; Pretre and Von Segesser, 1997). Williams and co-workers (2002) described a successful pregnancy following aortic root and arch replacement. Aortic root replacement during pregnancy has been associated with hypoxic-ischemic cerebral damage in a 29-week fetus (Mul and co-workers, 1998). Although Marfan syndrome itself is not an indication, the authors recommended cesarean delivery if there is aortic involvement. Otherwise, obstetrical indications for delivery are followed.

Aortic Coarctation. This is a relatively rare lesion often accompanied by abnormalities of other large arteries. For example, a bicuspid aortic valve is seen with echocardiography in a fourth of affected patients, and another 10 percent have cerebral artery aneurysms. Other associated lesions are persistent ductus arteriosus, septal defects, and Turner syndrome. The collateral circulation arising above the level of the coarctation expands, often to a striking extent, to cause localized erosion of rib margins by hypertrophied intercostal arteries. Typical findings on physical examination are hypertension in the upper extremities but normal or reduced blood pressures in the lower extremities. Sherer (2002) and Dizon-Townson and colleagues (1995) have described diagnoses during pregnancy using MRI.

EFFECTS ON PREGNANCY. The major complications of coarctation are congestive heart failure after long-standing severe hypertension, bacterial endocarditis of the bicuspid aortic valve, and aortic rupture. Maternal mortality rates average about 3 percent (McAnulty and co-workers, 1990). Because hypertension may worsen in pregnancy, antihypertensive therapy using β -blocking drugs is usually required. Aortic rupture is more likely to occur late in pregnancy or early in the puerperium. Cerebral hemorrhage from *circle of Willis aneurysms* may also develop. Beauchesne and associates (2001) described the outcomes of 188 pregnancies in 50 women from the Mayo Clinic who had coarctation and who became pregnant. There was one maternal death due to dissection at 36 weeks. Hypertension was common (30 percent) and was related to the presence of a significant coarctation gradient.

Congestive heart failure demands vigorous efforts to improve cardiac function and may warrant pregnancy interruption. Some authors have recommended that resection of the coarctation be undertaken during pregnancy to protect against the possibility of a dissecting aneurysm and aortic rupture. This poses significant risk, especially for the fetus, because all the collaterals must be clamped for variable periods of time.

Some authors recommend cesarean delivery to prevent transient arterial blood pressure elevations that commonly accompany labor. It is feared that such blood pressure increases might lead to rupture of either the aorta or coexisting cerebral aneurysms. Available evidence, however, suggests that cesarean delivery should be limited to obstetrical indications. Intrapartum bacterial endocarditis prophylaxis is given if bacteremia is suspected.

ISCHEMIC HEART DISEASE. Coronary artery disease, which may lead to *myocardial infarction*, is a rare complication of pregnancy. Although Mendelson and Lang (1995) cite the collective incidence of myocardial infarction complicating pregnancy to be 1 in 10,000, it probably is much lower than this. Frequently, women with coronary artery disease have classical risk factors such as cigarette smoking, hyperlipidemia, obesity, or hypertension. Bagg and colleagues (1999) reviewed 22 diabetic pregnant women with ischemic heart disease or class H diabetes (see [Chap. 52](#), p. 1180). They as well as Pombar (1995) and Reece (1986) and their colleagues documented unusually high mortality in pregnant diabetics who suffered myocardial infarction. Mousa (2000) and Sutaria (2000) and their associates each documented coronary artery occlusion in two pregnant smokers with hypercholesterolemia following a routine intramuscular injection of 0.5-mg ergometrine. Schulte-Sasse (2000) described myocardial ischemia associated with the use of prostaglandin E₁ vaginal suppositories. Karpati and co-workers (2004) reported that half of 55 women with shock from postpartum hemorrhage developed myocardial ischemia.

Diagnosis during pregnancy is not different from in the nonpregnant patient. Measurement of serum levels of the cardiac-specific contractile protein, *troponin I*, is accurate for diagnosis (Shade and associates, 2002). Shivvers and colleagues (1999) showed that troponin I was undetectable across normal pregnancy. Moreover, Kosica and colleagues (2002) found that levels do not increase following either vaginal or cesarean delivery. Myeloperoxidase, another serum marker to predict major cardiac events, has not been studied in pregnant women (Brennan and associates, 2003).

Pregnancy with Prior Ischemic Heart Disease. The advisability of pregnancy after a myocardial infarction is unclear. Ischemic heart disease is characteristically progressive, and because it is usually associated with hypertension or diabetes, pregnancy seems inadvisable.

Vinatier and associates (1994) reviewed 30 cases of pregnancy in women who had sustained an *infarction remote from pregnancy*. Although none of these women died, four had congestive heart failure and four had worsening angina during pregnancy. Pombar and co-workers (1995) reviewed outcomes of women with diabetes-associated ischemic heart disease and infarction. Three had undergone coronary artery bypass grafting before pregnancy. Of 17 women, eight died during pregnancy. Certainly, pregnancy increases cardiac workload, and all of these investigators concluded that ventricular performance should be assessed using ventriculography, radionuclide studies, echocardiography, or coronary angiography prior to conception. If there is no significant ventricular dysfunction, pregnancy will likely be tolerated. For the woman who becomes pregnant before these studies are performed, echocardiography should be done. Exercise tolerance testing may be indicated, and radionuclide ventriculography results in minimal radiation exposure for the fetus (see [Chap. 41](#), p. 981).

Myocardial Infarction During Pregnancy. Treatment is similar to that for nonpregnant patients. Hankins and co-workers (1985) reviewed 68 cases and reported an overall maternal mortality rate of 30 to 35 percent. Hands and colleagues (1990) found an overall mortality of 30 percent. Of 50 women who sustained infarction in the third trimester, 40 percent died, compared with 20 percent of the other 35 women who had an infarction earlier in pregnancy. Women who sustain an infarction less than 2 weeks prior to labor are at especially high risk of death (Esplin and Clark, 1999).

Acute management includes administration of nitroglycerin and morphine with close blood pressure monitoring (Esplin and Clark, 1999). Lidocaine is used to suppress malignant arrhythmias. Calcium-channel blockers or β -blockers are given if indicated. *Tissue plasminogen activator* has been used in pregnant women remote from delivery (Schumacher and associates, 1997). If the infarct has healed sufficiently, cesarean delivery is reserved for obstetrical indications, and most authors recommend epidural analgesia during labor (Esplin and Clark, 1999). Epidural analgesia or general anesthesia may be used for cesarean delivery. Camann and Thornhill (1999) recommend pulmonary artery catheter monitoring with an infarction within 6 months of delivery, or when there is ventricular dysfunction. Others, including us, recommend such monitoring only if there is cardiac dysfunction.

In some women, invasive or surgical procedures may be indicated because of unrelenting disease. Hands and associates (1990) reported successful use of percutaneous transluminal coronary angioplasty in a pregnant woman at 36 weeks. Sanchez-Ramos and co-workers (1994) and Craig and Ilton (1999) described percutaneous balloon angioplasty and transluminal intracoronary stenting. Garry and colleagues (1996) used an intra-aortic balloon pump in a woman who sustained an infarction at 25 weeks. They then performed bypass grafting at 32 weeks.

HYPERTROPHIC CARDIOMYOPATHY. Although concentric left ventricular hypertrophy commonly develops after long-standing hypertension, there is a familial as well as a sporadic form not related to hypertension termed *idiopathic hypertrophic subaortic stenosis*. Recent epidemiological studies suggest that the disorder is common, affecting approximately 1 in 500 adults (Maron, 2004). It is commonly associated with pheochromocytoma, Friedreich ataxia, Turner syndrome, and neurofibromatosis. In the half of cases that are inherited, about 50 percent are autosomally dominant disorders (Baughman, 1992). The abnormality is in the myocardial muscle, and it is characterized by idiopathic left ventricular myocardial hypertrophy that may provide a pressure gradient to left ventricular outflow (Lang and Borow, 1991). Diagnosis is confirmed by Doppler echocardiography.

The majority of affected women are asymptomatic, but dyspnea, anginal or atypical chest pain, syncope, and arrhythmias may develop. Complex arrhythmias may progress to sudden death, which is the most common form of death. Asymptomatic patients with runs of ventricular tachycardia are especially prone to sudden death. Symptoms are usually worsened by exercise. Nishimura and Holmes (2004) have provided a recent scholarly review.

Management in Pregnancy. Although limited reports suggest that pregnancy is well tolerated, congestive heart failure develops in 40 percent of cases (Benitez, 1996). Thaman and co-workers (2003) reviewed 271 pregnancies in 127 affected women. Although there were no maternal deaths, more than 25 percent experienced at least one adverse cardiac symptom including dyspnea, chest pain, or palpitations. Strenuous exercise is prohibited during pregnancy. Abrupt positional changes are avoided to prevent reflex vasodilation and decreased preload. Likewise, drugs that evoke diuresis or diminish vascular resistance are not used. If symptoms develop, especially angina, β -adrenergic or calcium-channel blocking drugs are given. The route of delivery is determined by obstetrical indications. Spinal analgesia is contraindicated, and even carefully administered epidural analgesia is controversial (Camann and Thornhill, 1999). Endocarditis prophylaxis is given if bacteremia is suspected (see [Table 44-7](#)). Infants rarely demonstrate inherited lesions at the time of birth.

45. Chronic Hypertension

INTRODUCTION

The prevalence of chronic hypertension in American women has been chronicled for years, beginning with the 1960-1962 National Health Examination Survey (National Center for Health Statistics, 1964). Now known as the National Health and Nutrition Examination Survey (NHANES), this ongoing study is conducted by the National Center for Health Statistics and provides periodic information on the health of the United States population. In its most recent report, the average prevalence of hypertension in women 18 to 39 years of age was 7.2 percent for 1999 and 2000 (Hajjar and Kotchen, 2003). This is a substantive increase when compared with 5.1 percent for 1988 to 1991 and 6.1 percent for 1991 to 1994. Importantly, one third of all hypertensive patients in the United States are unaware of their diagnosis. The importance of hypertension in relation to women's health care was stressed in the recent review by the American College of Obstetricians and Gynecologists (2002).

Chronic hypertension is one of the most common medical complications encountered during pregnancy. Its variable incidence and severity, along with the well-known proclivity for pregnancy to induce or aggravate hypertension, has caused confusion concerning the management of hypertensive pregnant women. Most women with antecedent hypertension demonstrate improved blood pressure control during pregnancy. Some women, however, have worsening of hypertension that is frequently accompanied by proteinuria, pathological edema, and convulsions. These latter women — whose chronic hypertension antedates pregnancy — are indistinguishable from a woman who develops severe preeclampsia in her first pregnancy.

DEFINITIONS

There is a wide range of blood pressures in normal adults as well as in those with chronic hypertension. Categorization therefore relates to acute or long-term adverse effects associated with sustained levels of those blood pressures. These associations with normal or abnormal blood pressures are primarily based on morbidity and mortality in men. A useful categorization is that provided by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. In its seventh report, the Joint National Committee (2003) used the classification and management scheme presented in [Table 45-1](#). Within these categories, morbidity or mortality is further influenced by age, gender, race, and personal behaviors, including smoking, excessive alcohol intake, obesity, and physical activity.

In adults, proven benefits accrue with treatment of chronic hypertension at sustained diastolic blood pressures of 90 mm Hg or greater (Korotkoff phase V), systolic pressures of 160 mm Hg or more, or both. Benefits are apparent even in otherwise healthy adults. Treatment at even lower levels may benefit patients with evidence of renal or cardiac dysfunction, those who have had a cerebrovascular thrombosis or hemorrhage, elderly patients, or patients with appreciable underlying atherosclerotic disease or postmyocardial infarction. The Seventh Joint National Committee report (2003) recommends:

1. In persons older than 50 years of age, systolic pressures greater than 140 mm Hg are a more important cardiovascular disease risk factor than diastolic pressure.
2. Individuals with a systolic blood pressure of 120 to 139 mm Hg or a diastolic blood pressure of 80 to 89 mm Hg should be considered as *prehypertensive* and require health-promoting lifestyle modifications to prevent cardiovascular disease.
3. Thiazide-type diuretics should be used in drug treatment for most patients with uncomplicated hypertension, either alone or combined with drugs from other classes.
4. Most adults with hypertension require two or more medications to achieve a blood pressure less than 140/90 mm Hg (less than 130/80 mm Hg in patients with diabetes or renal disease).

Throughout middle and old age, blood pressure is strongly and directly related to vascular (and overall) mortality and with values down to at least 115/75 mm Hg (Prospective Studies Collaboration, 2002; Qureshi and colleagues, 2002).

DIAGNOSIS

Chronic hypertension precedes pregnancy or may be apparent prior to 20 weeks (see [Chap. 34](#), p. 764). Some women without chronic hypertension have repeated pregnancies in which *transient hypertension* appears only late in pregnancy and regresses postpartum. This hypertension is evidence of latent hypertensive vascular disease and is analogous to gestational diabetes. Long-term follow-up studies of Chesley and co-workers (1976) and Sibai and colleagues (1986b, 1991, 1992) support this view.

In most women with hypertension antedating pregnancy, increased blood pressure is the only demonstrable finding. Some, however, have complications that increase the risks during pregnancy and may shorten life expectancy, including hypertensive or ischemic cardiac disease, renal insufficiency, or a prior cerebrovascular event. Such hypertensive vascular disease in pregnancy is encountered more frequently in older women.

Obesity is an important factor predisposing to chronic hypertension (see [Chap. 43](#)). Specifically, chronic hypertension may be increased as much as tenfold in obese women, and these women are more likely to develop superimposed preeclampsia. Diabetes mellitus is also prevalent in chronically hypertensive women, and its interplay with obesity is overwhelming. Heredity plays an important role, and indeed, a number of genes inherited as mendelian traits have been described to cause hypertension (Lifton and colleagues, 2001; Nabel, 2003). In some cases, candidate genes for preeclampsia and chronic hypertension have been described (Levesque and associates, 2004). Hypertension is common in African Americans and Mexican Americans, and frequently many members of the same family are hypertensive.

In most women with chronic hypertension, blood pressure falls in the second trimester and then rises during the third trimester to levels somewhat above those in early pregnancy ([Fig. 45-1](#)). Adverse outcomes in these women are dependent

largely on whether superimposed preeclampsia develops.

Figure 45-1. Systolic and diastolic blood pressures (mean \pm SEM) during pregnancy in 90 untreated chronically hypertensive women (* — *). Also included are blood pressures (mean \pm SD) from 22 women during normal pregnancy (●—●). (Data from MacGillivray and associates, 1969; Sibai and colleagues, 1990a.)

TREATMENT IN NONPREGNANT ADULTS

Even at the mildest end of the spectrum of abnormal blood pressures categorized in [Table 45-1](#), interventions to reduce pressure are beneficial. Almost 30 trials involving about 162,000 participants have established that antihypertensive treatment in adults with mild to moderate hypertension decreases mortality, stroke, and major cardiac events (Blood Pressure Lowering Treatment Trialists' Collaboration, 2003; Gueyffier and collaborators, 1997; Psaty and colleagues, 2003). Antihypertensive therapy is associated with reductions in stroke that average 35 to 40 percent, myocardial infarction 20 to 25 percent, and heart failure more than 50 percent (Neal and colleagues, 2000). In patients with stage 1 hypertension (systolic pressure 140 to 159 mm Hg, diastolic pressure 90 to 99 mm Hg, or both) and additional cardiovascular risk factors, achieving a sustained 12 mm Hg-reduction in systolic pressure during 10 years in 11 patients will prevent one death (Ogden and colleagues, 2000).

Regardless of pregnancy status, women with stage 1 hypertension would likely have been placed on antihypertensive medications and lifestyle modifications, including cessation of smoking ([Table 45-2](#)). Psaty and co-workers (2003) reported that low-dose diuretics were the most effective first-line treatment. In the ALLHAT Trial (2002) of 33,357 adults 55 years of age or older, thiazide-type diuretics were superior to and less expensive than angiotensin-converting enzyme (ACE) inhibitors or calcium-channel blockers in prevention of cardiovascular disease. Results were similar for women as reported by Wing and colleagues (2003) for the Second Australian National Blood Pressure Study Group.

Clearly, antihypertensive therapy in nonpregnant women of reproductive age with sustained diastolic pressures of 90 mm Hg or greater would be considered standard. In women diagnosed with presumed chronic hypertension prior to midpregnancy, however, the benefits and safety of instituting antihypertensive therapy are less clear.

PRECONCEPTIONAL AND EARLY PREGNANCY EVALUATION

Women with chronic hypertension should ideally be counseled prior to pregnancy (see [Chap. 7](#), p. 193). The duration of hypertension, degree of blood pressure control, and current therapy is ascertained. Women with average pressures greater than 135/85 mm Hg measured at home are considered to be hypertensive. Home measurement devices should be checked for accuracy (American Heart Association, 2004). Women's general health, daily activities, diet, and adverse behaviors are also assessed. Prior adverse events such as a cerebrovascular accident or myocardial infarction, as well as cardiac or renal dysfunction, are especially pertinent. Women with these are at markedly increased risk for a recurrence or worsening during pregnancy. Those who require multiple medications for hypertension control, or those who are poorly controlled, are also at increased risk for adverse pregnancy outcomes.

Renal, hepatic, and cardiac function should be assessed. Ophthalmological evaluation is important for women with long-standing chronic hypertension. Echocardiography is indicated in women with any prior adverse outcome or in those with long-term hypertension. Gainer and co-workers (2005a) found that pregnant women with chronic hypertension requiring medication commonly have underlying heart lesions such as left ventricular hypertrophy when evaluated by echocardiography. Cardiac dysrhythmias or evidence of left ventricular hypertrophy indicate long-standing or poorly controlled hypertension, or both. Women with these conditions are at increased risk for congestive heart failure during pregnancy (see [Chap. 42](#), p. 991).

Renal function is assessed by serum creatinine and quantification of proteinuria. If either is abnormal, there is further increased risk for adverse pregnancy outcomes. The Working Group Report on High Blood Pressure in Pregnancy (2000) of the National Heart, Lung, and Blood Institute concluded that the risks of fetal loss and accelerated deterioration of renal disease are increased if serum creatinine is above 1.4 mg/dL around the time of conception. It can be difficult to separate the effects of the pregnancy from progression of renal disease (Cunningham and associates, 1990; Jones and Hayslett, 1996). Severity of renal insufficiency is inversely proportional to an increased risk of hypertensive complications during pregnancy, although the relationship is not linear (see [Chap. 48](#), p. 1103). Most clinicians believe that pregnancy is relatively contraindicated in women who maintain persistent diastolic pressures of more than 110 mm Hg despite therapy, require multiple antihypertensives, or have a serum creatinine level of more than 2 mg/dL. Even stronger contraindications are prior cerebrovascular thrombosis or hemorrhage, myocardial infarction, or cardiac failure. Symptoms at rest and with activity should be determined. Some clinicians recommend that women with prior cardiac dysfunction undergo baseline and longitudinal vital capacity testing throughout pregnancy to identify early pulmonary congestion. We have no experience with this and prefer to assess the women clinically.

EFFECTS OF CHRONIC HYPERTENSION ON PREGNANCY

MATERNAL EFFECTS. Most women taking monotherapy and whose hypertension is well controlled prior to pregnancy do well. Even these women, however, are at increased risk for superimposed preeclampsia and placental abruption. Jain (1997) reported a maternal mortality of 230 per 100,000 live births in women with hypertension. The more severe the baseline maternal disease, especially with documented end-organ damage, the more likely these complications.

Pregnancy-aggravated hypertension manifests as a sudden increase in blood pressure. Systolic pressures greater than 200 mm Hg or diastolic pressures of 130 mm Hg or more may rapidly result in renal or cardiopulmonary dysfunction. When there is superimposed severe preeclampsia or eclampsia, the outlook for the mother is serious unless the pregnancy is terminated.

Placental abruption is another common and serious complication (see [Chap. 35](#), p. 811). Weissman-Brenner and associates (2004) have also reported aortic dissection at term (see [Chap. 44](#), p. 1034).

Superimposed Preeclampsia. There is no precise definition of superimposed preeclampsia in women with chronic hypertension. In their review, August and Lindheimer (1999) found that superimposed preeclampsia occurred in 4 to 40 percent of these women. The incidence is higher in women with severe hypertension in early pregnancy (Sibai, 1991). The risk of superimposed preeclampsia is directly related to the severity of baseline hypertension, as well as the need for treatment to achieve control. In a Maternal-Fetal Medicine Units Network trial, Caritis and co-workers (1998) used predefined criteria for preeclampsia in 774 women with chronic hypertension. They identified superimposed preeclampsia in 25 percent. In these same women, Sibai and co-workers (1998) reported that the incidence of superimposed preeclampsia was similar whether or not the women had baseline proteinuria. The incidence significantly increased, however, in those who had hypertension for at least 4 years or who had preeclampsia during a prior pregnancy. Zeeman and colleagues (2003) found that uterine artery Doppler velocimetry showing increased impedance at 16 to 20 weeks and was predictive of superimposed preeclampsia at 28 to 32 weeks in women with chronic hypertension.

PREVENTION. Trials of low-dose aspirin to prevent preeclampsia in women with chronic hypertension have shown little benefit. In an early study, Beauflis and colleagues (1985) reported that therapy with low-dose aspirin and dipyridamole reduced the incidence of superimposed preeclampsia or fetal growth restriction. In a European multicenter trial, Uzan and co-workers (1991) found that these two drugs were associated with increased birthweight and decreased risk of fetal growth restriction when given to high-risk women. In the Network study by Caritis and associates (1998) cited above, the incidence of superimposed preeclampsia and fetal growth restriction was similar in women given low-dose aspirin or placebo. Also, reduction of thromboxane B₂ maternal serum levels was not predictive of improved pregnancy outcomes with low-dose aspirin (Hauth and colleagues, 1998).

In a summary of randomized trials of low-dose aspirin for women with chronic hypertension, Mulrow and colleagues (2000) suggested that the only benefit may be fewer preterm deliveries. More recently, Coomarasamy and colleagues (2003) performed a meta-analysis of 14 trials involving a total of 12,416 women. The investigators concluded that low-dose aspirin therapy for women with risk factors significantly reduced the frequency of perinatal death, preeclampsia, and preterm labor.

Placental Abruption. Premature placental separation is discussed in detail in [Chapter 35](#) (see p. 811). From a number of reports, the incidence of placental abruption of about 1 in 150 pregnancies is increased in women with chronic hypertension. Sibai and colleagues (1998) reported this rate to be 1.5 percent of 776 women. Caritis and associates (1998) reported that 1 to 2 percent of 2539 women at high risk for preeclampsia enrolled in a low-dose aspirin trial had placental abruption. Hauth and co-workers (1995) performed a meta-analysis of low-dose aspirin trials in women at high and low risk for preeclampsia, and they identified placental abruption in about 1.4 percent of cases. Ferrer and associates (2000) reviewed nine observational trials and concluded that abruption doubled in women with chronic hypertension.

When hypertension is severe, the likelihood of abruption is concomitantly increased. Vigil-De Gracia and colleagues (2003) reported its incidence to be 8.4 percent in 154 women with severe chronic hypertension in the second half of pregnancy. Smoking further increases these risks (Ananth and colleagues, 1999).

Maternal Economic and Lifestyle Factors. There are few quantitative data to assess economic and lifestyle factors in pregnant women with chronic hypertension. These women require more time with their physicians, including office visits, fetal-maternal assessment in the third trimester, and increased hospitalization. Rest at home affects economic stability and family dynamics. Women must take more time off from work, and this is especially burdensome if women are self-employed or must care for children or other family members. These realities should be discussed during preconceptional or early pregnancy counseling (see [Chap. 7](#), p. 193).

FETAL AND NEWBORN EFFECTS. Almost all adverse perinatal outcomes are increased in pregnancies complicated by chronic hypertension. A systematic review has been provided by Ferrer and colleagues (2000).

Fetal Growth Restriction. The incidence and severity of restricted fetal growth are directly related to the severity of hypertension. Both are also dependent on other maternal factors, on the growth chart used to arrive at this diagnosis, and on the accuracy of gestational dating. Maternal factors include age; hypertension control, including the need for additional antihypertensive medications; and the presence of end-organ damage such as renal or cardiac dysfunction. Growth restriction is further increased in women who develop superimposed preeclampsia.

In the Network trial described above, Sibai and colleagues (1998) reported that 10.7 percent of 763 women with chronic hypertension had small-for-gestational age (SGA) perinates. If these women had proteinuria early in pregnancy, 23 percent had infants with birthweights less than the 10th percentile. Although fetal growth restriction did not develop, Gainer and co-workers (2005b) found that women with chronic hypertension requiring medication who developed superimposed preeclampsia displayed sustained, slower fetal growth velocity by sonography as early as 23 weeks.

Other Adverse Perinatal Outcomes. Indicated preterm birth is increased in women with chronic hypertension (Meis and co-workers, 1998). In the Network study described earlier, Sibai and colleagues (1998) reported that 33 percent of 763 women with chronic hypertension delivered before 37 weeks and 18 percent before 35 weeks. Rey and Couturier (1994) found a 34-percent incidence of delivery before 37 weeks. The perinatal death rate is increased threefold to fourfold in women with chronic hypertension ([Fig. 45-2](#)).

Figure 45-2. Perinatal death rates in women with chronic hypertension compared with that of either normotensive controls or general obstetrical populations. Outcomes are shown as odds ratio [log scale]. (Data from Ferrer and colleagues, 2000.)

MANAGEMENT DURING PREGNANCY

The goal for pregnancy complicated by chronic hypertension is to reduce adverse maternal or perinatal outcomes. Management is targeted toward prevention of moderate or severe hypertension and prevention, delay, or improvement of severe pregnancy-aggravated hypertension. To some extent, these goals can be achieved pharmacologically. Blood pressure self-monitoring is encouraged with caveats for the accuracy of automated devices (Brown and colleagues, 2004). Personal health behavioral modifications include dietary counseling and reduction of behaviors such as smoking, alcohol, cocaine, or other substance abuse (see [Table 45-2](#)).

It is accepted that pregnant women with *severe hypertension* must always be treated for maternal indications regardless of pregnancy status. This includes those with prior adverse outcomes to include cerebrovascular events, myocardial infarction, and cardiac or renal dysfunction. We agree with the philosophy of beginning antihypertensive treatment in otherwise healthy pregnant women with persistent diastolic pressures of 100 mm Hg or greater (August and Lindheimer, 1999; Working Group Report, 2000). With end-organ dysfunction, treatment of pregnant women with diastolic pressures of 90 mm Hg or higher is considered.

There are no data indicating salutary effects on pregnancy outcomes with simply lowering blood pressure. Importantly, the incidence of superimposed preeclampsia is not appreciably affected. Although there is minimal evidence that outcomes are improved by such treatment, the same evidence attests to the apparent safety of maternal antihypertensive therapy. The latter excludes angiotensin-converting enzyme (ACE) inhibitors and perhaps atenolol. Despite lack of scientific data that treatment improves maternal or perinatal outcomes, some clinicians recommend empirical antihypertensive therapy. For example, Sibai (2002) recommends therapy in women with high-risk (as opposed to low-risk) chronic hypertension. As emphasized by the Working Group Report (2000), there is a need for further trials in these women.

ANTIHYPERTENSIVE DRUGS. The following summary of antihypertensive drugs is categorized by their primary mode of action and as abstracted from several sources, including the *2004 Physicians' Desk Reference*. In nonpregnant adults with chronic hypertension, results of large trials of single-drug therapy cited earlier support conclusions of Frohlich (2003) and August (2003) that antihypertensive use should be based on proven efficacy. Moreover, this efficacy should be proven in persons with the same degree of hypertension.

Diuretics. Thiazide as well as loop-acting diuretics such as furosemide are commonly used (Brater, 1998). In nonpregnant patients, diuretics lower blood pressure in the short term by sodium and water diuresis and intravascular volume depletion. With time, there is *sodium escape*, and intravascular volume depletion is corrected. This may not be true in pregnant women. Sibai and colleagues (1984) assessed plasma volume in pregnancy in 20 chronically hypertensive women. Plasma volume expansion was only about 20 percent in the half who continued diuretic therapy throughout pregnancy compared with 50 percent in the other half who discontinued treatment early in pregnancy. Perinatal outcomes were similar in both groups.

Some aspect of lowered peripheral vascular resistance may contribute to the effectiveness of diuretics. They reduce long-term morbidity and mortality in nonpregnant individuals with chronic hypertension (Williams, 2001). Largely due to theoretical concerns regarding maternal plasma volume expansion, diuretics are usually not instituted as first-line therapy during pregnancy, particularly after 20 weeks (Working Group Report, 2000).

Adrenergic-Blocking Agents. Some of these drugs act *centrally* by reducing sympathetic outflow to effect a generalized decreased vascular tone. Central-acting agents include clonidine and α -methyldopa. *Peripherally* acting β -adrenergic receptor blockers also cause a generalized decrease in sympathetic tone. Examples are propranolol, metoprolol, and atenolol. Labetalol is a commonly used α/β -adrenergic blocker. Peripheral blockers are thought to have more potential for postural hypotension than centrally acting agents. The most commonly used drugs in pregnancy to treat hypertension are methyldopa or a β - or α/β -receptor blocker.

Vasodilators. Hydralazine relaxes arterial smooth muscle and has been used parenterally for decades to safely treat severe peripartum hypertension (see [Chap. 34](#), p. 793). Use of oral hydralazine monotherapy for chronic hypertension is not recommended because of its weak antihypertensive effects and resultant tachycardia. It may be effective for long-term use as an adjunct to other antihypertensives, especially if chronic renal insufficiency is present.

Calcium-Channel Blockers. These agents are divided into three subclasses based on their modification of calcium entry into cells and interference with binding sites on voltage-dependent calcium channels. Common agents include the dihydropyridine, nifedipine, and the phenylalkyl amine derivative, verapamil. These agents have negative inotropic effects and thus can worsen ventricular dysfunction and congestive heart failure. Pahor and associates (2000) concluded that they are inferior to other first-line drugs in nonpregnant hypertensives. There is little published experience with these agents during pregnancy (Smith and colleagues, 2000).

Angiotensin-Converting Enzyme Inhibitors. ACE inhibitors inhibit the conversion of angiotensin-I to the potent vasoconstrictor angiotensin-II. These agents have worrisome fetal effects when used in the second and third trimesters. As discussed in [Chapter 14](#) (see p. 349), ACE inhibitors are associated with fetal hypocalvaria and renal defects (Briggs and colleagues, 2002).

Angiotensin-receptor blockers act in a manner similar to ACE inhibitors. That is, instead of blocking the production of angiotensin-II, they inhibit binding to its receptor.

DRUG TREATMENT DURING PREGNANCY. As discussed, continuation of prepregnancy antihypertensive treatment when women become pregnant is debated. Although pressure reduction is beneficial to the mother, it at least theoretically can decrease uteroplacental perfusion to possibly jeopardize her fetus. Outcomes from the few observational reports are shown in [Table 45-3](#). To summarize, these investigators found that most pregnancy outcomes were good without treatment. Perinatal mortality rates were low unless superimposed preeclampsia developed. Over time, neonatal care has markedly improved, with a resultant continued decline in mortality since these earlier observational reports.

Some randomized trials of drug therapy in pregnant women with mild chronic hypertension are shown in [Table 45-4](#). Only three trials were reported during the 1990s, and only two were of appreciable size. Thus, data are not sufficient to provide a definitive answer regarding whether to treat women with mild or even moderate hypertension in pregnancy. An important observation of the two large and more contemporaneous studies was that no adverse outcomes were found in the women given treatment. Thus, it is not unreasonable to treat women with uncomplicated mild or moderate sustained chronic hypertension who would be prescribed antihypertensive therapy when not pregnant.

The concern over fetal growth restriction due to reduced placental perfusion by lowering maternal blood pressure is confounded because worsening blood pressure itself is associated with abnormal fetal growth. Breart and colleagues (1982) found that women with chronic hypertension whose diastolic pressure was less than 90 mm Hg had a 3-percent risk of fetal growth restriction, those with 90 mm Hg had a 6-percent risk, and those with 110 mm Hg or more had a 16-percent risk. Growth restriction was not increased with maternal treatment of chronic hypertension in the two most recent large randomized trials (see [Table 45-4](#)).

Results of the study of chronic hypertension in pregnant women reported by the Memphis group are summarized in [Table 45-5](#). In this trial by Sibai and colleagues (1990a), the aim of therapy was to maintain pressure less than 140/90 mm Hg. Women treated throughout pregnancy had significantly lower blood pressures than women randomized to no treatment but, importantly, adverse outcomes were not altered by treatment. More women however, who initially were not given treatment eventually required antihypertensive therapy for serious hypertension, defined as greater than 160/110 mm Hg.

In the study by the Gruppo di Studio Ipertensione in Gravidanza (1998), 283 women were randomized to treatment with slow-release nifedipine, 10 mg twice daily, or to no treatment. After this, all women were treated with nifedipine if diastolic pressure exceeded 110 mm Hg. The investigators found neither benefits nor harm in either group. The rate of preterm delivery was 45 percent in treated women which was not significant from that of 37 percent in nontreated women. Fetal growth and birthweight were similar in both groups.

Severe Chronic Hypertension. As discussed, the prognosis for pregnancy outcomes with chronic hypertension is related to the severity of disease before pregnancy. Many women with severe hypertension often have underlying renal disease (Cunningham and colleagues, 1990). In the study by Sibai and co-workers (1986a) shown in [Table 45-3](#), there were 44 pregnancies in women whose blood pressure at 6 to 11 weeks was 170/110 mm Hg or higher. They all were given treatment with α -methyl dopa and oral hydralazine to maintain blood pressures less than 160/110 mm Hg. They were hospitalized for treatment with parenteral hydralazine if blood pressures exceeded 180/120 mm Hg. Half of all the women developed superimposed preeclampsia, and all adverse perinatal outcomes were in this group. Specifically, all infants in the women with superimposed preeclampsia were preterm, and nearly 80 percent were growth restricted. The perinatal mortality rate was 48 percent. In the women with severe chronic hypertension who did not develop superimposed preeclampsia, only 5 percent of fetuses were growth restricted and all survived.

ANTIHYPERTENSIVE DRUG SELECTION. Adrenergic-blocking drugs have been used extensively in England, Scotland, and Australia to treat chronically hypertensive pregnant women (Redman, 1982; Rubin and colleagues, 1983; Walker and associates, 1983). The results of treatment with labetalol are consistent with the view that the drug offers no advantages over α -methyl dopa (Sibai and colleagues, 1990a). Butters and colleagues (1990) reported that atenolol treatment resulted in a higher incidence of growth-restricted neonates compared with that of untreated controls. Lydakis and colleagues (1999) studied 223 such women and concluded that atenolol treatment was associated with lower birthweight and ponderal indices (birthweight/length³). There was also a trend toward more preterm births when compared with the effects of other antihypertensives or of no treatment. Easterling and associates (1999) also concluded that atenolol therapy was associated with reduced infant birthweight. Montan and Ingemarsson (1989) reported ominous intrapartum fetal heart rate patterns in 20 percent of women receiving β -blocker therapy for hypertension. Ominous patterns were increased even more in growth-restricted fetuses as well as in half of women given epidural analgesia. Magee and Duley (2001) concluded that it is not clear if benefits outweigh the risks when β -blockers are used to treat mild to moderate chronic hypertension.

Experiences are too meager to make recommendations about routine use of nifedipine for pregnant women with chronic hypertension. Bartolus and associates (2000) reported the effects of maternal nifedipine on child development at 18 months. Outcomes were similar in 94 infants whose mothers were treated compared with those of 161 not exposed. Malformations were identified in 5.3 percent of nifedipine-exposed women compared with 1.2 percent of controls — the number of subjects precluded any tests for significance.

Mulrow and colleagues (2000) performed a review for the Agency for Healthcare Research and Quality and summarized the risks and benefits of antihypertensive agents given during pregnancy. They found no evidence of major adverse fetal or maternal events. Cockburn and colleagues (1982) found similar outcomes in 195 children born to hypertensive women participating in a randomized trial of methyl dopa treatment. (The children were followed to 7.5 years of age.)

Therapy Recommendations. The Working Group on High Blood Pressure in Pregnancy (2000) emphasizes the limited data from which to draw conclusions as to whether to treat mild chronic hypertension in pregnancy. The group did recommend empirical therapy in women whose blood pressures exceed threshold levels of 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic or with the presence of target organ damage such as left ventricular hypertrophy or renal insufficiency. They also concluded that early treatment of hypertension would probably reduce subsequent hospitalization during pregnancy. In the study by Sibai and associates (1990a), subsequent treatment was needed for dangerous hypertension in 11 percent of women not given initial treatment. This compared with only 6 percent in women initially randomized to either α -methyl dopa or labetalol earlier in pregnancy.

Methyl dopa has been extensively studied during pregnancy (Montan and colleagues, 1992, 1993). In their review, Ferrer and colleagues (2000) concluded that experience with methyl dopa in the first trimester is reasonably large, that no pattern of fetal anomalies has emerged, and that newer antihypertensives have not been sufficiently studied. For all of these reasons, Haddad and Sibai (1999) recommended methyl dopa as the initial agent for pregnant women with chronic hypertension.

FETAL ASSESSMENT. Women with well-controlled chronic hypertension with no complicating factors can generally be expected to have a good pregnancy outcome. Because even otherwise healthy women with mild hypertension

have an increased risk of superimposed preeclampsia and fetal growth restriction, serial antepartum assessment of fetal well-being as detailed in [Chapter 15](#) (see p. 373) is recommended by the American College of Obstetricians and Gynecologists (1999). There are no data from which to assess either benefits or harm associated with various monitoring strategies for these women (Ferrer and colleagues, 2000).

PREGNANCY-AGGRAVATED HYPERTENSION OR SUPERIMPOSED

PREECLAMPSIA. The cited incidence of superimposed preeclampsia for women with chronic hypertension varies depending on severity of underlying disease (see [Table 45-3](#)). In the prospective study by the Network, it was about 25 percent (Caritis and co-workers, 1998). The diagnosis may be difficult to make, especially in women with hypertension who have underlying renal disease with proteinuria (Cunningham and associates, 1990). Conditions that support the diagnosis of superimposed preeclampsia include new-onset proteinuria; neurological symptoms, including severe headaches and visual disturbances; generalized edema; oliguria; and certainly, convulsions or pulmonary edema. Laboratory abnormalities that support the diagnosis include increasing serum creatinine, thrombocytopenia, or appreciable serum hepatic transaminase elevations.

Some women with chronic hypertension have worsening during pregnancy with no other findings of superimposed preeclampsia. This is most commonly encountered near the end of the second trimester. In the absence of other supporting criteria for superimposed preeclampsia, including fetal growth restriction or decreased amniotic fluid volume, this likely represents the higher end of the normal blood pressure curve shown in [Figure 45-1](#). In such women, it is reasonable to begin or to increase the dose of antihypertensive therapy.

DELIVERY. In women with uncomplicated and well-controlled chronic hypertension and with documented normal fetal growth and amniotic fluid volume, it is our practice to await labor at term. In women with complications or in whom fetal testing becomes abnormal, induction is considered. Superimposed severe preeclampsia prompts delivery even with markedly preterm pregnancy. Special consideration for delivery prior to term of chronically hypertensive women with a multifetal gestation also is warranted. When these women develop preeclampsia, they have an increased risk for placental abruption and poor neonatal outcomes compared with those with a singleton pregnancy (Sibai and colleagues, 2000).

Vaginal delivery is usually attempted, even in women with severe preeclampsia. Most women can be induced successfully and deliver vaginally (Alexander and colleagues, 1999; Atkinson and associates, 1995). Epidural analgesia for labor pain is appropriate in women with chronic hypertension with or without preeclampsia (see [Chap. 19](#), p. 483).

POSTPARTUM CONSIDERATIONS. In many respects, postpartum observation and prevention and management of adverse complications are similar in women with severe chronic hypertension and in those with severe preeclampsia-eclampsia. The development of cerebral or pulmonary edema, heart failure, or renal dysfunction is especially high within 24 to 36 hours following delivery (Benedetti and colleagues, 1980, 1985; Cunningham and associates, 1986; Sibai and co-workers, 1990b). Following delivery, as maternal peripheral resistance increases, left ventricular workload also increases. This increase is further aggravated by appreciable amounts of interstitial fluid that are mobilized for excretion as endothelial damage is reversed. In these women, sudden hypertension — either moderate or severe — exacerbates diastolic dysfunction and causes pulmonary edema (Cunningham and colleagues, 1986; Gandhi and associates, 2001). Prompt hypertension control, along with diuretic therapy, usually quickly resolves pulmonary edema.

Women with chronic hypertension and superimposed severe preeclampsia most often have markedly contracted blood volumes compared with those of normal pregnant women (Silver and associates, 1998; Zeeman and colleagues, 2002). These women have marked vasoconstriction and, in general, have relatively increased blood loss, especially following cesarean delivery, which may cause appreciable postpartum prerenal oliguria. It may be difficult and hazardous to attempt to maintain intravascular volume and renal perfusion solely with intravenous crystalloid or colloid solutions. In such women, blood transfusion may be necessary to maintain intravascular volume to ensure tissue perfusion.

51. Hematological Disorders

INTRODUCTION

Pregnancy induces physiological changes that often confuse the diagnosis of hematological disorders and assessment of their treatment. This is especially true for anemia. A number of pregnancy-induced hematological changes are discussed in detail in [Chapter 5](#) (see p. 129). One of the most significant changes is blood volume expansion with a disproportionate plasma volume increase, resulting in a normally decreased hematocrit.

Pregnant women are susceptible to hematological abnormalities that may affect any woman of childbearing age. These include chronic disorders such as hereditary anemias; immunological thrombocytopenia; and malignancies, including leukemias and lymphomas. Other disorders arise during pregnancy because of pregnancy-induced demands, such as iron-deficiency and megaloblastic anemias. Pregnancy may also unmask underlying hematological disorders such as compensated hemolytic anemias caused by hemoglobinopathies or red cell membrane defects. Finally, any hematological disease may first arise during pregnancy, such as autoimmune hemolysis or aplastic anemia.

ANEMIAS

Extensive hematological measurements have been made in healthy nonpregnant women. As shown in [Table 51-1](#), anemia is defined as hemoglobin concentration less than 12 g/dL in nonpregnant women and less than 10 g/dL during pregnancy or the puerperium. The Centers for Disease Control and Prevention (1990) defined anemia as less than 11 g/dL in the first and third trimesters and less than 10.5 g/dL in the second trimester ([Fig. 51-1](#)).

The modest fall in hemoglobin levels during pregnancy is caused by a relatively greater expansion of plasma volume compared with the increase in red cell volume. The disproportion between the rates at which plasma and erythrocytes are added to the maternal circulation is greatest during the second trimester. The long-used term *physiological anemia* to describe this process is an oxymoron and should be discarded. Late in pregnancy, plasma expansion essentially ceases while hemoglobin mass continues to increase.

After delivery, the hemoglobin level typically fluctuates to a modest degree and then rises to and usually exceeds the nonpregnant level. The rate and magnitude of increase early in the puerperium result from the amount of hemoglobin added during pregnancy and the amount of blood loss at delivery modified by a puerperal decrease in plasma volume.

Frequency of Anemia. The frequency of anemia during pregnancy depends primarily on iron supplementation. It is more common among indigent women. Taylor and associates (1982) reported that hemoglobin levels at term averaged 12.7 g/dL among women who took supplemental iron compared with 11.2 g/dL for women who did not. Bodnar and associates (2001) studied a cohort of 59,248 pregnancies and found a prevalence of 27 percent for postpartum anemia. Although this was strongly correlated with prenatal anemia, it was found in 21 percent of women with normal prenatal hemoglobin levels.

Effects of Anemia on Pregnancy. The etiology of the more common anemias encountered in pregnancy are listed in [Table 51-2](#). The specific cause of anemia is important when evaluating effects on pregnancy outcome. For example, maternal and perinatal outcomes are altered markedly in women with sickle-cell anemia.

Most studies of the effects of anemia on pregnancy, such as those discussed in [Chapter 8](#) (see p. 216), describe large populations. These likely deal with nutritional anemias and specifically those due to iron deficiency. Klebanoff and co-workers (1991) studied nearly 27,000 women and found a slightly increased risk of preterm birth with midtrimester anemia. Lieberman and colleagues (1987) found an association with low hematocrit and preterm birth in black women. Anemia may be associated with fetal growth restriction that, according to Barker and associates (1990), may lead to adult cardiovascular disease (see [Chap. 38](#), p. 1028). Kadyrov and co-workers (1998) have provided evidence that maternal anemia influences placental vascularization by altering angiogenesis during early pregnancy.

According to the World Health Organization, anemia contributes to 40 percent of maternal deaths in third world countries (Viteri, 1994). The at-first paradoxical finding was that ironically, healthy women with higher hemoglobin concentrations are also at increased risk for adverse pregnancy outcome. These latter findings may result from the curtailment of normal blood volume expansion of pregnancy. For example, Murphy and colleagues (1986) described over 54,000 singleton pregnancies in the Cardiff Birth Survey and reported excessive perinatal morbidity with *high* maternal hemoglobin concentrations. Scanlon and associates (2000) studied the relationship between maternal hemoglobin levels and preterm or growth-restricted infants in 173,031 pregnancies. Women whose hemoglobin concentration was three standard deviations *below* the mean at 12 weeks had a 1.7-fold risk of preterm birth. Conversely, those women whose levels were three standard deviations *above* the mean at 12 or 18 weeks had 1.3- to 1.8-fold increases in fetal growth restriction.

Figure 51-1. Mean hemoglobin concentrations (●—●) and 5th and 95th (○—○) percentiles for healthy pregnant women taking iron supplements. (Data from Centers for Disease Control and Prevention, 1989.)

IRON-DEFICIENCY ANEMIA. The two most common causes of anemia during pregnancy and the puerperium are iron deficiency and acute blood loss. The Centers for Disease Control and Prevention (1989) estimated that about 8 million American women of childbearing age were iron deficient. In a typical singleton gestation, the maternal need for iron averages close to 800 mg—300 mg for the fetus and placenta and 500 mg, if available, for maternal hemoglobin mass expansion. Approximately 200 mg more are shed through the gut, urine, and skin. The total amount (1000 mg) considerably exceeds the iron stores of most women and results in iron-deficiency anemia.

With the rather rapid expansion of blood volume during the second trimester, iron deficiency is often manifested by an appreciable drop in hemoglobin concentration. In the third trimester, additional iron is needed to augment maternal hemoglobin and for transport to the fetus. Because the amount of iron diverted to the fetus is similar in a normal and in an iron-deficient mother, the newborn infant of a severely anemic mother does not suffer from iron-deficiency anemia. As discussed in [Chapter 17](#) (see p. 431), neonatal iron stores are related to maternal iron status and to cord clamping.

Diagnosis. Classical morphological evidence of iron-deficiency anemia is erythrocyte hypochromia and microcytosis is less prominent in the pregnant woman compared with that in the nonpregnant woman. Moderate iron-deficiency anemia during pregnancy usually is not accompanied by obvious morphological changes in erythrocytes. Serum ferritin levels, however, are lower than normal, and there is no stainable bone marrow iron. **Iron-deficiency anemia during pregnancy is the consequence primarily of expansion of plasma volume without normal expansion of maternal hemoglobin mass.**

The initial evaluation of a pregnant woman with moderate anemia should include measurements of hemoglobin, hematocrit, and red cell indices; careful examination of a peripheral blood smear; a sickle-cell preparation if the woman is of African origin; and measurement of serum iron, ferritin, or both. Serum ferritin levels normally decline during pregnancy (Goldenberg and colleagues, 1996). Levels less than 15 $\mu\text{g/L}$ confirm iron-deficiency anemia (Centers for Disease Control and Prevention, 1989). Van den Broek and colleagues (1998) found that a cutoff point of 30 $\mu\text{g/L}$ has an 85-percent positive and a 90-percent negative predictive value. Pragmatically, the diagnosis of iron deficiency in moderately anemic pregnant women usually is presumptive and based largely on exclusion.

When pregnant women with moderate iron-deficiency anemia are given adequate iron therapy, a hematological response is detected by an elevated reticulocyte count. The rate of increase of hemoglobin concentration or hematocrit is typically slower than in nonpregnant women due to the differences in blood volumes.

Treatment. Correction of anemia and restitution of iron stores can be accomplished with simple iron compounds—ferrous sulfate, fumarate, or gluconate—that provide about 200 mg daily of *elemental iron*. If the woman cannot or will not take oral iron preparations, then parenteral therapy is given (Andrews, 1999; Hallak and associates, 1997). There are equivalent increases in hemoglobin levels in women given either oral or parenteral iron therapy (Bayouneu and colleagues, 2002; Sharma and co-workers, 2004).

Transfusions of red cells or whole blood seldom are indicated unless hypovolemia from blood loss coexists or an emergency operative procedure must be performed on a severely anemic woman. To replenish iron stores, oral therapy should be continued for 3 months after anemia has been corrected.

ANEMIA FROM ACUTE BLOOD LOSS. In early pregnancy, anemia caused by acute blood loss is common in instances of abortion, ectopic pregnancy, and hydatidiform mole. More commonly, anemia from obstetrical hemorrhage is encountered postpartum. Massive hemorrhage demands immediate treatment as described in [Chapter 35](#) (see p. 839). After hypovolemia has been overcome and hemostasis achieved, residual anemia is treated with iron. In a moderately anemic woman (hemoglobin greater than 7 g/dL) who is hemodynamically stable, can ambulate without adverse symptoms, and is not septic, iron therapy is given for at least 3 months.

ANEMIA ASSOCIATED WITH CHRONIC DISEASE. Weakness, weight loss, and pallor have been recognized since antiquity as characteristics of chronic disease. A wide variety of disorders, such as chronic infections and neoplasms, result in moderate and sometimes severe anemia, usually with slightly hypochromic and microcytic erythrocytes. Chronic renal failure, cancer and chemotherapy, human immunodeficiency virus (HIV) infection, and chronic inflammation are the most common causes.

In nonpregnant patients with chronic inflammatory diseases, the hemoglobin concentration is rarely less than 7 g/dL, bone marrow cellular morphology is not altered, serum iron concentration is decreased, and serum ferritin levels usually are elevated. Thus, although slightly different from each other mechanistically, these anemias share similar features that include varying degrees and combinations of alterations in reticuloendothelial function, iron metabolism, and decreased erythropoiesis (Andrews, 1999).

During pregnancy, a number of chronic diseases may cause anemia, including chronic renal disease, suppuration, inflammatory bowel disease, systemic lupus erythematosus, granulomatous infections, malignant neoplasms, and rheumatoid arthritis. Chronic anemia is typically intensified as plasma volume expands out of proportion to red cell mass expansion.

Chronic Renal Disease. Any type of chronic renal insufficiency can be accompanied by anemia, usually due to erythropoietin deficiency with an element of anemia of chronic disease. During pregnancy, the degree of red cell mass expansion is inversely related to renal impairment. However, total blood volume expansion usually is normal and anemia is intensified (Cunningham and associates, 1990).

Pyelonephritis. Women who have acute *pyelonephritis* with sepsis syndrome often develop overt anemia. This is caused by acute red cell destruction from endotoxin-mediated sepsis, but with normal erythropoietin production (Cavenee and colleagues, 1994).

Treatment. Treatment with *recombinant erythropoietin* has been used successfully to treat anemia of chronic renal insufficiency, chronic inflammation, and malignancy (Goodnough and associates, 1997). Reports of its use during pregnancy are limited (Braga and colleagues, 1996; Vora and Gruslin, 1998). One worrisome side effect is hypertension, which is already prevalent in women with renal disease. In the study by Braga and co-workers (1996), one of the five treated pregnant women developed a placental abruption associated with hypertension. In addition, Casadevall and colleagues (2002) reported pure red cell aplasia and anti-erythropoietin antibodies in 13 nonpregnant patients given erythropoietin.

MEGALOBLASTIC ANEMIA. These anemias are characterized by blood and bone marrow abnormalities from impaired DNA synthesis. Worldwide, the prevalence of megaloblastic anemia during pregnancy varies considerably, and in

the United States, it is rare.

Folic Acid Deficiency. In the United States, megaloblastic anemia beginning during pregnancy almost always results from folic acid deficiency. In the past, this condition was referred to as *pernicious anemia of pregnancy*. It usually is found in women who do not consume fresh green leafy vegetables, legumes, or animal protein. As folate deficiency and anemia worsen, anorexia often becomes intense, further aggravating the dietary deficiency. In some instances, excessive ethanol ingestion either is the cause or contributes to folate deficiency.

In nonpregnant women, folic acid requirement is 50 to 100 $\mu\text{g}/\text{day}$. During pregnancy, requirements are increased, and 400 $\mu\text{g}/\text{day}$ are recommended (see [Chap. 8](#), p. 218). The earliest biochemical evidence is low plasma folic acid concentrations. The earliest morphological evidence usually is hypersegmentation of neutrophils, and newly formed erythrocytes are macrocytic. With preexisting iron deficiency, macrocytic erythrocytes cannot be detected by measurement of the mean corpuscular volume. Careful examination of a smear of peripheral blood, however, usually demonstrates some macrocytes. As the anemia becomes more intense, peripheral nucleated erythrocytes appear. At the same time, examination of the bone marrow discloses megaloblastic erythropoiesis. Anemia may then become severe, and thrombocytopenia, leukopenia, or both may develop. The fetus and placenta extract folate from maternal circulation so effectively that the fetus is not anemic despite severe maternal anemia. There have been instances in which newborn hemoglobin levels were 18 g/dL or more, whereas maternal values were as low as 3.6 g/dL (Pritchard and Scott, 1970).

TREATMENT. The treatment of pregnancy-induced megaloblastic anemia should include folic acid, a nutritious diet, and iron. As little as 1 mg of folic acid administered orally once daily produces a striking hematological response. By 4 to 7 days after beginning treatment, the reticulocyte count is increased, and leukopenia and thrombocytopenia are corrected.

PREVENTION. A diet sufficient in folic acid prevents megaloblastic anemia. A great deal of attention has been devoted to the role of folate deficiency in the genesis of neural-tube defects (see [Chap. 8](#), p. 218; see [Chap. 12](#), p. 302). The Centers for Disease Control and Prevention (1992) and the American College of Obstetricians and Gynecologists (1996) recommended that all women of childbearing age consume at least 0.4 mg of folic acid daily. Additional folic acid is given in circumstances in which folate requirements are increased, such as in multifetal pregnancy, hemolytic anemia, Crohn disease, alcoholism, and inflammatory skin disorders. There is evidence that women who previously have had infants with neural-tube defects have a lower recurrence rate if daily 4-mg folic acid is given prior to and throughout early pregnancy.

Vitamin B₁₂ Deficiency.

Megaloblastic anemia caused by lack of vitamin B₁₂, that is, cyanocobalamin, during pregnancy is exceedingly rare. In *Addisonian pernicious anemia*, a lack of intrinsic factor results in failure to absorb vitamin B₁₂. It is an extremely uncommon autoimmune disease in women of reproductive age and typically has its onset in women older than 40 years. Unless treated with vitamin B₁₂, infertility may be a complication. In our limited experience, vitamin B₁₂ deficiency in pregnant women is more likely encountered following partial or total gastric resection. Other causes are Crohn disease, ileal resection, and bacterial overgrowth in the small bowel.

During pregnancy, vitamin B₁₂ levels are lower than nonpregnant values because of decreased serum concentrations of carrier proteins, the *transcobalamins* (Zamorano and colleagues, 1985). Women who have had a total gastrectomy require 1000 μg of vitamin B₁₂ intramuscularly at monthly intervals. Those with a partial gastrectomy usually do not need such therapy, but vitamin B₁₂ levels during pregnancy should be measured.

ACQUIRED HEMOLYTIC ANEMIAS

Autoimmune Hemolytic Anemia. This is an uncommon condition, and the cause of aberrant antibody production is unknown. Typically both the direct and indirect antiglobulin (Coombs) tests are positive. Anemias caused by these factors may be due to warm-active autoantibodies (80 to 90 percent), cold-active antibodies, or a combination. These syndromes also may be classified as primary (idiopathic) or secondary due to underlying diseases or other factors. Examples of the latter include lymphomas and leukemias, connective tissue diseases, infections, chronic inflammatory diseases, or drug-induced (Provan and Weatherall, 2000). *Cold-agglutinin disease* may be induced by *Mycoplasma pneumoniae* or infectious mononucleosis.

Hemolysis and positive antiglobulin tests may be the consequence of either IgM or IgG anti-erythrocyte antibodies. Spherocytosis and reticulocytosis are characteristic of the peripheral blood smear. IgM antibodies do not cross the placenta, and thus fetal red cells are not affected.

There may be marked acceleration of hemolysis during pregnancy. Glucocorticoids usually are effective, and treatment is with prednisone, 1 mg/kg per day, or its equivalent. Coincidental thrombocytopenia usually is corrected by therapy. Transfusion of red cells is complicated by the presence of circulating anti-erythrocyte antibodies. Warming the donor cells to body temperature decreases their destruction by cold agglutinins.

Drug-Induced Hemolytic Anemia. This must be differentiated from other forms of autoimmune hemolytic anemia. Hemolysis typically is mild, resolves on withdrawing the drug, and can be prevented by avoidance of the drug. Mechanisms of action generally are through drug-mediated immunological injury to red cells. The drug may act as a high-affinity hapten with a red cell protein to which antidrug antibodies attach (e.g., IgM antipenicillin or anticephalosporin antibodies). Other drugs become low-affinity haptens and adhere to cell membrane proteins. Examples include probenecid, quinidine, rifampin, and thiopental. In other cases, the mechanism of antibody induction is unknown.

The severity of symptoms depends on the degree of hemolysis. Usually there is mild to moderate chronic hemolysis, but some drugs that act as low-affinity haptens may precipitate severe acute hemolysis. Garratty and associates (1999) described seven cases of severe direct Coombs-positive hemolytic anemia caused by cefotetan prophylaxis for obstetrical procedures. In most cases, withdrawing the offending drug results in reversal of symptoms. Corticosteroids are of questionable efficacy. Drug-induced hemolysis is much more often related to a congenital erythrocyte enzymatic defect, such as *glucose-6-phosphate*

dehydrogenase (G6PD) deficiency, especially in African-American women (see p. 1149).

Pregnancy-Induced Hemolytic Anemia. Unexplained hemolytic anemia during pregnancy is a rare but distinct entity in which severe hemolysis develops early in pregnancy and resolves within months after delivery. There is no evidence of an immune mechanism or for any intraerythrocytic or extraerythrocytic defects (Starksen and associates, 1983). Because the fetus-infant also may demonstrate transient hemolysis, an immunological cause is suspected. Maternal corticosteroid treatment usually is effective. We have observed one woman with recurrent hemolysis during several pregnancies, and in each instance, intense severe hemolytic anemia was controlled by prednisone given until delivery.

Paroxysmal Nocturnal Hemoglobinuria. Although commonly regarded as a hemolytic anemia, this hemopoietic stem cell disorder is characterized by formation of defective platelets, granulocytes, and erythrocytes. Paroxysmal nocturnal hemoglobinuria is acquired and arises from one abnormal clone of cells, much like a neoplasm (Packham, 1998). One mutated X-linked gene responsible for this condition is termed *PIG-A* because it codes for phosphatidylinositol glycan protein A. Resultant abnormal anchor proteins of the erythrocyte and granulocyte membrane make them unusually susceptible to lysis by complement (Provan and Weatherall, 2000).

This is an acquired chronic hemolytic anemia with insidious onset. The severity ranges from mild to lethal. Hemoglobinuria develops at irregular intervals and is not necessarily nocturnal. Hemolysis may be initiated by transfusions, infections, or surgery. Almost 40 percent of patients suffer venous thromboses, as well as renal dysfunction, hypertension, and Budd-Chiari syndrome. Median survival after diagnosis is 10 years, but spontaneous long-term remission occurs in 15 percent of cases (Hillmen and colleagues, 1995). Hillmen and associates (2004) reported decreased hemolysis from treatment with eculizumab, an antibody that inhibits complement activation. Bone marrow transplantation is the definitive treatment.

EFFECTS ON PREGNANCY. Paroxysmal nocturnal hemoglobinuria is a serious and unpredictable disease and pregnancy may be dangerous. Greene and colleagues (1983) reviewed 31 cases in pregnancy and found that complications developed in over 75 percent. Maternal mortality was 10 percent, and postpartum venous thrombosis occurred in almost 50 percent of the women. Solal-Celigny and co-workers (1988) reported eight pregnancies with only four surviving infants. In a multicenter study, De Gramont and colleagues (1987) reported complications in two thirds of 38 pregnancies. Although there were no maternal deaths, there was life-threatening hemolysis and hemorrhage.

Other Acquired Anemias. Fragmentation (microangiopathic) hemolysis with visible hemoglobinemia is seen with severe preeclampsia and eclampsia (Pritchard and associates, 1976). Mild degrees are likely present in most cases of severe disease and may be referred to as *HELLP syndrome*—hemolysis, elevated liver enzymes, and low platelets (see [Chap. 34](#), p. 773). The most fulminant acquired hemolytic anemia encountered during pregnancy is caused by the exotoxin of *Clostridium perfringens* (see [Chap. 42](#), p. 994) or by group A β -hemolytic streptococcus (see [Chap. 31](#), p. 721). Gram-negative bacterial endotoxin, that is, lipopolysaccharide, especially with severe pyelonephritis, may be accompanied by hemolysis and mild to moderate anemia (Cox and colleagues, 1991).

HEMOLYTIC ANEMIAS CAUSED BY INHERITED ERYTHROCYTE DEFECTS.

The normal erythrocyte is shaped like a biconcave disc, and there is a redundancy of membrane surface area relative to volume. This allows numerous cycles of reversible deformations as the erythrocyte withstands shearing forces within arteries and negotiates through splenic slits half the width of its cross-sectional diameter. Several inherited red cell membrane defects or enzyme deficiencies result in destabilization of the membrane lipid bilayer. The loss of lipids from the erythrocyte membrane causes a surface area deficiency and poorly deformable cells that undergo hemolysis ([Fig. 51-2](#)). There are varying degrees of anemia. Examples of these inherited membrane defects that cause accelerated destruction are *hereditary spherocytosis*, *pyropoikilocytosis*, and *ovalocytosis*.

Hereditary Spherocytosis. Several inherited molecular deficits in erythrocyte membrane proteins give rise to the syndrome of hereditary spherocytosis. Although most are due to an autosomally dominant, variably penetrant *spectrin* deficiency. Others are autosomally recessive or de novo gene mutations and may be caused by deficiency of *ankyrin*, *protein 4.2*, *moderate band 3*, or combinations thereof (Bunn and Rosse, 2001, Yawata and colleagues, 2000). These disorders are characterized by varying degrees of anemia and jaundice as the consequence of hemolysis. Confirmation of the diagnosis is by documentation of spherocytes on peripheral smear, reticulocytosis, and increased osmotic fragility.

Hemolysis with corresponding anemia is dependent on an intact spleen, which is usually enlarged. Splenectomy, although not correcting the membrane defect, does greatly reduce hemolysis, anemia, and jaundice. So-called *crisis*, characterized by severe anemia from accelerated red cell destruction or more likely failure of production, or both, may develop in the woman with a functioning spleen. Infection must be detected and vigorously treated. In some cases, red cell hypoplasia develops concomitantly with B19 parvovirus infection (see [Chap. 58](#), p. 1279).

PREGNANCY. In general, women with hereditary spherocytosis do well during pregnancy. Folic acid supplementation is recommended. Maberry and associates (1992) reported the Parkland Hospital experience with 50 pregnancies in 23 women with spherocytosis. In late pregnancy, the mean hematocrit was 31 percent (range 23 to 41) and reticulocyte counts ranged from 1 to 23 percent. There were eight abortions, and four of 42 infants were born preterm, but none were growth restricted. Infection in four women intensified hemolysis, and three required transfusions. Similar results were reported by Pajor and colleagues (1993) in 19 pregnancies in eight women. The newborn who has inherited hereditary spherocytosis may have hyperbilirubinemia and anemia. We observed the hemoglobin level to fall to as low as 5.0 g/dL by 5 weeks of age in one infant.

Red Cell Enzyme Deficiencies. A deficiency of erythrocyte enzymes used for anaerobic glucose utilization may cause *hereditary nonspherocytic anemia*. Most cases are inherited as autosomal recessive traits. *G6PD deficiency*, by far the most common, a well-known exception, is X-linked. There are more than 400 variants of G6PD, predominantly due to a base substitution leading to an amino acid replacement and a broad range of clinical severity (Beutler, 1991). In the A (homozygous) variant, both X chromosomes are affected, and erythrocytes are markedly deficient in normal enzyme activity. This condition is inherited by about 2 percent of African-American women. In the heterozygous variant, only one X chromosome is deficient. This condition occurs in 10 to 15 percent of African-American women and may confer some degree of protection against malaria (Mockenhaupt and colleagues, 2003). Random X-chromosome inactivation, or *lyonization*, results in a variable deficiency of enzyme activity. Infections or drugs may induce hemolysis in both heterozygous as well as

homozygous women. Anemia is usually episodic, although some variants induce chronic nonspherocytic hemolysis. Because young erythrocytes contain more enzyme activity than older erythrocytes, in the absence of bone marrow depression, anemia ultimately stabilizes and is corrected soon after the drug is discontinued.

Pyruvate kinase deficiency, although uncommon, is probably the next most common enzyme deficiency. It is inherited as an autosomal recessive trait. Due to recurrent transfusions in homozygous carriers, iron overload is common, and associated myocardial dysfunction should be monitored (Dolan and colleagues, 2002). Conservative management without transfusions can usually be accomplished (Ghidini and Korke, 1998). Recurrent hydrops fetalis due to homozygously affected fetuses has been described, and fetal anemia and pyruvate kinase deficiency were confirmed using funipuncture (Gilsanz and colleagues, 1993).

Other very rare enzyme abnormalities may cause hemolysis. Although the degree of chronic hemolysis varies, most episodes of severe anemia with enzyme deficiencies are induced by drugs or infections. During pregnancy, iron and folic acid are given, oxidant drugs are avoided, and bacterial infections are treated promptly.

Figure 51-2. Scanning electron micrograph showing (A) normal-appearing erythrocytes from a heterozygous carrier of recessive spherocytosis, and (B) her daughter, a homozygote with severe anemia. (From Agre, 1989, with permission.)

APLASTIC AND HYPOPLASTIC ANEMIA. Although rarely encountered during pregnancy, aplastic anemia is a grave complication. The diagnosis includes anemia, usually with thrombocytopenia, leukopenia, and markedly hypocellular bone marrow (Marsh and colleagues, 1999). The etiology can be identified in about a third of cases, and these are due to drugs and other chemicals, infection, irradiation, leukemia, immunological disorders, or inherited conditions such as *Fanconi anemia* and *Diamond-Blackfan syndrome* (Provan and Weatherall, 2000). The functional defect appears to be a marked decrease in committed marrow stem cells. The condition is likely immunologically mediated (Young and Maciejewski, 1997).

With immunosuppressive therapy and bone marrow transplantation, the 5-year survival rate is 75 percent. About half of patients have a good response and long-term survival when treated with antithymocyte globulin and cyclosporine (Marsh and associates, 1999; Rosenfeld and colleagues, 2003). Immunosuppressive therapy is also given for some months after transplantation. Previous blood transfusions, and even pregnancy, enhance the risk of graft rejection. This is the most common serious complication and causes two thirds of deaths within the first 2 years (Socie and co-workers, 1999).

Aplastic Anemia During Pregnancy. In most cases, aplastic anemia and pregnancy simultaneously occur by chance. It has been postulated that pregnancy induces erythroid hypoplasia (Aitchison and colleagues, 1989). Certainly, in a few women, hypoplastic anemia has been identified first during a pregnancy and then improved or even resolved when the pregnancy terminated, only to recur with a subsequent pregnancy (Bourantas and associates, 1997; Snyder and colleagues, 1991).

Rijhsinghani and Wiechert (1994) described two pregnancies in a woman with *Diamond-Blackfan anemia*. This rare form of pure red cell aplasia may be inherited in an autosomal recessive pattern. Some patients respond to glucocorticoid therapy, but most are transfusion-dependent. *Gaucher disease* is an autosomally recessive lysosomal enzyme deficiency that has multisystem involvement. When these women are pregnant, anemia and thrombocytopenia become worse (Granovsky-Grisaru and associates, 1995). In another report, *alglucerase* enzyme replacement improved pregnancy outcomes in six affected women (Elstein and colleagues, 1997).

The major risks to the pregnant woman with aplastic anemia are hemorrhage and infection (Ascarelli and co-workers, 1998). In cases reported since 1960, mortality during or after pregnancy has been 50 percent, and almost invariably, this is due to bleeding or sepsis. *Fanconi anemia* appears to be associated with a better prognosis (Alter and colleagues, 1991).

Management depends on gestational age, severity of disease, and whether treatment has been given. Supportive care includes continuous infection surveillance and prompt antimicrobial therapy. Granulocyte transfusions are given only during infections. Red cell transfusions are given for symptomatic anemia, and routinely to maintain the hematocrit at about 20. Platelet transfusions may be needed to control hemorrhage. Even when thrombocytopenia is intense, the risk of severe hemorrhage can be minimized using vaginal delivery.

There have been several case reports of successful pregnancies in women with bone marrow transplantation (Borgna-Pignatti and associates, 1996; Eliyahu and Shalev, 1994). We have followed two women with prior transplantation, and both demonstrated a normal pregnancy-induced hematological response, including red cell and plasma volume expansion. Sanders and colleagues (1996) reviewed outcomes in 41 women with 72 pregnancies following bone marrow transplantation. Excluding spontaneous and induced abortions, 52 resulted in liveborn infants, however, almost half of these pregnancies were complicated by preterm delivery or hypertension.

HEMOGLOBINOPATHIES

SICKLE-CELL HEMOGLOBINOPATHIES. Sickle hemoglobin (hemoglobin S) results from a single β -chain substitution of glutamic acid by valine because of an A for T substitution at codon 6 of the β -globin gene. Sickle-cell anemia (SS disease), sickle cell-hemoglobin C disease (SC disease), and sickle cell- β -thalassemia disease (S- β -thalassemia disease) are the most common sickle hemoglobinopathies and are associated with increased maternal and perinatal morbidity and mortality.

Pathophysiology. Red cells with hemoglobin S undergo sickling when deoxygenated and the hemoglobin aggregates. Constant sickling and de-sickling cause membrane damage, and the cell may become irreversibly sickled. Clinically, the hallmark of sickling episodes are periods during which there is ischemia and infarction in various organs. These produce clinical symptoms, predominately pain, which is often severe, and are called *sickle-cell crises*. There may be aplastic, megaloblastic, sequestration, and hemolytic crises.

Chronic and acute changes from sickling include bony abnormalities such as osteonecrosis of femoral and humeral heads; renal medullary damage; autosplenectomy in homozygous SS patients and splenomegaly in other variants; hepatomegaly; ventricular hypertrophy; pulmonary infarctions; pulmonary hypertension; cerebrovascular accidents; leg ulcers; and a propensity to infection and sepsis (Driscoll and colleagues, 2003; Gladwin and associates, 2004; Serjeant, 1997; Weatherall and Provan, 2000). The median age at death for women is 48 years.

Inheritance of Sickling Syndromes. The inheritance of the gene for S hemoglobin from each parent results in sickle-cell anemia. In the United States, 1 of 12 African-Americans has the sickle-cell trait, which results from inheritance of one gene for hemoglobin S and one for normal hemoglobin A. The computed incidence of sickle-cell anemia among African Americans is 1 in 576 ($1/12 \times 1/12 \times 1/4 = 576$), but the disease is less common during pregnancy because of earlier mortality, especially during early childhood.

About 1 in 40 African Americans has the gene for hemoglobin C. The theoretical incidence for co-inheritance of the gene for hemoglobin S and an allelic gene for hemoglobin C in an African-American child is about 1 in 2000 ($1/12 \times 1/40 \times 1/4$). Similarly, because the incidence of β -thalassemia minor is about 1 in 40 to 50, S- β -thalassemia occurs about 1 in 2000 ($1/12 \times 1/40 \times 1/4$).

Pregnancy and Sickle-Cell Syndrome. Pregnancy is a serious burden to women with any of the three major sickle hemoglobinopathies, especially hemoglobin SS disease. Ischemic necrosis of multiple organs, especially bone marrow, causes severe pain which usually becomes more frequent in pregnancy. Infections and pulmonary complications are common. Powars and colleagues (1986) compared maternal and perinatal outcomes from before and after 1972 and found that maternal mortality decreased from 6 to 1 percent. Poddar and colleagues (1986) reported a maternal mortality rate of 1.1 percent in 644 pregnancies complicated by hemoglobin SS disease. In addition to horrifically excessive maternal mortality, more than a third of pregnancies in women with sickle syndromes end in abortion, stillbirth, or neonatal death.

HEMOGLOBIN SC. In nonpregnant women, morbidity and mortality from SC disease are appreciably lower than from sickle-cell anemia. Indeed, fewer than half of women with SC disease have ever been symptomatic prior to pregnancy. During pregnancy and the puerperium, however, attacks of severe bone pain and episodes of pulmonary infarction and embolization become more common (Cunningham and associates, 1983). A particularly worrisome pulmonary complication is the *acute chest syndrome* discussed subsequently. In an 18-year prospective observational study from Parkland Hospital, the maternal mortality rate for women with hemoglobin SC disease was close to 2 percent (Pritchard and co-workers, 1973). As shown in [Table 51-3](#), maternal deaths with hemoglobin SC disease were as common as with SS disease. The perinatal mortality rate is somewhat greater than that of the general population but nowhere as great as with sickle-cell anemia.

Management During Pregnancy. Adequate management of pregnant women with sickle-cell hemoglobinopathies necessitates close observation. These women maintain hemoglobin mass by intense hemopoiesis to compensate for the markedly shortened erythrocyte life span. Thus, any factor that impairs erythropoiesis or increases red cell destruction, or both, aggravates the anemia. The folic acid requirements during pregnancy are considerable and supplementary folic acid is given.

One rather common danger is that the symptomatic woman may categorically be considered to be suffering from a sickle-cell crisis. As a result, serious obstetrical or medical problems that cause pain, anemia, or both, may be overlooked. Some examples are ectopic pregnancy, placental abruption, pyelonephritis, or appendicitis. **The term "sickle-cell crisis" should be applied only after all other possible causes of pain or fever or worsening anemia have been excluded.**

Pain is from intense sequestration of sickled erythrocytes with infarction in various organs. These episodes may develop acutely, especially late in pregnancy, during labor and delivery, and early in the puerperium. Acute infarction is usually accompanied by severe pain, and because the bone marrow is frequently involved, intense bone pain is common. A system for care of these women has been appropriately stressed by Rees and colleagues (2003). Intravenous hydration is given, along with opioids administered promptly for severe pain. Oxygen given via nasal cannula may decrease the intensity of sickling at the capillary level. We have found that red cell transfusions after the onset of severe pain do not dramatically improve the intensity of the pain and may not shorten its duration. Conversely, as discussed later, prophylactic transfusions almost always prevent vaso-occlusive episodes.

Covert bacteriuria and acute pyelonephritis are increased substantively, and screening and treatment for bacteriuria is essential. If pyelonephritis develops, sickle cells are extremely susceptible to endotoxin, which can cause dramatic and rapid red cell destruction while simultaneously suppressing erythropoiesis. Pneumonia, especially due to *Streptococcus pneumoniae*, is common. The Advisory Committee on Immunization Practices (1997) recommends polyvalent pneumococcal vaccine for these women. Influenza vaccine should be given annually. In addition, vaccination against *Haemophilus influenzae* type B is recommended for asplenic patients.

As many as 40 percent of patients suffer from *acute chest syndrome*, which is characterized by pleuritic chest pain, fever, cough, lung infiltrates, and hypoxia (Vichinsky and colleagues, 2000). The spectrum of pathology includes infection, infarction, pulmonary sequestration, and fat embolization from bone marrow ([Fig. 51-3](#)). Recurrent episodes may lead to restrictive chronic lung disease associated with arteriolar vasculopathy (Powars and co-workers, 1988). Pregnant women with sickle-cell anemia usually have some degree of *cardiac dysfunction* from ventricular hypertrophy. There is increased preload and decreased afterload with a normal ejection fraction and a high cardiac output. Chronic hypertension worsens this (Gandhi and colleagues, 2000). During pregnancy, the basal hemodynamic state characterized by high cardiac output and increased blood volume is augmented (Veille and Hanson, 1994). Although most women tolerate pregnancy without problems, complications such as severe preeclampsia or serious infections may result in ventricular failure (Cunningham and associates, 1986). With heart failure in these patients, pulmonary hypertension must be considered (Castro and associates, 2003; Stuart and Nagel, 2004).

Assessment of Fetal Health. Because of the high incidence of fetal growth restriction and perinatal mortality, serial fetal assessment is necessary. The American College of Obstetricians and Gynecologists (1999) recommends weekly antepartum fetal surveillance beginning at 32 to 34 weeks with serial ultrasonography to monitor fetal growth and amniotic fluid. Anyaegbunam and colleagues (1991) evaluated fetal well-being during 39 sickling crises in 24 women. Almost 60 percent had nonreactive stress tests, which became reactive with crisis resolution, and all had an increased uterine artery systolic-diastolic (S/D) ratio. At the same time, they found no changes in the umbilical artery S/D ratios. They concluded that transient effects of sickle-cell crisis do not compromise umbilical and hence fetal blood flow. At Parkland Hospital, we serially assess these women with ultrasound for fetal growth and amniotic fluid volume. Nonstress or contraction stress tests are not done routinely unless complications develop or fetal movement is reported to be diminished.

Labor and Delivery. Management is essentially identical to that for women with cardiac disease (see [Chap. 44](#), p. 1021). Women should be kept comfortable but not oversedated. Epidural analgesia is ideal. Compatible blood should be available. If a difficult vaginal or cesarean delivery is contemplated, and the hematocrit is less than 20 percent, packed erythrocyte transfusions are administered. Care must be taken to prevent circulatory overload and pulmonary edema from ventricular failure.

Prophylactic Red Cell Transfusions. These have been shown to decrease morbidity in sickle-cell syndromes when given perioperatively and during pregnancy or to prevent strokes in high-risk children (Adams and co-workers, 1998). The use of routine prophylactic transfusions during pregnancy remains controversial (American College of Obstetricians and Gynecologists, 2000a). Their most dramatic impact has been on maternal morbidity. In a 10-year study at Parkland Hospital, we offered prophylactic transfusions to all pregnant women with sickle-cell syndromes. Red cell transfusions were given throughout pregnancy to maintain the hematocrit greater than 25 percent and hemoglobin S no greater than 60 percent (Cunningham and Pritchard, 1979). There was minimal maternal morbidity such as pain, fever, and suppression of erythropoiesis. In a later study, these women were compared with historical controls not given blood, and there was a significant reduction in maternal morbidity and hospitalizations (Cunningham and associates, 1983). A comparative study by Howard and colleagues (1995) produced similar data.

In a multicenter trial, Koshy and colleagues (1988) randomized 72 pregnant women with sickle-cell disease to prophylactic or indicated transfusions. They reported a significant decrease in the incidence of painful sickle-cell crises with prophylactic transfusions but no differences in perinatal outcomes. Because of risks inherent with blood administration, they concluded that prophylactic transfusions were not necessary.

Current consensus is that management should be individualized. Some clinicians choose prophylactic transfusions in women with a history of multiple vaso-occlusive episodes and poor obstetrical outcomes (Castro and colleagues, 2003).

Complications. Morbidity from multiple transfusions is significant. Delayed hemolytic transfusion reactions occur in as many as 10 percent of patients (Garratty, 1997). Hepatitis is a major concern. At Parkland Hospital, the incidence of red cell isoimmunization was 3 percent per unit of blood transfused (Cox and associates, 1988). In 12 studies reviewed by Garratty (1997), a mean of 25 percent of chronically transfused sickle-cell patients had become isoimmunized. Although the specter of iron overload and transfusion hemochromatosis is worrisome, we found no evidence for this or for chronic hepatitis in liver biopsies from 40 women transfused during pregnancy (Yeomans and co-workers, 1990).

Other Therapy. There are several therapeutic schemes for sickle-cell patients, some of which are still experimental (Stuart and Nagel, 2004). Recently, Raff and colleagues (2002) reported that if compatible blood is not available because of red cell alloantibodies, a polymerized human hemoglobin solution in combination with erythropoietin may be considered for a sickling crisis. With erythropoietin, however, increasing hemoglobin S may be potentially harmful. Hemoglobin F induction has been studied for sickling and thalassemia syndromes. Some drugs stimulate gamma-chain synthesis and thus hemoglobin F, which inhibits polymerization of hemoglobin S and resultant sickling. Regimens of *hydroxyurea* along with either *5-azacytidine* or *recombinant erythropoietin* increase fetal hemoglobin production with fewer clinical sickling episodes (Schechter and Rodgers, 1995). Hydroxyurea also reduces sickle erythrocyte adherence to endothelium (Steinberg, 1999). In a follow-up study of patients in a randomized trial of hydroxyurea from 1992 to 1995, Steinberg and colleagues (2003) found that hydroxyurea reduced mortality. Experience with hydroxyurea in pregnancy is limited, but it is teratogenic in animals (Briggs and colleagues, 1998). Another cancer drug, *decitabine*, has been used in patients who are unresponsive to hydroxyurea (DeSimone and colleagues, 2002). Findings from a placebo-controlled trial of inhaled nitric oxide versus placebo suggested benefit for acute vaso-occlusive crises (Weiner and colleagues, 2003).

Bone marrow transplantation, as discussed on page 1149, has been used to provide normal hemoglobin A erythrocyte precursors (Walters and associates, 1996). According to Steinberg (1999), about 100 patients with sickle-cell anemia—mostly children—have undergone transplantation. Mortality is about 10 percent. Of 26 patients with at least 2-year follow-up, 22 had a stable donor engraftment and resolution of complications (Walters and colleagues, 2000). Pilot data from matched unrelated bone marrow transplantation indicates a 70-percent success rate with a 20-percent mortality rate (Vichinsky, 2002). Prenatal diagnosis of sickle-cell disease may allow for in utero *stem cell therapy* with hemoglobin A cells (Eddleman, 1998; Shaaban and Flake, 1999).

Experimental projects include a gene therapy technique using a modified β -globin gene that encodes a sickling resistant protein, which corrected the globin chain in transgenic hemoglobin SS "knock-out" mice (Pawliuk and colleagues, 2001). Orringer and colleagues (2001) reported preliminary success using purified poloxamer 188 (PP188) in nonpregnant sickle patients. This copolymer surfactant with antithrombotic properties improves microvascular blood flow by reducing blood viscosity and reducing adhesive frictional forces.

Contraception and Sterilization. Because of chronic debility, complications caused by pregnancy, and the predictably shortened life span of women with sickle-cell anemia, contraception and possibly sterilization are important considerations. According to the American College of Obstetricians and Gynecologists (2000b), estrogen-progesterone oral contraceptives have not been assessed well in women with sickle hemoglobinopathies. Many clinicians do not recommend their use because of potential adverse vascular and thrombotic effects (see [Chap. 32](#), p. 732).

Progesterone has been long known to prevent painful sickle-cell crises. Because of this, low-dose oral progesterone,

progesterone injections, or implants seem ideal. In one study, de Abood and associates (1997) reported significantly fewer and less intense pain crises in women given depot medroxyprogesterone intramuscularly. Intrauterine devices probably should not be used routinely because of increased risk of infection. The safest contraceptives are unfortunately those with the highest failure rates—condoms with foam and diaphragms. Permanent sterilization is also an option (see [Chap. 33](#), p. 751).

Sickle-Cell Trait. The heterozygous inheritance of the gene for hemoglobin S results in sickle-cell trait, or AS hemoglobin. The amount of S hemoglobin averages only about 30 percent. The frequency of sickle-cell trait among African-Americans is about 8 percent. The trait is not associated with increased abortion, perinatal mortality, low birthweight, or pregnancy-induced hypertension (Pritchard and associates, 1973; Tuck and co-workers, 1983). One unquestioned complication, however, is the twofold increased incidence of asymptomatic bacteriuria and urinary infection. **Sickle-cell trait therefore should not be considered a deterrent to pregnancy on the basis of increased maternal risks.**

Inheritance is a concern for the infant of a mother with sickle trait whenever the father carries a gene for some abnormal hemoglobins (S, C, D) or for β -thalassemia. Prenatal diagnosis through amniocentesis or chorionic villus sampling is now available (see [Chap. 12](#), p. 328). Xu and colleagues (1999) described single-blastomere DNA analysis, successful in vitro fertilization, and delivery of an unaffected neonate to parents both carrying sickle-cell trait.

Figure 51-3. Photomicrograph of a section of lung from a 21-year-old primipara with hemoglobin SC who died 36 hours postpartum after developing acute dyspnea. There was massive amounts of fat and bone marrow embolized to both lungs. (From Maberry and Cunningham, 1993.)

OTHER HEMOGLOBINOPATHIES

Hemoglobin C and C- β -Thalassemia. The single β -chain substitution of glutamic acid by lysine at position 6 results in production of hemoglobin C. It is quite common in West Africa, but only about 2 percent of African-Americans have hemoglobin C trait, which does not cause anemia or adverse pregnancy outcomes. When co-inherited with sickle-cell trait, hemoglobin SC causes the problems previously discussed on page 1150.

Pregnancy and homozygous hemoglobin C or hemoglobin C- β -thalassemia are relatively benign associations. Maberry and colleagues (1990) reported our experiences from Parkland Hospital as shown in [Table 51-4](#). Other than mild to moderate anemia, pregnancy outcomes were not different compared with that of the general obstetrical population. When severe anemia is identified, iron or folic acid deficiency or some other superimposed cause should be suspected. Supplementation with folic acid and iron is indicated.

Hemoglobin E. This is the second most common hemoglobin variant worldwide. Hemoglobin E results from a single β -chain substitution of lysine for glutamic acid at codon 26. The hemoglobin is susceptible particularly to oxidative stress. The heterozygous E trait is common in Southeast Asia. Hurst and co-workers (1983) identified homozygous hemoglobin E, hemoglobin E plus β -thalassemia, or hemoglobin E trait in 36 percent of Cambodians and 25 percent of Laotians. In addition, α - and β -thalassemia traits were prevalent in all groups.

Homozygous hemoglobin EE is associated with little or no anemia, hypochromia, marked microcytosis, and erythrocyte targeting. In our limited experience, pregnant women do not appear to be at increased risk. Iron-deficiency anemia as the consequence of intestinal parasites, repeated pregnancies, or both may co-exist. Conversely, doubly heterozygous *hemoglobin E- β -thalassemia* is a common cause of childhood anemia in Southeast Asia (Fucharoen and Winichagoon, 2000). It may cause severe anemia requiring transfusions during pregnancy (Hsia, 1991). Doubly heterozygous *hemoglobin SE* is usually benign, but Eichhorn and colleagues (1999) reported a sickle-like crisis in a patient with B19 parvovirus infection. It is not clear if hemoglobin SE disease is as ominous during pregnancy as hemoglobin SC or S- β -thalassemia disease (Ramahi and colleagues, 1988).

Hemoglobinopathy in the Newborn. Infants with homozygous SS, SC, and CC disease can be identified accurately at birth by cord blood electrophoresis. The Agency for Health Care Policy and Research (1993) of the U.S. Public Health Service has recommended that all newborn infants be tested for sickle-cell disease. In most states, such screening is performed routinely on blood submitted for phenylketonuria and hypothyroidism testing. The benefit of screening for sickle hemoglobinopathies is that there is clearly decreased mortality in children with sickle-cell disease identified at birth. They are given monthly prophylactic injections of penicillin G and assessed closely for risk factors for strokes (Adams and colleagues, 1998; Centers for Disease Control and Prevention, 2000).

Prenatal Diagnosis. Using polymerase chain reaction, prenatal diagnosis of sickle-cell anemia is simple, accurate, and rapid (see [Chap. 12](#), p. 308). The DNA is obtained by amniocentesis or chorionic villus sampling. Hemoglobin C and most instances of β -thalassemia can be identified by analysis of DNA polymorphism or by identifying in vitro the kinds of globin chains synthesized by fetal red cells.

THALASSEMIAS. The genetically determined hemoglobinopathies termed thalassemias are characterized by impaired production of one or more of the normal globin peptide chains. Abnormal synthesis rates may result in ineffective erythropoiesis, hemolysis, and varying degrees of anemia. Thalassemias are classified according to the globin chain that is deficient. Several hundred syndromes have been identified. The two major forms involve impaired production or stability either of α -peptide chains, causing α -thalassemia, or of β -chains, causing β -thalassemia. The incidence of these traits during pregnancy for all races is 1 in 300 to 500 (Gehlbach and Morgenstern, 1988).

Alpha-Thalassemias. Because there are four α -globin genes, the inheritance of α -thalassemia is more complicated than for β -thalassemia. Four clinical syndromes, the consequence of impaired α -globin chain synthesis, have been identified. For each syndrome, a close correlation has been established between clinical severity and the degree of impairment of synthesis of α -

globin chains. In most populations, the α -globin chain "cluster" or gene loci are duplicated on chromosome 16. Thus, the normal genotype for diploid cells can be expressed as $\alpha\alpha/\alpha\alpha$. There are two main groups of α -thalassemia determinants: α^0 -thalassemia is characterized by the deletion of both loci from one chromosome ($-/\alpha\alpha$), whereas α^+ -thalassemia is characterized by the loss of a single locus from one chromosome ($-\alpha/\alpha\alpha$ heterozygote) or both ($-\alpha/-\alpha$ homozygote).

There are two major phenotypes. The deletion of all four α -globin chain genes ($-/-$) characterizes *homozygous α -thalassemia*. Because α chains make up fetal hemoglobin, the fetus is affected. Without α -globin chains, hemoglobin Bart (γ_4) and hemoglobin H (β_4) are formed as abnormal tetramers.

Hemoglobin Bart has an appreciably increased affinity for oxygen, and *hemoglobin Bart disease* is a common cause of stillbirths in Southeast Asia. Hsieh and associates (1989) studied 20 such hydropic fetuses by funipuncture and reported that blood contained 65 to 98 percent Bart hemoglobin. The fetus dies either in utero or very soon after birth and demonstrates the typical features of nonimmune hydrops fetalis as shown in [Figure 51-4](#) (see [Chap. 29](#), p. 672). Lam and associates (1999) reported that sonography at 12 to 13 weeks was 100-percent sensitive and specific for identifying affected fetuses by measuring the cardiothoracic ratio. Carr and colleagues (1995) transfused a fetus with α -thalassemia at 25, 26, and 32 weeks and reversed its ascites. The transfusion-dependent infant was delivered at 34 weeks.

The compound heterozygous state for α^0 - and α^+ -thalassemia results in the deletion of three of four genes ($-/-\alpha$). There is only one functional α -globin gene per diploid genome. This is referred to as *hemoglobin H disease* (β_4) and is compatible with extrauterine life. The abnormal red cells at birth contain a mixture of hemoglobin Bart (γ_4), hemoglobin H (β_4), and hemoglobin A. The neonate appears well at birth but soon develops hemolytic anemia. Most hemoglobin Bart present at birth is replaced postnatally by hemoglobin H. The disease is characterized by hemolytic anemia, which may be severe and similar to β -thalassemia major. Anemia in these women usually is worsened during pregnancy.

A deletion of two genes results clinically in *α -thalassemia minor*, which is characterized by minimal to moderate hypochromic microcytic anemia. This may be due to α^0 - or α^+ -thalassemia traits. Thus, genotypes may be $-\alpha/-\alpha$ or $-/\alpha\alpha$. Differentiation is only by DNA analysis (Weatherall and Provan, 2000). Because there is no associated clinical abnormality with α -thalassemia minor, it often goes unrecognized. Hemoglobin Bart is present at birth, but as its levels drop, it is not replaced by hemoglobin H. Red cells are hypochromic and microcytic, and the hemoglobin concentration is normal to slightly depressed. Women with α -thalassemia minor tolerate pregnancy quite well.

The single gene deletion ($-\alpha/\alpha\alpha$) is the silent carrier state. No clinical abnormality is evident in the individual with a single gene deletion.

FREQUENCY. The relative frequency of α -thalassemia minor, hemoglobin H disease, and hemoglobin Bart disease varies remarkably among racial groups. All of these variants are encountered in Asians. In individuals of African descent, however, even though α -thalassemia minor is demonstrated in about 2 percent, hemoglobin H disease is extremely rare and hemoglobin Bart disease is unreported. Asians usually have α^0 -thalassemia minor with both gene deletions typically from the same chromosome ($-/\alpha\alpha$), whereas in blacks with α^+ -thalassemia minor, one gene is deleted from each chromosome ($-\alpha/-\alpha$). The α -thalassemia syndromes appear sporadically in other racial and ethnic groups. Diagnosis of α -thalassemia minor as well as α -thalassemia major in the fetus can be accomplished by DNA analysis using molecular techniques (American College of Obstetricians and Gynecologists, 2000c).

Beta-Thalassemias. These are the consequence of impaired production of β -globin chains or impaired stability of α chains. More than 150 point mutations in the β -globin gene have been described (Weatherall, 2000). Most are single-nucleotide substitutions that produce transcription or translation defects, RNA splicing or modification, or frameshifts which result in highly unstable hemoglobins. Thus, deletional and nondeletional mutations affect β -globin RNA. The $\delta\gamma\beta$ -gene "cluster" is on chromosome 11.

In β -thalassemia, there is decreased β -chain production, and excess α chains precipitate to cause cell membrane damage. In addition, β -thalassemia may be due to impaired α -chain stability. Kihm and colleagues (2002) recently identified a molecular chaperone that regulates α -globin subunit stability, α -hemoglobin-stabilizing protein (AHSP), which forms a stable complex with free α -globin and prevents precipitation. Mutations in AHSP may modify the clinical picture of β -thalassemia. For example, an overexpression of AHSP may convert β -thalassemia major to β -thalassemia intermedia. These basic defects lead to the panorama of pathology that characterizes homozygous β -thalassemia, so-called β -thalassemia major or *Cooley anemia*. With heterozygous β -thalassemia minor, hypochromia, microcytosis, and slight to moderate anemia develop without the intense hemolysis that characterizes the homozygous state. The hallmark of the common β -thalassemias is an elevated hemoglobin A_2 level.

In the typical case of *thalassemia major*, the neonate is healthy at birth, but as the hemoglobin F level falls, the infant becomes severely anemic and fails to thrive. A child who is entered into an adequate transfusion program develops normally until the end of the first decade, when effects of iron loading become apparent. Prognosis is improved by iron chelation therapy with deferoxamine (Olivieri and associates, 1998). A female who survives beyond childhood usually is sterile, and life expectancy even with transfusion therapy is shortened. Prior to the standardization of iron chelation and transfusions, pregnancy in women with severe thalassemia was rare. Aessopos (1999), Daskalakis (1998), and Kumar (1997) and their colleagues reported a total of 63 pregnancies without severe complications. All these investigators stressed the need for intensive surveillance and exclusion of women with underlying cardiomyopathy.

With *β -thalassemia minor*, hemoglobin A_2 , which is composed of two α - and two δ -globin chains, is increased to more than 3.5 percent. Simultaneously, hemoglobin F, which is composed of two α - and two γ -globin chains, is usually increased to more than 2 percent. Anemia is mild, and the red cells are hypochromic and microcytic. There is usually pregnancy-induced augmentation of erythropoiesis and, using 51 chromium-tagged erythrocytes, we have documented normal blood volume expansion with slightly subnormal red cell mass expansion.

There is no specific therapy for β -thalassemia minor during pregnancy. Prophylactic iron and folic acid are given. Sheiner and associates (2004) reported that fetal growth restriction and oligohydramnios were increased twofold in 261 affected women.

Prenatal diagnosis of β -thalassemia using chorionic villus sampling can be carried out at 9 to 13 weeks (Weatherall and Provan, 2000). This analysis may be difficult and is not always successful. Techniques include a combination of site-specific restriction endonuclease analysis, restriction fragment polymorphism linkage analysis, polymerase chain reaction, and oligonucleotide probes (Monni and co-workers, 1993). Preimplantation blastomere biopsy has been described by Galvani (2000) and Kanavakis (1999) and their associates. In addition, fetal human leukocyte antigen typing has been described (Orofino and colleagues, 2003).

Figure 51-4. Stillborn hydropic fetus with extremely large placenta caused by homozygous α -thalassemia. (From Hsia, 1991, with permission.)

POLYCYTHEMIA. Excessive erythrocytosis during pregnancy is usually related to chronic hypoxia due to congenital cardiac disease or a pulmonary disorder (see [Chap. 44](#), p. 1028). Occasionally, it is from heavy cigarette smoking. We have encountered otherwise healthy young pregnant women who were heavy smokers with chronic bronchitis and hematocrits of 55 to 60 percent! Brewer and colleagues (1992) described a woman with persistent erythrocytosis associated with a placental site tumor. If polycythemia is severe, the probability of a successful pregnancy outcome is low.

Polycythemia vera is a myeloproliferative hemopoietic stem cell disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic precursors. It likely is an acquired genetic disorder of stem cells and is seen in older patients (Provan and Weatherall, 2000). Measurement of serum erythropoietin by radioimmunoassay differentiates polycythemia vera (low values) from secondary polycythemia (high values). Symptoms are related to increased blood viscosity, and thrombotic complications are common. Ruch and Klein (1964) described a woman whose nonpregnant hematocrit was as high as 63. During her pregnancies her hematocrit ranged from a low of 35 during the second trimester to 44 at term. Fetal loss has been reported to be high in women with polycythemia vera (Tefferi and associates, 2000).

PLATELET DISORDERS

Thrombocytopenia in pregnant women may be inherited or idiopathic. More often, it is associated with the following disorders: acquired hemolytic anemia, severe preeclampsia or eclampsia, severe hemorrhage with blood transfusions, consumptive coagulopathy from placental abruption or similar hypofibrinogenemic states, septicemia, systemic lupus erythematosus, antiphospholipid antibody syndrome, aplastic anemia, and megaloblastic anemia from severe folate deficiency. It also may result from viral infection, exposure to a variety of drugs, allergic reaction, and irradiation (George, 2000).

GESTATIONAL THROMBOCYTOPENIA. Normal pregnancy may be accompanied by a physiological decrease in platelet concentration. This is usually evident in the third trimester and is due predominantly to hemodilution. At least until recently, there was no evidence that platelet life span is decreased or that there is excessive platelet activation in normal pregnancy (Baker and Cunningham, 1999; Star and colleagues, 1997). In studies of platelet activation in preeclampsia, Holthe and associates (2004) demonstrated that platelets from normally pregnant women expressed higher basal CD63 levels, indicating platelet activation, and that platelet counts were significantly lower than in nonpregnant women.

Thus, *gestational thrombocytopenia* is considered normal, and it is a diagnosis of exclusion. Obviously, the definition used for thrombocytopenia is important. In their review, Rouse and associates (1998) cite an incidence of 4 to 7 percent for gestational thrombocytopenia, defined by platelet counts of less than 150,000/ μ L. Burrows and Kelton (1993a) reported that 6.6 percent of 15,471 pregnant women had platelet counts of less than 150,000/ μ L, and in 1.2 percent they were less than 100,000/ μ L. They reported that almost 75 percent of 1027 women whose platelet counts were less than 150,000/ μ L were found to have normal-variant incidental thrombocytopenia. The others had either a hypertensive disorder of pregnancy (21 percent) or an immunological disorder (4 percent). In another study, Boehlen and associates (2000) found that 11.6 percent of 6770 pregnant women had platelet counts of less than 150,000/ μ L. In this study, 116,000/ μ L was 2.5 standard deviations below the mean. Al-Kouatly and colleagues (2003) found a much higher rate of thrombocytopenia in triplet gestations, affecting nearly a third of cases. In contrast to thrombocytopenia in singletons, more than 70 percent of cases were due to hypertensive disorders.

INHERITED THROMBOCYTOPENIAS. The *Bernard-Soulier syndrome* is characterized by lack of platelet membrane glycoprotein (GPIb/IX), which causes severe dysfunction. Maternal antibodies against fetal GPIb/IX antigen can cause isoimmune fetal thrombocytopenia. Peng and colleagues (1991) described an affected woman who during four pregnancies had episodes of postpartum hemorrhage, gastrointestinal hemorrhage, and fetal thrombocytopenia. Fujimori and associates (1999) described a similarly affected woman whose neonate died from thrombocytopenic intracranial hemorrhage.

Chatwani and associates (1992) reported a woman with autosomally dominant *May-Hegglin anomaly* but whose infant was not affected. Urato and Repke (1998) also described such a woman who was delivered vaginally, yet despite a platelet count of 16,000/ μ L, she did not bleed excessively. The neonate inherited the anomaly, but also had no bleeding despite a platelet count of 35,000/ μ L. Fayyad and colleagues (2002) managed three pregnancies in a woman with May-Hegglin anomaly. In the first, the mother had a term cesarean delivery of an unaffected infant; in the second, she had a fetal demise with multiple placental infarcts; and in the third, she received low-dose aspirin (75 mg/d) and gave birth to an unaffected infant.

IMMUNE THROMBOCYTOPENIC PURPURA. This is also called *idiopathic thrombocytopenic purpura (ITP)* and is usually the consequence of antibodies directed against platelets. Antibody-coated platelets are destroyed

prematurely in the reticuloendothelial system, especially the spleen. The mechanism of production of these platelet-associated immunoglobulins—PAIgG, PAIgM, and PAIgA—is not known, but most investigators consider them to be autoantibodies.

The American Society of Hematology convened a panel to formulate guidelines for diagnosis and management of ITP (George and colleagues, 1996). Acute ITP is most often a childhood disease that follows a viral infection. Most cases resolve spontaneously, although perhaps 10 percent become chronic. Conversely, in adults, immune thrombocytopenia is primarily a chronic disease of young women and rarely resolves spontaneously.

Secondary forms of chronic thrombocytopenia appear in association with systemic lupus erythematosus, lymphomas, leukemias, and a number of systemic diseases. For example, about 2 percent of patients with thrombocytopenia have positive serological tests for lupus, and in some cases there are high levels of anticardiolipin antibodies. As many as 10 percent of HIV-positive patients have associated thrombocytopenia (Glantz and Roberts, 1994; Scaradavou, 2002).

Outcomes for adults with primary ITP are shown in [Table 51-5](#). Only a small number recover spontaneously, and for those who do not, platelet counts usually range from 10,000 to 100,000/ μ L. In those whose platelet counts remain less than 30,000/ μ L, or those with significant bleeding at higher levels, treatment with prednisone, 1 to 2 mg/kg, raises the platelet count in about two thirds of cases, but relapse is exceedingly common (George and associates, 1996). Glucocorticoids suppress phagocytic activity of the splenic monocyte-macrophage system. Godeau and colleagues (2002) reported results of a randomized trial of intravenous immunoglobulin or high-dose methylprednisolone given for three days. These were followed by oral prednisone or placebo. Intravenous immunoglobulin plus oral prednisone was most effective, although methylprednisolone with prednisone was effective and well tolerated. Recently, Cheng and colleagues (2003) found that 85 percent of adults with ITP responded to high-dose dexamethasone. Half had a sustained response at 6 months.

For patients with no response to corticosteroid therapy in 2 to 3 weeks, those in whom massive doses are needed to sustain remission, or those with frequent recurrences, splenectomy is indicated. In about 60 percent, there is substantive improvement as the consequence of decreased splenic removal of platelets and reduced antibody production. Massive doses (400 mg/kg) of gamma globulin given intravenously over 5 days result in satisfactory platelet count elevation in two thirds of patients. Such therapy may be useful in patients with life-threatening thrombocytopenia refractive to other therapy, or preoperatively before splenectomy.

Therapy is problematic for the 30 percent of adults who do not respond to corticosteroids or splenectomy. Immunosuppressive drugs, including azathioprine, cyclophosphamide, and cyclosporine, have been used with some success. Danazol, vinca alkaloids, plasma exchange, and high-dose dexamethasone pulse therapy have been described.

Immune Thrombocytopenia and Pregnancy. There is no evidence that pregnancy increases the risk of relapse in women with previously diagnosed immune thrombocytopenia. Nor does it make the condition worse in women with active disease. It is certainly not unusual for women who have been in clinical remission for several years to have recurrent thrombocytopenia during pregnancy. Although this may be from closer surveillance, hyperestrogenemia has also been suggested as a cause.

Treatment is considered if the platelet count is less than 50,000/ μ L (George and associates, 1996). Prednisone in a dose of 1 mg/kg per day may be required for improvement, and most likely treatment will have to be continued throughout pregnancy. Corticosteroid therapy usually produces amelioration, but in refractory disease, high-dose immunoglobulin is given intravenously. Clark and Gall (1997) reviewed 16 case reports of 21 pregnancies in which ITP was treated with immunoglobulin. All but four responded with posttreatment platelet counts greater than 50,000/ μ L, and in 11 cases, counts exceeded 100,000/ μ L. Such therapy is expensive, and in 2003, hospital costs for a 5-day course of treatment ranged from \$5500 to \$8000 for a 70-kg person. In addition, shortages of immunoglobulin for high-dose infusion are not uncommon (Centers for Disease Control and Prevention, 1999).

In pregnant women with no response to steroid or immunoglobulin therapy, splenectomy may be effective. In late pregnancy, surgery technically is more difficult, and cesarean delivery may be necessary for exposure.

FETAL AND NEONATAL EFFECTS. Platelet-associated IgG antibodies cross the placenta and may cause thrombocytopenia in the fetus-neonate. Fetal death from hemorrhage occurs occasionally (Webert and associates, 2003). The severely thrombocytopenic fetus is at increased risk for intracranial hemorrhage with labor and delivery. This fortunately is unusual. Payne and colleagues (1997) reviewed studies of maternal ITP published since 1973 and added their experiences with 55 cases. Of a total of 601 newborns, 12 percent had severe thrombocytopenia defined as less than 50,000/ μ L. Six infants had intracranial hemorrhage, and in three the initial platelet count was greater than 50,000/ μ L.

Considerable attention has been directed at identifying the fetus with potentially dangerous thrombocytopenia. All investigators have concurred that there is not a strong correlation between fetal and maternal platelet counts (George and associates, 1996; Payne and co-workers, 1997). Because of this, there have been attempts to quantify the relationship between maternal IgG free platelet antibody, platelet-associated antibody, and fetal platelet count. Again, there is little concurrence. Kaplan and associates (1990) and Samuels and colleagues (1990) reported conflicting results in using indirect platelet immunoglobulin for identification of high-risk neonates. They both found, however, that a history of ITP remote from pregnancy increased the likelihood of neonatal thrombocytopenia.

Burrows and Kelton (1993a) detected neonatal umbilical cord platelets of less than 50,000/ μ L in 19 of 15,932 consecutive newborns (0.12 percent). But only 1 of 756 mothers with gestational thrombocytopenia had an affected infant. Of 1414 hypertensive women with thrombocytopenia, five infants had thrombocytopenia. Conversely, of 46 mothers with immune thrombocytopenic purpura, four infants had thrombocytopenia. Importantly, isoimmune thrombocytopenia was associated with profound thrombocytopenia with cord platelet counts less than 20,000/ μ L. One of these fetuses died, and two others had intracranial hemorrhage (see later discussion). In a similar population study, Boehlen and associates (1999) determined antiplatelet antibodies in 430 pregnant women whose platelet counts were less than 150,000/ μ L. Antibodies were detected in 9 percent but had no predictive value. Sainio and co-workers (2000) performed cord platelet counts in almost 4500 neonates. About 2 percent were less than 150,000/ μ L, and only 0.2 percent (1 in 410) were less than 50,000/ μ L. All cases with bleeding were due to isoimmune thrombocytopenia.

Detection of Fetal Thrombocytopenia. There are no clinical characteristics or laboratory tests that accurately predict fetal

platelet count. This led Scott and associates (1983) to recommend intrapartum fetal scalp platelet determinations once the cervix was 2 cm dilated and the membranes ruptured. Cesarean delivery was performed for fetuses with platelet counts less than 50,000/ μ L. Daffos and colleagues (1985) subsequently reported percutaneous umbilical cord blood sampling for platelet quantification with a high complication rate (see [Chap. 13](#), p. 330). Berry and associates (1997) reported no complications but found only a high negative predictive value. Payne and colleagues (1997) summarized six such studies reported since 1988. Of 195 cases, severe neonatal thrombocytopenia of less than 50,000/ μ L was found in 7 percent, however, serious complications from cordocentesis were identified in 4.6 percent.

Because of the low incidence of severe neonatal thrombocytopenia and morbidity, Burrows and Kelton (1993b), Silver and colleagues (1995), Payne and associates (1997) and the American Society of Hematology (George and co-workers, 1996) all concluded that fetal platelet determinations and cesarean delivery are not necessary. Peleg and Hunter (1999) surveyed members of the Society of Maternal-Fetal Medicine and received a 60-percent response. Only a third of respondents recommended fetal testing with chronic ITP, and a fourth would perform fetal testing in women with new-onset ITP during pregnancy.

ISOIMMUNE THROMBOCYTOPENIA. Platelet isoimmunization can develop in a manner identical to erythrocyte antigen isoimmunization. Its incidence may be as high as 1 in 1000 to 5000 births (Richmond and colleagues, 2003). If fetal platelet antigens for which maternal platelets are negative gain access to the mother's circulation, she then may produce antibodies that are manifest in subsequent pregnancies. The most common antibody is against PL^{A1} platelet-specific antigen. About 2 percent of Caucasians are homozygous for PL^{B1} antigen and thus are exposed to isoimmunization by PL^{A1} antigens (Jaegtvik and associates, 2000). The first pregnancy is affected in about half of cases. This disorder is discussed in [Chapter 29](#) (see p. 677).

THROMBOCYTOSIS. Also called *thrombocythemia*, thrombocytosis generally is defined as platelets persisting in numbers greater than 450,000/ μ L. Common causes of *secondary* or *reactive thrombocytosis* are malignant tumors, iron deficiency, hemorrhage, inflammatory diseases, and connective tissue disorders. Platelet counts seldom exceed 800,000/ μ L in these secondary disorders, and prognosis depends on the underlying disease. On the other hand, *essential thrombocytosis* is a myeloproliferative disorder that accounts for most cases in which platelet counts exceed 1 million/ μ L. Thrombocytosis usually is asymptomatic, but arterial and venous thromboses may develop. Cortelazzo and colleagues (1995) reported that myelosuppression with hydroxyurea for nonpregnant patients with essential thrombocytosis decreased thrombotic episodes from 24 to 4 percent compared with those of untreated controls.

Pregnancy. Although reports indicate that pregnancies associated with thrombocytosis have excessive spontaneous abortions, placental infarctions, and preterm delivery, this likely is not the case. Beard and co-workers (1991) and Randi and colleagues (1994) described essentially normal pregnancies in women whose mean platelet counts were greater than 1.25 million/ μ L. Treatment that has been suggested during pregnancy includes aspirin, dipyridamole, heparin, plateletpheresis, or combinations thereof (Griesshammer and associates, 2003). Delage and co-workers (1996) reviewed 11 cases in which interferon- α was given during pregnancy with successful outcomes. They also described a woman at midpregnancy who had platelets of 2.3 million/ μ L and transient blindness. Thrombocytapheresis and interferon- α were used to keep the platelets at around 1 million/ μ L until delivery.

THROMBOTIC MICROANGIOPATHIES. Although not proven a primary platelet disorder, there almost always is some degree of thrombocytopenia. Moschcowitz (1925) described *thrombotic thrombocytopenic purpura* by the pentad of thrombocytopenia, fever, neurological abnormalities, renal impairment, and hemolytic anemia. Gasser and colleagues (1955) later described the similar *hemolytic uremic syndrome*, which had more profound renal involvement and fewer neurological aberrations. The British Committee for Standards in Haematology has recently published guidelines on diagnosis and management of thrombotic microangiopathic hemolytic anemias (Allford and associates, 2003). The syndromes have an incidence of 2 to 6 per million per year (Miller and colleagues, 2004).

Although it is likely that different causes account for the variable findings within these syndromes, they currently are clinically indistinguishable in adults (Moake, 1998). There is, however, a pure form of the hemolytic uremic syndrome in children, incited by viral or bacterial infection with severe prothrombin disturbance in which thrombin generation and inhibition of fibrinolysis precede the renal injury (Chandler and colleagues, 2002). There is no evidence that postpartum renal failure is a separate syndrome (Robson and associates, 1968). This probably accounts for the unusual case of severe preeclampsia with hemolysis and thrombocytopenia that does not respond to delivery (Kahra and associates, 1998; Magann and colleagues, 1994).

Pathogenesis. Microthrombi, consisting of hyaline material made up of platelets and small amounts of fibrin, develop within arterioles and capillaries. These aggregates produce ischemia or infarctions in various organs. The general consensus is that intravascular platelet aggregation stimulates the cascade of events leading to end-organ failure. Although there is endothelial activation and damage, it is unclear whether this is a consequence or a cause. Unusually large multimers of von Willebrand factor have been identified with active disease. Later, it was shown that the endothelial-derived metalloproteinase responsible for cleaving von Willebrand factor is neutralized by antibodies during an acute episode (Furlan and colleagues, 1998; Tsai and associates, 1998). More recently, Levy and colleagues (2001) identified the *ADAMTS13* gene that encodes the protease. They found that defects in this gene result in various clinical presentations of thrombotic microangiopathy (Moake, 2002; 2004).

Clinical Presentation. Thrombotic microangiopathies are characterized by thrombocytopenia, fragmentation hemolysis, and variable organ dysfunction. A viral prodrome may precede up to 40 percent of cases. Neurological symptoms develop in up to 90 percent of patients and include headache, altered consciousness, convulsions, fever, or stroke. Because renal involvement is common, the two syndromes are difficult to separate (Moake, 1998). Renal failure is thought to be more severe with the hemolytic uremic syndrome, and in half of the cases, dialysis is required.

Hematological Abnormalities. Thrombocytopenia is usually severe. Fortunately, even with very low platelet counts, spontaneous severe hemorrhage is uncommon. Microangiopathic hemolysis is associated with moderate to marked anemia, and transfusions are frequently necessary. The blood smear is characterized by erythrocyte fragmentation with schizocytosis. The reticulocyte count is high, and nucleated red blood cells are numerous. Consumptive coagulopathy, although common, is usually subtle and clinically insignificant.

Treatment. Plasmapheresis and exchange transfusion with normal plasma have remarkably improved the outcome for patients with these formerly commonly fatal diseases. Red cell transfusions are imperative for life-threatening anemia. Rock and colleagues (1991) found plasma exchange to be superior to plasma infusion in nonpregnant patients, but overall mortality was still 30 percent. Bell and co-workers (1991) reported their experiences with 108 patients treated at Johns Hopkins Hospital, and 10 percent of these patients were pregnant. Those with minimal neurological symptoms were given prednisone, 200 mg daily. If there were neurological abnormalities or rapid clinical deterioration, plasmapheresis and plasma exchange were performed daily. About a fourth of patients with mild disease responded to prednisone alone. Of those requiring plasmapheresis, relapses were common, but overall survival was 91 percent. As emphasized by Hayward (1994) and Shumak (1995) and their associates, relapses develop in 20 to 30 percent and include long-term sequelae such as renal impairment.

Pregnancy and Thrombotic Microangiopathy. Evidence is lacking that pregnancy predisposes women to develop thrombotic microangiopathies. Over a 25-year period, Dashe and co-workers (1998) encountered 11 pregnancies complicated by these syndromes or their presumed variants among nearly 275,000 obstetrical patients within our well-defined catchment area for Parkland Hospital. This frequency of 1 in 25,000 is about the same as in our general nonobstetrical hospital population.

It is not surprising that severe preeclampsia and eclampsia complicated further by thrombocytopenia and overt hemolysis have been confused with thrombotic thrombocytopenic purpura and vice versa (Hsu and colleagues, 1995; Magann and co-workers, 1994). One constant feature of thrombotic microangiopathies is hemolytic anemia, which is rarely severe with preeclampsia, even with the *HELLP syndrome*. Although deposition of hyaline microthrombi within the liver is seen with thrombotic microangiopathy, hepatocellular necrosis characteristic of preeclampsia has not been described. In addition, whereas delivery is imperative to treat preeclampsia in women with the HELLP syndrome, there is no evidence that thrombotic microangiopathy is improved by delivery (Letsky, 2000). Finally, microangiopathy syndromes are usually recurrent and unassociated with pregnancy. For example, 7 of 11 women described by Dashe and colleagues (1998) had recurrent disease either when not pregnant or within the first trimester of a subsequent pregnancy.

Unless the diagnosis is unequivocally one of these thrombotic microangiopathies, rather than severe preeclampsia, the response to pregnancy termination should be evaluated before resorting to plasmapheresis and exchange transfusion, massive-dose glucocorticoid therapy, or other therapy. **Plasmapheresis is not indicated for preeclampsia-eclampsia complicated by hemolysis and thrombocytopenia.**

In the past, maternal and perinatal mortality was as high as 70 to 80 percent (Weiner, 1987). With plasma therapy, maternal survival is now excellent. Egerman and co-workers (1996) described 11 pregnant women whom they treated with plasmapheresis. There were two maternal and three fetal deaths. In our experiences at Parkland Hospital, five of eight women treated by plasmapheresis had a dramatic salutary response (Dashe and associates, 1998).

LONG-TERM PROGNOSIS. Pregnant women with thrombotic microangiopathy have a number of long-term complications. In the study by Dashe and associates (1998), 9-year follow-up disclosed multiple recurrences; renal disease requiring dialysis, transplantation, or both; severe hypertension; and transfusion-acquired infectious diseases. Two women died remote from pregnancy — one from dialysis complications and one from HIV infection transmitted by blood or plasma transfusions. Egerman and colleagues (1996) reported similar observations. Although it is not possible to ascertain if the guarded prognosis in these women is different from the nonpregnant course, clearly, development of thrombotic microangiopathy during pregnancy has severe immediate and long-term mortality.

INHERITED COAGULATION DEFECTS

Obstetrical hemorrhage, a common event, is rarely the consequence of an inherited defect in the coagulation mechanism. Several syndromes, however, are particularly important.

HEMOPHILIAS. There are two types of hemophilias, which are seen in varying degrees. They are considered mild, moderate, or severe, corresponding to plasma factor levels of 6 to 30, 2 to 5, or less than 1 percent, respectively (Mannucci and Tuddenham, 2001).

Hemophilia A is an X-linked recessively transmitted disease characterized by a marked deficiency of *small component* antihemophilic factor (factor VIII:C). It is rare among women compared with men, in whom the heterozygous state is responsible for the disease. Although heterozygous women have diminished factor VIII levels, almost invariably the homozygous state is the requisite for hemophilia A. In a few instances, it appears in women spontaneously as a newly mutant gene.

The genetic and clinical features of severe deficiency of factor IX — *Christmas disease* or *hemophilia B* — are quite similar to those of hemophilia A. Guy and associates (1992) reviewed five cases in pregnancy, all with a favorable outcome. They recommended administration of factor IX where levels are below 10 percent.

The degree of risk for each of these hemophilias is influenced markedly by the level of circulating factor VIII:C or factor IX. If the level is at or very close to zero, the risk is major. In female carriers, activity is expected to average 50 percent, but there is a range due to lyonization (Letsky, 2000). If levels fall below 10 to 20 percent, hemorrhage may occur. These clotting factors increase appreciably during normal pregnancy and in carriers of hemophilia A and B. Desmopressin may also stimulate factor VIII:C release. The risk of hemorrhage is reduced by avoiding lacerations, minimizing episiotomy, and maximizing postpartum myometrial contractions and retraction. Kadir and co-workers (1997) reported that 20 percent of carriers had postpartum hemorrhage, and in two, it was massive.

An affected male fetus may develop hematomas with either vaginal or cesarean delivery (Kadir and associates, 1997). After delivery, the risk of hemorrhage in the neonate increases, especially if circumcision is attempted.

Whenever the mother has hemophilia A or B, all of her sons will have the disease, and all of her daughters will be carriers. If she is a carrier, half of her sons will inherit the disease and half of her daughters will be carriers. Prenatal diagnosis of

hemophilia is possible in some families using chorionic villus biopsy (see [Chap. 13](#), p. 329). The confirmation of a male fetus also identifies a 50-percent risk of inheriting hemophilia.

FACTOR VIII OR IX INHIBITORS. Rarely, antibodies directed against factor VIII or IX are acquired and may lead to life-threatening hemorrhage. These antibodies may be troublesome in patients with hemophilia A or B. This phenomenon has also been identified rarely in women during the puerperium. The prominent clinical feature is severe, protracted, repetitive hemorrhage from the reproductive tract starting a week or so after an apparently uncomplicated delivery (Reece and associates, 1988). The activated partial thromboplastin time is markedly prolonged. Treatment has included multiple transfusions of whole blood and plasma; huge doses of cryoprecipitate; large volumes of an admixture of activated coagulation factors, including porcine factor VIII; immunosuppressive therapy; and attempts at various surgical procedures, especially curettage and hysterectomy. Another treatment involves bypassing factor VIII or IX by the use of activated forms of factors VII, IX, and X. A recombinant activated factor VII (NovoSeven) stops bleeding in up to 75 percent of patients with inhibitors (Mannucci and Tuddenham, 2001). It has also been used in cases of intractable obstetrical hemorrhage caused by uterine atony as well as multiple transfusions in nonhemophilic patients (Bouwmeester and colleagues, 2003; Danilou and associates, 2003).

VON WILLEBRAND DISEASE. Clinically, von Willebrand disease is actually a heterogeneous group of about 20 functional disorders involving aberrations of factor VIII complex and platelet dysfunction. These abnormalities are the most commonly inherited bleeding disorders, and their prevalence is as high as 1 to 2 percent (Mannucci, 2004). Most of von Willebrand variants are inherited as autosomal dominant traits. Examples are types I and II which are the most common variants. Type III, which is the most severe, is phenotypically recessive.

The *von Willebrand factor* (vWF) is a series of large plasma multimeric glycoproteins that form part of the factor VIII complex. It is essential for normal platelet adhesion to subendothelial collagen and formation of a primary hemostatic plug at the site of blood vessel injury. It also plays a major role in the stabilization of the coagulant properties of factor VIII. The procoagulant component is the antihemophilic factor or factor VIII:C, which is a glycoprotein synthesized by the liver. Conversely, von Willebrand precursor, which is present in platelets as well as plasma, is synthesized by endothelium and megakaryocytes under the control of autosomal genes on chromosome 12. The von Willebrand factor antigen (vWF:Ag) is the antigenic determinant measured by immunoassays. Von Willebrand disease rarely is acquired when antibodies to vWF develop in autoimmune or lymphoproliferative disorders (Handin, 2001).

Clinical Presentation. Symptomatic patients usually present with evidence of a platelet defect. The possibility of von Willebrand disease is usually considered in women with bleeding suggestive of a chronic disorder of coagulation. The classical autosomal dominant form usually is symptomatic in the heterozygous state. The less common but clinically more severe autosomal recessive form is manifest when inherited from both parents, both of whom typically demonstrate little or no disease. Type I, which accounts for 75 percent of von Willebrand variants, is characterized clinically by easy bruising; epistaxis; mucosal hemorrhage; and excessive bleeding with trauma, including surgery. Its laboratory features are usually a prolonged bleeding time, prolonged partial thromboplastin time, decreased vWF antigen, decreased factor VIII immunological as well as coagulation-promoting activity, and inability of platelets in plasma from an affected person to react to a variety of stimuli.

Effect of Pregnancy. Pregnant women with von Willebrand disease often develop normal levels of factor VIII coagulant activity as well as vWF antigen, although the bleeding time still may be prolonged. These levels may double or triple by term. If factor VIII activity is very low, or if there is bleeding, treatment is recommended. Desmopressin by infusion may transiently increase factor VIII and vWF factor levels (Mannucci, 2004). With significant bleeding, 15 or 20 units or "bags" of cryoprecipitate are given every 12 hours. Alternatively, factor VIII concentrates may be given that contain high-molecular-weight vWF multimers (Alfanate, Hemate-P). These concentrates are highly purified and are heat treated to destroy HIV. Lubetsky and associates (1999) have described continuous infusion with Hemate-P in nonpregnant patients during nine surgical procedures and in another woman during a vaginal delivery.

Pregnancy outcomes in women with von Willebrand disease are generally good but postpartum hemorrhage is encountered in up to 50 percent of cases. Conti and associates (1986) summarized 38 cases, and in a fourth, bleeding was reported with abortion, delivery, or the puerperium. Greer and colleagues (1991) reported that eight of 14 pregnancies were complicated by postpartum hemorrhage. Kadir and co-workers (1998) reported their experiences from the Royal Free Hospital in London with 84 pregnancies and described a 20-percent incidence of immediate postpartum hemorrhage and another 20 percent had late hemorrhage. Most cases were associated with low vWF levels in untreated women, and none given treatment peripartum had hemorrhage.

Inheritance. Although most patients with von Willebrand disease have heterozygous variants with a mild bleeding disorder, the disease can be severe. Certainly when both parents have the disorder, their homozygous offspring develop a serious bleeding disorder. Mullaart and colleagues (1991) reported periventricular hemorrhage in a 32-week fetus who inherited type IIa von Willebrand disease from her father. Chorionic villus biopsy with DNA analysis to detect the missing genes has been accomplished (see [Chap. 13](#), p. 329). Some authorities recommend cesarean delivery to avoid trauma to a possibly affected fetus if the mother has severe disease.

OTHER INHERITED COAGULATION FACTOR DEFICIENCIES. A number of rare coagulopathies may be inherited in a manner similar to the hemophilias. *Factor VII deficiency* is a rare autosomal recessive disorder. The gene that codes for factor VII is on chromosome 13. Normally, factor VII increases during pregnancy, but it may do so only mildly in women with factor VII deficiency (Fadel and Krauss, 1989). Treatment with factor VIIa has been reported during labor, delivery and the puerperium (Eskandari and associates, 2002).

Factor X or Stuart-Prower factor deficiency is extremely rare and is inherited as an autosomal recessive trait. Factor X levels typically rise by 50 percent during normal pregnancy. Konje and colleagues (1994) described a woman with 2-percent activity who was given prophylactic treatment with plasma-derived factor X, which raised plasma levels to 37 percent. Despite this, she suffered an intrapartum placental abruption. Bofill and co-workers (1996) gave intrapartum fresh-frozen plasma to a woman with less than 1-percent factor X activity, and she delivered spontaneously without incident.

Factor XI (plasma thromboplastin antecedent) deficiency probably is the consequence of an autosomal trait that is manifest as severe disease in homozygotes but a minor defect in heterozygotes. This deficiency state is most prevalent in Ashkenazi Jews, and it is rarely seen in pregnancy. Muslow and colleagues (1987) described 41 deliveries in 17 women with factor XI deficiency, none of whom required transfusions. They also described a woman who developed a spontaneous hemarthrosis at 39 weeks. Kadir and associates (1998) described 29 pregnancies in 11 women. In none of these did factor XI levels increase; 15 percent had immediate postpartum hemorrhage, and another 25 percent had delayed hemorrhage. David and colleagues (2002) reported three cases in which factor XI deficiency was first diagnosed after obstetrical hemorrhage. Peripartum treatment with factor XI concentrate at the time of delivery prevents hemorrhage (Letsky, 2000).

Factor XII deficiency is another autosomal recessive disorder that rarely complicates pregnancy. An increased incidence of thromboembolism is encountered in nonpregnant patients with this deficiency. Lao and colleagues (1991) reported an affected pregnant woman in whom placental abruption developed at 26 weeks.

Factor XIII deficiency is autosomal recessive and may be associated with maternal intracranial hemorrhage (Letsky, 2000). Treatment is given with fresh frozen plasma.

Autosomally inherited abnormalities of fibrinogen usually involve the formation of a functionally defective fibrinogen, and are commonly referred to as *dysfibrinogenemias* (Edwards and Rijhsinghani, 2000). Familial *hypofibrinogenemia*, and sometimes *afibrinogenemia*, are infrequent recessive disorders. In some cases, both conditions occur—*hypodysfibrinogenemia* (Deering and colleagues, 2003). Our experience suggests that hypofibrinogenemia represents a heterozygous autosomal dominant state with 50 percent of the offspring affected. Typically, thrombin-clottable protein level in these patients has ranged from 800 to 110 mg/dL when nonpregnant, and this increases by 40 or 50 percent in normal pregnancy. Those pregnancy complications that give rise to acquired hypofibrinogenemia (i.e., placental abruption) are more common with fibrinogen deficiency. Trehan and Fergusson (1991) and Funai and associates (1997) described successful outcomes in two women in whom fibrinogen or plasma infusions were given weekly or biweekly throughout pregnancy.

THROMBOPHILIAS. Several important regulatory proteins inhibit clotting. There are physiological antithrombotic proteins that act as inhibitors at strategic sites in the coagulation cascade to maintain blood fluidity under normal circumstances. Inherited deficiencies of these inhibitory proteins are caused by mutations of genes influencing their control. Because they may be associated with recurrent thromboembolism, they are collectively referred to as *thrombophilias*. Examples include *antithrombin III*; *protein C* and its co-factor, *protein S*; *activated protein C resistance* from factor V single-gene mutations; a function-enhancing mutation in the *prothrombin gene (G20210A)*; and *hyperhomocystinemia*. Because these deficiencies are typically associated with thromboembolism, they are discussed in detail in [Chapter 47](#) (see p. 1074).

52. Diabetes

INTRODUCTION

The prevalence of diagnosed diabetes among American adults has increased by 40 percent in 10 years from 4.9 percent in 1990 to 6.9 percent in 1999 (Narayan and colleagues, 2003). Even worse is that it is estimated that this incidence will increase another 165 percent by 2050. To put this into perspective, the lifetime risk of diabetes in individuals born in 2000 is 33 percent for males and 39 percent for females! This increase primarily is due to type 2 diabetes, which is also referred to as *diabesity*, because of the strong relationship with the current epidemic of obesity in the United States and other countries (Gale, 2003; Mokdad and colleagues, 2003). Other aspects of adverse effects of obesity on health and pregnancy outcome are discussed in [Chapter 43](#).

The increasing prevalence of type 2 diabetes in general, and in younger people in particular, has led to an increasing number of pregnancies with this complication (Feig and Palda, 2002; Ferrara and colleagues, 2004). Many women found to have gestational diabetes are likely to have type 2 diabetes that has previously gone undiagnosed (Feig and Palda, 2002). Indeed, the incidence of diabetes complicating pregnancy has increased about 40 percent between 1989 and 2002 (Martin and colleagues, 2003).

There is keen interest in events that precede diabetes, which includes the *mini-environment of the uterus*, where it is believed that early imprinting can have effects later in life (Saudek, 2002). For example, in utero exposure to maternal hyperglycemia leads to fetal hyperinsulinemia, causing an increase in fetal fat cells, which leads to obesity and insulin resistance in childhood (Feig and Palda, 2002). This in turn leads to impaired glucose tolerance and diabetes in adulthood. Thus, a cycle of fetal exposure to diabetes leading to childhood obesity and glucose intolerance is set in motion. This sequence has been reported in Pima Indians as well as a heterogeneous Chicago population (Silverman and colleagues, 1995).

CLASSIFICATION

Diabetes is now classified based on the pathogenic processes involved (Powers, 2001). Absolute insulin deficiency characterizes type 1 diabetes, whereas defective insulin secretion or insulin resistance characterizes type 2 diabetes ([Table 52-1](#)). The terms insulin-dependent diabetes mellitus (IDDM) and noninsulin-dependent diabetes mellitus (NIDDM) are no longer used. Age is also no longer used in classification, because β -cell destruction can occur at any age; most commonly, onset is before age 30, but in 5 to 10 percent of affected individuals, onset is after 30 years of age. Type 2 diabetes, although most typical with increasing age, also occurs in obese adolescents.

Diabetes is the most common medical complication of pregnancy. Women can be separated into those who were known to have diabetes before pregnancy — *pregestational* or *overt*, and those diagnosed during pregnancy — *gestational*. In 2002, slightly more than 131,000 American women had pregnancies complicated by diabetes, representing 3.3 percent of all live births (Martin and colleagues, 2003). More than 90 percent of these women had gestational diabetes.

CLASSIFICATION DURING PREGNANCY. [Table 52-2](#) shows a classification recommended by the American College of Obstetricians and Gynecologists in 1986. This was replaced in 1994 because, according to the College, "a single classification based on the presence or absence of good maternal metabolic control and the presence or absence of maternal diabetic vasculopathy is more helpful." In the 1986 classification, women diagnosed with gestational diabetes are subdivided according to their degree of glycemia. Specifically, those with fasting hyperglycemia, which is defined as 105 mg/dL or greater, are placed into class A₂. About 15 percent of women with gestational diabetes exhibit fasting hyperglycemia (Sheffield and co-workers, 1999). Women in classes B to H, corresponding to the White classification (1978), have overt diabetes antedating pregnancy. The White system emphasizes that end-organ derangements, especially involving the eyes, kidneys, and heart, have significant effects on pregnancy outcome.

DIAGNOSIS OF OVERT DIABETES DURING PREGNANCY. Women with high plasma glucose levels, glucosuria, and ketoacidosis present no problem in diagnosis. Similarly, women with a random plasma glucose level greater than 200 mg/dL plus classic signs and symptoms such as polydipsia, polyuria, and unexplained weight loss or a fasting glucose exceeding 125 mg/dL are considered to have overt diabetes by the American Diabetes Association (2004). The new diagnostic cutoff value for overt diabetes of a fasting plasma glucose of 126 mg/dL or higher is used because data indicate the risk of retinopathy rises dramatically at that fasting level. Women at the opposite end of the spectrum, or those with only minimal metabolic derangement, may be difficult to identify. The likelihood of impaired carbohydrate metabolism is increased appreciably in women who have a strong familial history of diabetes, have given birth to large infants, demonstrate persistent glucosuria, or have unexplained fetal losses.

Reducing substances are commonly found in the urine of pregnant women. Commercially available dipsticks may be used to identify glucosuria while avoiding a positive reaction from lactose. Even then, glucosuria most often does not reflect impaired glucose tolerance, but rather augmented glomerular filtration (see [Chap. 5](#), p. 138). Nonetheless, the detection of glucosuria during pregnancy warrants further investigation (Gribble and coauthors, 1995).

DETECTION OF GESTATIONAL DIABETES. Gestational diabetes is defined as carbohydrate intolerance of variable severity with onset or first recognition during pregnancy. This definition applies whether or not insulin is used for treatment. Undoubtedly, some women with gestational diabetes have previously unrecognized overt diabetes. Sheffield and co-workers (1999) studied outcomes in 1190 diabetic women delivered at Parkland Hospital between 1991 and 1995. They found that women with fasting hyperglycemia diagnosed before 24 weeks had pregnancy outcomes similar to those for women in classes B through FR. Thus, fasting hyperglycemia early in pregnancy likely represents overt diabetes. Bartha and colleagues (2000) also found that women diagnosed to have gestational diabetes early in pregnancy are a high-risk subgroup.

Screening. Despite more than 30 years of research, there is no consensus regarding the optimal approach to screening for gestational diabetes. The major issues include whether universal or selective screening should be used and which plasma glucose level after a 50-g glucose test threshold is best to identify women at risk for gestational diabetes (Bonomo and colleagues, 1998; Danilenko-Dixon and colleagues, 1999).

Since 1980, there have been four international workshop-conferences on gestational diabetes, and participants have attempted to provide consensus statements on screening (Metzger and Coustan, 1998). At the most recent 1997 workshop, prior recommendations for *universal screening* were changed to *selective screening* using the guidelines shown in [Table 52-3](#). It was recommended that screening for gestational diabetes should be performed between 24 and 28 weeks in those women not known to have glucose intolerance earlier in pregnancy. This evaluation is usually done in two steps. In the two-step procedure, a 50-g oral glucose challenge test is followed by a diagnostic 100-g oral glucose tolerance test if results exceed a predetermined plasma glucose concentration.

Plasma glucose level is measured 1 hour after a 50-g glucose load without regard to the time of day or time of last meal. A value of 140 mg/dL (7.8 mmol/L) or higher identifies 80 percent of all women with gestational diabetes. Using a value of 130 mg/dL (7.2 mmol/L) or higher increases the yield to more than 90 percent; however, 20 to 25 percent of women have positive test results compared with 14 to 18 percent when the 140 mg/dL or greater cutoff value is used. Recommended criteria for interpretation of the 100-g diagnostic glucose tolerance test are shown in [Table 52-4](#). Pennison and Egerman (2001) compared perinatal outcomes in 130 women with gestational diabetes diagnosed using the National Diabetes Data Group Criteria with those of 43 women diagnosed using the Carpenter and Coustan criteria and concluded that the benefits of the latter were unclear.

In two different surveys, more than 95 percent of obstetricians and residency programs were found to screen all pregnant women for gestational diabetes, usually between 25 and 29 weeks (Gabbe and co-workers, 1998; Owen and colleagues, 1995). The American College of Obstetricians and Gynecologists (2001) has concluded that it may be appropriate to use selective screening in some clinical settings and universal screening in others. Brody and colleagues (2003) reviewed the evidence and concluded that it is insufficient to recommend for or against routine screening.

The day-to-day reproducibility of the 50-g screening test has also been tested (Espinosa de los Monteros and co-workers, 1993). Although 90 percent of normal results were reproducible the next day, only 83 percent of abnormal test results were reproducible. Murphy and colleagues (1994) studied the accuracy and precision of reflectance photometers (Accu-Check III) for screening. Use of this glucometer required redefining the circumstances for testing as well as threshold values for abnormal results. It seems best to avoid these devices for screening.

Diagnosis. There is not international agreement as to the optimal glucose tolerance test for the definitive diagnosis of gestational diabetes. The World Health Organization (1985) has recommended the 75-g 2-hour oral glucose tolerance test, and this approach is often used in Europe (Weiss and colleagues, 1998). In the United States, the *100-g 3-hour oral glucose tolerance test* performed after an overnight fast remains the standard (American College of Obstetricians and Gynecologists, 2001). Even so, Catalano and co-workers (1993) found that the 100-g 3-hour test was not reproducible in 25 percent of women when repeated 1 week after the initial test. They attributed this to increased norepinephrine-mediated gluconeogenesis from maternal stress at initial testing.

GESTATIONAL DIABETES

Use of the word *gestational* implies that diabetes is induced by pregnancy, perhaps from exaggerated physiological changes in glucose metabolism (see [Chap. 5](#), p. 127). An alternative explanation is that gestational diabetes is type 2 diabetes unmasked or discovered during pregnancy. For example, Harris (1988) found that the prevalence of undiagnosed glucose intolerance in nonpregnant women between the ages of 20 and 44 years was virtually identical to the prevalence of gestational diabetes. Catalano and colleagues (1999) compared longitudinal changes in insulin sensitivity, insulin response, and endogenous glucose production in women with normal glucose tolerance with those in women with gestational diabetes. They found that women with gestational diabetes had abnormalities in glucose metabolism that are hallmarks of type 2 diabetes.

Use of the diagnostic term *gestational diabetes* has been encouraged to communicate the need for increased surveillance and to convince women of the need for further testing postpartum. The likelihood of fetal death with appropriately treated gestational diabetes has been found no different than in the general population (Metzger and Coustan, 1998). The most important perinatal concern is excessive fetal growth, which may result in birth trauma. **More than half of women with gestational diabetes ultimately develop overt diabetes in the ensuing 20 years, and there is mounting evidence for long-range complications that include obesity and diabetes in their offspring.**

MATERNAL AND FETAL EFFECTS. There has been an important shift in focus concerning adverse fetal consequences of gestational diabetes. Importantly, unlike in women with overt diabetes, fetal anomalies are not increased (Sheffield and colleagues, 2002). Similarly, whereas pregnancies in women with overt diabetes are at greater risk for fetal death, this danger is not apparent for those who have only postprandial hyperglycemia (namely, class A₁ gestational diabetes) (Lucas and co-workers, 1993; Sheffield and colleagues, 2002).

In contrast, gestational diabetes with elevated fasting glucose class A₂ has been associated with unexplained stillbirth similar to overt diabetes (Johnstone and colleagues, 1990). The American Diabetes Association (1999a) has concluded that fasting hyperglycemia defined as more than 105 mg/dL may be associated with an increased risk of fetal death during the last 4 to 8 weeks of gestation. Adverse maternal effects include an increased frequency of hypertension and cesarean delivery.

Macrosomia. Fetal macrosomia is defined by the American College of Obstetricians and Gynecologists (2000) as infants whose birthweight exceeds 4500 g. The perinatal focal point is avoidance of difficult delivery due to macrosomia, with concomitant birth trauma associated with shoulder dystocia. Except for the brain, most fetal organs are affected by the macrosomia that commonly characterizes the fetus of a diabetic woman. Macrosomic infants of diabetic mothers are described as anthropometrically different from other large-for-gestational age infants (McFarland and associates, 2000; Modanlou and colleagues, 1982). Specifically, those whose mothers are diabetic have excessive fat deposition on the shoulders and trunk,

which predisposes to shoulder dystocia (Fig. 52-1). Similarly, Bernstein and Catalano (1994) reported that fat infants of diabetic women more often required cesarean delivery for cephalopelvic disproportion. Fortunately, shoulder dystocia is uncommon, even in women with gestational diabetes. For example, Magee and colleagues (1993) diagnosed shoulder dystocia in 3 percent of women with class A₁ diabetes. None of their infants sustained brachial plexus injuries.

Macrosomia is compatible with the long-recognized association between fetal hyperinsulinemia resulting from maternal hyperglycemia, which in turn stimulates excessive somatic growth. Similarly, neonatal hyperinsulinemia may provoke hypoglycemia within minutes of birth. The incidence varies greatly depending on the threshold used to define significant neonatal hypoglycemia. According to the American Diabetes Association (1995), values less than 35 mg/dL at term are abnormal. A lower value is considered abnormal in preterm infants, because glycogen stores have not reached term levels. Magee and co-workers (1993) reported that 4 percent of infants of women with gestational diabetes required intravenous glucose therapy for hypoglycemia.

There is extensive evidence that insulin and the insulin-like growth factors I (IGF-I) and II (IGF-II) play a role in the regulation of fetal growth (see Chap. 38, p. 895). Insulin is secreted by fetal pancreatic β -cells primarily during the second half of gestation and is believed to stimulate somatic growth and adiposity. These growth factors, which structurally are proinsulin-like polypeptides, are produced by virtually all fetal organs and are potent stimulators of cell differentiation and division. Verhaeghe and co-workers (1993) measured cord IGFs and insulin (C-peptide) concentrations throughout gestation in women without diabetes and found that levels correlated with birthweight. Large-for-gestational age infants had significantly increased levels of these factors. Other factors implicated in macrosomia include epidermal growth factor and leptin (Loukovaara and colleagues, 2004; Okereke and colleagues, 2002).

Maternal obesity is an independent and more important risk factor for large infants in women with gestational diabetes than is glucose intolerance (Leonardi and Bottoms, 1996; Lucas and colleagues, 1993). Moreover, maternal obesity is an important confounding factor in the diagnosis of gestational diabetes. Johnson and colleagues (1987) reported that 8 percent of 588 women who weighed more than 250 pounds had gestational diabetes compared with less than 1 percent of women who weighed less than 200 pounds. Landon and colleagues (1994) and Zhang and co-workers (1995) found that the risk of gestational diabetes was increased in women with truncal obesity.

Figure 52-1. This macrosomic infant who weighed 6050 g was born to a woman with gestational diabetes.

MANAGEMENT. Women with gestational diabetes can be divided into two functional classes using fasting glucose. Insulin therapy is usually recommended when standard dietary management does not consistently maintain the fasting plasma glucose at less than 95 mg/dL or the 2-hour postprandial plasma glucose at less than 120 mg/dL (American College of Obstetricians and Gynecologists, 2001). Whether insulin should be used in women with lesser degrees of fasting hyperglycemia (105 mg/dL or less before dietary intervention) is unclear because there have been no controlled trials to identify ideal glycemia targets for prevention of fetal risks. The Fourth International Workshop Conference on Gestational Diabetes (Metzger and Coustan, 1998), however, recommended that maternal capillary glucose levels be kept at 95 mg/dL or less in the fasting state.

Diet. There are no available data comparing diet therapy alone with no treatment in women with gestational diabetes (American College of Obstetricians and Gynecologists, 2001). The American Diabetes Association (2000) has recommended nutritional counseling with individualization based on height and weight and a diet that provides an average of 30 kcal/kg/d based on prepregnant body weight for nonobese women. Although the association acknowledges that the most appropriate diet for women with gestational diabetes has not been established, it has suggested that obese women with a body mass index greater than 30 kg/m² may benefit from a 30- to 33-percent caloric restriction. This should be monitored with weekly tests for ketonuria, because maternal ketonemia has been linked with impaired psychomotor development in the offspring (Rizzo and colleagues, 1995).

Exercise. This is known to be important in nonpregnant patients. The American College of Obstetricians and Gynecologists (2001) reviewed three randomized trials of exercise in women with gestational diabetes (Avery, 1997; Bung, 1993; Jovanovic-Peterson, 1989, and all their colleagues). They suggested that exercise improved cardiorespiratory fitness without improving pregnancy outcome. Dempsey and colleagues (2004) found that physical activity during pregnancy reduced the risk of gestational diabetes. Brankston and associates (2004) reported that resistance exercise helped avoid insulin therapy in overweight women with gestational diabetes.

Plasma Glucose Control. Postprandial surveillance for gestational diabetes has been shown to be superior to preprandial surveillance, and because glycemic control is significantly improved, less neonatal hypoglycemia, less macrosomia, and fewer cesarean deliveries for dystocia result. These conclusions have been challenged, however, because women in these studies had fasting glucose values that were consistent with overt diabetes.

Prophylactic insulin given to decrease complications related to macrosomia in class A₁ diabetic women with fasting euglycemia has not been proved beneficial. Langer and co-authors (1994) reviewed 23 reports from 1979 through 1993 and found that none demonstrated improved perinatal outcomes related to any management approach, including prophylactic insulin treatment. There have been only three randomized studies to date (Garner, 1997; Nordlander, 1989; Thompson, 1990, and all their colleagues). Intensive therapy had little effect on birthweight, birth trauma, operative delivery, or neonatal complications.

Langer and colleagues (1994) managed 1145 women with gestational diabetes using an "intensified" approach guided by

glucometer measurements seven times each day. Goals included fasting glucose levels between 60 and 90 mg/dL and postprandial levels less than 120 mg/dL. In contrast, another 1316 women in the "conventional" management group had the same glucose control goals, but used blood glucose test strips in place of glucometers. Women in both groups underwent glucose surveillance for an average of 12 weeks, and a similar number of glucose measurements were performed in each study group—approximately 350 per patient. Although mean glucose values were not different between the two management groups, macrosomia, cesarean delivery, and shoulder dystocia were significantly reduced in women managed intensively.

Kjos and colleagues (2001) randomized 98 women with gestational diabetes and fasting plasma glucose levels between 105 and 120 mg/dL to empirical insulin therapy versus insulin given only if the fetal abdominal circumference measured with ultrasonography indicated macrosomia. This allowed 93 percent of the women in the ultrasound group to be managed without insulin. There were no differences in macrosomia or birth trauma between the two groups.

INSULIN. Most practitioners—93 percent according to Owen and colleagues (1995)—initiate insulin therapy in women with gestational diabetes if fasting glucose levels exceeding 105 mg/dL persist despite diet therapy. At Parkland Hospital, this is accomplished in a specialized outpatient clinic, but occasionally hospitalization is necessary.

Experts differ in their approach to insulin therapy in gestational diabetes. A total dose of 20 to 30 units given once daily, before breakfast, is commonly used to initiate therapy. The total dose is usually divided into two thirds intermediate-acting insulin and a third short-acting insulin. Once therapy has been initiated, it must be recognized that the level of glycemia control to reduce fetal and neonatal complications has not been established. DeVeciana and colleagues (1995) studied 66 pregnant women with class A₂ diabetes in whom insulin was initiated for fasting hyperglycemia. The women were randomized to glucose surveillance using either preprandial or 1-hour postprandial capillary blood glucose concentrations measured by glucometer. Postprandial surveillance was shown to be superior in that blood glucose control was significantly improved and was associated with fewer cases of neonatal hypoglycemia (3 versus 21 percent), less macrosomia (12 versus 42 percent), and fewer cesarean deliveries for dystocia (24 versus 39 percent).

ORAL HYPOGLYCEMIC AGENTS. The American College of Obstetricians and Gynecologists (2001) has not recommended these agents during pregnancy. Langer and colleagues (2000) randomized 257 women with gestational diabetes to insulin or *glyburide* therapy. Near normoglycemic levels were achieved equally well with either regimen. There were no apparent neonatal complications attributable to the glyburide. In a follow-up report, Conway and co-workers (2004) found that women with fasting glucose levels greater than 110 mg/dL did not adequately respond to glyburide therapy.

Metformin, which has been used as a treatment for infertility due to polycystic ovarian disease, also has been reported to reduce the incidence of gestational diabetes in women who use the drug throughout pregnancy (Glueck and colleagues, 2004). Even so, it is usually recommended that metformin be discontinued once pregnancy is diagnosed (Harborne and colleagues, 2003).

OBSTETRICAL MANAGEMENT. In general, women with gestational diabetes who do not require insulin seldom require early delivery or other interventions. Whether elective cesarean delivery is used to avoid brachial plexus injuries in macrosomic infants is an important issue. The American College of Obstetricians and Gynecologists (2001) has suggested that cesarean delivery should be considered in women with a sonographically estimated fetal weight of 4500 grams or more. Gonen and colleagues (2000) retrospectively analyzed the effects of a policy of elective cesarean delivery when estimated fetal weight exceeded 4500 grams in a general obstetrical population of more than 16,000 deliveries. **Elective cesarean delivery had no significant effect on the incidence of brachial plexus injury.**

Elective induction to prevent shoulder dystocia in women with sonographically diagnosed fetal macrosomia, compared with spontaneous labor, is also controversial. Conway and Langer (1996) found that elective delivery reduced the rate of shoulder dystocia from 2.2 to 0.7 percent. In contrast, Combs and colleagues (1993b) and Adascheck and associates (1996) found no advantages.

There is no consensus regarding whether antepartum fetal testing is necessary, and if so, when to begin such testing in women without severe hyperglycemia (American College of Obstetricians and Gynecologists, 2001; Metzger and Coustan, 1998). This is based on the low risk of fetal death. Women who require insulin therapy for fasting hyperglycemia, however, typically undergo fetal testing and are managed as if they had overt diabetes.

POSTPARTUM CONSEQUENCES. The Fourth International Workshop-Conference on Gestational Diabetes recommended that women diagnosed with gestational diabetes undergo evaluation with a 75-g oral glucose tolerance test at 6 to 12 weeks after delivery (Table 52-5). Women whose 75-g test is normal should be reassessed at a minimum of 3-year intervals (American Diabetes Association, 2003). Although postpartum follow-up of women diagnosed with gestational diabetes was recommended throughout the 1990s, reports on compliance have only recently become available. Kaufmann and colleagues (1999) measured physician and patient compliance rates during a 5-year postpartum follow-up period in 66 such women. Compliance was poor, and only 30 percent of the women reported receiving a yearly 2-hour glucose tolerance test, although the risk of developing diabetes was 60 percent in others tested on an annual basis.

These recommendations for postpartum follow-up are based on the 50-percent likelihood of women with gestational diabetes developing overt diabetes within 20 years (O'Sullivan, 1982). If fasting hyperglycemia develops during pregnancy, diabetes is more likely to persist postpartum. For example, in women with fasting glucose levels of 105 to 130 mg/dL, 43 percent were found to be overtly diabetic (Metzger and colleagues, 1985). When fasting glucose exceeded 130 mg/dL during pregnancy, 86 percent of women became overtly diabetic. Insulin therapy during pregnancy, and especially before 24 weeks, is a powerful predictor of diabetes after the pregnancy (Dacus and co-workers, 1994; Greenberg and colleagues, 1995).

Women with gestational diabetes are also at risk for cardiovascular complications associated with abnormal serum lipids, hypertension, and abdominal obesity—the *metabolic syndrome* (see Chapter 43, p. 1009). Pallardo and colleagues (1999) evaluated cardiovascular disease risk factors in 788 women with gestational diabetes 3 to 6 months postpartum. They found that the degree of postpartum glucose intolerance was significantly associated with these risk factors.

Recurrence of gestational diabetes in subsequent pregnancies was documented in 20 of 30 women reported by Philipson and Super (1989). Obese women were more likely to have impaired glucose intolerance in subsequent pregnancies. Thus, lifestyle behavioral changes, including weight control and exercise between pregnancies, likely would prevent recurrence of gestational diabetes as well as modify onset and severity of type 2 diabetes later in life (Pan and associates, 1997). Interestingly, perinatal outcomes in women with previous gestational diabetes but with normal glucose tolerance tests during a subsequent pregnancy were not improved with regard to birthweight, macrosomia, route of delivery, and neonatal complications (Danilenko-Dixon and colleagues, 2000). Finally, Lu and colleagues (2002) found that women *without* gestational diabetes in their first pregnancy were unlikely to have gestational diabetes when screened in a second pregnancy.

Contraception. Low-dose hormonal contraceptives may be used safely by women with recent gestational diabetes (see [Chap. 32](#), p. 731). The rate of subsequent diabetes in oral contraceptive users is not significantly different than in those who did not use hormonal contraception (Kjos and colleagues, 1990a).

GESTATIONAL DIABETES AT PARKLAND HOSPITAL. Universal glucose screening was not performed at Parkland until 1997. Selective screening was instead based on many of the risk factors previously enumerated. For these women, a standard 50-g oral glucose tolerance test was performed between 24 and 28 weeks without regard to recent meal status. The criteria shown in [Table 52-4](#) were used. Women diagnosed to have class A₁ gestational diabetes were seen weekly in a specific clinic designed to provide dietary counseling. Fasting plasma glucose measurements were obtained at each visit. Women without other complications such as hypertension or postterm gestation were permitted to enter spontaneous labor, and antepartum testing was not used. Women diagnosed to have class A₂ gestational diabetes were managed as overt diabetics, as described later.

In January 1997, universal screening for gestational diabetes was performed between 24 and 28 weeks using a standard 1-hour, 50-g oral glucose challenge test. All obstetrical management practices previously used during selective screening were continued. The practice of universal screening doubled the number of women tested in one year from approximately 4300 to 8200. Importantly, universal screening for gestational diabetes did not increase or decrease obstetrical outcomes attributable to this diagnosis (Casey and colleagues, 1999).

PREGESTATIONAL (OVERT) DIABETES

Unlike gestational diabetes, it is unquestioned that overt diabetes has a significant impact on pregnancy outcome. The embryo, the fetus, and the mother can experience serious complications directly attributable to diabetes. The likelihood of successful outcomes with overt diabetes is related somewhat to the degree of glycemic control, but more importantly, to the degree of any underlying cardiovascular or renal disease. Therefore, as the alphabetic classification shown in [Table 52-2](#) worsens, the likelihood of good pregnancy outcomes lessen.

Hanson and Persson (1993) prospectively chronicled the effects of overt diabetes on pregnancy outcomes in Sweden. Their unique analysis included all deliveries between 1983 and 1985, during which period 491 insulin-dependent women in classes B or worse were identified. Their outcomes were compared with those of 279,000 pregnancies in women without diabetes ([Table 52-6](#)). Pregnant women with diabetes experienced significantly worse pregnancy outcomes. As shown in [Table 52-7](#), women in the more advanced classes of overt diabetes increasingly developed preeclampsia. Indeed, 54 percent of those in class F with diabetic nephropathy developed this complication. Similar results have been reported for France and the Netherlands (Diabetes Pregnancy Group, France, 2004; Evers and co-workers, 2004).

FETAL EFFECTS. Improved fetal surveillance, neonatal intensive care, and maternal metabolic control have reduced perinatal losses with overt diabetes to 2 to 4 percent. These rates have seemingly plateaued because the two major causes of fetal death—congenital malformations and unexplained fetal death—remain unchanged by medical intervention (Garner, 1995b).

Abortion. Several studies have shown that first-trimester abortion is associated with poor glycemic control (Greene and colleagues, 1989; Mills and associates, 1988a). In 215 women with type 1 diabetes enrolled for prenatal care by Rosenn and colleagues (1994) before 9 weeks, 24 percent had miscarriages. Only women with type 1 diabetes and initial glycohemoglobin A_{1c} concentrations greater than 12 percent or persistent preprandial glucose concentrations greater than 120 mg/dL were at increased risk for abortion.

Preterm Delivery. Pregestational diabetes is a risk factor for preterm birth. The Maternal-Fetal Medicine Units Network of the National Institute of Child Health and Human Development analyzed pregnancy outcomes in 461 women with pregestational diabetes (Sibai and colleagues, 2000). Investigators reported that 9 percent of these women spontaneously delivered before 35 weeks compared with 4.5 percent of nondiabetic women. Moreover, 7 percent of diabetic women compared with 2 percent of normal women underwent indicated preterm delivery.

Malformations. The incidence of major malformations in women with type 1 diabetes is about 5 percent (Sheffield and co-workers, 2002). Fetal anomalies account for almost half of perinatal deaths in diabetic pregnancies. Importantly, diabetes is not associated with increased risk for fetal chromosomal abnormalities. Specific types of anomalies linked to maternal diabetes and their relative incidence are summarized in [Table 52-8](#).

It is generally believed that the increased risk of severe malformations is the consequence of poorly controlled diabetes both preconceptionally as well as early in pregnancy. Miller and co-workers (1981) suggested that women with lower glycosylated hemoglobin values at conception had fewer fetuses with anomalies compared with women with abnormally high values. Mills and colleagues (1988b) from the Diabetes in Early Pregnancy Study did not totally corroborate these findings. More than 600 women with diabetes were enrolled in this investigation, and the investigators concluded that a normal glycosylated hemoglobin distribution did not guarantee that diabetes-associated anomalies would be avoided. Conversely, not all women with an elevated level had poor outcomes. Investigators observed that women in whom periconceptional glucose control was optimized had a 5-percent fetal malformation rate compared with 9 percent in the group who presented after organogenesis was complete. Ray and colleagues (2001) performed a meta-analysis of seven studies addressing preconceptional care

published between 1970 and 2000. They concluded that such care was associated with a lower risk of congenital anomalies and this was associated with lower glycosylated hemoglobin values.

Unexplained Fetal Demise. Stillbirths without identifiable causes are a phenomenon found in pregnancies complicated by pregestational diabetes. They are declared "unexplained" because no factors such as obvious placental insufficiency, abruption, fetal growth restriction, or oligohydramnios are apparent. These infants are typically large-for-gestational age and die before labor, usually at 35 weeks or later (Garner, 1995a). In the Swedish study shown in [Table 52-6](#), the incidence of unexplained stillbirths was 1 percent.

Investigations using cordocentesis have provided new insights into acid-base metabolism in fetuses of diabetic mothers. Salvesen and colleagues (1992, 1993) reported decreased fetal pH and increased P_{CO_2} , lactate, and erythropoietin in diabetic pregnancies. Such findings lend credence to the long-held hypothesis that hyperglycemia-mediated chronic aberrations in transport of oxygen and fetal metabolites may account for unexplained fetal deaths (Pedersen, 1977).

Between 1984 and 1993, Richey and co-workers (1995) were at the bedside in two pregnancies at Parkland Hospital where otherwise unexplained fetal deaths were seemingly in progress. In both of these rare clinical instances, the fetus was macrosomic and there was excessive amniotic fluid. Both fetuses were acidemic before labor, and both placentae were hydropic due to edema of the chorionic villi. These features were linked to maternal hyperglycemia, and it was hypothesized that osmotically induced villous edema led to impaired fetal oxygen transport.

Explicable stillbirths due to placental insufficiency also occur with increased frequency in women with overt diabetes, usually in association with severe preeclampsia. This, in turn, is increased in women with advanced diabetes and vascular complications. Similarly, ketoacidosis can cause fetal death.

Hydramnios. Although diabetic pregnancies are often complicated by hydramnios, the cause is unclear. A likely, although unproven explanation is fetal polyuria resulting from fetal hyperglycemia (see [Chap. 21](#), p. 528). In a study from Parkland Hospital, Dashe and co-authors (2000) found that the amniotic fluid index parallels the amniotic fluid glucose level among women with diabetes. This finding suggests that the hydramnios associated with diabetes is a result of increased amniotic fluid glucose concentration.

NEONATAL EFFECTS. Before tests of fetal health and maturity became available, preterm delivery was deliberately effected to avoid unexplained fetal deaths. Although this practice has been abandoned, there is still an increased frequency of preterm delivery in women with diabetes (Sibai and co-workers, 2000). Most preterm births are associated with advanced diabetes and superimposed preeclampsia.

Modern neonatal care has largely eliminated neonatal deaths due to immaturity. Cnattingius and colleagues (1994) reported only one infant death due to immaturity in 914 singleton births to B to F diabetic women. Conversely, neonatal *morbidity* due to preterm birth continues to be a serious consequence. Indeed, some of the morbidities in these infants are considered to be uniquely related to aberrations in maternal glucose metabolism.

Respiratory Distress. Conventional obstetrical teaching through the late 1980s generally held that fetal lung maturation was delayed in diabetic pregnancies. Thus, these infants were at increased risk for respiratory distress (Gluck and Kulovich, 1973). Subsequent observations have challenged this concept, and gestational age rather than overt diabetes is likely the most significant factor associated with neonatal respiratory distress (Berkowitz and colleagues, 1996; Kjos and colleagues, 1990b).

Hypoglycemia. A rapid decrease in plasma glucose concentration after delivery is characteristic of the infant of a diabetic mother. This is attributed to hyperplasia of the fetal β -islet cells induced by chronic maternal hyperglycemia. Taylor and associates (2002) found that neonatal hypoglycemia (blood glucose less than 45 mg/dL before the second feeding) was related to maternal blood glucose exceeding 145 mg/dL during labor. Prompt recognition and treatment of the hypoglycemic infant has minimized sequelae.

Hypocalcemia. Defined as serum calcium concentration less than 7 mg/dL, hypocalcemia is one of the major metabolic derangements in infants of diabetic mothers. Its cause has not been explained. Theories include aberrations in magnesium-calcium economy, asphyxia, and preterm birth (Cruikshank and co-workers, 1980). In the randomized study by DeMarini and colleagues (1994), 137 pregnant women with type 1 diabetes were managed with strict versus customary glucose control to ascertain the effect of maternal glucose levels on neonatal hypocalcemia. Almost a third of infants in the customary control group developed hypocalcemia compared with only 18 percent of those in the strict control group. Gestational age and preeclampsia were also implicated.

Hyperbilirubinemia. The pathogenesis of hyperbilirubinemia in infants of diabetic mothers is uncertain. Factors implicated have included preterm birth and polycythemia with hemolysis. Venous hematocrits of 65 to 70 volume percent have been observed in as many as 40 percent of these infants (Salvesen and associates, 1992). Renal vein thrombosis is also reported to result from polycythemia.

Cardiac Hypertrophy. Infants of diabetic pregnancies may have hypertrophic cardiomyopathy that occasionally progresses to congestive heart failure (Gandhi and co-authors, 1995; Reller and Kaplan, 1988). These infants typically have macrosomia, and fetal hyperinsulinemia has been implicated in the pathogenesis of heart disease. Way (1979) reported that the cardiomyopathy generally disappears by 6 months of age.

Long-Term Cognitive Development. Rizzo and colleagues (1995) used multiple tests of intelligence and psychomotor development to assess 196 children of diabetic women up to 9 years of age. They concluded that maternal diabetes had a negligible impact on cognitive development.

Inheritance of Diabetes. Offspring born to women with overt diabetes have a low risk of developing type 1 diabetes; the incidence ranges from 1 to 3 percent (Garner, 1995b). The risk is 6 percent if only the father has overt diabetes. If both parents have type 1 diabetes, the risk is 20 percent. McKinney and colleagues (1999) studied 196 children with type 1 diabetes and found that older maternal age and maternal type 1 diabetes are important risk factors. Plagemann and colleagues (2002)

have implicated breast feeding by diabetic mothers in the genesis of childhood diabetes.

Altered Fetal Growth. The incidence of macrosomia rises significantly when mean maternal blood glucose concentrations exceed 130 mg/dL (Willman and co-authors, 1986). Some authors have objected to classification of these infants as either "macrosomic" or "nonmacrosomic," because this ignores the observation that virtually all are *growth promoted* (Bradley and associates, 1988). This is discussed in [Chapter 38](#) (see p. 904). As shown in [Figure 52-2](#), the birthweight distribution of infants of diabetic mothers is skewed toward consistently heavier birthweights compared with that of normal pregnancies.

Landon and co-workers (1989) performed serial ultrasound examinations during the third trimester in 79 women with diabetes and observed that excessive fetal abdominal circumference growth was detectable by 32 weeks ([Fig. 52-3](#)). This suggests that excessive weight accrues primarily during the third trimester. Keller and colleagues (1990), however, reported that some macrosomic fetuses can be recognized before 24 weeks. Similarly, Rey and co-authors (1999) and Raychaudhuri and Maresh (2000) concluded that macrosomia was determined primarily by early pregnancy diabetes control.

Figure 52-2. Distribution of birthweights (standard deviation from the normal mean for gestational age) for 280 infants of diabetic mothers and 3959 infants of normal mothers. (From Bradley and co-workers, 1988, with permission.)

Figure 52-3. Comparison of abdominal circumference growth curve for appropriate-for-gestational age (AGA) and large-for-gestational age (LGA) fetuses of diabetic mothers. Growth is accelerated at 32 weeks in the LGA group. (From Landon and co-workers, 1989, with permission.)

MATERNAL EFFECTS. Diabetes and pregnancy interact significantly such that maternal welfare can be seriously jeopardized. With the possible exception of diabetic retinopathy, however, the long-term course of diabetes is not affected by pregnancy.

Even though uncommon, maternal deaths in women with diabetes are still increased 10-fold (Cousins, 1987). They most often result from ketoacidosis, hypertension, preeclampsia, and pyelonephritis. The rare woman with coronary artery disease (class H diabetes) is at particular risk. Pombar and colleagues (1995) reviewed 17 such women and reported that only half survived pregnancy (see [Chapter 44](#), p. 1036).

Diabetic Nephropathy. This is the leading cause of end-stage renal disease in the United States (see [Chapter 48](#), p. 1102). The incidence of renal failure is nearly 30 percent in individuals with type 1 diabetes and ranges from 4 to 20 percent in those with type 2 diabetes. Importantly, the incidence of nephropathy in individuals with type 1 diabetes declined during the 1980s, presumably from improved glucose control. The Diabetes Control and Complications Trial (2002) found that there was a 25-percent decrease in nephropathy for each 10-percent decrease in hemoglobin A_{1C} levels.

Clinically detectable nephropathy in type 1 disease begins with microalbuminuria \approx 30 to 300 mg/24 h of albumin. This may manifest as early as 5 years after the onset of diabetes (Nathan, 1993). After another 5 to 10 years, overt proteinuria (more than 300 mg/24 h of albumin) develops in patients destined to have end-stage renal disease. Hypertension invariably develops during this period, and renal failure ensues typically in the next 5 to 10 years.

Approximately 5 percent of pregnant women with diabetes are class F (Hanson and Persson, 1993; Siddiqi and associates, 1991). These women have significantly increased preeclampsia and indicated preterm delivery. As shown in [Table 52-7](#), approximately 50 percent develop preeclampsia. Combs and associates (1993a) measured urinary protein excretion before 20 weeks in 311 diabetic women. In those with proteinuria that exceeded 500 mg/day, 38 percent developed preeclampsia. They also found that women with microproteinuria defined as 190 to 500 mg/day had an increased risk of preeclampsia. Conversely, in an analysis of 460 women with classes B through F-R diabetes, How and colleagues (2004) did not find an increased rate of preeclampsia in women with microproteinuria. Chronic hypertension with diabetic nephropathy increased the risk of preeclampsia to 60 percent. Gordon and associates (1996) reported that chronic renal insufficiency as well as heavy proteinuria before 20 weeks were predictive of preeclampsia.

There appear to be no long-term sequelae of pregnancy on diabetic nephropathy. Chaturvedi and associates (1995) studied long-term complications in 1358 European women with type 1 diabetes, of whom 582 had been pregnant. The incidence of either micro- or microalbuminuria was not increased in women with prior pregnancies compared with that of nulliparas. Still, renal involvement carries a guarded long-term prognosis for these women. Miodovnik and colleagues (1996) found that a fourth of 46 women with class F diabetes developed end-stage renal failure at a mean of 6 years after pregnancy. This is not dissimilar from women with other severe nephropathies (see [Chapter 48](#), p. 1104).

Diabetic Retinopathy. Retinal vasculopathy is a highly specific complication of both type 1 and type 2 diabetes. Its prevalence is related to duration of diabetes. After 20 years, nearly all patients with type 1 diabetes and more than 60 percent of those with type 2 diabetes have some degree of retinopathy (American Diabetes Association, 1999b). In the United States, diabetic retinopathy is the most important cause of visual impairment in persons younger than 60 years of age. Frank (2004) has recently reviewed this complication of diabetes.

The first and most common visible lesions are small microaneurysms followed by blot hemorrhages when erythrocytes escape from the aneurysms. These areas leak serous fluid that forms hard exudates. These features are termed *benign* or *background* or *nonproliferative retinopathy* and would place a pregnant woman in class D regardless of the duration of diabetes (see [Table](#)

[52-2](#)). With increasingly severe retinopathy, the abnormal vessels of background eye disease become occluded, leading to retinal ischemia with infarctions that appear as *cotton wool exudates*. These are considered *preproliferative retinopathy*. In response to ischemia, there is neovascularization on the retinal surface and out into the vitreous cavity, and these obscure vision when there is hemorrhage. Laser photocoagulation as shown in [Figure 52-4](#) before hemorrhage reduces the rate of progression of visual loss and blindness by half. The procedure is done as indicated during pregnancy for affected women. Siddiqi and colleagues (1991) reported that almost a third of 175 insulin-dependent pregnant women examined by 10 weeks had background retinal changes (class D) or proliferative retinopathy (class R).

The effects of pregnancy on proliferative retinopathy are controversial (Garner, 1995b). It has been long taught that this complication is a rare example of pregnancy having long-term adverse effects. Klein and co-workers (1990) concluded that pregnancy worsened proliferative retinopathy. Conversely, Chaturvedi and co-authors (1995) found an equivalent prevalence of background and proliferative retinopathy in multiparas and nulliparous women. Most authors agree that laser photocoagulation and good glycemic control during pregnancy minimize the potential for deleterious effects of pregnancy (Garner, 1995b).

Ironically, there are case reports that link "acute" rigorous metabolic control during pregnancy to acute worsening of retinopathy (Dahl-Jorgensen and colleagues, 1985; Van Ballegoie and associates, 1984). In a study of 201 women with retinopathy, McElvy and colleagues (2001) found that almost 30 percent suffered progression of eye disease during pregnancy despite intensive glucose control. That said, Wang and co-workers (1993) have observed that retinopathy worsened during the critical months of rigorous glucose control, but in the longer term, deterioration of eye disease slowed. In the report by McElvy and co-workers (2001), progression of retinopathy was associated with reduced fetal growth. Lauszus and colleagues (1998), however, reported that proliferative retinopathy, per se, did not worsen perinatal outcome.

In a preliminary report, Kitzmiller and colleagues (1999) implicated insulin lispro in the development of proliferative retinopathy during pregnancy. Conversely, Buchbinder and associates (2000) found no evidence that such therapy was linked to the development or progression of diabetic retinopathy in a study of 13 treated pregnant women.

Diabetic Neuropathy. Although uncommon, some pregnant women have peripheral symmetrical sensorimotor diabetic neuropathy. A form of this, known as *diabetic gastropathy*, is very troublesome in pregnancy because it causes nausea and vomiting, nutritional problems, and difficulty with glucose control. Treatment with metoclopramide and H₂-receptor antagonists is sometimes successful. *Hyperemesis gravidarum* is further discussed in [Chapter 49](#) (see p. 1113).

Preeclampsia. Hypertension induced or exacerbated by pregnancy is the major complication that most often forces preterm delivery in diabetic women. According to Garner (1995b), the perinatal mortality rate is increased 20-fold for preeclamptic women with diabetes compared with those who remain normotensive. Special risk factors for preeclampsia include any vascular complications and preexisting proteinuria, with or without chronic hypertension. Sibai and colleagues (2000) reported the risk of preeclampsia to be 11 percent in class B, 22 percent in class C, 21 percent in class D, and 36 percent in classes F-R. Savvidou and colleagues (2002) described impaired vascular reactivity in pregnant women with type 1 diabetes that may make them more susceptible to the development of preeclampsia. Interestingly, the incidence of preeclampsia does not seem to be related to glucose control (Garner and co-authors, 1990). Management of preeclampsia is discussed in [Chapter 34](#).

Ketoacidosis. Although ketoacidosis affects only about 1 percent of diabetic pregnancies, it remains one of the most serious complications (Garner, 1995b). Diabetic ketoacidosis may occur as a result of hyperemesis gravidarum, use of β -sympathomimetic drugs for tocolysis, infections, and use of corticosteroids to induce fetal lung maturation. The incidence of fetal loss is about 20 percent with ketoacidosis.

Kent and colleagues (1994) found that only half of young women with recurrent ketoacidosis had successful pregnancies compared with 95 percent of women without ketoacidosis. Noncompliance is a prominent factor, and ketoacidosis and poor compliance have long been considered prognostically bad signs in pregnancy (Pedersen and colleagues, 1974).

Infections. Almost all types of infections are increased in diabetic pregnancies. Stamler and co-authors (1990) reported that almost 80 percent of women with type 1 diabetes develop at least one episode of infection during pregnancy compared with 25 percent in those without diabetes. Common infections include candida vulvovaginitis, urinary infections, respiratory tract infections, and puerperal pelvic infections. Cousins (1987) observed that antepartum pyelonephritis developed in 4 percent of women with type 1 diabetes compared with 1 percent in those without diabetes. Cousins also reported that renal infection was associated with increased preterm delivery. Fortunately, these latter infections can be minimized by screening for asymptomatic bacteriuria (see [Chap. 48](#), p. 1095).

Figure 52-4. Retinal photographs from a 30-year-old diabetic woman. **A.** Optic nerve head showing severe proliferative retinopathy characterized by extensive networks of new vessels surrounding the optic disc. **B.** A portion of the acute photocoagulation full "scatter" pattern following argon laser treatment. (From Elman and colleagues, 1990, with permission.)

MANAGEMENT. The goals of management are tailored somewhat uniquely for pregnant women. Management preferably should begin before pregnancy and include specific goals during each trimester.

Preconception. To prevent early pregnancy loss as well as congenital malformations in infants of diabetic mothers, optimal medical care and patient education are recommended before conception. This is also discussed in [Chapter 7](#). Unfortunately, unplanned pregnancies, thus preempting preconceptional care, continue to occur in approximately 60 percent of these women (Holing and co-authors, 1998). Thus, diabetic women frequently begin pregnancy with suboptimal glucose control (Casele and Laifer, 1998).

The American Diabetes Association (1999a) has defined optimal preconceptional glucose control using insulin to include self-monitored preprandial glucose levels of 70 to 100 mg/dL and postprandial values of less than 140 mg/dL and less than 120 mg/dL at 1 and 2 hours, respectively. Hemoglobin A_{1c} or A_{1c} measurement, which expresses an average of circulating glucose for the past 4 to 8 weeks, is useful to assess early metabolic control. Optimal preconceptional glycated hemoglobin values have been defined as those within or near the upper limit of normal for a specific laboratory or within three standard deviations of the normal mean (American Diabetes Association, 1999a). The most significant risk for malformations is with levels exceeding 10 percent (American College of Obstetricians and Gynecologists, 1994). Folate, 400 µg/day, is given preconceptionally and during early pregnancy to decrease the risk of neural-tube defects (Milunsky and co-workers, 1989).

First Trimester. Careful monitoring of glucose control is essential. For this reason, many clinicians hospitalize these women during early pregnancy to institute an individualized glucose control program and to provide education concerning the ensuing months of pregnancy. It also provides an opportunity to assess the extent of vascular complications of diabetes and to precisely establish gestational age.

Maternal glycemic control can usually be achieved with *multiple daily insulin injections* and adjustment of dietary intake. Oral hypoglycemic agents are not usually used because they may cause fetal hyperinsulinemia. Piacquadio and colleagues (1991) demonstrated increased rates of congenital malformations, especially ear defects, in infants of women treated during early pregnancy with oral hypoglycemic drugs (see p. 1175).

Subcutaneous insulin infusion by a calibrated pump may be used during pregnancy. It has both advantages and disadvantages, and as emphasized by Kitzmiller and associates (1985) and Leveno and colleagues (1988), any salutary pregnancy effects have yet to be determined. Patients who use an insulin pump must be highly motivated and compliant so as to minimize the risk of nocturnal hypoglycemia (Gabbe and Graves, 2003).

The goals of self-monitored capillary blood glucose control recommended during pregnancy are shown in [Table 52-9](#). Self-monitoring of capillary glucose levels using glucometers is strongly recommended as this involves the woman in her own care. Parretti and colleagues (2001) measured maternal capillary glucose responses to meals throughout normal pregnancies to better characterize glucose goals for management of diabetic women ([Table 52-10](#)).

New technology under development may provide noninvasive glucose monitoring. Such an automatic and painless means to obtain blood glucose information would undoubtedly greatly facilitate patient compliance. Tamada and colleagues (1999) reported clinical results in nonpregnant diabetics with such a monitoring device (Cygnus, Inc., Redwood City, California). It extracts glucose through the skin using electrical potentials— a process known as iontophoresis. It then measures glucose concentrations in the extracted sample. The device provides up to three glucose readings per hour and causes only transient mild skin irritation at the sensor site. These investigators found close agreement between noninvasive glucose measurements and those obtained by standard fingersticks.

The Committee on Maternal Nutrition of the National Research Council has recommended a total caloric intake of 30 to 35 kcal/kg of ideal body weight, given as three meals and three snacks daily (Garner, 1995b). An ideal dietary composition is 55 percent carbohydrate, 20 percent protein, and 25 percent fat with less than 10 percent saturated fat. There are no studies to support or refute these guidelines. Obese women may be managed with lower caloric intake as long as weight loss and ketonuria are avoided.

Euglycemia based on normal pregnancy blood glucose values is the goal in management of women with overt diabetes, but achieving this goal is not always possible. Thus, individualized programs are often necessary to avoid both excessive hyperglycemia as well as frequent episodes of hypoglycemia. Diabetes tends to be unstable in the first trimester, followed by a stable period, and then by an increase in insulin requirement after about 24 weeks (Steel and co-workers, 1994). This rise is due to the increased production of pregnancy hormones, which are insulin antagonists (see [Chap. 3](#), p. 74 and [Chap. 5](#), p. 127). The absolute increase in mean insulin requirement was 52 units in 237 women with type 1 diabetes, but there was wide variation (Steel and associates, 1994). The magnitude of increase was directly related to maternal weight and inversely related to the duration of diabetes.

Rosenn and colleagues (1995) assessed the impact of maternal hypoglycemia in 84 pregnant women with overt diabetes. Clinically significant hypoglycemia with glucometer values less than 35 mg/dL was documented in 70 percent of the women, with a peak incidence between 10 and 15 weeks. Almost 25 percent of these 84 women experienced unconsciousness, and 15 percent developed seizures as a result of hypoglycemia. These investigators recommended caution in attempting euglycemia in women with recurrent episodes of hypoglycemia.

We have reported that good pregnancy outcomes can be achieved in women with mean preprandial plasma glucose values up to 143 mg/dL (Leveno and associates, 1979). Interestingly, in women with diabetes who are not pregnant, the Diabetes Control and Complications Trial Research Group (1993) found that similar glucose values— intensive control was defined as mean values less than 155 mg/dL— delayed and slowed diabetic retinopathy, nephropathy, and neuropathy. Thus, women with overt diabetes who have glucose values considerably above those defined as normal both during and after pregnancy can expect good outcomes.

Second Trimester. Maternal serum alpha-fetoprotein concentration at 16 to 20 weeks is used in association with targeted ultrasound at 18 to 20 weeks in an attempt to detect neural-tube defects and other anomalies (American College of Obstetricians and Gynecologists, 1994). The program and its details are discussed in [Chapter 12](#) (see p. 319). Maternal alpha-fetoprotein levels may be lower in diabetic pregnancies, and interpretation is altered accordingly (Martin and associates, 1990). Adjunctive ultrasonography is important; Albert and colleagues (1996) identified 72 percent of 29 fetal anomalies in 289 diabetic pregnancies.

Third Trimester and Delivery. In the woman with overt diabetes in the class B or C White classification, cesarean delivery has commonly been used to avoid traumatic birth of a large infant at or near term. In women with more advanced diabetes, especially those with vascular disease, the reduced likelihood of successfully inducing labor remote from term has also contributed appreciably to an increased cesarean rate. Labor induction may be attempted when the fetus is not excessively large and the cervix is considered favorable (see [Chap. 22](#), p. 536). In the reports cited earlier with low perinatal mortality, the cesarean rate ranged from 50 to 80 percent (Gabbe, 1977; Kitzmiller, 1978; Leveno, 1979; Martin, 1987; Schneider, 1980,

and all their associates). The cesarean delivery rate for women with overt diabetes has remained at about 80 percent for the past 25 years at Parkland Hospital.

It is important to considerably reduce or delete the dose of long-acting insulin given on the day of delivery. Regular insulin should be used to meet most or all of the insulin needs of the mother at this time, because insulin requirements typically drop markedly after delivery. We have found that constant insulin infusion by calibrated pump is most satisfactory ([Table 52-11](#)). During labor and after either cesarean or vaginal delivery, the woman should be hydrated adequately intravenously as well as given glucose in sufficient amounts to maintain normoglycemia. Capillary or plasma glucose levels should be checked frequently, and regular insulin should be administered accordingly. It is not unusual for the woman to require virtually no insulin for the first 24 hours or so and then for insulin requirements to fluctuate markedly during the next few days. Infection must be promptly detected and treated.

CONTRACEPTION

There is no single contraceptive method appropriate for all women with diabetes. Because of the risk of vascular disease, hormonal contraceptives may be problematic. Many clinicians are reluctant to recommend intrauterine devices in women with diabetes, primarily because of a possible increased risk of pelvic infections. All of these concerns, along with available options, are discussed in [Chapter 32](#). For many of these reasons, and because of frequent associated morbidity with chronic diseases, many overtly diabetic women elect puerperal sterilization as discussed in [Chapter 33](#). This option should be made readily available.

53. Thyroid and Other Endocrine Disorders

INTRODUCTION

A variety of endocrine disorders can complicate pregnancy and vice versa. Diabetes mellitus is the most common and is discussed in [Chapter 52](#). Thyroid disorders are also common in young women, and thus they are frequently encountered during pregnancy. In addition, there are a number of less common endocrinopathies that may have devastating effects on pregnancy outcome (e.g., pheochromocytoma).

The pathogenic basis of most endocrinopathies is disordered autoimmunity. A number of autoantigens, autoantibodies, and cellular immune elements have been identified to cause destruction or stimulation of thyroid, pancreatic, or adrenal glandular tissue (Baker, 1997). In many cases, a nonspecific event (e.g., viral infection) initiates an antigen and organ-specific response with subsequent immune-mediated glandular destruction. Frequently, a genetic predisposition may also be involved, such as inheritance of major histocompatibility complex antigens. Certain environmental factors may predispose to development of some autoimmune endocrinopathies. Finally, intriguing evidence has accrued that fetal lymphocytes, stem cells, DNA, or both may take up residence in maternal organs during pregnancy and form the basis for some autoimmune diseases.

Thyroid Physiology. The impact of pregnancy on maternal thyroid physiology is substantial. Changes in the structure and function of the gland sometimes cause confusion in the diagnosis of thyroid abnormalities. These are discussed in detail in [Chapter 5](#) (see p. 141) and are discussed below.

Moderate thyroid enlargement occurs due to glandular hyperplasia, and thyroid volume determined ultrasonographically increases, although its echostructure and echogenicity remain unchanged (Rasmussen and colleagues, 1989). Iodide uptake by the maternal gland is increased, and daily thyroxine secretion is probably increased. In early pregnancy at least, thyroxine is transferred from mother to fetus, and with fetal hypothyroidism, transfer continues throughout pregnancy (Calvo and associates, 2002; Vulsma and colleagues, 1989). Thyroid hormone is necessary for normal development of the brain and mental function (Forrest, 2004). Maternal serum concentration of *thyroid-binding globulin* is increased considerably along with total or bound hormone levels.

Thyrotropin, or *thyroid-stimulating hormone (TSH)*, currently plays a central role in screening and diagnosis of many thyroid disorders. In early pregnancy, thyrotropin activity decreases because of thyroid stimulation from the weak crossover activity of chorionic gonadotropin (Grossman and associates, 1997). The hormone does not cross the placenta. In the first 12 weeks when chorionic gonadotropin levels are maximal, free thyroxine levels increase, and these suppress thyrotropin levels ([Fig. 53-1](#)). Accordingly, *thyrotropin-releasing hormone (TRH)* is undetectable in maternal serum. Beginning at midpregnancy, fetal serum TRH is detectable but does not increase, and there is only minimal placental transfer (Bajoria and co-workers, 1998).

Figure 53-1. Maternal serum thyrotropin levels across pregnancy in 13,851 women. (From Dashe and colleagues, 2003, with permission.)

THYROID DISEASES

Taken in aggregate, thyroid disorders are common in young women. The incidence of hyperthyroidism, hypothyroidism, and thyroiditis is each approximately 1 percent. There is an intimate relationship between maternal and fetal thyroid function. The fetus is dependent on maternal thyroxine, and drugs that affect the maternal thyroid also affect the fetal gland. Clinical thyrotoxicosis may be stimulated by gestational trophoblastic disease. Thyroid autoantibodies have been associated with increased early pregnancy wastage, and uncontrolled thyrotoxicosis and untreated hypothyroidism are both associated with adverse pregnancy outcomes. Finally, there is evidence that the severity of autoimmune thyroid disorders is ameliorated during pregnancy, only to be exacerbated postpartum.

AUTOIMMUNE THYROID DISEASE. Most thyroid disorders are inextricably linked to the presence of autoantibodies to various cell components. Several antibodies variably stimulate thyroid function, block function, or cause thyroid inflammation that may lead to destruction. These not uncommonly coexist.

Thyroid-stimulating autoantibodies, also called *thyroid-stimulating immunoglobulins*, attach to the thyrotropin receptor and activate it, causing thyroid hyperfunction and growth. These antibodies are identified in the majority of patients with classic Graves disease. Simultaneous production of *thyroid-stimulating blocking antibodies* may blunt this effect (Weetman, 2000).

Thyroid peroxidase antibodies, previously called thyroid *microsomal autoantibodies*, have been identified in 10 to 20 percent of pregnant women (Jansson and associates, 1988; Kuijpers and co-workers, 2001). Up to half develop *autoimmune thyroiditis* that may be transient, but thyroid failure occurs in a significant number of women (Amino and colleagues, 2000). These antibodies are also associated with miscarriage and Down syndrome (Abramson and Stagnaro-Green, 2001; Cuckle and colleagues, 1988). As with other autoimmune endocrinopathies, there usually is a precipitating event such as a viral illness that interacts with genetic and other factors. For example, Pacini and associates (1998) found serum thyroid antibodies in 30 percent of preadolescent girls exposed to radioactive fallout from the Chernobyl disaster, compared with 3 percent of nonexposed controls. Some investigators regard pregnancy as an inciting event (Amino and colleagues, 2000).

As shown in [Figure 53-2](#), all of these antibodies have a characteristic pattern during pregnancy and the first year postpartum. In many cases, these patterns parallel clinical disease activity. Detection of peroxidase antibodies in early pregnancy or postpartum identifies women at high risk for postpartum thyroid dysfunction and at lifelong risk for permanent thyroid failure (Hidaka and associates, 1994; Premawardhana and co-workers, 2000).

Autoimmune thyroid disease is much more common in women than in men. One intriguing explanation for this disparity is fetal-to-maternal cell trafficking. When fetal lymphocytes enter the maternal circulation, they may live for more than 20 years. Stem cell interchange likely occurs also, and these can reside in a number of maternal tissues, including the thyroid gland (Bianchi and Romero, 2003; Khosrotehrani and associates, 2004). Maternal *microchimerism* with male fetuses has been demonstrated using the *SRY* sex-determining gene for foreign cell identification. About a third of women who have borne a male fetus have *SRY*-positive lymphocytes in their peripheral blood. Specimens from women with thyroiditis or Graves disease have *SRY*-positive thyrocyte microchimerism with greater frequency and intensity than controls (Ando and associates, 2002; Klintschar and colleagues, 2001). These are presumed to have arisen from stem cells transferred from the male fetus.

Figure 53-2. Schematic change across pregnancy and up to 1-year postpartum of serum levels of free thyroxine and various antithyroid antibodies. Arbitrary units are used to depict reciprocal relationships. From early pregnancy until delivery, levels of thyroid-stimulating antibodies (○—○) and thyroid peroxidase antibodies (⊙—⊙) decrease. At the same time, levels of serum free thyroxine (X—X) also decrease. Postpartum, the trend is reversed. (Data from Amino and associates, 2003; Fung and colleagues, 1988; Kung and Jones, 1998.)

HYPERTHYROIDISM. Symptomatic thyrotoxicosis, or hyperthyroidism, complicates about 1 in 1000 to 2000 pregnancies (Mestman and colleagues, 1995). The incidence cited by Casey and associates (2003) was 3.9 per 1000, including women identified before pregnancy (Table 53-1). Because normal pregnancy simulates some clinical findings similar to thyroxine (T_4) excess, mild thyrotoxicosis may be difficult to diagnose. Some suggestive findings include tachycardia that exceeds that with normal pregnancy, elevated sleeping pulse rate, thyromegaly, exophthalmos, and failure to gain weight despite adequate food intake. Laboratory confirmation is an elevated serum free T_4 level along with a markedly depressed thyrotropin level. The thyrotropin assay is sensitive to less than 0.1 mU/L, and this has led to discovery of *subclinical* hyperthyroidism, which Casey and co-workers (2003) identified in 1.5 percent of pregnant women. Rarely, hyperthyroidism is caused by abnormally high serum triiodothyronine (T_3) levels—so-called T_3 -toxicosis.

SUBCLINICAL HYPERTHYROIDISM. This relatively new clinical entity was defined when sensitive thyrotropin assays became available. It is encountered in about 1 percent of patients and is characterized by an abnormally low serum thyrotropin concentration in concert with normal thyroid hormone levels (Roberts and Ladenson, 2004). When not due to exogenous thyroxine intake, about half of these eventually developed normal thyrotropin concentrations. Long-term effects in those with persistent subclinical thyrotoxicosis are for the most part currently unclear. Because the condition may cause cardiac arrhythmias, ventricular hypertrophy, and osteopenia, affected patients should be periodically monitored.

Thyrotoxicosis and Pregnancy. The overwhelming cause of thyrotoxicosis in pregnancy is *Graves disease*, an organ-specific autoimmune process usually associated with thyroid-stimulating antibodies as discussed previously. As shown in Figure 53-2, thyroid-stimulating antibody activity declines during pregnancy, leading to chemical remission in many women (Amino and co-workers, 1982; Kung and Jones, 1998). Amino and colleagues (2003) have found that blocking antibodies are also decreased during pregnancy.

TREATMENT. Thyrotoxicosis during pregnancy can nearly always be controlled by thioamide drugs. Some clinicians prefer *propylthiouracil* because it partially inhibits the conversion of T_4 to T_3 and it crosses the placenta less readily than *methimazole*. Although not definitely proven, methimazole use in early pregnancy has been associated with otherwise rarely encountered *esophageal* and *choanal atresia* as well as *aplasia cutis* (Diav-Citrin and Ornoy, 2002). Wing and co-workers (1994) studied 185 pregnant thyrotoxic women and showed that both drugs are effective and safe. Transient leukopenia manifests in about 10 percent, but this does not require cessation of therapy. In about 0.2 percent, *agranulocytosis* develops suddenly and mandates discontinuance of the drug. It is not dose related, and because of its acute onset, serial leukocyte counts during therapy are not helpful (Cooper, 2003; Mestman and colleagues, 1995). If fever or sore throat develop, patients are instructed to discontinue medication immediately and to report for a complete blood count (Vanderpump and associates, 1996). About 20 percent of all patients treated with propylthiouracil develop *antineutrophil cytoplasmic antibodies*, but only a small percentage of these develop serious vasculitis (Helfgott, 2002). Finally, although thioamides have the potential to cause fetal complications, these are uncommon. In some cases, thioamides may even be therapeutic, because thyrotropin-blocking antibodies also cross the placenta and stimulate the fetal thyroid gland to cause thyrotoxicosis.

The dose of propylthiouracil is empirical, and for nonpregnant patients, the American Thyroid Association recommends an initial daily dose of 100 to 600 mg for propylthiouracil or 10 to 40 mg for methimazole (Singer and colleagues, 1995). In a study of 509 nonpregnant thyrotoxic patients, Reinwein and associates (1993) randomized therapy with either 10 or 40 mg of methimazole. At 6 weeks, 85 and 92 percent respectively, were euthyroid. In pregnant women given either thioamide, Wing and colleagues (1994) reported the median time to normalization of thyroid function tests to be 7 to 8 weeks.

In our experience, overt thyrotoxicosis in pregnant women requires higher doses (Davis and colleagues, 1989). With a propylthiouracil dose that averaged 600 mg daily, only half of women had a remission, and in these the dose was decreased to less than 300 mg daily within 8 weeks. In a third, however, it was necessary to increase the dose. Kriplani and colleagues (1994) reported similar findings.

Other therapy includes *thyroidectomy* after thyrotoxicosis is medically controlled. However, this seldom is done during pregnancy. It may be appropriate for the very few women who cannot adhere to medical treatment or in whom drug therapy proves toxic (Davison and co-workers, 2001).

Ablation with therapeutic radioactive iodine is contraindicated. Therapeutic doses given to treat maternal thyroid disease may also cause fetal thyroid gland destruction. If given unintentionally, most clinicians recommend abortion. Any exposed infant must be carefully evaluated for hypothyroidism (Berg and colleagues, 1998). The incidence of fetal

hypothyroidism depends on gestational age and dose of radioiodine given (Berlin, 2001). There is no evidence that therapeutic radioiodine given before pregnancy causes fetal anomalies if enough time has passed to allow radiation effects to dissipate and the woman is euthyroid (Ayala and associates, 1998; Casara and colleagues, 1993).

Thyroid Storm and Heart Failure. Thyroid storm is an acute, life-threatening, hypermetabolic state in patients with thyrotoxicosis. Storm is rare in pregnancy. In contrast, heart failure from cardiomyopathy caused by the profound myocardial effects of thyroxine is quite common in pregnant women (Sheffield and Cunningham, 2004). As shown in [Table 53-2](#), heart failure developed in 8 percent of 90 women with uncontrolled thyrotoxicosis. In these women, cardiomyopathy is characterized by a high-output state (Klein and Kaia, 1998). Similar changes during normal pregnancy are additive or synergistic. Thus, the pregnant woman with thyrotoxicosis has minimal cardiac reserve, and decompensation is usually precipitated by preeclampsia, anemia, sepsis, or a combination of these. Fortunately, thyroxine-induced cardiomyopathy is ultimately reversible (Sheffield and Cunningham, 2004).

MANAGEMENT. Treatment of thyrotoxic storm or heart failure is similar and should be carried out in an intensive care unit (Zeeman and colleagues, 2003). Specific treatment consists of 1 g of propylthiouracil given orally or crushed and placed through a nasogastric tube. This drug is continued in 200-mg doses every 6 hours. An hour after initial propylthiouracil dosing, iodide is given to inhibit thyroidal release of T_3 and T_4 . It is given intravenously as 500 to 1000 mg of sodium iodide every 8 hours; orally as 5 drops of supersaturated solution of potassium iodide (SSKI) every 8 hours; or as Lugol solution, 10 drops orally every 8 hours. With a history of iodine-induced anaphylaxis, lithium carbonate, 300 mg every 6 hours, is given instead (Burch and Wartofsky, 1993). Some investigators recommend maintenance of serum lithium levels of 0.5 to 1.5 mmol/L. Most authorities recommend dexamethasone, 2 mg intravenously every 6 hours for four doses, to further block peripheral conversion of T_4 to T_3 . If a β -blocker drug is given to control tachycardia, its effect on heart failure must be considered. Propranolol, labetalol, and esmolol have all been used successfully intrapartum (Bowman and colleagues, 1998). Concurrent, severe preeclampsia, infection, or anemia should be aggressively managed.

Pregnancy Outcome. Perinatal outcomes in neonates of women with thyrotoxicosis depend on whether metabolic control is achieved. Excess thyroxine may cause spontaneous miscarriage (Anselmo and associates, 2004). In untreated women, or in those who remain hyperthyroid despite therapy, there is a higher incidence of preeclampsia, heart failure, and adverse perinatal outcomes (see [Table 53-2](#)). Perinatal mortality varied from 6 to 12 percent in several studies.

FETAL AND NEONATAL EFFECTS. In most cases, the perinate is euthyroid. In some cases, however, hyper- or hypothyroidism may occur. Either condition can develop with or without a goiter. If fetal thyroid disease is suspected, nomograms are available for sonographic measurement of the thyroid (Ranzini and co-workers, 2001). Newborns exposed to excessive maternal thyroxine may have any of several clinical presentations.

1. The fetus or newborn may manifest goitrous thyrotoxicosis caused by placental transfer of thyroid-stimulating immunoglobulins. This is related to maternal serum antibody levels and may be predicted in the fetus whose thyromegaly does not respond to maternal thioamide treatment (Cohen and colleagues, 2003; Peleg and associates, 2002). *Nonimmune hydrops* and fetal demise have been reported with fetal thyrotoxicosis (Nachum and co-workers, 2003; Stulberg and Davies, 2000). If thyrotoxic, the fetus is treated with maternal administration of thioamide drugs (Duncombe and Dickerson, 2001). If hypothyroid, it is treated with injection of intra-amniotic thyroxine. In some cases, neonatal thyrotoxicosis may require short-course antithyroid drug treatment.
2. Fetal exposure to maternally administered thioamides may cause goitrous hypothyroidism ([Fig. 53-3](#)). In some cases, a fetal goiter is detected ultrasonographically, and cord blood sampling can be used to diagnose hypothyroidism, which can be treated with intra-amniotic thyroxine (Davidson and colleagues, 1991). Amniotic fluid total and free T_4 levels have also been studied (Singh and co-workers, 2003). Reports of adverse fetal effects have been exaggerated, and current data indicate that thioamides carry an extremely small risk (Momotani and associates, 1997; O'Doherty and colleagues, 1999). Of the 239 treated thyrotoxic women shown in [Table 53-1](#), there was evidence of hypothyroidism in only four infants despite relatively high doses of propylthiouracil. At least four long-term studies have found no abnormal intellectual and physical development of these children (Mestman, 1998).
3. The fetus may develop nongoitrous hypothyroidism from transplacental passage of maternal thyrotropin-receptor blocking antibodies (Gallagher and associates, 2001).
4. Even after maternal thyroid gland ablation, usually with ^{131}I radioiodine, fetal thyrotoxicosis may result from transplacental thyroid-stimulating antibodies.

FETAL DIAGNOSIS. Fetal evaluation is somewhat controversial. For example, Nachum and colleagues (2003) recommend fetal blood sampling if maternal thyroid-stimulating antibodies are abnormal, or if there is evidence in the fetus of growth restriction, heart failure, or goiter, with or without tachycardia. Antibody testing is not standard, and Kilpatrick (2003) recommends its use only if the mother has previously undergone ^{131}I ablation. Because fetal hyper- or hypothyroidism may cause hydrops, growth restriction, goiter, or tachycardia, fetal blood sampling seems appropriate if these conditions develop in pregnancy complicated by Graves disease (Brand and co-workers, 2005).

Hyperemesis Gravidarum. Many women with hyperemesis gravidarum have abnormally high serum thyroxine levels and low thyrotropin levels (see [Chap. 49](#), p. 1113). This results from thyrotropin receptor stimulation from massive β —but normal for pregnancy β —concentrations of chorionic gonadotropin. Rarely do these women have clinical thyrotoxicosis, and thyroxine and serum thyrotropin values become more normal by midpregnancy (see [Fig. 53-1](#)). This condition is also termed *gestational thyrotoxicosis*. Even if it is associated with hyperemesis, treatment is not warranted (American College of Obstetricians and Gynecologists, 2002).

Gestational Trophoblastic Disease. Thyroxine levels in women with molar pregnancy usually are appreciably elevated. Because these tumors are usually now diagnosed early, clinically apparent hyperthyroidism has become less common (Goodwin and Hershman, 1997). This is discussed further in [Chapter 11](#) (see p. 277).

Figure 53-3. Term neonate delivered of a woman with a 3-year history of thyrotoxicosis that recurred at 26 weeks' gestation. The mother was given methimazole, 30 mg daily and was euthyroid at delivery. Laboratory studies showed that the infant was hypothyroid.

HYPOTHYROIDISM. Most adult hypothyroidism results from glandular destruction by autoantibodies, particularly antithyroid peroxidase antibodies. Hypothyroid disorders are thus related to Graves thyrotoxicosis. As discussed on page 1191, both disorders are possibly related to bidirectional fetal cell transfer during a prior pregnancy.

In most patients, hypothyroidism is difficult to diagnose clinically. The distinction of overt from subclinical hypothyroidism frequently is made by laboratory assessment. *Clinical or overt hypothyroidism* is diagnosed when an abnormally high serum thyrotropin level is accompanied by an abnormally low thyroxine level. *Subclinical hypothyroidism* is defined by an elevated serum thyrotropin level with *normal* serum thyroxine (Surks and associates, 2004). *Severe* hypothyroidism with pregnancy is uncommon, probably because it is often associated with infertility and increased miscarriage rates (Abalovich and colleagues, 2002).

Incidence in Pregnancy. In the study by Casey and colleagues (2003), the overall incidence of hypothyroidism was 2.5 percent (see [Table 53-1](#)). Overt thyroid deficiency was found in 1.3 per 1000 and subclinical disease in 23 per 1000.

SUBCLINICAL HYPOTHYROIDISM. The incidence of subclinical hypothyroidism in all women between 18 and 45 years of age is about 5 percent (Canaris and colleagues, 2000). Of these, 2 to 5 percent per year progress to overt thyroid failure. Heredity is a potent risk factor. Other risk factors for thyroid failure include type 1 diabetes and antimicrobial antibodies. At this time, evidence that subclinical hypothyroidism is associated with hypertension, cardiac dysfunction, and dyslipidemia is not conclusive enough to warrant thyroxine replacement (Surks and associates, 2004). These authors went on to say that if the serum thyrotropin levels exceed 10 mU/L, some physicians choose to give thyroxine therapy but that there is no evidence of its beneficial effects. Possible effects of subclinical hypothyroidism on pregnancy outcome are subsequently discussed.

Pregnancy Outcome with Overt Hypothyroidism. A few studies, although limited, indicate that *overt hypothyroidism* is associated with excessive adverse perinatal outcomes ([Table 53-3](#)). If thyroid deficiency is reversed before pregnancy, there usually are normal perinatal outcomes (Matalon and associates, 2003; Wolfberg and collaborators, 2003). Replacement therapy is with thyroxine, 50 to 100 μg daily. Serum thyrotropin levels are measured at 4- to 6-week intervals and thyroxine adjusted by 25- to 50- μg increments until they reach normal values.

Pregnancy is associated with an increase in thyroxine requirements of about a third (Alexander and associates, 2004; Mandel and colleagues, 1990). In a study of 259 mothers with hypothyroidism given thyroxine replacement throughout pregnancy, Blazer and associates (2003) reported slightly higher thyrotropin levels in their newborns compared with those of normal control women. This suggests that the nonpregnant thyroxine replacement dose was insufficient for pregnancy. Because a similar increased requirement is seen in postmenopausal women with hypothyroidism who are given estrogen replacement, this increased demand in pregnancy may be caused by increased estrogen production (Arafah, 2001).

There is no doubt that maternal and fetal thyroid abnormalities are related. In both, thyroid function is dependent on adequate iodide ingestion, and deficiency early in pregnancy can cause maternal hypothyroidism. In addition, maternal antithyroid antibodies that cause thyroiditis may result in hypothyroidism in both mother and infant. Dussault and Fisher (1999) studied mothers of 259 hypothyroid newborns detected by the Quebec screening program and found a 20-percent incidence of thyroid dysfunction.

Subclinical Hypothyroidism and Pregnancy. Two studies published in 1999 suggested that maternal hypothyroidism may impair fetal neuropsychological development. In one study, Pop and associates (1999) studied a group of women beginning at 12 weeks' gestation. Children born to women with free T_4 levels below the 10th percentile were at increased risk for impaired psychomotor development. In the other study, Haddow and colleagues (1999) retrospectively evaluated children born to 48 untreated women whose serum thyrotropin values exceeded the 98th percentile. Some offspring of these women had diminished school performance, reading recognition, and IQ scores. Importantly, while described as "subclinically hypothyroid," these women had significantly lower mean serum free thyroxine levels, and thus had overt hypothyroidism. Subsequently, Casey and co-workers (2003) identified subclinical hypothyroidism in 2.3 percent of 17,298 women screened before midpregnancy. These women had significantly higher incidences of preterm birth, placental abruption, and admission of infants to the intensive care nursery ([Table 53-4](#)).

SCREENING IN PREGNANCY. Because of the 1999 studies indicating possible long-term neuropsychological effects in children born to women with asymptomatic hypothyroidism, some organizations recommended development of prenatal screening and treatment programs. Others emphasized the unknowns concerned with population screening (Davies, 2000). Specifically, the American College of Obstetricians and Gynecologists (2002) concluded that observational data from the Haddow study were consistent with the *possibility* that subclinical hypothyroidism was associated with adverse neuropsychological development. The College thus recommended against implementation of screening until further studies were done to validate or refute these findings. One major concern is that it seems unlikely that treatment given *after* the period of early cerebral development would be totally efficacious to prevent neurological damage (Utiger, 1999).

Because of all the uncertainties, at least two consensus conferences have been held to help elucidate these findings. One was arranged by the American Thyroid Association, the American Association of Clinical Endocrinologists, and the Endocrine Society (Surks and associates, 2004). The other was held in 2004 by the Centers for Disease Control and Prevention in conjunction with the American Thyroid Association. Both groups recommended against routine prenatal thyrotropin screening at this time. The American Thyroid Association (2004) has since recommended randomized placebo-controlled trials to determine any risks

or benefits of detecting and treating subclinical hypothyroidism in pregnancy. It is again emphasized that the 1999 Hadow study included pregnant women with *overt*, albeit mild, *hypothyroidism*.

Iodine Deficiency. In the United States over the past 25 years, iodide fortification of table salt and bread products has diminished, and iodide deficiency has been identified in some of the population (Hollowell and associates 1998; Malee and co-workers, 2004). Adequate iodide is requisite for normal fetal neurological development beginning soon after conception. The recommended daily intake during pregnancy is at least 220 $\mu\text{g}/\text{day}$ (American Thyroid Association, 2004).

The World Health Organization (WHO) estimated in 1990 that 20 million people worldwide have varying degrees of preventable brain damage due to fetal iodide deficiency (Hetzl, 1994). Neurodevelopmental abnormalities are dependent on the degree of deficiency. Although it is doubtful that *mild deficiency* causes intellectual impairment, supplementation prevents fetal goiter (Fadeyev and colleagues, 2003). Conversely, *severe deficiency* is associated with frequent and severe damage such as encountered with *endemic cretinism* (Delange, 2001). Although not quantified, it is presumed that *moderate deficiency* has intermediate and variable effects on intellectual and psychomotor function (Glinioer, 2001).

Iodide supplementation before pregnancy prevents neurological morbidity from severe deficiency and apparently does so partially even if given after pregnancy is established. Cao and co-workers (1994) studied pregnancies in a severely iodine-deficient region of China. Women given supplementation before 28 weeks had infants with a 2-percent incidence of moderate or severe neurological abnormalities. The incidence was 9 percent in women who did not receive supplements until the last trimester. The WHO has ongoing programs of universal salt iodization in areas of endemic iodine deficiency (Delange, 2001). Addition of supplemental iodine to prenatal vitamins has been proposed (Malee and associates, 2004).

Congenital Hypothyroidism. Because the clinical diagnosis of hypothyroidism in neonates is usually missed, newborn mass screening was introduced in 1974 and is now required by law. Congenital hypothyroidism is found in about 1 in 4000 to 7000 infants by these programs. For example, in the first 20 years of screening in Texas, 1 in 2500 of 6 million newborns had confirmed hypothyroidism (Drummond-Borg and colleagues, 2003).

About 75 percent of hypothyroid infants have thyroid agenesis or dysmorphogenesis, and another 10 percent have transient hypothyroidism (Lindsay and Toft, 1997). Early and aggressive thyroxine replacement is critical for these infants. Follow-up data from infants identified by screening programs who were treated promptly and adequately are encouraging. Except in those with severe congenital hypothyroidism, sequelae including intellectual impairment are typically preventable (Burrow and colleagues, 1994). Unfortunately, Grant and colleagues (1992) reported that 8 percent of 449 infants with congenital hypothyroidism also had other major associated anomalies.

PRETERM INFANTS. Transient hypothyroxinemia is common in preterm infants, and it had been assumed that treatment with thyroxine is not necessary. Van Wassenaer and colleagues (1997) randomized 157 infants born before 30 weeks to daily thyroxine or placebo. There were no differences in the groups when evaluated at 2 years with psychomotor and neurological testing. In another randomized trial, Briet and co-workers (2001) supplemented neonates and reported better mental outcomes at 2 years in those born before 29 weeks compared with those born after 29 weeks.

POSTPARTUM THYROIDITIS. Transient autoimmune thyroiditis has consistently been found in 5 to 10 percent of women during the first year after childbirth (Amino and colleagues, 2000; Dayan and Daniels, 1996). The propensity for thyroiditis antedates pregnancy and is directly related to increasing serum levels of thyroid autoantibodies. Women with high antibody titers in early pregnancy commonly are affected (Pearce and co-workers, 2003). Up to 25 percent of women with type 1 diabetes develop postpartum thyroid dysfunction (Alvarez-Marfany and associates, 1994). In some women with quiescent Graves disease, a recurrence of hyperthyroxinemia may be stimulated by thyroid destruction (Iitaka and co-workers, 2004).

In clinical practice, thyroiditis is diagnosed infrequently because it typically develops months after delivery and has vague and nonspecific symptoms. These include depression, carelessness, and memory impairment (Hayslip and colleagues, 1988). Looked at another way, Kuijpers and associates (2001) found that peroxidase antibodies were a high-risk marker for postpartum depression. Not all studies are consistent, and Lucas and co-workers (2001) found a 1.7-percent incidence of postpartum depression at 6 months in women with thyroiditis as well as in controls.

Pathogenesis. Most women with postpartum thyroiditis have a positive assay result for microsomal autoantibodies. Histologically, there is a destructive lymphocytic thyroiditis. Affected women usually have antibodies throughout pregnancy, but as shown in [Figure 53-2](#), their production is suppressed. Other risk factors are previous thyroid dysfunction or a family history of thyroid or other autoimmune disease. As discussed on page 1190, fetal cell microchimerism may be linked causally to thyroiditis (Ando and Davies, 2003).

Clinical Manifestations. The two recognized clinical phases of postpartum thyroiditis are summarized in [Table 53-5](#). Between 1 and 4 months after delivery, approximately 4 percent of all women develop transient *destruction-induced thyrotoxicosis* from excessive release of hormone from glandular disruption (Lucas and colleagues, 2000). The onset is abrupt, and a small, painless goiter is commonly found. Although there may be many symptoms, only fatigue and palpitations are more frequent in thyrotoxic women compared with that in controls. Antithyroid medications such as thioamides are ineffective. If symptoms are severe, a β -blocker may be given. Approximately two thirds of these women return to a euthyroid state, but the other third develop transient or permanent hypothyroidism.

Between 4 and 8 months postpartum, 2 to 5 percent of all women develop *hypothyroidism* from thyroiditis (Amino and associates, 2000; Jansson and co-workers, 1988). From thyroiditis onset, hypothyroidism can develop within one month. About a third will have gone through the thyrotoxic phase. Thyromegaly and other symptoms are common and more prominent than during the thyrotoxic phase. Thyroxine replacement is given for 6 to 12 months.

Women who experience either type of postpartum thyroiditis have about a 30-percent risk of developing permanent hypothyroidism (Muller and colleagues, 2001; Premawardhana and associates, 2000). Others may develop subclinical disease. Half of these women with thyroiditis who are positive for peroxidase antibodies develop permanent hypothyroidism by 6 to 7 years.

NODULAR THYROID DISEASE. Management of a palpable thyroid nodule during pregnancy depends on the stage of gestation. Small nodules detected by sensitive ultrasonic methods are common during pregnancy in some populations. Kung and associates (2002) used high-resolution sonography to study 221 Chinese women and found that 15 percent had nodules larger than 2 mm. Almost half of these were multiple. These small nodules usually enlarged modestly across pregnancy and did not regress postpartum. Nodules over 5 mm³ that persisted at 3 months postpartum were biopsied, and most showed nodular hyperplasia. None was malignant. In these same 221 women, eight (3.6 percent) had clinically palpable nodules larger than 1 cm. Although none of these was malignant, previous studies have reported that up to 40 percent of solitary nodules are malignant (Doherty and co-workers, 1995; Rosen and Walfish, 1986). Even so, the majority are low-grade neoplasms.

Most authorities recommend against radioiodine scanning in pregnancy, although tracer doses used are associated with minimal fetal irradiation (see [Chap. 41](#), p. 981). *Ultrasound* examination reliably detects nodules greater than 0.5 cm, and their solid or cystic nature also can be determined. *Fine-needle aspiration* is an excellent method for assessment, and tumor markers and immunostaining are reliable to evaluate for malignancy (Bartolazzi and associates, 2001; Hegedus, 2004). Mestman (1999) has recommended biopsy for nonfunctional solitary nodules, before midpregnancy for solid lesions over 2 cm and cystic lesions over 4 cm.

Because most thyroid carcinomas are well differentiated and pursue an indolent course, some practitioners recommend that surgery be postponed until after delivery. In either case, there should be a multidisciplinary approach (American College of Obstetricians and Gynecologists, 2002). Moosa and Mazzaferri (1997) studied 61 women with thyroid cancer diagnosed during pregnancy. In 75 percent, thyroidectomy was delayed until after delivery and outcomes were similar to those in nonpregnant controls. In their reviews, Driggers and co-workers (1998) and Morris (1998) found minimal fetal loss attributed to thyroid cancer surgery. We are of the view that thyroid surgery can be safely performed before 24 to 26 weeks (i.e., the time before surgery *might* stimulate preterm labor).

PARATHYROID DISEASES

The function of *parathyroid hormone (PTH)* is to maintain extracellular fluid calcium concentration. This 115-amino acid hormone acts directly on bone and kidney and indirectly on small intestine through its effects on synthesis of vitamin D (1,25-(OH)₂D) to increase serum calcium. Secretion is regulated by serum ionized calcium concentration through a negative feedback system. *Calcitonin* is a potent hypocalcemic parathyroid hormone that acts in many ways as a physiological parathyroid hormone antagonist. The interrelationships between these hormones and calcium metabolism, as well as *PTH-related protein* produced by fetal tissue, are discussed in [Chapter 5](#) (see p. 142).

Because of substantive fetal calcium needs 300 mg/day in late pregnancy and a total of 30 g as well as increased renal calcium loss from augmented glomerular filtration, PTH levels were assumed to be increased in pregnant women. With newer assay methods, however, Seely and co-workers (1997) as well as others have reported a significant decrease in intact 1-84 PTH level longitudinally during pregnancy. At the same time, they showed a twofold increase in serum concentrations of 1,25-dihydroxyvitamin D, which is probably of placental and decidual origin. Presumably this latter hormone increases gastrointestinal absorption to meet the needs of pregnancy. At the same time, total serum calcium levels decline to parallel the decreased serum albumin concentration (Power and associates, 1999). Importantly, however, ionized calcium levels are unchanged in pregnancy (Dahlman and colleagues, 1994). According to Molitch (2000), even if immunoreactive hormone levels are decreased, the biological activity on the kidney is normal.

HYPERPARATHYROIDISM. Hypercalcemia is caused by hyperparathyroidism or cancer in 90 percent of cases. Primary hyperparathyroidism from elevated levels of PTH is relatively common, and its incidence peaks between the third and fifth decades (Potts, 2001). Because many automated laboratory systems include measurement of serum calcium, more cases are being detected (Mestman, 2002). Almost 80 percent are caused by a solitary adenoma and another 15 percent by hyperfunction of all four glands. In most tumor-related cases, the malignancy and the cause of increased serum calcium are obvious. PTH produced by tumors is similar but not identical to the natural hormone, and therefore it is usually not detected by routine assays. In most patients, the serum calcium is elevated to within only 1 mg/dL over the upper normal limit. This may help to explain why only 20 percent of those who have abnormally elevated levels are symptomatic. In most of these patients, serum levels are stable over a 10-year period (Bilezikian and Silverberg, 2004). In a fourth, however, symptoms become apparent when the serum calcium continues to rise. *Hypercalcemic crisis* manifests as stupor, nausea, vomiting, weakness, fatigue, and dehydration.

Management of hyperparathyroidism in nonpregnant patients is controversial. Silverberg and colleagues (1999) compared surgical excision with observation in 121 patients with primary hyperparathyroidism. Half were cured by parathyroidectomy and their bone density improved. Of the half observed, about a fourth had progression of disease, and six of eight who had nephrolithiasis had a recurrence. The second National Institutes of Health Consensus Development Conference recently updated its recommendations, which include parathyroid surgery when the serum calcium exceeds 1.0 mg/dL of the upper normal range (Bilezikian and colleagues, 2002).

Hyperparathyroidism in Pregnancy. In a recent review, Schnatz (2002) found fewer than 200 reported cases. It is presumed that many hypercalcemic pregnant women with hyperparathyroidism are either not detected or not reported. As in nonpregnant patients, hyperparathyroidism is usually caused by a parathyroid adenoma. Cases have been described as due to ectopic parathyroid hormone production, or even more rarely to parathyroid carcinoma (Montoro and colleagues, 2000). Symptoms include hyperemesis, generalized weakness, renal calculi, and psychiatric disorders. Occasionally pancreatitis is the presenting finding (Dahan and Chang, 2001).

Pregnancy theoretically improves hyperparathyroidism because of significant calcium shunting to the fetus as well as augmented renal excretion (Power and colleagues, 1999). When the "protective effects" of pregnancy are withdrawn, however, there is significant danger of postpartum hypercalcemic crisis. Early reports described excessive stillbirths, preterm deliveries, and neonatal tetany in pregnancy complicated by hyperparathyroidism (Shangold and associates, 1982). Currently, with earlier

detection and management, adverse effects are much less common (Schnatz, 2002).

MANAGEMENT. If pregnant women are symptomatic, surgical removal of the parathyroid adenoma is preferable (Mestman, 2002). Elective neck exploration during pregnancy is usually well tolerated (Graham and associates, 1998; Kort and colleagues, 1999). In one woman, a mediastinal adenoma was removed at 23 weeks (Rooney and co-workers, 1998). If pregnant women are asymptomatic, they may be given oral phosphate, 1 to 1.5 g daily in divided doses. Serum calcium may decrease so that parathyroidectomy can be postponed until after delivery.

For women with dangerously elevated serum calcium levels, or in those who are mentally obtunded (*hypercalcemic crisis*), emergency treatment is instituted. Diuresis with intravenous normal saline is begun so that urine flow exceeds 150 mL/hr. *Furosemide* is given in conventional doses to block tubular calcium reabsorption. Careful attention to prevent hypokalemia and hypomagnesemia is important. Adjunctive therapy includes *mithramycin*, which inhibits bone resorption; *calcitonin*, which decreases skeletal calcium release; and oral phosphorus.

NEONATAL EFFECTS. In normal infants, cord blood calcium levels are higher than maternal levels. With maternal hyperparathyroidism, abnormally elevated maternal and thence fetal levels further suppress fetal parathyroid function. Thus, at birth there is a rapidly decreasing newborn calcium level, which reaches a nadir at 24 to 48 hours. About 15 to 25 percent of these infants develop severe hypocalcemia with or without tetany (Molitch, 2000). In some cases, neonatal tetany alone has stimulated a search to diagnose maternal parathyroid adenoma (Beattie and co-workers, 2000).

HYPOPARATHYROIDISM. The most common cause of hypocalcemia is hypoparathyroidism that usually follows parathyroid or thyroid surgery. Chronically hypocalcemic pregnant women may have a fetus with skeletal demineralization. Treatment usually prevents symptomatic hypocalcemia. The woman is given 1,25-dihydroxyvitamin D₃ (calcitriol), dihydrotachysterol, or large doses of vitamin D (50,000 to 150,000 U/day); calcium gluconate or calcium lactate (3 to 5 g/day); and a diet low in phosphates. The fetal risks from large doses of vitamin D have not been established. Caplan and Beguin (1990) observed that whereas the calcitriol dose had to be increased in five women during the second half of pregnancy, it could be reduced during lactation.

PREGNANCY-ASSOCIATED OSTEOPOROSIS. It is unlikely that normal pregnancy causes osteopenia in most women (Kaur and associates, 2003; To and co-workers, 2003). That said, some women develop idiopathic osteoporosis while pregnant or lactating. The cause of this is controversial, but most authorities believe that pregnancy unmasks preexisting bone disease (Black and co-workers, 2000; Henderson and colleagues, 2000). For example, Rizzoli and Bonjour (1996) suggested that accentuated lordosis in pregnancy leads to pain and fractures in the already osteopenic woman. The most common symptom of osteoporosis is back pain in late pregnancy or postpartum. Other symptoms are hip pain, either unilateral or bilateral, and difficulty in weight bearing (Dunne and colleagues, 1993; Smith and associates, 1995). In more than half of women, no apparent reason for osteopenia is found. Some known causes include heparin, prolonged bed rest, and corticosteroid therapy (von Mandach and co-workers, 2003). In a few cases, overt hyperparathyroidism or thyrotoxicosis eventually develops.

Idiopathic osteonecrosis of the femoral head during normal pregnancy has been described (Chang and associates, 1993; Gribble and Berres, 2001). We have seen osteonecrosis only as a known complication of sickle-cell disease, prolonged heparin therapy, or corticosteroid therapy (Spencer and colleagues, 1999).

Treatment is problematical, but most clinicians recommend calcium and vitamin D supplementation. Long-term follow-up indicates that although bone density improves, these women, as well as their offspring, may have chronic osteopenia (Blanch and co-workers, 1994; Carbone and colleagues, 1995).

ADRENAL GLAND DISORDERS

Pregnancy has profound effects on adrenal cortical secretion and its control or stimulation. These interrelationships are discussed in detail in [Chapter 5](#) (see p. 143). Serum corticotropin levels increase after a marked reduction in early pregnancy, undoubtedly related to corticotropin-releasing hormone synthesized by the placenta (Carr and Rainey, 1994). The considerable increase in plasma cortisol is explained by increased transcortin production and binding. In addition, plasma renin increases, which increases angiotensin II and in turn aldosterone secretion. Baseline adrenal medullary hormone secretion is probably unaffected. Although there is no evidence that pregnancy causes any specific adrenal disorders, a number may coexist with pregnancy.

PHEOCHROMOCYTOMA. These are chromaffin tumors that secrete catecholamines. Most are located in the adrenal medulla, but 10 percent are located in the sympathetic ganglia. In adults, they are called the *10-percent tumor* because 10 percent are bilateral, 10 percent are extra-adrenal, and about 10 percent are malignant. There is an association with medullary thyroid carcinoma and hyperparathyroidism in some of the autosomally dominant or recessive *multiple endocrine neoplasia syndromes* as well as in neurofibromatosis and von Hippel-Lindau disease. Pheochromocytomas are common findings at autopsy but are frequently not diagnosed. Only 0.1 percent of hypertensive patients have a pheochromocytoma.

Symptoms are usually paroxysmal and manifest as hypertensive crisis, seizure disorders, or anxiety attacks. Hypertension is sustained in 60 percent of patients, but half of these also have paroxysmal crises. Other symptoms during paroxysmal attacks are headaches, profuse sweating, palpitations, and apprehension. Chest pain, tachycardia, nausea and vomiting, and pallor or flushing are also common.

The standard screening test is quantification of catecholamine metabolites in a 24-hour urine specimen (Keely, 1998). Diagnosis is established by measurement of a 24-hour urine collection with at least two of three assays for free catecholamines, metanephrines, or vanillylmandelic acid (VMA). Determination of plasma catecholamine levels is accurate but is associated with technical difficulties (Conlin, 2001; Lenders and associates, 2002). In nonpregnant women, adrenal localization is usually successful with either computed tomography (CT) or magnetic resonance imaging (MRI). Extra-adrenal

tumors may also be localized using these, but occasionally ^{131}I -metaiodobenzylguanidine (MIBG) scanning is necessary for localization.

In most cases today, preferred treatment is laparoscopic adrenalectomy (Lal and Duh, 2003).

Pheochromocytoma Complicating Pregnancy. These tumors are rare but dangerous complications of pregnancy. Geelhoed (1983) cited an earlier review of 89 cases in which 43 mothers died. Maternal death was much more common if the tumor was not diagnosed antepartum (58 versus 18 percent). With modern diagnostic methods and management, maternal survival has improved. Shown in [Table 53-6](#) are results from two reviews done during two contiguous eras. Maternal mortality decreased from 16 to 4 percent. **There were no maternal deaths when the diagnosis was made antepartum.** Fortunately, antepartum diagnosis has now become common.

There are several methods for tumor localization during pregnancy. Ahlawat and colleagues (1999) reported that 21 of 22 tumors were found using sonography, 10 of 11 using CT, and 10 of 10 using MRI ([Fig. 53-4](#)).

In some cases, the principal challenge is to differentiate preeclampsia from the hypertensive crisis caused by pheochromocytoma. Combs and colleagues (1989) have shown that cardiac output falls during paroxysmal hypertension; thus, adverse fetal effects must be considered. In one instance, a postpartum woman presented with dilated cardiomyopathy (Ahn and associates, 2003).

As in nonpregnant patients, there are individual considerations. For example, Grimbert and colleagues (1999) diagnosed two pheochromocytomas during 56 pregnancies in 30 women with *von Hippel-Lindau disease*. Bassoon-Zaltzman and associates (1995) described a normotensive 20-week pregnant woman with intermittent ventricular tachycardia caused by a bladder pheochromocytoma.

MANAGEMENT. Immediate control of hypertension and symptoms with an α -adrenergic blocker such as *phenoxybenzamine* is imperative. The dose is 10 to 30 mg, two to four times daily. After α -blockade is achieved, β -blockers may be given for tachycardia if necessary. In selected cases, surgical exploration and tumor removal may be performed during pregnancy. Successful laparoscopic removal of an adrenal pheochromocytoma has been described in 16- and 20-week pregnancies (Janetschek and associates, 1998). Favorable outcomes were described for 10 of 26 women in whom the diagnosis was made in pregnancy. Blood pressure was controlled pharmacologically during cesarean delivery that was accompanied by tumor resection (Ahlawat and colleagues, 1999). Recurrent tumors are troublesome, and even with good blood pressure control, dangerous peripartum hypertension may develop. We have cared for three women in whom recurrent pheochromocytoma was identified during pregnancy. Hypertension was managed with phenoxybenzamine in all three. Two infants were healthy, but a third was stillborn in a mother with a massive tumor burden who was receiving phenoxybenzamine, 100 mg daily. In all three women, tumor resection was done postpartum. One woman died of persistent metastases several years later.

Figure 53-4. Coronal magnetic resonance image taken in a 32-week pregnant woman shows a right-sided pheochromocytoma (arrow) and its position in relation to the liver. (Courtesy of Dr. Diane Twickler.)

CUSHING SYNDROME. Long-term exposure to glucocorticoids leads to Cushing syndrome, which is either corticotropin-dependent or -independent (Williams and Dluhy, 2001). **The most common cause of Cushing syndrome is iatrogenic corticosteroid treatment.** The cause of endogenous Cushing syndrome is increased adrenal cortisol production. Most cases are due to *Cushing disease*, bilateral adrenal hyperplasia that is, stimulated by corticotropin-producing pituitary adenomas. Most of these are microadenomas less than 1 cm, and half are 5 mm or less. Occasionally, abnormal secretion of hypothalamic corticotropin-releasing factor may cause corticotropic hyperplasia. Hyperplasia may also be caused by nonendocrine tumors that produce polypeptides similar to either corticotropin-releasing factor or corticotropin. About a fourth of cases of Cushing syndrome are corticotropin-independent. Most are caused by an adrenal adenoma, which is usually bilateral, and half are malignant. Occasionally, androgens may cause rather severe virilization (Danilowicz and colleagues, 2002).

The typical body habitus is caused by adipose tissue deposition, which characteristically results in *moon facies*, a *buffalo hump*, and *truncal obesity*. Fatigability and weakness, hypertension, hirsutism, and amenorrhea are each encountered in 75 to 85 percent of nonpregnant patients (Williams and Dluhy, 2001). Personality changes, cutaneous striae, and easy bruisability are common. Up to 20 percent have nephrolithiasis. Confirmation is by elevated plasma cortisol that cannot be suppressed by dexamethasone or by elevated 24-hour urine free cortisol excretion (Boscaro and colleagues, 2001). Neither test is totally accurate, and both are harder to interpret in obese patients. CT and MRI are used to localize pituitary and adrenal tumors or hyperplasia.

Pregnancy and Cushing Syndrome. Because most women with Cushing syndrome have amenorrhea, associated pregnancy is rare. Otherwise, pregnant women usually have classic clinical findings. Buescher and co-workers (1992) found only about 70 reported cases, and Kamiya and colleagues (1998) summarized 97 cases from the Japanese literature. The distribution of causes of the syndrome is different in pregnant women. For example, most cases were caused by adrenal tumors, of which 80 percent were benign. These reports stressed difficulties in diagnosis because of pregnancy-induced increases in plasma cortisol, corticotropin, and corticotropin-releasing factor. Measurement of 24-hour urinary free cortisol excretion is recommended, with consideration for the elevation in normal pregnancy. Molitch (2000) emphasizes that in normal pregnancy the diurnal variation is unchanged.

Maternal complications include hypertension in 60 to 90 percent and gestational diabetes in about 50 percent. Heart failure is common during pregnancy, and Buescher and associates (1992) reported three maternal deaths in 65 pregnancies. Perinatal

morbidity and mortality are correspondingly high. Preterm delivery was reported in 60 percent and perinatal mortality in about 25 percent.

MANAGEMENT. Long-term medical therapy for Cushing syndrome usually is ineffective. Ketoconazole blocks steroid production, and it has been used successfully. Definitive therapy is resection of the pituitary or adrenal adenoma or bilateral adrenalectomy for hyperplasia. During pregnancy, management of hypertension in mild cases may suffice until delivery. Otherwise, pituitary adenomas causing Cushing disease are treated by transsphenoidal resection (Boscaro and colleagues, 2001; Mellor and associates, 1998). Removal of an adrenal adenoma in pregnancy can be curative (Kamiya and colleagues, 1998; Keely, 1998).

Antepartum treatment of 16 pregnant women with Cushing syndrome was summarized by Aron and associates (1990). In six women, unilateral adrenalectomy was performed for an adenoma; in five, bilateral resection was done for hyperplasia; four were treated with either *metypapone*, *aminoglutethimide*, or *cyproheptadine*; and one underwent pituitary irradiation. A few cases during pregnancy have been successfully treated with oral *ketoconazole* (Berwaerts and co-workers, 1999). Because it also blocks testicular steroidogenesis, treatment during pregnancy with a male fetus is worrisome. *Mifepristone*, the norethindrone derivative used for abortion and labor induction, has shown promise for treating Cushing disease. However, it cannot be used in pregnancy.

ADRENAL DEFICIENCY. Primary adrenocortical insufficiency, or *Addison disease*, is rare. More than 90 percent of the glands must be destroyed for symptoms to develop. In the majority of cases, it is caused by *idiopathic autoimmune adrenalitis*, which has surpassed tuberculosis and histoplasmosis as common causes. There is an increased incidence of concurrent Hashimoto thyroiditis, premature ovarian failure, type 1 diabetes, and Graves disease. These *polyglandular autoimmune syndromes* also include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis.

Adrenal Insufficiency and Pregnancy. Untreated adrenal hypofunction frequently causes infertility, but with replacement therapy, ovulation is restored. If untreated, common symptoms include weakness, fatigue, nausea and vomiting, and weight loss (Mestman, 2002). Because serum cortisol levels are increased during pregnancy, initial diagnostic evaluation should include documentation of a lack of response to infused corticotropin (O'Shaughnessy and Hackett, 1984).

Seaward and colleagues (1989) found only five cases of Addison disease during pregnancy published since 1972. They reported a woman with unrecognized Addison disease who suffered a placental abruption and fetal death associated with Addisonian crisis. Albert and associates (1989) reported successful pregnancy outcomes in six women in whom adrenal insufficiency had been diagnosed before conception.

Most pregnant women with Addison disease are already taking cortisone-like drugs and these are continued. With treatment, the pregnant woman is observed for evidence of either inadequate or excessive steroid replacement. During labor, delivery, and postpartum, or after a surgical procedure, steroid replacement must be increased appreciably to approximate the normal adrenal response—so-called *stress doses*. Hydrocortisone, 100 mg, is usually given intravenously every 8 hours. It is important that shock from causes other than adrenocortical insufficiency (e.g., hemorrhage or sepsis) be recognized and treated promptly.

PRIMARY ALDOSTERONISM. Hyperaldosteronism is caused by an adrenal aldosteronoma in about 75 percent of cases, and idiopathic bilateral adrenal hyperplasia in the remainder (Ganguly, 1998). Findings include hypertension, hypokalemia, and muscle weakness. High serum or urine levels of aldosterone confirm the diagnosis.

Pregnancy and Hyperaldosteronism. Progesterone blocks aldosterone action, thus, there are very high levels of aldosterone in normal pregnancy (see [Chap. 5](#), p. 143). It therefore is not surprising that there may be amelioration of symptoms and electrolyte abnormalities during pregnancy (Biglieri and Slaton, 1967; Murakami and associates, 2000). Unless an unequivocal adrenal adenoma is localized by CT or MRI for resection, medical therapy is given. In many cases, hypertension responds to *spironolactone*, but β -blockers or calcium-channel blockers also may be required. Tumor resection is curative, and laparoscopic adrenalectomy should prove useful during pregnancy (Ganguly, 1998).

Webb and Bayliss (1997) reviewed 15 cases of primary aldosteronism associated with pregnancy. Most presented with hypertension and hypokalemia, and in 10, an adrenal adenoma was identified. Baron and associates (1995) reported curative adrenalectomy at 17 weeks for an adenoma. Nezu and co-workers (2000) described two women found to have an aldosteronoma postpartum. They were normotensive throughout pregnancy, but developed severe hypertension several weeks postpartum.

PITUITARY DISEASES

The normal pituitary enlarges in pregnancy, predominately from lactotrophic cellular hyperplasia. These effects are from estrogen stimulation as discussed in [Chapter 5](#) (see p. 141).

PROLACTINOMAS. These adenomas have been found to be relatively common since the advent of widely available assays for serum prolactin. Symptoms include amenorrhea, galactorrhea, and hyperprolactinemia. Tumors are classified arbitrarily by their size, determined by imaging: a microadenoma is 10 mm or less, and a macroadenoma is greater than 10 mm. Treatment for microadenomas is usually with bromocriptine, which is a dopamine agonist and powerful prolactin inhibitor. Treatment frequently restores ovulation. For suprasellar macroadenomas, most recommend surgical therapy before pregnancy is attempted (Schlechte, 2003).

Prolactinomas and Pregnancy. Molitch (1985) analyzed outcomes in almost 250 pregnant women with previously untreated *microadenomas*. Only four women developed symptomatic enlargement during pregnancy, and another 11 who remained asymptomatic had radiographic evidence of enlargement. Albrecht and Betz (1986) reviewed 352 pregnancies in women with microadenomas and reported incidences of 2.3 percent for visual disturbances, 4.8 percent for headaches, and 0.6 percent

diabetes insipidus. Conversely, symptomatic enlargement of *macroadenomas* during pregnancy is more common. When the tumor has extended into the suprasellar region, 15 to 35 percent of women have tumor enlargement during pregnancy that cause visual disturbances, headaches, and diabetes insipidus (Schlechte, 2003). Kupersmith and colleagues (1994) described visual loss during pregnancy in six of eight women with macroadenomas.

Molitch (2000) recommends that pregnant women with microadenomas be queried regularly for headaches and visual symptoms. Those with macroadenomas should also have visual field testing during each trimester. Serial serum prolactin levels are not recommended because of normal increases during pregnancy. CT or MRI is recommended only if symptoms develop. Symptomatic tumor enlargement is treated immediately with bromocriptine, however, relative resistance of macroprolactinomas has been described (Shanis and Check, 1996). More than 6000 pregnant women have taken bromocriptine at some time during pregnancy, and there have been no adverse effects (Molitch, 2001). Surgery is undertaken for women with no response. Gondim and colleagues (2003) have described transnasal transseptal minimally invasive endoscopic resection.

ACROMEGALY. This is caused by excessive growth hormone, usually from an acidophilic or a chromophobic pituitary adenoma. In normal pregnancy, pituitary growth hormone levels decrease as placental epitopes are secreted. Conventional radioimmunoassays cannot differentiate between the two causal adenomas. Diagnosis is confirmed by the failure of an oral glucose tolerance test to suppress pituitary growth hormone (Molitch, 2000). Pregnancy is rare in women with acromegaly, possibly because half are hyperprolactinemic.

Management is similar to that for prolactinomas, with close monitoring for symptoms of tumor enlargement. Bromocriptine is not as effective as it is for prolactinomas, and surgery may be necessary for symptomatic tumor enlargement during pregnancy (Prager and Braunstein, 1995). Herman-Bonert and associates (1998) and Neal (2000) have reported successful treatment of pregnant women with *octreotide*.

DIABETES INSIPIDUS. Vasopressin deficiency is usually due to a hypothalamic or pituitary stalk disorder rather than to a pituitary lesion (Lamberts and associates, 1998). True diabetes insipidus is a rare complication of pregnancy (Hime and Richardson, 1978). Only a few cases have been cared for in the last 45 years at Parkland Hospital, during which time there were over 350,000 deliveries.

Preferable therapy is intranasal administration of *desmopressin*, the synthetic analogue of vasopressin, which is 1-deamino-8-d-arginine vasopressin (DDAVP). Ray (1998) reviewed 53 cases in which DDAVP was used during pregnancy with no adverse sequelae. Most women require increased doses during pregnancy, likely because of an increased metabolic clearance rate stimulated by placental vasopressinase (Lindheimer and Barron, 1994). By this same mechanism, *subclinical diabetes insipidus* may become symptomatic during an otherwise normal pregnancy (Iwasaki and colleagues, 1991). Krege and associates (1989) reviewed 17 such cases. A case of diabetes insipidus during pregnancy has been described as arising from a hemorrhage into a macroadenoma and another following an occluded ventriculoperitoneal shunt (Freeman and co-workers, 1992; Goolsby and Harlass, 1996). Another case was described that manifested during pregnancy as oligohydramnios and diabetes insipidus that did not resolve postpartum (Hanson and colleagues, 1997). Another cause is pituitary infarction with severe obstetrical hemorrhage (see below). In our experience, transient secondary diabetes insipidus is more likely encountered with *acute fatty liver of pregnancy* (see [Chap. 50](#), p. 1127). This likely is due to altered vasopressinase clearance because of hepatic dysfunction. Harper and associates (1987) described transient disease in a 38-week pregnant woman with biopsy-proven viral hepatitis.

SHEEHAN SYNDROME. In 1937, Sheehan reported that pituitary ischemia and necrosis associated with obstetrical blood loss may cause hypopituitarism. Contemporaneously, these events are rare (Vaphiades and colleagues, 2003). One woman who was undelivered developed hemorrhage and necrosis with lymphocytic hypophysitis (Lee and Pless, 2003). When it occurs acutely, affected women may have persistent hypotension, tachycardia, hypoglycemia, and failure of lactation. Subsequent deficiencies of some or all pituitary responsive hormones may develop. For example, as discussed above, diabetes insipidus with or without anterior pituitary deficiency has been described following massive obstetrical hemorrhage and prolonged shock (Kan and Calligerous, 1998). Ammini and Mathur (1994) described 12 cases of Sheehan syndrome encountered in New Delhi. The average duration of onset of symptoms was 5 years. Pituitary apoplexy can also occur with infarction of a macroadenoma (Kaiser, 2001).

LYMPHOCYTIC HYPOPHYSITIS. This autoimmune pituitary disorder is characterized by massive infiltration by lymphocytes and plasma cells with parenchymal destruction of the gland. The majority of cases have been associated with pregnancy (Madsen, 2000; Patel and associates, 1995; Thodou and colleagues, 1995). There are varying degrees of hypopituitarism or symptoms of mass effect, including headaches and visual field defects. A sellar mass is seen on CT or MRI. A mass accompanied by a modestly elevated serum prolactin level (less than 100 pg/mL) suggests lymphocytic hypophysitis, whereas levels exceeding 200 pg/mL are encountered with a prolactinoma. Associated hypothyroidism is common. Pressman and colleagues (1995) reviewed 44 cases and found that 25 percent had other autoimmune diseases. Treatment is with hormone replacement, but the disease may be self-limited (Gagneja and associates, 1999). Surgery during pregnancy is warranted only in cases of severe chiasmal compression unresponsive to corticosteroid therapy (Lee and Pless, 2003). With infertility, both spontaneous and ovulation-induced pregnancies have been successful (Verdu and colleagues, 1998).

54. Connective Tissue Disorders

INTRODUCTION

Connective tissue disorders, also referred to as *collagen-vascular disorders*, cause generalized clinical findings and are principally characterized by connective tissue abnormalities that are mediated by a variety of autoantibodies. These are also called *immune-complex diseases* because many are mediated by deposition of immune complexes in specific organ or tissue sites. Some disorders that are characterized by sterile inflammation, especially of the skin, joints, blood vessels, and kidney, are referred to as *rheumatic diseases*. For inexplicable reasons, many of these rheumatic diseases primarily affect women. Another major category of connective tissue diseases includes inherited disorders of bone, skin, cartilage, blood vessels, and basement membranes. Examples of these are Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome.

IMMUNE-MEDIATED CONNECTIVE TISSUE DISEASES

Although the pathogenesis has not been elucidated, immune-mediated disorders can be separated into those clearly associated with autoantibody formation and those without evidence of the rheumatoid factor, the so-called seronegative spondyloarthropathies (Hahn, 1997). The former category includes systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis (scleroderma), mixed connective tissue disease, dermatomyositis, polymyositis, and a variety of vasculitis syndromes. The seronegative spondyloarthropathies are strongly associated with the presence of the HLA-B27 antigen but not the rheumatoid factor (Benjamin and Parham, 1992; Moll, 1994). These include ankylosing spondylitis, psoriatic arthritis, Reiter disease, and likely the arthritis syndromes associated with ulcerative colitis and Crohn disease.

Because renal involvement is common and often adversely affects pregnancy, a search for coexisting renal involvement is paramount. Hypertension likewise is common, and exacerbation during pregnancy frequently forces early delivery (Wolfberg and colleagues, 2004). In some of these immune-mediated diseases, *antiphospholipid antibodies* are formed that can cause injury to maternal vasculature and to the placenta.

Immunological Aspects. The immune system is designed to protect cells, tissues, and organs perceived as *self* and to attack and destroy foreign or *nonself* antigenic material by the production of antibodies. This protection has two phases. The first is the *innate phase*, which is broad and rapid and is mediated through neutrophils, macrophages, and complement. The second is the *adaptive phase*, which is precise and is caused by antigen-specific reactions through T and B lymphocytes that result in memory for future exposures (Parkin and Cohen, 2001).

For some as yet unknown reason, the immune system may be stimulated to begin producing antibodies directed against self or normal tissues. These "misdirected" antibodies are called *autoantibodies*. The stimulus responsible for their production is unknown, but a variety of inciting reasons are suspected that include bacterial or viral injury to genetically susceptible tissues.

Autoantibodies induce destruction in susceptible tissues by at least two mechanisms. The *cytotoxic mechanism* involves direct antibody attachment to a specific surface antigen, which results in cell injury or destruction. The *immune-complex mechanism* results in tissue damage when the antigen-antibody complex attaches to a susceptible tissue. The complex may then incite a complement response or *cascade*, resulting in the release of chemotactic substances that attract polymorphonuclear cells.

The *major histocompatibility complex (MHC)* is a series of 40 to 50 genes located on the short arm of chromosome 6, and is known as the *human leukocyte antigen (HLA)* complex. These genetic loci code for distinct cell-surface glycoproteins, including transplantation antigens, and are involved in self and nonself recognition. Class I antigens include HLA-A, -B, and -C. Class II antigens include HLA-DR, -DQ, and -DP. Through a variety of complex interactions, including T- and B-cell stimulation and interaction with immunoglobulins and the complement system, nonself antigens or, in the abnormal state, self antigens (normal tissue), are destroyed.

Immune-Mediated Disease and Pregnancy. Very few immune disorders appear to arise only during pregnancy. Maternal isoimmunization from fetal red cell or platelet antigens is the most common (see [Chap. 29](#), p. 663). Some theories of the cause of preeclampsia-eclampsia (see [Chap 34](#), p. 766) and recurrent abortion (see [Chap 9](#), p. 235) implicate an immunological basis.

Some pregnancy-induced immune alterations may modulate connective tissue disorders (see [Chap. 5](#), p. 130). Although it is generally thought that these immunological changes have negligible effects on immune-mediated collagen-vascular disorders, the effects of large amounts of estrogen, progesterone, and prolactin must be considered. For example, estrogens upregulate and androgens downregulate T-cell response, and a number of cytokines are regulated by sex hormones (Lockshin and Druzin, 1995; Refojo and colleagues, 2003). In addition, recall that autoimmune rheumatic diseases mostly affect women. Lockshin (2002) postulates a modulating effect of hormones rather than a causative role.

Fetal Cell Microchimerism. Fetal cells are present in maternal blood starting in the first trimester (Sitar and associates, 2005). An intriguing phenomenon has been used to explain the predilection of autoimmune disorders for women. For example, there have been many observations on the role of *fetal cell microchimerism* to explain immune-mediated diseases (Adams and Nelson, 2004). By this putative mechanism, persistent fetal cells in the maternal circulation stimulate the production of autoantibodies and underlie autoimmune conditions. In this scheme, fetal cells such as thymocytes become engrafted in maternal tissues, or "immortal" long-lived lymphocytes circulate. Lupus may therefore represent a chronic graft-versus-host response to transplacentally acquired fetal cells, as suggested for some thyroid diseases and systemic sclerosis (Artlett and associates, 1998; Jimenez and Artlett, 2005; Srivatsa and associates, 2001). Women with lupus have also been found to have male cells in every histologically abnormal tissue type, but not in normal tissue. Although this suggests that fetal cells may be associated with lupus, it is unclear if this causes disease or is an effect of disease progression, or even unrelated (Johnson and colleagues, 2001). Interestingly, microchimeric cells may also be beneficial by helping repair damaged or diseased tissue, suggesting these fetal cells may have a beneficial role (Barinaga, 2002).

SYSTEMIC LUPUS ERYTHEMATOSUS. Lupus is a heterogeneous syndrome with a complex

pathogenesis, and its genetic contribution is clustered on the 1q and 6p chromosomes (Tsokos, 2001). Immune system abnormalities include overactive B lymphocytes that are responsible for autoantibody production. These result in tissue and cellular damage when autoantibodies or immune complexes are directed at one or more cellular nuclear components (Mills, 1994). Almost 90 percent of cases are in women. The prevalence in women of childbearing age is about 1 in 500 (Lockshin and Sammaritano, 2000). The 10- and 20-year survival rates are 75 and 50 percent (Jacobsen and colleagues, 1999). Infection, lupus flares, end-organ failure, and cardiovascular disease account for most deaths.

Some autoantibodies produced in patients with lupus are shown in [Table 54-1](#). Genetic influences are implicated by a higher concordance with monozygotic compared with dizygotic twins and a 10-percent frequency in patients with one affected family member. The relative risk of disease is increased threefold if HLA-DR2 or -DR3 genes are found (Arnett, 1997). Under the influence of multiple genes, often triggered by environmental stimuli and highly influenced by gender, a number of clinical syndromes may develop, fulfilling diagnostic criteria for lupus.

Clinical Findings. Lupus is notoriously variable in its presentation, course, and outcome (Gladman and Urowitz, 1997). Clinical manifestations may be confined initially to one organ system, with others becoming involved as the disease progresses ([Table 54-2](#)). Alternatively, the disease may initially manifest by multisystem involvement. Common findings are malaise, fever, arthritis, rash, pleuropericarditis, photosensitivity, anemia, and cognitive dysfunction. At least half of patients have renal involvement. *Libman-Sacks endocarditis* was described with lupus but likely is due to anticardiolipin antibodies (Hojnik and associates, 1996). Associated hemodynamic dysfunction is uncommon, but it has been reported (Moysakis and colleagues, 2002). In addition, these valvular lesions may cause thromboembolic seeding.

Laboratory Findings. Identification of antinuclear antibodies (ANA) is the best screening test, however, a positive test result is not specific for lupus. For example, low titers are found in normal individuals, other autoimmune diseases, acute viral infections, and chronic inflammatory processes. Several drugs can also cause a positive reaction. Antibodies to double-stranded DNA (dsDNA) and to Smith (Sm) antigens are relatively specific for lupus, whereas other antibodies are not (see [Table 54-1](#)).

Anemia is common, and there may be leukopenia and thrombocytopenia. Proteinuria and casts are found in the half of patients with glomerular lesions, and there may be renal insufficiency. Other laboratory findings include false-positive syphilis serology, prolonged partial thromboplastin time, and positive serum rheumatoid factor assay.

Diagnosis. The revised criteria of the American Rheumatism Association for diagnosis of systemic lupus are in [Table 54-3](#). If any four or more of these 11 criteria are present, serially or simultaneously, the diagnosis of lupus is made.

Drug-Induced Lupus. Numerous drugs have been reported to induce a lupus-like syndrome. These include procainamide, quinidine, hydralazine, α -methyl dopa, phenytoin, and phenobarbital. Drug-induced lupus is rarely associated with glomerulonephritis, and it usually regresses when the medication is discontinued (Rubin, 1997).

Lupus and Maternal Outcome. Important factors for pregnancy outcome include whether disease is active at the beginning of pregnancy, age and parity, coexistence of other medical or obstetrical disorders, and whether there are antiphospholipid antibodies.

During pregnancy, lupus improves in a third of women, remains unchanged in a third, and worsens in the remaining third. Thus, in any given pregnancy, the clinical condition can worsen or *flare* without warning (Khamashta and colleagues, 1997; Ruiz-Irastorza and co-workers, 1996). Petri (1998) reported a 7-percent risk of major morbidity during pregnancy and estimated a 1 in 20 chance of a life-threatening event. Generally, these are due to renal impairment, myocarditis, or serositis.

Interestingly, Leong and colleagues (1994) reported that serum lipid levels in nonpregnant patients reflect intensity of lupus activity, particularly renal disease. Women with lupus are at increased risk for accelerated atherogenesis and premature cardiac disease. Certain medications have been shown to improve lupus symptoms as well as lower serum lipid levels. Because there are increased serum lipid levels in normal pregnancy, these associations may be related to disease severity only in some cases. This deserves further evaluation.

In studies in which women served as their own nonpregnant controls, investigators have universally reported increased disease activity during pregnancy (Petri, 1991; Ruiz-Irastorza, 1996; Zulman, 1980, and all their co-workers). For example, Petri (1998) reported an increased incidence of renal and hematological flares, but no change in overall severity. **One fact is certain: lupus can be life threatening to both the mother and her fetus-infant.** The clinician must remain vigilant about the development of such life-threatening dangers.

In general, pregnancy outcome is better if:

1. Lupus activity has been quiescent for at least 6 months before conception.
2. There is no active renal involvement manifest by proteinuria or renal dysfunction.
3. Superimposed preeclampsia does not develop.
4. There is no evidence of antiphospholipid antibody activity.

Lupus Nephropathy. Renal disease is more common if antiphospholipid antibodies are detected (Moroni and co-workers, 2004). Women with nephropathy whose disease stays in remission usually have a good pregnancy outcome. Packham and associates (1992) found similar outcomes in 64 pregnancies before and after nephritis was diagnosed. Hypertension developed and proteinuria worsened in half of these women during pregnancy. Huong (2001), Julkunen (1993b), Moroni (2002), and all their colleagues reported similar findings. Of the 125 pregnancies reported by Lockshin (1989), 63 percent of women with preexisting renal disease developed preeclampsia compared with only 14 percent of those without underlying renal disease.

Although most authorities recommend continuation of immunosuppressive therapy during pregnancy in women with nephritis, it is not clear whether the dosage should be increased peripartum. Although it is often stated that this is the time that

activation or exacerbations are most likely to develop, firm evidence is not conclusive.

LUPUS VERSUS PREECLAMPSIA-ECLAMPSIA. Preeclampsia is common in all women with lupus, and superimposed preeclampsia is encountered even more often in those with nephropathy. It may be difficult, if not impossible, to differentiate lupus nephropathy from severe preeclampsia (Repke, 1998). It has not been proven if decreased complement values or increased anti-DNA titers are useful to identify worsening lupus activity. If identified, these laboratory features support the diagnosis of a reactivation of lupus nephritis, termed *renal flare*. According to Petri (1998), most women with renal flares during pregnancy do not develop hypertension. Central nervous system involvement with lupus may culminate in convulsions similar to those of eclampsia. Thrombocytopenia, with or without hemolysis, may further confuse the diagnosis. Management is identical to that for preeclampsia-eclampsia, described in [Chapter 34](#). Corticosteroid therapy is continued. The most common causes of death in these women when not pregnant are malignant hypertension with glomerulonephritis and neurological catastrophes such as seizures, strokes, and coma.

Management During Pregnancy. Management consists primarily of monitoring the clinical conditions of both maternal and fetal patients and maternal laboratory values. Pregnancy-induced thrombocytopenia and proteinuria resemble lupus disease activity, and the identification of a lupus flare is confounded by the increase in facial and palmar erythema of normal pregnancy (Lockshin and Sammaritano, 2003). Some authorities have advocated a number of numerical scales to emphasize ongoing disease activity. Components are weighted for severity, including the SLE-Pregnancy Disease Activity Index (SLEPDAI) and the Lupus Activity Index (Buyon and colleagues, 1999; Ruiz-Irasforza and associates, 2004).

Monitoring of lupus activity and identification of pending lupus flares by a variety of laboratory techniques has been recommended. The sedimentation rate is uninterpretable because of pregnancy-induced hyperfibrinogenemia. Although falling or low levels of complement components C_3 , C_4 , and CH_{50} are more likely to be associated with active disease, higher levels provide no insurance against disease activation. Varner and co-workers (1983) found no correlation between clinical manifestations of disease and complement levels. Our experiences, as well as those of Lockshin and Druzin (1995), have been similar. Buyon and colleagues (1999) recommended that hypocomplementemia should be attributed to disease activity in pregnant women in the following circumstances: (1) when there is decreased C_3 , C_4 , or CH_{50} levels without evidence of a synthetic defect; (2) when levels of C_3 , C_4 , or CH_{50} fall by 25 percent as pregnancy progresses; or (3) when there are normal levels of C_3 , C_4 , or CH_{50} but other evidence of complement activation such as abnormal levels of C_{3a} .

Serial hematological studies may detect changes in disease activity. Hemolysis is characterized by a positive Coombs test, anemia, reticulocytosis, and unconjugated hyperbilirubinemia. Thrombocytopenia, leukopenia, or both may develop. According to Lockshin and Druzin (1995), chronic thrombocytopenia in early pregnancy may be due to *antiphospholipid antibodies*. Later, thrombocytopenia may indicate the onset of preeclampsia.

Serum transaminase activity reflects hepatic involvement, as does a rise in serum bilirubin. Azathioprine therapy also may induce enzyme elevations. Urine is tested frequently to detect new-onset or worsening proteinuria. Overt proteinuria that persists is an ominous sign, even more so if accompanied by other evidence of the nephrotic syndrome or abnormal serum creatinine levels.

The fetus should be closely observed for adverse effects. Fetal growth is monitored closely and careful attention is given to the development of hypertension. Singesen and colleagues (1985) and Petri (1998) recommend screening for anti-SS-A and anti-SS-B antibodies, and if found, fetal cardiac function should be evaluated (see p. 1215). Although we routinely evaluate the fetus for an arrhythmia, we do not screen for these antibodies. As discussed in [Chapter 15](#) (see p. 383), antepartum fetal surveillance is done as outlined by the American College of Obstetricians and Gynecologists (1999). Farine and associates (1998) reported an 11-percent incidence of absent end-diastolic umbilical artery velocity in 56 fetuses.

Unless hypertension develops, or there is evidence of fetal compromise or growth restriction, pregnancy is allowed to progress to term. Peripartum corticosteroids in "stress doses" are given to women who are taking these drugs or who recently have done so.

PHARMACOLOGICAL TREATMENT. There is no cure, and complete remissions are rare. Approximately a fourth of patients have mild disease, which is not life threatening, but may be disabling because of pain and fatigue. Arthralgia and serositis are managed by *nonsteroidal anti-inflammatory drugs*, including aspirin. Because of the risk of premature closure of the fetal ductus arteriosus, therapeutic doses probably should not be used after 24 weeks (Briggs and colleagues, 2002). Low-dose aspirin, however, can be used safely throughout gestation (see p. 1218). Severe disease is managed with *corticosteroids* such as prednisone, 1 to 2 mg/kg per day. After the disease is controlled, this is tapered to a daily dose of 10 to 15 mg each morning. Corticosteroid therapy can result in the development of gestational or even type 1 diabetes. Long-term antibody-based immunoadsorption has been used in pregnancy for removal of autoantibodies and lipoproteins in women with serious complications who did not respond to conventional therapy (Dittrich and colleagues, 2002).

Immunosuppressive and cytotoxic agents such as *azathioprine* and *cyclophosphamide* are beneficial in controlling active disease (Contreras and colleagues, 2004; Hahn, 2001). In nonpregnant patients, they are usually reserved for lupus nephritis or disease that is steroid resistant. Azathioprine is less toxic, and recommended daily oral doses are 2 to 3 mg/kg. It is avoided during pregnancy unless life-threatening complications develop. Although Ramsey-Goldman and associates (1993) found that women exposed to either drug did not have more adverse pregnancy outcomes, Enns and associates (1999) reported that cyclophosphamide is teratogenic.

Antimalarials help control skin disease. Although these agents cross the placenta, *hydroxychloroquine* has not been associated with congenital malformations (stensen, 1998). Because of the long half life of antimalarials, and because discontinuing therapy can precipitate a lupus flare, most authors recommend their continuation if in use (Borden and Parke, 2001; Harris, 2002). Levy and colleagues (2001) randomized 20 pregnant women to hydroxychloroquine or placebo and reported improvement in SLEPDAI scores when the drug was compared with placebo.

When severe disease supervenes, usually with a lupus flare, high-dose glucocorticoid therapy is given. Petri (1998) recommends pulse therapy consisting of methylprednisolone, 1000 mg per 24 hours for 3 days, then a return to maintenance doses if possible.

Long-term Prognosis and Contraception. In general, women with lupus and chronic vascular or renal disease should limit family size because of morbidity associated with the disease as well as increased adverse perinatal outcomes. Tubal sterilization may be advantageous. It is performed with greatest safety postpartum or whenever the disease is quiescent. Oral contraceptives must be used with caution in women with lupus because vascular disease is relatively common. Progestin-only implants and injections provide effective contraception with no known effects on lupus flares. Intrauterine devices probably should not be prescribed if the woman is receiving immunosuppressive therapy (see [Chap. 32](#), p. 739).

Effects of Lupus on the Fetus and Neonate. Fetal growth restriction and perinatal mortality and morbidity are increased significantly in pregnancies complicated by lupus ([Table 54-4](#)). Prognosis is worsened with a lupus flare; significant proteinuria; renal impairment; and with associated hypertension, development of preeclampsia, or both (Aggarwal, 1999; Carmona, 1999; Rahman, 1998; Scott, 2002, and all their associates). The reasons at least partially responsible for adverse fetal consequences include decidual vasculopathy with placental infarction and decreased perfusion (Hanly and colleagues, 1988; Lubbe and Liggins, 1984). Anti-SS-A (Ro) and anti-SS-B (La) antibodies may damage the fetal heart and conduction system, causing neonatal death (Alexander and co-workers, 1992; Tseng and Buyon, 1997). For example, women with livedo reticularis and lupus or a lupus-like illness, but who do not produce antiphospholipid antibodies, display increased rates of pregnancy complications (Sangle and associates, 2005). The recurrence risk in subsequent offspring for cutaneous lupus is 25 percent, and for congenital heart block it is 10 to 15 percent (Julkunen and colleagues, 1993a).

NEONATAL LUPUS. This unusual syndrome is characterized by skin lesions, or *lupus dermatitis*; a variable number of hematological and systemic derangements; and occasionally congenital heart block (Boh, 2004; Tseng and Buyon, 1997). Thrombocytopenia and hepatic involvement may also manifest (Weston and colleagues, 1999). The incidence is about 5 to 10 percent. One report suggests that neonatal lupus may appear up to 4 weeks after birth (Stirnemann and associates, 2002). Lockshin and co-workers (1988) prospectively followed 91 infants born to women with lupus; four had definite neonatal lupus and four had possible disease. Cutaneous lupus, thrombocytopenia, and autoimmune hemolysis are transient and clear within a few months (Lee and Weston, 1984).

CONGENITAL HEART BLOCK. This is the consequence of diffuse myocarditis and fibrosis in the region between the atrioventricular node and bundle of His. Buyon and colleagues (1993) reported that congenital heart block occurred almost exclusively in infants of women with antibodies to the SS-A or SS-B antigens. They may cause otherwise unexplained stillbirths (Ottaviani and co-workers, 2004). Even in the presence of such antibodies, however, the incidence of arrhythmia is only 3 percent (Lockshin and associates, 1988). The cardiac lesion is permanent, and a pacemaker is generally necessary. Long-term prognosis is not good, and a third of affected infants die within 3 years (Waltuck and Buyon, 1994).

Maternal corticosteroid administration to treat fetal heart block is controversial. Richards and associates (1990) described such a fetus whose ascites cleared promptly with maternal therapy even though heart block and bradycardia persisted. Shinohara and colleagues (1999) reported no heart block in 26 neonates whose mothers received corticosteroid maintenance therapy before 16 weeks. By contrast, 15 of 61 neonates with heart block were born to women in whom corticosteroid therapy was begun after 16 weeks. Saleeb and colleagues (1999) recommend fluorinated steroids.

ANTIPHOSPHOLIPID ANTIBODIES. Several antibodies directed against negatively charged phospholipids have been described and studied in detail over the past 25 years. These antiphospholipid antibodies include *lupus anticoagulant (LAC)* and *anticardiolipin antibodies (ACAs)*. They may be of IgG, IgM, and IgA classes, alone or in combination. Although they may be found in normal persons, they also are associated with the *antiphospholipid antibody syndrome (APS)*. This is characterized by recurrent arterial or venous thromboses, thrombocytopenia, and fetal losses—especially stillbirths—during the second half of pregnancy (Branch and Khamashta, 2003; Oshiro and associates, 1996; Warren and colleagues, 2004).

APS may occur alone or in association with lupus or other autoimmune disorders. Central nervous system involvement is one of the most prominent clinical manifestations and includes arterial and venous thrombotic events, psychiatric features, and other nonthrombotic neurological syndromes (Sanna and co-workers, 2003). Interestingly, APS may mimic the presentation of multiple sclerosis (Ruiz-Irastona and associates, 2001).

Feinstein and Rapaport (1972) introduced the term *lupus anticoagulant* in a review of acquired inhibitors of coagulation. This was based on the early recognition that certain patients with lupus had some coagulation tests that were prolonged and thus suggested anticoagulant activity. Paradoxically, the so-called anticoagulant is powerfully thrombotic in vivo, although the LAC prolongs all phospholipid-dependent coagulation tests, including the prothrombin time, partial thromboplastin time, and Russell viper venom time. Each of these tests requires a phospholipid surface to which other clotting factors attach and combine ([Fig. 54-1](#)).

Thus, detection of the LAC is based indirectly on the prolongation of in vitro tests by this circulating antiphospholipid antibody. ACA usually is detected serologically using enzyme-linked immunoabsorbent assay (ELISA). Most often IgM anticardiolipin antibodies that are found alone are stimulated by infections or drugs and are innocuous (Silver and colleagues, 1996).

Pathophysiology. Many patients with lupus have circulating antibodies specifically directed either against cardiolipin(s) or against phospholipid-binding proteins such as β_2 -glycoprotein I (apolipoprotein H). The latter are associated with arterial thrombosis (Lopez and associates, 2004). ACAs apparently bind directly to β_2 -glycoprotein I, and these proteins act as a co-factor in this antigen-antibody reaction (Chamley and co-workers, 1999).

The major activity of β_2 -glycoprotein I appears to be its phospholipid-dependent anticoagulant inhibition of prothrombinase activity of platelets and ADP-induced platelet aggregation (Shi and colleagues, 1993). β_2 -glycoprotein I competitively inhibits the binding of coagulation factors, especially factor XII and the prothrombinase complex to negatively charged phospholipid surfaces, and prevents activation of the coagulation cascade (Schousboe and Rasmussen, 1995). An antibody directed against β_2 -glycoprotein I would bind and prevent it from acting as a phospholipid-dependent anticoagulant. β_2 -glycoprotein I is found in high concentrations on the surface of the syncytiotrophoblast (see [Chap. 3](#), p. 54). This might be expected, because it is a

critical area to ensure that coagulation does not occur. In addition, β_2 -glycoprotein I may be involved in implantation, because it is known that this protein binds heparin. Moreover, trophoblastic cells have heparin-like binding sites. Thus, a local loss of β_2 -glycoprotein I by an antibody directed against it might prevent implantation or result in intervillous space thrombosis, or both (Chamley and associates, 1999).

LAC appears to require a co-factor for its in vitro anticoagulant function. Specifically, it does not bind directly to negatively charged phospholipids, but instead, it binds to phospholipid-bound prothrombin (Galli and Bevers, 1994). Other phospholipid-binding proteins may be involved in the pathophysiology of the APS. These include *protein C* and *protein S*, both endogenous anticoagulants, and *annexin V*. The latter is also known as placental anticoagulant protein I or lipocortin V, and it coats the syncytiotrophoblast in high concentration (Chamley, 1999). Thus, an antibody that binds protein C or S would result in venous, arterial, or decidual thrombosis, while binding of annexin V would result in coagulation and thrombosis in the intervillous space (see [Fig. 54-1](#)).

Rand and co-workers (1997b) reported that placental tissue from pregnancy complicated by the APS had significantly less apical membrane-associated annexin V than normal placenta. Exposure of placental villous cultures to five antiphospholipid IgGs also resulted in a significant reduction in apical membrane annexin V. In another study, there was a reduction in annexin V in endothelial cell tissue cultures exposed to antiphospholipid antibodies (Rand and colleagues, 1997a). The pathophysiology of this sequence of events is illustrated in [Figure 54-1](#).

These discoveries led to the development of direct assays to measure antibodies against β_2 -glycoprotein I and prothrombin. The latter are increased in and associated with pregnancies complicated by the APS (Faden, 1997; Falcon, 1997; Forastiero, 1997; Ogasawara, 1996, and all their co-workers). Conversely, others have not observed a clinically significant association with these antibodies (Lee, 1999; Lynch, 1999; Tinahones, 1998, and all their associates).

Association of Antiphospholipid Antibodies with Lupus. Patients with clinical lupus frequently are found to have LAC and ACAs. Love and Santoro (1990) reviewed 29 series that included more than 1000 patients with lupus and reported an average frequency of 34 percent for LAC and 44 percent for ACAs. In nearly half, both antibodies were found.

In general, patients with LAC have higher levels of ACAs, and about a third of those with biological false-positive tests for syphilis have ACAs (Branch, 1991). Conversely, only about 20 percent of patients with identifiable ACAs have LAC. Importantly, in patients with lupus, documentation of either ACA or LAC is a risk factor for thrombosis, neurological disorders, and thrombocytopenia (Love and Santoro, 1990). As discussed in [Chapter 9](#) (see p. 235), these antibodies have also been associated with excessive pregnancy loss (Kutteh and colleagues, 1999). Hojnik and colleagues (1996) reported that *Libman-Sacks endocarditis* is much more prevalent in patients with lupus who have antiphospholipid antibodies. These antibodies have been associated with the development of "primary" vaso-occlusive disease involving different organs. In the kidney, this has been documented by renal biopsy (Nochy and colleagues, 1999).

Antiphospholipid Antibodies in Normal Pregnancy. About 5 percent of all otherwise healthy nonpregnant populations screened have nonspecific antiphospholipid antibodies in low titers. This has been documented also during pregnancy. Lockwood and colleagues (1989) studied 737 normally pregnant women and found that two (0.3 percent) had lupus anticoagulant and 16 (2.2 percent) had elevated concentrations of either IgM- or IgG-ACAs. Harris and Spinnato (1991) studied 1449 consecutive pregnant women and found 1.8 percent positive for IgG-anticardiolipin and 4.3 percent for IgM-anticardiolipin antibodies. Pattison and co-workers (1993) studied 933 consecutive prenatal patients and found nine (0.1 percent) with ACAs, 11 (1.2 percent) with LACs, and two women with both. Yasuda and associates (1995) found that 7 percent of 860 pregnant Japanese women had ACAs.

Diagnosis of Antiphospholipid Antibody Syndrome. By international consensus, APS is diagnosed on the basis of clinical and laboratory criteria (Levine and co-workers, 2002). One of two clinical criteria that include vascular thrombosis or certain pregnancy morbidity must be present. In addition, at least two laboratory criteria that include LAC activity, or medium- to high-positive specific IgG- or IgM-ACAs must be confirmed on two occasions 6 weeks apart.

Several indications for testing are listed in [Table 54-5](#). Branch and Khamashta (2003) recommend conservative interpretation of results based on repeated tests from a reliable laboratory that are consistent with each clinical case. Because only approximately 20 percent of patients with APS have a positive LAC reaction alone, both the clotting test to identify the LAC and the anticardiolipin ELISA test must be performed.

Efforts have been made to standardize ACA assays by using ELISA, and values are reported in units and expressed as either *negative* or *low*, *medium*, or *high positive* (Harris and colleagues, 1987). Despite this, there still is no totally accurate standardization for these assays (Branch and Khamashta, 2003). Interlaboratory variation can be large, and agreement between commercial kits is also poor.

Tests for the LAC are nonspecific coagulation tests. The *partial thromboplastin time* is generally prolonged because the anticoagulant interferes with conversion of prothrombin to thrombin in vitro. Tests considered most specific are the *dilute Russell viper venom test (dRVVT)* and the *platelet neutralization procedure*. There is currently disagreement as to which of these is best for screening. However, if any are positive after adding normal plasma, the diagnosis is confirmed.

Pathophysiology of Antiphospholipid Antibodies in Pregnancy. There is a strong association between the LAC and high levels of ACAs with decidual vasculopathy, placental infarction, fetal growth restriction, early-onset preeclampsia, and recurrent fetal death. Some of these women, like those with lupus, also have a high incidence of venous and arterial thromboses, cerebral thrombosis, hemolytic anemia, thrombocytopenia, and pulmonary hypertension (Khamashta and colleagues, 1997; Silver and associates, 1994).

MECHANISM OF ACTION. It is not precisely known how these antibodies act, but it is likely that their actions are multifactorial. According to Chamley (1999), platelets may be damaged directly by antiphospholipid antibody or indirectly by binding β_2 -glycoprotein I, which causes platelets to be susceptible to aggregation. Rand and colleagues (1997a, 1997b, 1998) propose that phospholipid-containing endothelial cell or syncytiotrophoblast membranes may be damaged directly by the

antiphospholipid antibody or indirectly by antibody binding to either β_2 -glycoprotein I or annexin V (see [Fig. 54-1](#)). This prevents the cell membranes from protecting the syncytiotrophoblast and endothelium and results in exposure of basement membrane. It is known that damaged platelets adhere to exposed basement membrane of endothelium and syncytiotrophoblast and result in thrombus formation (Lubbe and colleagues, 1983).

There are other proposed mechanisms. Pierro and co-workers (1999) reported that antiphospholipid antibodies decreased decidual production of the vasodilating prostaglandin E_2 . Decreased protein C or S activity as well as increased prothrombin activation have been reported (Ogunyemi and associates, 2002; Zangari and colleagues, 1997). Amengual and co-workers (2003) presented evidence that thrombosis with APS is due to activation of the tissue factor pathway. Recent studies suggest that uncontrolled placental complement activation by antiphospholipid antibodies may play a role in fetal loss and growth restriction (Holers and colleagues, 2002).

ADVERSE PREGNANCY OUTCOMES. There is no doubt that antiphospholipid antibodies are associated with increased fetal wastage (see [Chap. 9](#), p. 235). In most early reports, however, women were usually included because they had repeated adverse outcomes. Moreover, as previously discussed, the incidence of antiphospholipid antibodies in the general obstetrical population is about 5 percent. Currently, data are too limited to draw precise conclusions concerning the impact of these antibodies on adverse pregnancy outcomes. According to the Utah group, fetal deaths are more characteristic than first-trimester miscarriages (Oshiro and co-workers, 1996; Roque and colleagues, 2001).

Looking at the issue another way, the incidence of these antibodies may be increased in adverse obstetrical outcomes associated with the syndromes. Polzin and colleagues (1991) identified antiphospholipid antibodies in a fourth of 37 women with growth-restricted fetuses. None had evidence of LAC. Branch and co-workers (1989) found a 16-percent incidence of antiphospholipid antibodies in 43 women with severe preeclampsia before 34 weeks. Six of the seven women with antibodies also had LAC, and one woman had multiple cerebral infarctions. Similarly, Moodley and associates (1995) found antibodies in 11 percent of 34 women with severe preeclampsia before 30 weeks.

When otherwise unexplained fetal deaths are examined, ACAs do not appear to play a significant role. Haddow and co-workers (1991) measured ACAs in 309 pregnancies with fetal death and found no differences when compared with 618 normal pregnancies. Despite a worse pregnancy outcome, there was no evidence of greater endothelial cell activation during pregnancy in women who were receiving treatment for APS (Stone and colleagues, 2003).

Treatment Guidelines. As aptly stated by Branch and Khamashta (2003), because of the heterogeneity of studies, current treatment recommendations may be confusing to the clinician. As discussed in [Chapter 47](#) (see p. 1078), women with prior thromboembolic events who have antiphospholipid antibodies should be given heparin in subsequent pregnancies (American College of Obstetricians and Gynecologists, 2000). Women with high-titer ACA or with LAC activity and a previous second- or third trimester fetal death not attributable to other causes should be treated (Dizon-Townson and Branch, 1998; Lockshin and Druzin, 1995). Similarly, women with recurrent early pregnancy loss and high titers of antibodies may benefit from therapy (Kutteh, 1996). A number of treatments for women with antiphospholipid antibodies have been evaluated, including low-dose aspirin, prednisone, heparin, and immunoglobulin (Levine and colleagues, 2002). These are thought to counteract the adverse action of antiphospholipid antibodies by affecting both the immune and coagulation systems.

Low-dose aspirin, 60 to 80 mg given daily, blocks the conversion of arachidonic acid to thromboxane A_2 while allegedly sparing prostacyclin production (Kaaja and co-workers, 1993; Lellouche and colleagues, 1991). This results in reduced thromboxane A_2 , which aggregates platelets and causes vasoconstriction, while sparing prostacyclin, which has the opposite effect. There appear to be no major side effects from low-dose aspirin other than a slight risk of small vessel bleeding during surgical procedures.

Heparin is used in doses of 5000 to 10,000 units administered subcutaneously every 12 hours. Some authors recommend measurement of heparin levels because clotting tests may be altered by LAC. According to Cowchock (1998), preinjection heparin levels are monitored to ensure protection of patients most at risk of thromboembolism. The rationale for heparin therapy is to prevent venous and arterial thrombotic episodes. Heparin therapy also prevents thrombosis in the microcirculation, including the decidual-trophoblastic interface (Toglia and Weg, 1996). As discussed, heparin binds to β_2 -glycoprotein I, which coats the syncytiotrophoblast. This prevents binding of anticardiolipin and anti- β_2 -glycoprotein I antibodies to their surfaces, which likely prevents cellular damage (Chamley, 1999; Schousboe and Rasmussen, 1995). Heparin also binds to antiphospholipid antibodies in vitro, and likely in vivo (Ermel and associates, 1995). Heparin therapy is associated with a number of complications. These are discussed in detail in [Chapter 47](#) (see p. 1083) and include bleeding, thrombocytopenia, osteopenia, and osteoporosis. Most consider *low-molecular-weight heparin* preparations as a reasonable substitute.

Glucocorticoids likely should not be used with "primary" APS (i.e., without an associated connective tissue disorder). Even so, some patients with these conditions can be expected to develop an associated disorder such as lupus over time (Carbone and colleagues, 1999). In instances of "secondary" APS, the dose of prednisone should be maintained at the lowest effective level to prevent flares. Steroid therapy has significant adverse effects, including osteopenia, osteoporosis, and pathological fractures. Steroids also impede wound healing, and they induce gestational and overt diabetes (Laskin and co-workers, 1997).

Immunoglobulin therapy has usually been reserved for women with overt disease, heparin-induced thrombocytopenia, or both. It is used when other first-line therapies have failed, especially in the setting of preeclampsia and fetal growth restriction (Cowchock, 1996, 1998; Heilmann and colleagues, 2003; Petri, 1997; Silver and Branch, 1997). Immunoglobulin is administered intravenously in doses of 0.4 g/kg daily for 5 days (total dose of 2 g/kg). This is repeated monthly, or it is given as a single dose of 1 g/kg each month. Immunoglobulin has been evaluated in a preliminary placebo-controlled study by Branch and colleagues (2000). The drug may cause anaphylactic reactions, especially in women who have IgA deficiency due to anti-IgA antibodies.

Immunosuppressive therapy has also not been well evaluated, but azathioprine and cyclosporine do not appear to improve standard therapies (Silver and Branch, 1997). Methotrexate and cyclophosphamide are contraindicated because of teratogenic potential (Enns and associates, 1999).

RESULTS OF TREATMENT. Although improved outcomes are reported with some of the preceding treatments, Branch and Khamashta (2003) cautioned that recurrent fetal loss is still 20 to 30 percent. Thus, low-dose aspirin and corticosteroid therapy are not universally successful. In one study, Lockshin and co-workers (1989) reported that 23 of 32 women with a prior fetal death and antiphospholipid antibody greater than 40 IgG units had a recurrent fetal death despite treatment with prednisone, aspirin, or both. Conversely, some women with lupus and antiphospholipid antibodies have normal pregnancy outcomes without treatment. In addition, women with LAC and prior bad pregnancy outcomes have had liveborn infants without treatment (Trudinger and associates, 1988).

Current data suggest the most efficacious therapy to be low-dose heparin 5000 to 10,000 units administered subcutaneously, twice daily given along with low-dose aspirin, 60 to 80 mg once daily. If active lupus also is present, then prednisone is usually also given.

Figure 54-1. Mechanisms of reduction of annexin V levels and acceleration of coagulation associated with antiphospholipid antibodies. **A.** Anionic phospholipids (-) on the surface of the cell-membrane bilayer serve as potent co-factors for assembly of three coagulation complexes: tissue factor-VIIa (TF-VIIa) complex, IXa-VIIIa complex, and Xa-Va complex. The phospholipids thus accelerate blood coagulation by generating factors IXa and Xa. Factor Xa yields factor IIa (thrombin), which in turn cleaves fibrinogen to form fibrin. **B.** When antiphospholipid antibodies are absent, annexin V forms clusters that bind to the surface of anionic phospholipids and inhibit coagulation. **C.** Directly or through an interaction with protein-phospholipid co-factors, antiphospholipid antibodies disrupt the ability of annexin V to cluster on the phospholipid surface. This reduces binding affinity of annexin V, which permits more anionic phospholipid to be available to form complexes with coagulation proteins. Coagulation is thus accelerated and thrombosis promoted. (From Rand and colleagues, 1997a, with permission.)

RHEUMATOID ARTHRITIS. This is a chronic multisystem disease of unknown cause with an immunologically mediated pathogenesis. Infiltrating T cells secrete cytokines that mediate inflammation and systemic symptoms. Its prevalence is about 0.8 percent, and women are affected three times more often than men (Lipsky, 2001). The cardinal feature is inflammatory synovitis that usually involves the peripheral joints. The disease has a propensity for cartilage destruction, bony erosions, and joint deformities. Onset is generally between 35 and 50 years of age.

There is a genetic predisposition, and the results of several studies have shown a higher disease concordance among monozygotic than dizygotic twins (15 versus 4 percent) (Lee and Weinblatt, 2001). There is also an association with the class II major histocompatibility complex molecule HLA-DR4 as well as HLA-DRB1 alleles (Harney and colleagues, 2003). A prolonged duration of cigarette smoking also appears to increase the risk of rheumatoid arthritis in women (Karlson and colleagues, 1999). Hazes and colleagues (1990) reported a protective effect of pregnancy in the development of rheumatoid arthritis. Conversely, van Dunne and associates (2004) found that miscarriage is associated with accelerated joint destruction.

Clinical Manifestations. Rheumatoid arthritis is a chronic polyarthritis with symptoms of synovitis, fatigue, anorexia, weakness, weight loss, depression, and vague musculoskeletal symptoms. The hands, wrists, knees, and feet are commonly involved. Pain, aggravated by movement, is accompanied by swelling and tenderness. Extra-articular manifestations include rheumatoid nodules, vasculitis, and pleuropulmonary symptoms. The 1987 revised criteria of the American Rheumatism Association have approximately a 90-percent specificity and sensitivity for the diagnosis (Arnett and colleagues, 1988).

Management. Treatment is directed at pain relief, reduction of inflammation, protection of articular structures, and preservation of function. Physical and occupational therapy and self-management instructions are essential. Aspirin or nonsteroidal anti-inflammatory drugs are the cornerstone of symptomatic therapy. The relatively new cyclooxygenase-2 (COX-2) inhibitors are used widely because of decreased gastrointestinal ulceration. Glucocorticoid therapy may be added, and 7.5 mg of prednisone daily for the first 2 years of active disease substantively reduces progressive joint erosions (Kirwan and colleagues, 1995). Otherwise, corticosteroids are avoided if possible, but low-dose therapy is used by some clinicians, along with salicylates.

More recently, Lee and Weinblatt (2001) described a paradigm shift in treatment of rheumatoid arthritis. In this scheme, *disease-modifying antirheumatic drugs (DMARDs)* are given early. There are a variety of DMARDs, and most have considerable toxicity. These include hydroxychloroquine, sulfasalazine, azathioprine, cyclosporine, methotrexate, and gold compounds. More recently, the tumor necrosis factor biological-response modifiers etanercept and infliximab have been approved for use. Orthopedic surgery for joint deformities, including replacement, is commonly performed.

Effects of Pregnancy. In 1938, Hench reported marked improvement in the inflammatory component of rheumatoid arthritis during pregnancy. Conversely, postpartum exacerbation is common (Lockshin and Druzin, 1995). As discussed on page 1210, sex hormones supposedly interfere with a number of putative processes involved in arthritis pathogenesis, including immunoregulation and interactions with the cytokine system (Masi and associates, 1999; Stensen, 1999; Wilder and Elenkov, 1999).

Unger and associates (1983) reported that amelioration of rheumatoid arthritis correlated with serum levels of *pregnancy-associated α_2 -glycoprotein*. This compound has immunosuppressive properties and may suppress at least one mediator of an inflammatory response, interleukin-2 (Nicholas and colleagues, 1985). Nelson and co-workers (1993) reported that amelioration of disease was associated with a disparity in HLA class II antigens between mother and fetus. They suggested that the maternal immune response to paternal HLA antigens may play a role in pregnancy-induced remission of arthritis.

Silman and associates (1992) performed a case-control study of 88 women with rheumatoid arthritis and reported that pregnancy had a "protective effect" for disease onset. Conversely, there was a sixfold increased likelihood of new-disease onset in the first 3 months postpartum. Iijima and associates (1998) observed only two new cases in 2547 postpartum women. Barrett and co-workers (2000a) reported that a flare was more common if women were breast feeding.

In a prospective study, Stensen and Husby (1983) confirmed the amelioration of symptoms during early pregnancy in women with rheumatoid arthritis. They also described exacerbations within 3 months postpartum in 11 of 12 women. In a study from Leiden, van der Horst-Bruinsma and colleagues (1998) found that a favorable outcome was related to maternal-fetal MHC class II incompatibility. Conversely, Barrett and co-workers (2000b) performed a prospective study in the United Kingdom, and 140 women recruited during the last trimester were seen at 1 and 6 months postpartum. There was only a modest fall in objective disease activity. Only 16 percent had complete remission. At least 25 percent had substantive levels of disability. Thus, although overall disease actually did not exacerbate postpartum, the mean number of inflamed joints increased significantly. Thus, most women with rheumatoid arthritis improve during pregnancy, some women develop disease during pregnancy, and others become worse (Nelson and Stensen, 1997).

Stensen (1991) reviewed outcomes of 76 pregnancies in 51 women with *juvenile rheumatoid arthritis*. Pregnancy had no effects on presentation of disease, but disease activity became quiescent or remained so during pregnancy. Postpartum flares were common, as discussed for rheumatoid arthritis. Joint deformities were common in these women, and 15 of 20 cesarean deliveries were done for contracted pelvises or joint prostheses. These observations are supported by the summary of similar results in 39 Polish women with a history of juvenile rheumatoid arthritis (Musiej-Nowakowska and Ploski, 1999).

Perinatal Outcome. There are no obvious adverse effects of rheumatoid arthritis on pregnancy outcome, including preterm labor (Klippel and Cecere, 1989). Although Kaplan (1986) reported that women who later develop the disease have had a higher-than-expected incidence of spontaneous abortion, Nelson and colleagues (1992) did not observe this.

Management During Pregnancy. In a national population-based cohort study in Norway, Skomsvoll and colleagues (2002) found that women with rheumatic disease were at high risk for adverse pregnancy outcome. It may be that large doses of aspirin or other nonsteroidal anti-inflammatory drugs typically used to treat these diseases might adversely affect the fetus and neonate (see [Chap. 14](#), p. 355). Concerns include impaired hemostasis, prolonged gestation, and premature closure of the ductus arteriosus (Briggs and colleagues, 2002). Nonetheless, these drugs remain appropriate for treatment of symptomatic women during pregnancy. Corticosteroids are also used as indicated. Gold compounds have been used in pregnancy, but their fetal effects are largely unknown. Immunosuppressive therapy with azathioprine, cyclophosphamide, or methotrexate is not routinely used during pregnancy. Of these, only azathioprine should be considered for use during early pregnancy because the other agents are teratogenic (Buckley and co-workers, 1997; Enns and associates, 1999; Ramsey-Goldman and Shilling, 1997). As discussed on page 1219, a number of newer agents have been used in nonpregnant patients.

If cervical spine involvement exists, particular attention is warranted during pregnancy. Subluxation is common, and pregnancy, at least theoretically, predisposes to this because of joint laxity, as discussed in [Chapter 5](#) (see p. 144).

Contraception. Combination oral contraceptives are a logical choice because of their effectiveness and the possibility they might improve rheumatoid arthritis (Bijlsma and Van Den Brink, 1992). In fact, all reversible methods of contraception discussed in [Chapter 32](#) are appropriate except intrauterine devices, which should not be used in immunosuppressed women.

SYSTEMIC SCLEROSIS (SCLERODERMA). This is a multisystem disorder of unknown etiology characterized by fibrosis and thickening of the skin resulting from accumulation of connective tissue and by involvement of visceral organs. Its prevalence averages 1 in 10,000, with a 3-to-1 female dominance. This strong prevalence for women and the increased incidence in the years following childbirth has led to the hypothesis that *microchimerism* may be involved in the pathogenesis of systemic sclerosis (Maloney and associates, 1999; Nelson and colleagues, 1998). As discussed on page 1210, small amounts of fetal cells or DNA are found in maternal blood or tissues (Lambert and collaborators, 2004). Artlett and co-workers (1998) demonstrated Y-chromosomal DNA in 32 of 69 women (46 percent) with systemic sclerosis compared with that in only 4 percent of controls. Fetal cells are likely present long before fibrosis develops (Sawaya and associates, 2004). Also, low concentrations of male DNA may normally remain in the maternal circulation for decades after birth of a male infant (see [Chap. 13](#), p. 331). Lambert and colleagues (2002) used quantitative methods and found that higher degrees of microchimerisms are due to intact cells and not free DNA. Maloney and colleagues (1999) have shown persistent maternal microchimerism in six of nine immunocompetent women with systemic sclerosis. Whether this contributes to the development of systemic sclerosis currently is unresolved (Ichinohe and colleagues, 2002; Russo-Stieglitz and associates, 2001).

Clinical Course. Symptoms with systemic sclerosis involve its attacks on the gastrointestinal tract, heart, lungs, and kidneys. *Overlap syndrome* refers to the presence of systemic sclerosis with features of other connective tissue disorders. *Mixed connective tissue disease* is a term used for the syndrome involving features of lupus, systemic sclerosis, polymyositis, rheumatoid arthritis, and high titers of anti-RNP antibodies (see [Table 54-1](#)).

The hallmark of the disease is overproduction of normal collagen. This results in fibrosis of skin and the gastrointestinal tract, especially the distal esophagus. Pulmonary interstitial fibrosis along with vascular changes may cause pulmonary hypertension. Antinuclear antibodies are found in 95 percent of patients, and immunoincompetence is common. Common symptoms are Raynaud phenomenon (95 percent) and swelling of the distal extremities and face. Half of patients have symptoms from esophageal involvement, especially fullness and epigastric burning pain. Pulmonary involvement is common and causes dyspnea. Mortality is high with renal or pulmonary involvement, and 10-year survival is less than 50 percent. Renal failure causes half of the deaths. Women with limited cutaneous disease such as the *CREST syndrome* ¶—*calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia* ¶— have milder disease.

Even though systemic sclerosis cannot be cured, treatment directed at end-organ involvement can relieve symptoms and improve function. Corticosteroids are helpful only for inflammatory myositis, pericarditis, and hemolytic anemia. *Angiotensin-converting enzyme (ACE) inhibitors* are most effective for hypertension and progressive renal failure (Gilliland, 2001). Although Steen (1999) reported the use of ACE inhibitors under such conditions during pregnancy without fetal effects, these agents have been associated with severe fetal consequences (see [Chap. 14](#), p. 349).

There has been one multicenter randomized trial of *recombinant human relaxin* in nonpregnant patients with systemic sclerosis. In this study, Seibold and co-workers (2000) reported improvement of skin thickening and mobility after 24 weeks of use.

Effects on Pregnancy. Pregnancy outcome with scleroderma is related to the severity of underlying disease. In the past, a high cited incidence of maternal deaths was due to case reports that did not accurately reflect the risks involved. In a review of 94 pregnancies, Maymon and Fejgin (1989) found that a third of women had exacerbations of symptoms during pregnancy. The maternal mortality rate was 15 percent and was due to hypertension, renal failure, or cardiopulmonary complications. The fetal mortality rate was 20 percent.

Steen and colleagues (1989, 1999) reported more optimistic outcomes in 214 women with systemic sclerosis, 45 percent of whom had had diffuse disease. Major complications included *renal crisis* in three women, characterized by malignant hypertension and renal failure that was not considered different from that of nonpregnant women with systemic sclerosis during the same period. They reported that the risks of preterm delivery, fetal growth restriction, and perinatal mortality were increased but not dramatically so. A higher incidence of prediagnosis early pregnancy wastage was observed in one case-control study (Silman and Black, 1988).

As perhaps expected, dysphagia and reflux esophagitis are aggravated by pregnancy (Steen, 1999). Dysphagia results from loss of esophageal motility due to neuromuscular dysfunction. A decrease in amplitude or disappearance of peristaltic waves in the lower two thirds of the esophagus is seen with manometry. Symptomatic treatment for reflux is described in [Chapter 49](#) (see p. 1114). Chin and colleagues (1995) described a woman with scleroderma who developed a Mallory-Weiss tear from persistent vomiting.

Women with renal insufficiency and malignant hypertension have an increased incidence of superimposed preeclampsia. In the presence of rapidly worsening renal or cardiac disease, pregnancy termination should be considered.

Vaginal delivery may be anticipated, unless the soft tissue thickening wrought by scleroderma produces dystocia requiring abdominal delivery. Tracheal intubation for general anesthesia has special concerns because of limited ability of these women to open their mouths widely (Black and Stevens, 1989). Because of esophageal dysfunction, aspiration is also more likely, and epidural analgesia is preferable.

Contraception. Scleroderma may be associated with subfertility (Lambe and colleagues, 2004). For those who do not choose pregnancy, several reversible contraceptive methods are acceptable. That said, hormonal agents, especially combination oral contraceptives, probably should not be used, especially in women with pulmonary, cardiac, or renal involvement (see [Chap. 32](#), p. 731). Due to the progressive and often unrelenting nature of progressive systemic sclerosis, permanent sterilization should also be considered (see [Chap. 33](#), p. 751).

VASCULITIS SYNDROMES. Inflammation and damage to blood vessels may be primary or due to another disease. Most cases are presumed to be caused by immunopathogenetic mechanisms, specifically, immune-complex deposition. These syndromes are difficult to classify because of overlap. One classification includes systemic necrotizing vasculitis such as polyarteritis nodosa, Wegener granulomatosis, temporal or giant cell arteritis, Takayasu arteritis, Henoch-Schonlein purpura, and cutaneous or hypersensitivity arteritis.

Polyarteritis Nodosa. This type of systemic necrotizing vasculitis is an uncommon disease with protean manifestations. The pathological lesion is necrotizing vasculitis of small and medium-sized arteries. The classic variety is one of the progressive vasculitis syndromes characterized clinically by myalgia, neuropathy, gastrointestinal disorders, hypertension, and renal disease. About a fourth of cases are associated with hepatitis B antigenemia.

Symptoms are nonspecific and vague. Fever, weight loss, and malaise are present in over half of cases. Renal failure, hypertension, and arthralgias are common (Rao and associates, 1998). The diagnosis of polyarteritis nodosa is made on biopsy. Treatment consists of high-dose prednisone plus cyclophosphamide. Using this regimen, a 90-percent long-term remission is expected. Vasculitis due to hepatitis B antigenemia responds to lamivudine (see [Chap. 50](#), p. 1132).

PREGNANCY. Only a few documented cases of polyarteritis nodosa in association with pregnancy have been reported. Although definitive conclusions are unclear, certainly if active arteritis is identified during pregnancy, mortality is high. Owen and Hauth (1989) reviewed the courses of 12 pregnant women. In seven, polyarteritis first manifested during pregnancy, and it was rapidly fatal by 6 weeks postpartum. The diagnosis was not made until autopsy in six of the seven women. Four women continued pregnancy, resulting in one stillborn and three successful outcomes.

Wegener Granulomatosis. This is a necrotizing granulomatous vasculitis of the upper and lower respiratory tract and kidney. According to Sneller (1995), common lesions include sinusitis and nasal disease (90 percent), pulmonary infiltrates or nodules (85 percent), glomerulonephritis (75 percent), and musculoskeletal lesions (65 percent). It is uncommon and usually encountered after 50 years of age. Only a few cases have been reported in association with pregnancy (Fields and colleagues, 1991; Luisiri and associates, 1997; Palit and Clague, 1990; Puzner and co-workers, 1994).

Takayasu Arteritis. So-called *pulseless disease*, this syndrome is most prevalent in young women. It is a chronic inflammatory arteritis affecting large vessels. Unlike *temporal arteritis*, which occurs almost exclusively after 55 years of age, the onset of Takayasu arteritis is almost exclusively in patients before age 40. It is associated with abnormal angiography of the upper aorta and its main branches, resulting in upper extremity vascular impairment. Noninvasive methods such as computed tomography or magnetic resonance angiography can be used to detect this disorder prior to the development of severe vascular compromise (Numano and Kobayashi, 1999).

Takayasu arteritis may respond symptomatically to corticosteroid therapy, however, it is not curative. Surgical bypass or angioplasty have improved survival.

Severe renovascular hypertension, cardiac involvement, or pulmonary hypertension worsen pregnancy prognosis. Despite this,

from their review of 14 cases, Nagey and colleagues (1983) reported good pregnancy outcomes. Subsequent reports and reviews support this (Johnston and colleagues, 2002; Langford and Kerr, 2002). When the abdominal aorta is involved, however, pregnancy outcome is disastrous (Sharma and associates, 2000).

Most authors advise that blood pressure be taken in the lower extremity. Epidural analgesia has been advocated for labor and delivery (Langford and Kerr, 2002).

DERMATOMYOSITIS AND POLYMYOSITIS. These are uncommon acute, subacute, or chronic inflammatory diseases of unknown cause involving mainly skin and muscle. Prevailing theories are that the syndromes are caused by viral infections, autoimmune disorders, or both. Polymyositis is a subacute inflammatory myopathy that is frequently associated with one of the autoimmune connective tissue disorders. Dermatomyositis is manifest as a characteristic rash accompanying or preceding weakness. Laboratory manifestations include elevated muscle enzyme levels in serum and an abnormal electromyogram. Confirmation is by biopsy. It usually occurs alone but can overlap with scleroderma or mixed connective tissue disease. The disease usually responds to high-dose corticosteroid therapy, and immunosuppressive drugs such as azathioprine or methotrexate are usually also required (Dalakas and Hohlfeld, 2003).

About 15 percent of adults who develop dermatomyositis have an associated malignant tumor. The time of appearance of the two diseases may be separated by several years. The most common sites of associated cancer are breast, lung, stomach, and ovary. There are only a few reports of dermatomyositis complicating pregnancy. King and Chow (1985) reported five uneventful pregnancies in three women with dermatomyositis. Gutierrez and colleagues (1984) reviewed outcomes in 10 pregnancies among seven women with active disease and found three abortions, three perinatal deaths, and five preterm deliveries. Rosenzweig and colleagues (1989) reviewed 24 pregnancy outcomes in 18 women with primary polymyositis-dermatomyositis. In half, the diagnosis preceded pregnancy. Of these, a fourth had an exacerbation in the second or third trimester. Excluding abortions, there were two perinatal deaths and two growth-restricted neonates. In the other half in whom disease became manifest first during pregnancy, outcomes were less favorable. One woman died 6 weeks postpartum. Excluding abortions, half of the eight pregnancies resulted in perinatal death. Ohno and associates (1992) and Papapetropoulos and co-workers (1998) described similar cases.

The best form of contraception for these women is not known. Contraceptives containing hormones probably should not be used, unfortunately, little data are available. Although sterilization might seem at first to be an obvious choice, some women have mild chronic disease, and others may experience a permanent remission if an associated malignancy is identified and cured.

INHERITED CONNECTIVE TISSUE DISORDERS

MARFAN SYNDROME. This autosomal dominant connective tissue disorder affects both sexes equally with a prevalence of 2 to 3 per 10,000. There appears to be no racial or ethnic basis for the syndrome. The *FBN1* gene that mutates is on the long arm of chromosome 15 (Dietz and colleagues, 2002; Loeys and colleagues, 2002). The *FBN1* gene has a high mutation rate, and there are many mild cases in which the intrinsic connective tissue lesion is subclinical with no effect on longevity.

In severe disease, there is degeneration of the elastic lamina in the media of the aorta, which predisposes to aortic dilatation or dissecting aneurysm. Early death in Marfan syndrome is ultimately caused by either valvular insufficiency and congestive heart failure or rupture of a dissecting aneurysm. Mor-Yosef and colleagues (1988) report an increased frequency of dissecting and ruptured aneurysms during pregnancy, especially in the last trimester. The syndrome was reviewed by Elkayam and associates (1995) and is discussed in detail in [Chapter 44](#) (p. 1034).

EHLERS-DANLOS SYNDROME. This disease is characterized by a variety of changes in connective tissue, including hyperelasticity of the skin. In the more severe types, there is a strong tendency for fatal rupture of any of several arteries to cause either strokes or bleeding. Rupture of the colon or uterus has been described. There are at least 11 types of disease based on skin, joint, or other tissue involvement; some are autosomal dominant, some recessive, and some X-linked. The estimated aggregate prevalence is about 1 in 5000 (Prockop and colleagues, 2001). Types I, II, and III are autosomally dominant, and each accounts for about 30 percent of cases. There is overlap between these types, and in most, the underlying molecular defect of collagen or procollagen is unknown.

Women with Ehlers-Danlos syndrome have an increased frequency of preterm rupture of membranes, preterm delivery, and antepartum and postpartum hemorrhage. Tissue fragility makes episiotomy repair and cesarean delivery difficult. Sorokin and colleagues (1994) surveyed women members of the Ehlers-Danlos National Foundation. They reported a stillbirth rate of 3 percent, a preterm delivery rate of 23 percent, a cesarean delivery rate of 8 percent, and problematic postpartum bleeding in 15 percent. Case reports and literature reviews have been provided by Hordnes (1994) and Sakala and Harding (1991).

55. Neurological and Psychiatric Disorders

INTRODUCTION

Neurological and psychiatric disorders during pregnancy are as common as they are in all women of reproductive age, if not more so. In some cases, pregnancy may predispose to some of these disorders, or it may act to worsen them. For example, Bell palsy and benign intracranial hypertension appear to be more common during pregnancy. Depression, a common affliction of young women, is definitely linked to pregnancy and the puerperium.

NEUROLOGICAL DISORDERS

Neurological diseases are relatively common in women of childbearing age. Many of these disorders once precluded childbearing, but therapeutic advances have changed this. Currently, many women with chronic neurological disease become pregnant, and most of these conditions are compatible with a successful pregnancy outcome. Neurological diseases do contribute to maternal mortality (Shehata and Okosun, 2004), however, and most affected pregnant women require special therapy and entail specific risks with which the clinician should be familiar.

Diagnosis of Neurological Disease During Pregnancy.

Most women with chronic neurological disease have been diagnosed before pregnancy. Occasionally, however, new neurological symptoms arise during gestation and must be distinguished from complications of pregnancy. Because neurological symptoms may involve cognitive as well as neuromuscular functions, they must also be distinguished from psychiatric disorders. In general, pregnant women should receive the same evaluation as other patients, and if indicated, the techniques discussed subsequently should not be withheld.

Central Nervous System Imaging.

Various imaging techniques have been developed during the past 30 years that have revolutionized the visualization of anatomical lesions responsible for neurological disease.

Computed tomography (CT) and *magnetic resonance imaging (MRI)* have opened new vistas for the diagnosis, classification, and management of many neurological and psychiatric disorders. As discussed in [Chapter 41](#) (see p. 979), both are safe during pregnancy (see [Table 41-7](#)). In some diseases (e.g., hemorrhagic lesions), cranial CT is preferable to MRI, whereas in others, it is complementary. CT is commonly used whenever rapid diagnosis is necessary to decide between medical and surgical management of an acute neurological catastrophe.

In less acute situations, MRI is often the imaging modality of choice during pregnancy because of its low radiation exposure. It is helpful in diagnosing demyelinating diseases, screening for arteriovenous malformations, evaluating congenital and developmental nervous system abnormalities, identifying posterior fossa lesions, and diagnosing spinal cord diseases. A relative disadvantage is the limited space available to a patient within the scanner, which may hinder monitoring critically ill patients. In addition, the claustrophobic conditions of the scanner may not be tolerated by some pregnant women. Premedication may be beneficial. Alternatively, an open MRI scanner may be used to accommodate claustrophobic patients. Scanning times are longer, however, and image quality may be lower than with standard MRI (Schnitker and Light, 2001). For both MRI and CT, women should be positioned in a left lateral tilt with a wedge under their right hips to avoid hypotension and to diminish aortic pulsations, which may degrade the image.

Cerebral angiography with contrast injection, usually via the femoral artery, is a valuable adjunct to the diagnosis and treatment of some cerebrovascular diseases. *Fluoroscopy* involves more radiation than most radiographic procedures but can be performed if necessary during pregnancy with careful abdominal shielding.

HEADACHE. The most common neurological complaint during pregnancy is headache ([Table 55-1](#)). There are several causes, and their classification was recently updated by the International Headache Society (2004). More than 90 percent of headaches are tension or migraine headaches (Paulson, 1995).

Tension Headache.

Characteristic features of tension headaches include muscle tightness and pain that can persist for hours in the back of the neck and head. There are no associated neurological disturbances. The pain usually responds to rest, massage, application of heat or ice, anti-inflammatory medications, or mild tranquilizers. Patients with recurrent tension headaches may benefit from counseling about stress management, including biofeedback techniques. Headaches may also be a symptom of depression.

Migraine Headache. The term *migraine* describes a periodic, incapacitating neurovascular disorder. It is characterized by episodic attacks of severe headache and autonomic nervous system dysfunction (Goadsby and colleagues, 2002). The International Headache Society (2004) classifies three migraine types based on the presence or absence of an aura and chronicity. Migraine without aura is characterized by a unilateral throbbing headache, nausea and vomiting, or photophobia. About a third of patients have migraine with an aura (classic migraine) with similar symptoms preceded by premonitory neurological phenomena such as visual scotoma or hallucinations. This type of migraine can sometimes be averted if medication is taken at the first premonitory sign. Chronic migraine is defined as migraine headache occurring at least 15 days each month for more than 3 months without obvious cause.

Migraines may begin in childhood, peak in adolescence, and tend to diminish in both frequency and severity with advancing years. Stewart and colleagues (1992) reported that 18 percent of women and 6 percent of men suffer from migraine headaches at some time. Migraines are especially common in young women and have been linked to hormone levels in an as yet unclear relationship. The exact pathophysiology of migraines is uncertain, but they occur when neuronal dysfunction leads to decreased cortical blood flow, activation of vascular and meningeal nociceptors, and stimulation of the trigeminal sensory

neurons (Silberstein, 2004). Kruit and co-workers (2004) recently described a predilection for the posterior circulation. In some cases, migraine is associated with stroke (Tietjen, 2000). Tzourio and colleagues (1995) reported a three- to sixfold increase in ischemic stroke in young women with migraines, although the absolute risk was small; it increased from 10 to 20 per 100,000. Migraineurs who smoked or used oral contraceptives, however, were particularly vulnerable and had a 10- to 14-fold increased risk.

EFFECTS OF PREGNANCY. From studies with a total of more than 1500 pregnant women, approximately 70 percent of women with migraines experience a dramatic improvement during pregnancy (Uknis and Silberstein, 1991; Welch, 1994). Menstrual migraine typically improves, most likely because it is provoked by the drop in estrogen levels just before menstruation and is thus relieved by the high estrogen levels of pregnancy (Aube, 1999; Fettes, 1997). Women with menstrual migraines can expect a relapse postpartum.

For nonmenstrual migraine headaches, pregnant women perceive either no change or worsening of symptoms. About 15 percent of migraine headaches appear for the first time during pregnancy and often develop in the first trimester, when hormone levels are rising (Aube, 1999). These migraines are more likely to be preceded by an aura. Because migraine symptoms are similar to those of other more serious disorders, the new onset of neurological symptoms should prompt a complete evaluation, including neuroimaging as needed.

MANAGEMENT. Most migraine headaches respond to simple analgesics such as aspirin, ibuprofen, or acetaminophen, especially if given early. Butalbital-containing products are no more effective than placebo (Wenzel and Sarvis, 2002). Severe headaches should be treated aggressively with intravenous hydration, parenteral antiemetics, and opioids if necessary (American College of Obstetricians and Gynecologists, 2002c). Antiemetics, such as promethazine, are frequently needed and are commonly given in combination with meperidine. One randomized trial involving 179 migraineurs showed that acupuncture is as effective as sumatriptan for early treatment of migraine (Melchart and colleagues, 2003).

Almost half of migraines with aura can be aborted by ergotamine. These potent vasoconstrictors should be avoided in pregnancy (Au and colleagues, 1985). Anomalies in exposed fetuses have been reported (Graham, 1983; Hughes, 1988; Verloes, 1990, and all their colleagues). Importantly, when given parenterally to the peripartum woman, ergotamine may be associated with myocardial infarction, pulmonary edema, bronchospasm, bowel infarction, and stroke (Reprotox, 2003a).

Triptans are serotonin 5-HT_{1B/2D}-receptor agonists found in the cranial arteries and dura mater. They relieve headaches by causing intracranial vasoconstriction and are highly effective in the treatment of migraine headaches (Silberstein, 2004). The drugs also relieve nausea and vomiting and greatly reduce the need for analgesics. At least five are available to be given orally, by injection, as rectal suppository, or as a nasal spray. Sumatriptan has not been studied extensively in pregnancy, but it appears to be safe (Reprotox, 2003b). Three series totaling 768 exposures have shown no adverse pregnancy effects (Kallen, 2001; Olesen, 2000; O'Quinn, 1999, and all their colleagues). The manufacturer's Sumatriptan and Naratriptan Registry (2002) of 348 cases has also failed to identify any teratogenic effects.

For women with frequent migraine headaches, prophylactic therapy is indicated (American College of Obstetricians and Gynecologists, 2002c). Amitriptyline, 10 to 150 mg/day; propranolol, 20 to 80 mg three times daily; atenolol, 50 to 100 mg/day; or labetalol, 50 to 150 mg two times daily, are safe in pregnancy and have been used with success (Dey and associates, 2002; Kaniecki, 2003).

SEIZURE DISORDERS. Approximately 0.5 to 2.0 percent of the population, including as many as 1.1 million American women of childbearing age, have epilepsy, which complicates 1 in 200 pregnancies (Brodie and Dichter, 1996; Yerby, 1994). Convulsive disorders are the second most prevalent and certainly the most serious common neurological condition encountered in pregnant women. Epilepsy itself can alter fetal development and can affect the course of pregnancy, labor, and delivery. In addition, the teratogenic effects of several anticonvulsant medications are unquestioned. On the other hand, pregnancy can exacerbate epilepsy by altering the metabolism of these anticonvulsant medications.

Pathophysiology.

A seizure is defined as a paroxysmal disorder of the central nervous system characterized by an abnormal neuronal discharge with or without loss of consciousness. Epilepsy encompasses a number of different syndromes whose cardinal feature is a predisposition to recurrent unprovoked seizures (Chang and Lowenstein, 2003). This definition excludes seizures due to acute metabolic derangement or an acute central nervous system insult. Epileptic syndromes fit into two broad categories, which are subsequently discussed.

Partial seizures originate in one localized area of the brain and affect a correspondingly localized area of neurological function. They are believed to result from trauma, abscess, tumor, or perinatal factors, although a specific lesion is rarely demonstrated. *Simple motor seizures* start in one region of the body and progress toward other areas on the same side of the body, producing tonic and then clonic movements. Simple seizures can affect sensory function or produce autonomic dysfunction or psychological changes. Consciousness is usually not lost, and recovery is rapid. *Partial seizures* can secondarily generalize, producing loss of consciousness and convulsions. *Complex partial seizures*, also called *temporal lobe* or *psychomotor seizures*, usually involve clouding of the consciousness.

Generalized seizures involve both hemispheres of the brain simultaneously and may be preceded by an aura before an abrupt loss of consciousness. There is a strong hereditary component. In grand mal seizures, loss of consciousness is followed by tonic contraction of the muscles and rigid posturing, and then by clonic contractions of all extremities while the muscles gradually relax. Return to consciousness is gradual, and the patient may remain confused and disoriented for several hours. *Absence seizures*, also called *petit mal seizures*, are a form of generalized epilepsy that involve a brief loss of consciousness without muscle activity and are characterized by immediate recovery of consciousness and orientation.

Accurate seizure classification and consideration of the risks and benefits specific to each medication must factor into the appropriate selection of any anticonvulsant (see [Chap. 14](#), p. 347 and [Table 14-4](#)).

Causes of Seizures. Some identifiable causes of convulsive disorders in adolescents and young adults include trauma, alcohol

and other drug-induced withdrawals, brain tumors, biochemical abnormalities, or arteriovenous malformations. A search for all of these is necessary when a new-onset seizure disorder is encountered in a pregnant woman. The diagnosis of idiopathic epilepsy is one of exclusion. Lumbar puncture, skull radiography, and arteriography have been largely replaced by CT, MRI, or both.

Epilepsy During Pregnancy.

The major pregnancy-related threats to women with epilepsy are an increase in seizure frequency and risk of congenital malformations in their fetuses. Hollingsworth and Resnik (1988) reviewed studies involving 2385 pregnancies and found increased seizure frequency in 35 percent of women, decreased frequency in 15 percent, and no change in 50 percent. Increased seizure frequency is often associated with subtherapeutic anticonvulsant levels or a lower seizure threshold, or both. Subtherapeutic levels are caused by a variety of factors, some of which are amenable to therapeutic intervention. Nausea and vomiting lead to missed doses; decreased gastrointestinal motility and the use of antacids reduces drug absorption; expanded intravascular volume lowers serum drug levels; induction of hepatic, plasma, and placental enzymes increases drug metabolism; and increased glomerular filtration hastens drug clearance. These changes are minimized in part by the fact that decreased protein binding during pregnancy increases free drug levels. In addition, women often self-discontinue medication because of teratogenicity concerns. Appropriate counseling can often avert this pitfall.

The seizure threshold can be affected by a variety of pregnancy-related factors, including exhaustion from sleep deprivation and hyperventilation and pain during labor. Women with the most recalcitrant disease are susceptible to minor changes and are at greatest risk of increased seizure frequency during pregnancy.

Women with epilepsy who take anticonvulsant medications have an increased risk of congenital malformations in the fetus (see [Chap. 14](#), p. 347). Recent evidence suggests that untreated epilepsy is not associated with increased malformations (Holmes and colleagues, 2001). Almost 10 percent of the offspring of individuals with epilepsy develop a seizure disorder later in life.

Early studies suggested that women with epilepsy have an increased risk of a variety of pregnancy complications other than seizures, but much of these data were flawed by ascertainment bias and failure to address the confounding effects of alcohol and drug abuse and of socioeconomic factors. More recent data indicate only a small increase in risk. For example, Olafsson and colleagues (1998) performed a population-based study of all women with epilepsy who gave birth in Iceland during a 19-year period. Although these women had a twofold increased cesarean delivery rate, the risk of other adverse obstetrical events was similar to that for the general population. The risk of major congenital malformations was increased 2.7-fold in the neonates of women with epilepsy, but the mean birthweight and perinatal mortality were not different. In a cohort study in Montreal, Richmond and co-workers (2004) found that women with epilepsy had an increased incidence of nonproteinuric hypertension and labor induction as well as increased cardiovascular anomalies in their children.

Management

PRECONCEPTIONAL COUNSELING. For a number of reasons, women with epilepsy may benefit from preconceptional counseling (see [Chap. 7](#), p. 191). This discussion should address the optimal anticonvulsant management, including a switch to the least teratogenic drug if possible or a reduction in the number of anticonvulsant types prescribed. Although some clinicians recommend that medications be limited if possible to the older, more traditional anticonvulsants, namely, phenytoin, carbamazepine, and phenobarbital, some newer drugs may actually have less teratogenic potential. Eight newer anticonvulsant drugs that are available were recently reviewed by LaRoche and Helmers (2004a, b).

Other topics should include diet; activity, including refraining from driving during the first trimester if pregnancy-associated vomiting prevents therapeutic drug levels; prenatal fetal evaluation; and optimal labor and delivery management. Folic acid supplementation should also be given.

Postpartum contraception should be discussed. Anticonvulsants such as phenobarbital, primidone, phenytoin, and carbamazepine may cause breakthrough bleeding and oral contraceptive failure because they induce hepatic P₄₅₀ microsomal enzyme systems, which in turn increase estrogen metabolism. Although an increased failure rate is speculative, the American College of Obstetricians and Gynecologists (1990) has recommended that oral contraceptives containing 50 µg of estrogen be used in women with epilepsy who take anticonvulsants. Oral contraceptives are not associated with exacerbation of seizures.

PRENATAL CARE. The major goal of pregnancy management is seizure prevention. To accomplish this, treatment for nausea and vomiting should be provided, seizure-provoking stimuli should be avoided, and medication compliance should be emphasized. In general, anticonvulsant medication should be maintained at the lowest dosage associated with seizure control. Although some clinicians routinely monitor serum drug levels during pregnancy, antenatal serum drug levels may be unreliable because of altered protein binding. Free or unbound drug levels, although more helpful, are not widely available. Lander and Eadie (1991) reported that seizure control is not improved by routine drug level monitoring. For these reasons, drug levels may be measured only following seizures or if noncompliance is suspected.

Some investigators recommend vitamin K for women taking phenytoin because it has been implicated in functionally defective neonatal vitamin K-dependent clotting factors II, VII, IX, and X. Cornelissen and associates (1993) demonstrated diminished vitamin K levels in 50 percent of cord blood samples from women taking anticonvulsants compared with 20 percent of those from women in a control group. It is not clear, however, that vitamin K crosses the placenta, and hemorrhage in the newborn is usually prevented by prompt parenteral administration of vitamin K (see [Chap. 29](#), p. 676). For these reasons, many clinicians do not administer vitamin K to pregnant women with epilepsy.

A midpregnancy specialized ultrasonographic examination may aid in identifying anomalies (see [Chap. 16](#), p. 392). Tests of fetal well-being are generally not performed for epilepsy alone but may be indicated if there is poor fetal growth, inadequate seizure control, or co-morbid maternal conditions.

CEREBROVASCULAR DISEASES. These diseases refer to abnormalities of one or more blood vessels of the brain, with the majority involving the arterial system. The resultant pathology is termed *stroke*, which is defined as acute ischemic neurological damage caused by embolization or occlusion — *ischemic stroke* — or rupture of a cerebral vessel —

hemorrhagic stroke (Warlow and colleagues, 2003). Some causes of stroke are shown in [Table 55-2](#).

The Pregnancy Mortality Surveillance System, initiated in 1987 by the Centers for Disease Control and Prevention (2003) to monitor maternal deaths in all 50 states, reported that stroke caused 5 percent of maternal deaths from 1991 to 1999 and accounted for approximately 23 deaths per year. Analyses of several large data bases in the United States have shown that there are approximately 13 to 18 cases of stroke per 100,000 deliveries (Lanska and Kryscio, 1998, 2000). In Toronto, Jaigobin and Silver (2000) identified 34 cases of stroke among 50,700 women delivered at one hospital—an incidence of 67 per 100,000. In another study that included more than 1.4 million deliveries, the co-variables most significantly associated with peripartum stroke included cesarean delivery; hypertension; and fluid, electrolyte, and acid-base disorders (Lanska and Kryscio, 2000). In a population-based cohort of more than 1 million Swedish pregnant women, severe preeclampsia was associated with a sixfold increased risk of stroke, and there was almost a 100-fold risk of stroke around the time of delivery (Ros and associates, 2002).

The postpartum period is the time of greatest risk, especially for hemorrhagic stroke. Kittner and colleagues (1996) reviewed the records of all women from 15 to 44 years of age in the Central Maryland and Washington, D.C., area who were diagnosed with stroke between 1988 and 1991. Among 254 cases, 31 were associated with pregnancy. The relative risk of stroke was 0.7 during pregnancy but increased to 8.7 postpartum. The relative risk of intracerebral hemorrhage was 2.5 during pregnancy and increased to 28-fold postpartum.

Ischemic Stroke.

These may result from thrombosis or thromboembolism of an artery or from venous thrombosis.

CEREBRAL ARTERY THROMBOSIS. The vast majority of thrombotic strokes are caused by atherosclerosis and thus typically affect older individuals. The internal carotid artery is the most commonly affected site, and the majority of cases are preceded by one or more transient ischemic attacks. At the time of stroke, a patient may present with sudden onset of severe headache, hemiplegia or other neurological deficits, or seizures. A thorough evaluation should be performed, including serum lipid profile, echocardiography, and cranial CT or angiography as necessary. The patient should also be evaluated for antiphospholipid antibody syndrome (see [Chap. 54](#), p. 1215). Cerebral thrombosis and other thrombotic complications develop more frequently in women who have antiphospholipid antibodies. These may cause as many as a third of ischemic strokes in otherwise healthy patients younger than 50 years (Branch, 1990).

Therapy for thrombotic stroke includes rest, analgesia, and aspirin. Although there is evidence that prompt treatment with low-molecular-weight heparin or recombinant tissue plasminogen activator (t-PA or alteplase) may improve outcome with acute ischemic stroke, this is not without risk (Warlow and colleagues, 2003). To be effective, t-PA must be administered without delay, and this can result in it being given before radiological evaluation confirms arterial occlusion. Caplan and colleagues (1997) estimated that among every 100 patients who are eligible for thrombolysis according to current guidelines, 25 or more do not have arterial occlusions. These individuals have a 5- to 10-percent risk of intracerebral hemorrhage from the therapy.

The recurrence risk for ischemic stroke in association with pregnancy is low, unless a specific, persistent cause is identified. Lamy and colleagues (2000) studied 489 consecutive women of reproductive age with stroke, of which 373 were ischemic. There were 37 women with an ischemic stroke during pregnancy or the puerperium, and none of their 24 subsequent pregnancies was complicated by recurrent stroke. In another report by Coppage and associates (2004), 23 women with strokes before pregnancy due to a variety of causes had 35 subsequent pregnancies without a recurrent stroke. In the report from the Antiphospholipid Antibodies and Stroke Study Investigators (APASS Investigators, 2004), there was no difference in the risk of recurrent ischemic stroke in 1770 nonpregnant patients with or without anticardiolipin or antiphospholipid antibodies if preventative treatment was given with warfarin or aspirin.

CEREBRAL EMBOLISM. This usually involves the middle cerebral artery and is more common during the latter half of pregnancy or early puerperium (Lynch and Nelson, 2001). The diagnosis can be made with confidence only after thrombosis and hemorrhage have been excluded, which may be difficult. Because cerebral artery embolization and thrombosis are both followed by infarction, they can be difficult to distinguish. The diagnosis of thromboembolism is more certain if an embolic source is identified. The most common origin of emboli is a cardiac arrhythmia, especially atrial fibrillation associated with rheumatic valvular disease. Emboli also may arise from rheumatic heart disease without arrhythmia or from mitral valve prolapse. Finally, emboli from infective endocarditis must be considered (Cox and associates, 1988). Management of embolic stroke consists of supportive measures and consideration of anticoagulation.

CEREBRAL VENOUS THROMBOSIS. Lateral or superior sagittal venous sinus thrombosis usually occurs in the puerperium, and often in association with preeclampsia, sepsis, or thrombophilias. Venous thrombosis is more common in patients with inherited thrombophilias, lupus anticoagulant, or antiphospholipid antibodies (see [Chap. 54](#), p. 1215). It has also been reported in association with thyrotoxicosis (Ra and co-workers, 2001).

Cerebral venous thrombosis is rare in developed countries, with reported incidences ranging from 1 in 11,000 to 1 in 45,000 (Cross, 1968; Lanska and Kryscio, 1997; Simolke, 1991, and all their colleagues). In contrast, because of the link with sepsis and preeclampsia, cerebral venous thrombosis remains common in undeveloped countries. Srinivasan (1984) reported its incidence in Madurai, India, to be 1 in 250 deliveries.

Headache is the most common presenting symptom (73 percent) and 10 percent of these women have convulsions (Cantu and Barinagarmenteria, 1993). MRI is the procedure of choice (Cartlidge, 2000). Management includes anticonvulsants to control seizures and antimicrobials if septic thrombophlebitis is suspected. Heparin anticoagulation is controversial, because spontaneous bleeding may develop. Donaldson and Lee (1994) recommend that the consequences of heparin be risked, especially if there is no hemorrhagic infarction demonstrated by tomography. In a small randomized study, Einhaupl and associates (1991) described improved outcomes in nonpregnant patients given heparin therapy. In all cases the prognosis is guarded, but survivors can expect to have a recurrence rate of only 1 to 2 percent, including during subsequent pregnancy (Mehraein and colleagues, 2003; Pathan and Kittner, 2003; Preter and co-workers, 1996).

Hemorrhagic Stroke. Two distinct categories of hemorrhagic stroke are recognized.

INTRACEREBRAL HEMORRHAGE. Bleeding into the substance of the brain most commonly is caused by spontaneous rupture of small vessels damaged by chronic hypertension (Qureshi and colleagues, 2001; Takebayashi and Kaneko, 1983). In pregnancy, there often is hypertension with superimposed preeclampsia, or occasionally pure preeclampsia ([Fig. 55-1](#)). Hemorrhage can also be precipitated by crack cocaine abuse (Witlin and associates, 2000). Intracerebral hemorrhage has a higher mortality rate than subarachnoid hemorrhage because of its location (Cartlidge, 2000). In the series reported by Jaigobin and Silver (2000), 3 of 13 pregnant women with hemorrhagic stroke died. These experiences underscore the importance of proper management for acute hypertension to prevent cerebrovascular pathology (see [Chap. 34](#), p. 776).

SUBARACHNOID HEMORRHAGE. These bleeds are more likely caused by an underlying cerebrovascular malformation in an otherwise normal patient. Ruptured aneurysms cause 80 percent of all subarachnoid hemorrhages, and ruptured arteriovenous malformations (AVMs), coagulopathies, angiopathies, venous thromboses, infections, drug abuse, tumors, and trauma cause the remainder. Rupture of a cerebral aneurysm or angioma or bleeding from an AVM occurs in 1 in 75,000 pregnancies. This incidence does not differ from that in the general nonobstetrical population, but the mortality rate during pregnancy is reported to be as high as 35 percent (Dias and Sekhar, 1990; Minielly and associates, 1979). Case-control studies from Japan and New Zealand found that nulligravidity significantly increased the risk of subarachnoid hemorrhage (Mhurchu and co-workers, 2001; Okamoto and colleagues, 2001).

Intracerebral Aneurysm. According to Bendok and colleagues (1998), ruptured intracerebral aneurysms cause 25 percent of all cerebrovascular deaths and 8 percent of all strokes. During pregnancy, bleeding from aneurysms is three times more common than bleeding from AVMs (Dias and Sekhar, 1990). Although aneurysms are more likely to bleed during the second half of pregnancy, about 20 percent bleed during the first half (Dias and Sekhar, 1990). As in the nonpregnant population, most aneurysms identified during pregnancy are in the circle of Willis and 20 percent are multiple (Stoodley and co-workers, 1998). The cardinal symptom is sudden severe headache, accompanied by visual changes, cranial nerve abnormalities, focal neurological deficits, or altered consciousness. Patients typically have signs of meningeal irritation, tachycardia, hypertension, low-grade fever, leukocytosis, and proteinuria.

Prompt diagnosis and treatment may prevent potentially lethal complications. Noncontrast CT of the head is the preferred test initially, because MRI may not show the changes of acute hemorrhage until several hours into its evolution (Warlow and colleagues, 2003). If the CT scan is normal but the clinical picture strongly suggests subarachnoid hemorrhage, the cerebrospinal fluid should be examined to confirm the presence of blood. If found, angiography is done to locate the lesion (Roman and associates, 2004).

Treatment includes bed rest, analgesia, and sedation, with neurological monitoring and strict control of blood pressure, usually best accomplished in an intensive care unit. The decision to attempt repair of a potentially accessible aneurysm during pregnancy depends in part on the risk of recurrent hemorrhage and the risks of surgery. With conservative treatment only, the risk of subsequent bleeding from the aneurysm is 20 to 30 percent for the first month and then 3 percent per year. Recurrent hemorrhage leads to death in 70 percent of these patients (Bendok and colleagues, 1998). Surgical excision may be recommended for accessible aneurysms. For women near term, cesarean delivery followed by craniotomy is a consideration. If neurosurgery is performed remote from term, fetal conditions should be optimized. Although fetuses generally tolerate hypothermia well, hypotension is problematic and should be avoided. There appears to be no advantage to pregnancy termination unless there is associated preeclampsia.

Some authorities allow vaginal delivery if labor occurs at least at 2 months after hemorrhage and subsequent repair of an aneurysm. A major obstetrical problem concerns the management of delivery in women who survive subarachnoid hemorrhage, but in whom surgical repair is not done. Some authorities, but certainly not all, recommend against bearing down and thus favor cesarean delivery (Cartlidge, 2000). Others recommend cesarean delivery only if the aneurysm bled in the third trimester (Wiebers, 1988).

Arteriovenous Malformations. The incidence of bleeding from cerebral AVMs is not increased during pregnancy (Finnerty and co-workers, 1999). In a study from Parkland Hospital, Simolke and associates (1991) encountered only one case in nearly 90,000 deliveries ([Fig. 55-2](#)). Although some data suggest that AVMs bleed with similar frequency throughout gestation, Dias and Sekhar (1990) reported increased frequency with advancing gestational age. Data also show that the risk of bleeding from an AVM increases with maternal age (Karlsson and colleagues, 1997).

In nonpregnant patients, there is no consensus on whether all of these lesions should be resected, even when they are accessible. The risk of recurrent hemorrhage in unoperated lesions is high. Without surgery 5 to 7 percent will bleed again within the first year and 2 to 3 percent per year thereafter (Itoyama and associates, 1989). The mortality rate in nonpregnant patients is 10 percent after the first hemorrhage, 13 percent after the second hemorrhage, and approximately 20 percent after subsequent hemorrhages (Wilkins, 1985). The mortality rate is reported to be even higher during pregnancy. Indeed, 28 percent of pregnant women die after the first bleeding event (Dias and Sekhar, 1990).

The decision to operate should be based on neurosurgical considerations (Finnerty and associates, 1999). Because of the high risk of recurrent hemorrhage from an unresected or inoperable lesion, the route of delivery following a bleeding episode during pregnancy is critical. As for ruptured aneurysm, it seems best to avoid vaginal delivery if the malformation was not surgically excised.

Figure 55-1. Cranial computed tomography showing a massive, ultimately fatal, right-sided intracerebral hemorrhage with associated contralateral hydrocephaly. The 23-year-old primigravid woman refused hospitalization for gestational hypertension, and she next was seen comatose with blood pressures as high as 260/160 mm Hg.

Figure 55-2. Magnetic resonance imaging of a left-sided frontal lobe arteriovenous malformation. The lesion caused subarachnoid bleeding at 29 weeks in a 24-year-

old primigravida who presented with severe headache, nausea, and vomiting. (From Simolke and colleagues, 1991, with permission.)

DEMYELINATING OR DEGENERATIVE DISEASES. Demyelinating diseases compose a group of neurological disorders that involve focal or patchy destruction of central nervous system myelin sheaths accompanied by an inflammatory response. The degenerative diseases are multifactorial and are characterized by progressive neuronal death.

Multiple Sclerosis.

The yearly incidence of multiple sclerosis (MS) is 7 per 100,000, and the prevalence of MS is 120 per 100,000 (Compston and Coles, 2002). Because MS affects women twice as often as men and usually begins in the 20s and 30s, women of reproductive age are most susceptible. Susceptibility appears to be genetic. Most disease sufferers are of northern European descent, and the familial recurrence rate is 15 percent (Compston and Coles, 2002). The incidence of MS in offspring is increased 15-fold. Genes conferring susceptibility include the major histocompatibility complex and $TNF\alpha$.

MS results from the autoimmune destruction of oligodendrocytes, the cells that synthesize myelin. It is theorized that this abnormal immune response is triggered in susceptible individuals by exposure to certain bacteria and viruses, possibly *Chlamydia pneumoniae*, human herpesvirus 6, or Epstein-Barr virus (Derfuss and colleagues, 2001; Levin and associates, 2003).

There are four forms of MS (Confavreux and colleagues, 2000; Lublin and Reingold, 1996). As many as 85 percent of affected individuals present with *relapsing-remitting MS*, characterized by unpredictable recurrent episodes of focal or multifocal neurological dysfunction followed by full recovery. Some relapses appear to be triggered by infection, and over time, relapses lead to persistent deficits. Eventually there is *secondary progression*, when the disease pursues a progressive downhill course after each relapse. A small number of patients present initially with *primary progressive MS*, which is characterized by gradual progression of disability from the time of initial diagnosis. *Progressive-relapsing MS* refers to primary progressive MS with apparent relapses.

Classic symptoms include loss of vision or diplopia, and more than 40 percent of patients have optic neuritis during the course of disease. In fact, 75 percent of women who are diagnosed with isolated optic neuritis develop multiple sclerosis within 15 years. Other common symptoms are dysarthria, muscle weakness, hyperreflexia, spasticity, paresthesia, ataxia and intention tremor, nystagmus, diminished vibratory sense, and bladder dysfunction. The diagnosis is one of exclusion and is confirmed by cerebrospinal fluid analysis and MRI. The characteristic multifocal white matter lesions, termed plaques, are present in more than 95 percent of patients and represent discrete areas of demyelination (Compston and Coles, 2002).

The goal of treatment is to arrest the disease and also to provide symptomatic relief. Several studies have shown that decreasing the amount of inflammation during the initial episode improves the disease course, in part by reducing the number and extent of white matter lesions. For example, weekly treatment with *interferon- β 1a* for 2 years significantly reduces progression of MS (Comi and colleagues, 2001). Because depression, thrombotic thrombocytopenic purpura, and various autoimmune reactions are side effects of treatment, patients receiving interferon should be closely monitored (Walther and Hohlfeld, 1999).

Natalizumab is an α_4 -integrin antagonist that reduced the development of brain lesions and lowered the frequency of relapses in patients with relapsing MS during a 6-month trial (Miller and colleagues, 2003). Other medications used to diminish inflammation include *glatiramer acetate*, a mixture of synthetic polypeptides that interferes with T-cell function; *azathioprine*, which inhibits lymphocyte proliferation; and *mitoxantrone*, which prevents DNA synthesis and repair in rapidly dividing cells (Edan, 1997; Johnson, 1995; Palace, 1997, and all their co-workers). Data concerning the safety of these drugs in pregnancy are limited, but none of the drugs appears to be teratogenic (Reprotox, 2002).

Corticosteroids may diminish the severity of acute flares, but they have no effect on permanent disability. Although several investigators have found positive effects with the use of intravenous immunoglobulin for the treatment of relapsing-remitting MS, Hommes and associates (2004) found no clinical benefit in patients with secondary progressive MS. Symptomatic relief can be provided by analgesics; carbamazepine, phenytoin, or amitriptyline for neurogenic pain; baclofen for spasticity; α_2 -adrenergic blockade to relax the bladder neck; and cholinergic and anticholinergic drugs to stimulate or inhibit bladder contractions.

EFFECTS OF PREGNANCY. Pregnancy appears neither to precipitate MS nor, in most cases, to have a deleterious effect on its course. Several studies indicate that women who have been pregnant have less deterioration than those who have not (Damek and Shuster, 1997). Acute exacerbation of MS during the first few months postpartum is common, possibly because of the reversal of the relative immune suppression of pregnancy (Cartlidge, 2000; Schneider and associates, 1996). In a review of eight observational studies of more than 1000 pregnancies, Abramsky (1994) found that the disease worsened during pregnancy in only 10 percent of women, but relapsed in a third in the puerperium. Roulet and colleagues (1993) reported a 43 percent postpartum exacerbation rate. Conversely, Sadovnick and co-workers (1994) found that postpartum relapses were no more common than in nonpregnant controls.

Uncomplicated MS usually has no adverse effects on pregnancy outcome. Women may become fatigued more easily, and those with bladder dysfunction are prone to urinary infection. Labor is unaffected, and the indications for cesarean delivery are obstetrical. Women with spinal lesions at or above T6 are at risk for autonomic dysreflexia (see p. 1240). Because of this, epidural analgesia is recommended (Weinreb, 1994). The incidence of postpartum exacerbation is not altered by epidural analgesia (Bader, 1994).

Postpartum exacerbations may prevent women from breast feeding. These may also inhibit the ability to provide general newborn care, and the need for assistance during this period should be anticipated (Nelson and colleagues, 1988).

Huntington Disease. This degenerative disease of the cerebral cortex and basal ganglia is characterized by a combination of choreoathetotic movements and progressive dementia. Because the mean age of onset is 40 years, Huntington disease rarely complicates pregnancy. It is inherited as an autosomal dominant trait, and prenatal diagnosis is now possible (see [Chap. 12](#), p. 299). Prenatal screening is controversial because pregnancy termination is rarely considered for a late-onset adult disease.

MYASTHENIA GRAVIS. This immune-mediated neuromuscular disorder affects about 1 in 10,000 persons and has a predilection for women of childbearing age. The etiology is unknown, but genetic factors likely play a role; for example, it is more common in those with the HLA-B8 antigen. The pathological basis of the disease is IgG-mediated destruction of postsynaptic striated muscle acetylcholine receptors. Without adequate receptors, acetylcholine produces diminished end plate action potentials that inconsistently trigger muscle action potentials, resulting in weakened muscle contractions. Accordingly, myasthenia gravis is characterized by easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. Cranial muscles are involved early and disparately, and diplopia and ptosis are common. Facial muscle weakness causes difficulty in smiling, chewing, and speaking. In 85 percent of patients, the weakness becomes generalized.

The disease course is marked by exacerbations and remissions, especially when it first becomes clinically apparent. Unfortunately, remissions are not always complete and are seldom permanent. Systemic diseases, concurrent infections, and even emotional upset may precipitate exacerbations or crises, of which there are three types: *myasthenic crises*, characterized by severe muscle weakness, inability to swallow, and respiratory muscle paralysis; *refractory crises*, characterized by the same symptoms but unresponsive to the usual therapy; and *cholinergic crises*, in which excessive cholinergic medication leads to nausea, vomiting, muscle weakness, abdominal pain, and diarrhea. All three can be life threatening, but a refractory crisis is a medical emergency. Women with bulbar myasthenia are at particular risk during a crisis because they may be unable to swallow or even ask for help.

Myasthenia is manageable but not curable. About 75 percent of patients have thymic hyperplasia or a thymoma, and some patients, especially young women, respond to thymectomy with remission (Cartlidge, 2000). Anticholinesterase medications such as *pyridostigmine*, an analogue of neostigmine, bring about improvement by impeding degradation of acetylcholine but seldom produce normal muscle function. Ironically, the side effects of overdose are increased weakness, which is sometimes difficult to differentiate from myasthenic symptoms. Nearly all patients respond to immunosuppressive therapy with corticosteroids, azathioprine, and cyclosporine (Cartlidge, 2000). Cyclophosphamide is used for refractory cases. Short-term clinical improvement has been reported following intravenously administered immunoglobulin or plasmapheresis.

Effects of Pregnancy. Because the greatest period of risk is within the first year following diagnosis, it is preferable to postpone pregnancy until there is sustained symptomatic improvement (Cartlidge, 2000). Antepartum management includes close observation with liberal bed rest and prompt treatment of any infections. Most patients respond well to pyridostigmine administered every 3 to 4 hours. Those in remission who become pregnant while taking corticosteroids or azathioprine should continue these. Acute onset of myasthenia or its exacerbation demands prompt hospitalization and supportive care. *Plasmapheresis* should be used for emergency situations, taking care not to provoke maternal hypotension or hypovolemia (Drachman, 1994). *Thymectomy* has been performed during pregnancy in cases refractory to medical management (Ip and colleagues, 1986).

Pregnancy does not appear to affect the course of myasthenia gravis. The enlarging uterus may compromise respiration, and the fatigue common to most pregnancies may be tolerated poorly. The disease course during pregnancy is unpredictable. In two observational studies of 123 women, about 20 percent worsened during pregnancy (Batocchi and associates, 1999; Djelmis and co-workers, 2002). Maternal deaths are usually due to complications of myasthenia or its treatment (Plauche, 1991).

Myasthenia gravis does not affect smooth muscle, and most women with the disease have normal labor, which they tolerate well. Oxytocin can be administered as necessary. Close observation and prompt respiratory support are essential. Narcotics must be used with care to avoid respiratory depression. In addition, any drug with a curare-like effect must be avoided; examples include magnesium sulfate, muscle relaxants used with general anesthesia, and aminoglycoside antimicrobials. Amide-type local anesthetic agents should be used for epidural analgesia for labor (Bader, 1994). Cesarean delivery is for obstetrical indications, and regional analgesia is preferred unless there is significant bulbar involvement or respiratory compromise. During second-stage labor, some women may have impairment of voluntary expulsive efforts, and forceps delivery may be necessary.

Neonatal Effects.

In most patients with myasthenia, acetylcholine-receptor IgG antibodies have been detected, which can cross the placenta and affect the fetus. About 10 to 20 percent of exposed neonates develop symptoms, and in most of these, antibodies are detected (Batocchi and associates, 1999). Neonatal symptoms are most likely if the mother produces autoantibodies directed against embryonic rather than adult acetylcholine receptors (Vernet-der Garabedian and colleagues, 1994). Transient symptomatic myasthenia gravis in an affected neonate typically results in a feeble cry, poor suckling, and respiratory distress. All of these can be corrected by parenteral neostigmine or small doses of edrophonium. Although symptoms usually resolve within 2 to 6 weeks as the antibodies are cleared, the perinatal death rate among neonates of mothers with myasthenia was considerably higher (68 per 1000) than the background rate (Plauche, 1991).

NEUROPATHIES. Peripheral neuropathy is a general term used to describe a disorder of peripheral nerve(s).

Because neuropathy can result from a variety of causes, its discovery should prompt a search for an etiology. Polyneuropathies are often associated with systemic diseases such as diabetes, with drug or environmental toxin exposure, or with genetic diseases. Mononeuropathies signify focal involvement of a single nerve trunk and imply local causation such as trauma, compression, or entrapment (England and Asbury, 2004).

Guillain-Barre Syndrome. This syndrome is an acute demyelinating polyradiculoneuropathy. In more than 67 percent of cases of Guillain-Barre syndrome, there is clinical or serological evidence of a viral infection, such as cytomegalovirus or

Epstein-Barr virus. Approximately 10 percent of cases develop within weeks following a surgical procedure (Kuwabara, 2004). In 1977, an outbreak of the disease occurred following immunization against swine influenza. The syndrome is thought to be immune-mediated, but its pathogenesis is unclear. The main pathological finding is a primary T-cell lymphocytic infiltration of cranial nerves, ventral and dorsal roots, dorsal root ganglia, peripheral nerves, lymph nodes, liver, heart, spleen, and other organs, apparently occurring aberrantly in response to a precipitating infection (Ropper, 1992).

Clinical features include areflexic paralysis with mild sensory disturbances and at times, evidence of autonomic dysfunction. The full syndrome develops after 1 to 3 weeks. Management is supportive, but patients should be hospitalized because about 25 percent need ventilatory assistance and the mortality rate for this complication is high. Corticosteroids have not been effective, although plasmapheresis or intravenous high-dose immunoglobulin (0.4 g/kg per day for 5 days) has been shown to be beneficial if begun within 1 to 2 weeks of symptom onset (van der Meche and colleagues, 1992). Almost 85 percent of patients recover fully, but about 3 percent die from complications of the acute condition.

EFFECTS OF PREGNANCY. Pregnancy does not appear to increase the incidence of Guillain-Barre syndrome. It is, however, increased threefold postpartum, with the first 2 weeks being a time of particularly increased risk (Cheng and co-workers, 1998). When the syndrome does develop during pregnancy, the course of the disease does not seem to be changed. After an insidious onset, paresis and paralysis most often continue to ascend, and respiratory insufficiency can then become a common and serious problem. In a series reported by Hurley and colleagues (1991), about a third of affected pregnant women ultimately required ventilatory support, and the overall maternal mortality rate was 13 percent. Kuller and associates (1995) and Rockel and co-workers (1994) described successful outcomes in pregnant women in whom plasmapheresis was performed. High-dose immunoglobulin may also be administered safely in pregnancy (Chan and colleagues, 2004).

Bell Palsy. This acute idiopathic peripheral facial paralysis of unknown etiology is relatively common, especially in women of reproductive age. Women are affected two to four times more often than men of the same age, and pregnant women are affected three to four times more often than nonpregnant women (Cohen and colleagues, 2000). The onset is usually abrupt and painful, with maximum weakness within 48 hours. In some cases, hyperacusis and loss of taste accompany varying degrees of facial muscle paralysis.

Increased extracellular fluid, viral inflammation, and the relative immune suppression of pregnancy are thought to be predisposing factors. In addition, many cases are associated with or herald the development of preeclampsia (Shapiro and associates, 1999). One study described the experience of five Canadian centers during 11 years and found that women who developed Bell palsy had an incidence of preeclampsia or pregnancy-induced hypertension fivefold higher than the national average (Shmorgun and colleagues, 2002).

EFFECTS OF PREGNANCY. It is not known if pregnancy alters the prognosis for spontaneous recovery from Bell palsy. Gillman and colleagues (2002) found that only 50 percent of pregnant women recovered to a satisfactory level after 1 year, compared with about 80 percent of nonpregnant women and men. Bilateral disease and recurrence in a subsequent pregnancy are prognostic markers for incomplete recovery (Cohen and associates, 2000). Electroneurography may also be helpful in determining prognosis. It is best used in those with complete paralysis and performed after the third day of loss but within the first 2 weeks. A greater percentage of nerve function loss and faster rate of loss predict a worse prognosis (Gilden, 2004).

No specific treatment improves prognosis (Peitersen, 2002). The bulk of evidence suggests that corticosteroids do not hasten resolution, and surgical decompression is seldom indicated. Supportive care includes prevention of injury to the constantly exposed cornea, facial muscle massage, and reassurance. Regional analgesia does not exacerbate the neuropathy (Dorsey and Camann, 1993).

Carpal Tunnel Syndrome. Characteristics of this syndrome include burning, numbness, or tingling in the inner half of one or both hands, and wrist pain and numbness extending into the forearm and sometimes into the shoulder. A variety of conditions, including pregnancy, are associated with it. It is caused by increased pressure in the carpal tunnel, leading to ischemia of the median or (less frequently) ulnar nerves (Katz and Simmons, 2002). Seror (1998) reported that 67 percent of pregnant women with carpal tunnel syndrome had evidence of an acute median nerve lesion at the wrist with a motor or sensory conduction block (or both) and that approximately 10 percent had signs of severe denervation. Symptoms are bilateral in 80 percent of cases and often exhibit a diurnal pattern (Seror, 1998).

Carpal tunnel syndrome should be distinguished from De Quervain tendonitis, which is caused by swelling of the conjoined tendons and sheaths near the distal radius. Nerve conduction studies may be helpful in distinguishing these entities.

The incidence of carpal tunnel syndrome seems to vary according to how vigilantly the diagnosis is sought. Researchers in one large Italian study determined the incidence of carpal tunnel syndrome during the third trimester of pregnancy, when tissue edema is greatest. They found that carpal tunnel syndrome was diagnosed clinically in more than 50 percent and confirmed by neurophysiological evaluation in 42 percent (Padua and colleagues, 2001). In a follow-up study by the same group, 54 percent of women who experienced carpal tunnel syndrome during pregnancy still had some symptoms 1 year later (Padua and co-workers, 2002). In contrast, Stolp-Smith and colleagues (1998) made the diagnosis in fewer than 1 percent of nearly 11,000 pregnant women and found that virtually all cases resolved satisfactorily after pregnancy.

Carpal tunnel syndrome is usually self-limited, and in most cases symptomatic treatment is sufficient. A splint applied to a slightly flexed wrist and worn during sleep keeps the carpal bones in the optimal position to relieve pressure on the nerves and thus provides relief for the majority of sufferers (Courts, 1995). Most symptoms regress after delivery, although surgical decompression and corticosteroid injections may become necessary (Dammers and associates, 1999; Gerritsen and co-workers, 2002). In rare instances, symptoms persist or recur long after pregnancy, and surgical release is required (al Qattan and colleagues, 1994).

SPINAL CORD INJURY. Of the 11,000 spinal cord injuries each year, at least 50 percent are in patients of reproductive age, and 18 percent of these are women (American College of Obstetricians and Gynecologists, 2002b). Fertility is not impaired, and in a survey of 472 women of reproductive age with spinal cord injury, Jackson and Wadley (1999) found that approximately 67 percent resumed intercourse after the injury, and almost 14 percent became pregnant.

Women with spinal cord injury have lower-birthweight neonates and experience more pregnancy complications than unaffected women. The majority of women have either asymptomatic bacteriuria or symptomatic urinary infection. Serum creatinine levels are used to detect renal compromise caused by repeated infection and in predicting pregnancy outcome (see [Chap. 7](#), p. 197). Significant bowel dysfunction and aggravation of constipation develop in more than half of women. Anemia and pressure necrosis of the skin are also common (Baker and associates, 1992; Glickman and Kamm, 1996).

Two serious and life-threatening complications can develop. If the spine is transected above T10, the cough reflex is impaired, and respiratory function may be compromised. Pulmonary function tests may be indicated, and some women with high lesions may need ventilatory support in late pregnancy or in labor. In women with lesions above T5-T6, *autonomic dysreflexia* can develop. With this complication, stimuli from structures innervated below the level of the lesion—usually the bowel, bladder, or uterus—lead to massive disordered sympathetic stimulation. Vasoconstriction and sudden catecholamine release follow with severe hypertension and a range of symptoms, including a throbbing headache, facial flushing, sweating, bradycardia, tachycardia, arrhythmia, and respiratory distress. Dysreflexia can be precipitated by a variety of stimuli, including urethral, bladder, rectal, or cervical distention; catheterization; cervical dilatation; uterine contractions; or manipulation of pelvic structures (American College of Obstetricians and Gynecologists, 2002b). In a report by Westgren and colleagues (1993), 12 of 15 women at risk for dysreflexia suffered at least one episode during pregnancy.

Spinal or epidural analgesia extending to T10 prevents dysreflexia and should be instituted at the start of labor. If severe symptoms present before the epidural has been placed, the first step is to stop whatever stimulus provoked the episode. Then an antihypertensive agent or a peripheral vasodilator should be given.

Uterine contractions are not affected by cord lesions, and labor is usually easy, even precipitous, and comparatively painless. If the lesion is below T12, uterine contractions are felt normally. For lesions above T12, the risk of delivery at home can be minimized by teaching women to palpate for uterine contractions. Some practitioners recommend tocodynamometry and weekly cervical examinations beginning at about 28 weeks. Hughes and associates (1991) recommend elective hospitalization between 36 and 37 weeks. Up to 20 percent of women deliver preterm (Westgren and co-workers, 1993).

Vaginal delivery is preferred, with epidural or spinal analgesia used to minimize autonomic dysreflexia. Prolonged second-stage labor may be expedited with forceps or vacuum.

SHUNTS FOR MATERNAL HYDROCEPHALUS. Pregnancies in women with ventriculoperitoneal, ventriculoatrial, or ventriculopleural shunts for hydrocephalus have been described, and outcomes have usually been satisfactory (Landwehr and colleagues, 1994). In some cases, the shunts become obstructed typically late in pregnancy. Wisoff and associates (1991) reported that neurological complications developed in 13 of 17 pregnancies in women with preexisting shunts, including headaches (60 percent), nausea and vomiting (35 percent), lethargy (30 percent), ataxia (20 percent), and gaze paresis (20 percent). Most responded to conservative management. If CT discloses acute hydrocephaly, the shunt can be tapped or pumped several times daily. However, surgical revision is sometimes necessary.

Vaginal delivery is preferred, and unless there is a meningocele, epidural analgesia is permitted (Bader, 1994). Some authorities believe that subarachnoid block is contraindicated, but others support its use (Littleford and colleagues, 1999). Antimicrobial prophylaxis is indicated if the peritoneal cavity is entered for cesarean delivery or tubal sterilization.

BRAIN DEATH. Cases of maternal brain death during pregnancy have been described in which life-support systems and parenteral alimentation were used for extended periods of time while the fetus achieved maturity (Bernstein, 1989; Dillon, 1982; Field, 1988, and all their co-workers). Aggressive tocolysis and antimicrobial therapy also have been used (Catanzarite and colleagues, 1997). Although not always successful, such therapy occasionally is attempted (Feldman and colleagues, 2000). The ethical, financial, and legal implications, both civil and criminal, that arise from attempting or not attempting such care are profound.

BENIGN INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI).

This condition is characterized by increased intracranial pressure without hydrocephalus, possibly as the result of either overproduction or underabsorption of cerebrospinal fluid. Symptoms include headache in at least 90 percent of cases and visual disturbance, such as loss of a visual field or central visual acuity, in 70 percent (Evans and Friedman, 2000). Other complaints are stiff neck, back pain, pulsatile tinnitus, facial palsy, ataxia, or paresthesias. The syndrome is commonly found in young women, especially those who are obese or who recently have gained weight. Criteria for diagnosis include elevated cerebrospinal fluid pressure and normal composition, along with normal cranial CT or MRI findings. Cerebrospinal fluid prolactin concentration usually is significantly increased even in men and nonpregnant women (Bates and associates, 1982).

Benign intracranial hypertension is usually self-limited. If needed, treatment aims to prevent visual defects by lowering the elevated pressure. Repeated lumbar punctures to remove cerebrospinal fluid lower pressure and can be performed safely without brainstem herniation if there is no ventriculomegaly. Drugs given during pregnancy to lower pressure include acetazolamide, furosemide, or dexamethasone. In rare cases, lumboperitoneal shunting of spinal fluid is necessary.

Effects of Pregnancy.

Benign intracranial hypertension is probably not more prevalent during pregnancy. Pregnancy, however, may be coincident with the new onset of symptoms, and women who already have the diagnosis may become symptomatic during pregnancy (Huna-Baron and Kupersmith, 2002). It is usually detected by midpregnancy, is self-limited, and resolves postpartum.

Pregnancy does not alter treatment. Medication as described above, repeated lumbar punctures, and a salt-restricted diet are generally successful in reducing symptoms. Lumboperitoneal shunting is also an option (Landwehr and colleagues, 1994). Some authorities have recommended that these women be followed with serial visual field testing during pregnancy because visual loss can become permanent (Evans and Friedman, 2000). Huna-Baron and Kupersmith (2002) followed 16 pregnancies in 240 women with benign intracranial hypertension. Visual field loss occurred in four women and was permanent in one. Visual field loss is often coincident with the development of papilledema.

Pregnancy complications are likely due to the associated obesity, not to pseudotumor. In their review of 54 pregnancies, Katz and associates (1989) did not report increased adverse perinatal outcomes. Labor is permitted, the route of delivery is decided by obstetrical indications, and epidural analgesia is not contraindicated.

CHOREA GRAVIDARUM. Involuntary writhing of the limbs or facial muscles, called chorea, may develop during pregnancy and is known as chorea gravidarum (Golbe, 1994). Because most cases in the past were linked to rheumatic fever, chorea is now rare. It can still develop in association with streptococcus A infection, but more often may be caused by collagen-vascular disease (Prasher and Barrett, 1993). According to Branch (1990), up to 2 percent of patients with systemic lupus erythematosus exhibit chorea, and most of these have antiphospholipid antibodies (see [Chap. 54](#), p. 1215). Omdal and Roalso (1992) described a woman with chorea gravidarum who had a recurrence while taking steroidal contraceptives 20 years later.

PSYCHIATRIC DISORDERS

Pregnancy and the puerperium are at times sufficiently stressful to provoke mental illness. Such illness may represent recurrence or exacerbation of a preexisting psychiatric disorder, or may be the onset of a new disorder. In a Swedish population-based study, Andersson and associates (2003) found that the point prevalence of psychiatric disorders during pregnancy is 14 percent.

ADJUSTMENT TO PREGNANCY. Women respond in a variety of ways psychologically to the stressors of pregnancy. They may express persistent concerns about fetal health, postpartum child care and lifestyle changes, or fear of childbirth pain. Anxiety and functional impairment are common (Morewitz, 2003). The level of perceived stress is significantly higher for women whose fetus is at high risk for a congenital malformation and for those who have medical and obstetrical complications (Josefsson and colleagues, 2002).

Because psychological stress often increases in the puerperium, this is a time of increased risk for mental illness. For example, 10 to 20 percent of women develop a nonpsychotic postpartum depressive disorder within 6 months of delivery (Josefsson and colleagues, 2002). Others have a severe, psychotic illness following delivery that usually is manic-depressive (Wisner and associates, 2002). Data of Evans and co-workers (2001) indicate that depressive disorders are just as common during pregnancy as in the puerperium.

PRENATAL EVALUATION. Many mental illnesses, especially depression, develop during the reproductive years. According to Andersson and associates (2003), the point prevalence of psychiatric disorders is 3.3 percent for major depression, 6.9 percent for minor depression, and 6.6 percent for anxiety disorders. Screening for mental illness is done during the first prenatal examination to ascertain psychiatric disorders, including hospitalizations, outpatient care, prior or current use of psychoactive medications, and current symptoms ([Table 55-3](#)).

Risk factors should be evaluated. A prior personal or family history of depression is a significant risk for recurrent depression. Women with a history of sexual abuse also are more likely to have depressive symptomatology, negative life events, and physical and verbal abuse before and during pregnancy (Benedict and co-workers, 1999). Substance abuse, violence, and depression are also linked (Horrigan and colleagues, 2000). Women who report one of these factors should be carefully monitored for evidence of the other two (see [Chaps. 7](#), p. 193 and 42, p. 997). In addition, because eating disorders may be exacerbated by pregnancy, affected women should be followed closely.

CLASSIFICATION OF MENTAL DISORDERS. The Diagnostic and Statistical Manual (DSM-IV) is written and periodically updated by the American Psychiatric Association (1994). Its purpose is to assist in the classification of mental disorders, and it specifies criteria required for each diagnosis.

Major Mood Disorders.

These include major depression ☞— a unipolar disorder ☞— and manic-depression ☞— a bipolar disorder that includes both manic and depressive episodes.

MAJOR DEPRESSION. The National Mental Health Association (2004) estimates that each year 12 million women in the United States have a depressive disorder. The lifetime incidence is 12 percent. Even worse, only half ever seek care.

Major depression is multifactorial, prompted by both genetic and environmental factors. First-degree relatives of individuals with depression have a 25-percent risk of being similarly affected, and female relatives may be at even higher risk (Tsuang and Faraone, 1996). The families of affected individuals often include members with alcohol abuse and anxiety disorders, suggesting a link between these three diagnoses (Doris and associates, 1999). Provocative conditions leading to depression include life events that prompt grief reactions, substance abuse, use of certain medications, and other medical disorders. Although life events can trigger depression, genes influence the liability to life events, making the distinction between genetic and environmental factors difficult.

BIPOLAR DISORDER. Manic-depressive illness also has a strong genetic component. The risk that monozygotic twins are both affected is 40 to 70 percent, and the risk that first-degree relatives of individuals with manic-depression have a similar illness is 5 to 10 percent (Muller-Oerlinghausen and colleagues, 2002). Periods of depression last at least 2 weeks. In addition, affected individuals have manic episodes, defined as distinct periods during which there is an abnormally raised, expansive, or irritable mood. Potential causes of mania or manic symptoms include substance abuse such as cocaine, hyperthyroidism, and central nervous system tumors. About 10 to 20 percent of patients with manic-depression commit suicide, and major mood disorders as a group contribute to two thirds of all suicides in the United States.

Schizophrenia. This common major form of mental illness affects 1 percent of the population (Harvard Medical School, 1999a). Four major subtypes of schizophrenia are recognized: catatonic, disorganized, paranoid, and undifferentiated. The hallmarks of paranoid schizophrenia are delusions, hallucinations, flat or blunted affect, and confused or impoverished speech.

Research using brain scanning techniques such as positron emission tomography and functional magnetic resonance imaging have shown that schizophrenia is a degenerative brain disorder. Subtle anatomical brain abnormalities are present early in life and worsen with time. They include atrophy in and around the limbic region, thalamus, and cerebral cortex; abnormally low blood flow in the frontal lobes; and abnormal brain wave responses (Harvard Medical School, 1999b).

Schizophrenia has a major genetic component, with 50-percent concordance in monozygotic twins. If one parent has schizophrenia, the risk to offspring is 5 to 10 percent. Some data, including a strong association between schizophrenia and the velocardiofacial syndrome, suggest that genes influencing disease development are located on chromosome 22q11 (Murphy, 2002).

Signs of illness begin approximately at 20 years of age, and commonly, work and psychosocial functioning deteriorate over time. Because women have a slightly later onset than men and are less susceptible to autism and other neurodevelopmental abnormalities, many investigators theorize that estrogen has a protective effect. Affected women may marry and become pregnant before symptoms manifest. With appropriate treatment, patients may experience a decrease or cessation of symptoms. Within 5 years from the first signs of illness, 60 percent have social recovery, 50 percent are employed, 30 percent are mentally handicapped, and 10 percent require continued hospitalization (American Psychiatric Association, 1994).

Patients with *schizoaffective disorder* have a chronic deteriorating psychotic disorder similar to schizophrenia but combined with prominent mood symptoms. Although the psychosis rarely abates, the mood symptoms often improve with therapy.

Anxiety Disorders. Examples of these relatively common disorders include panic attack, panic disorder, social phobia, specific phobia, obsessive-compulsive disorder, posttraumatic stress disorder, and generalized anxiety disorder. All are characterized by irrational fear, tension, and worry, accompanied by physiological changes such as trembling, nausea, hot or cold flashes, dizziness, dyspnea, insomnia, and frequent urination (Mufson, 2002). These disorders are treated with psychotherapy and medication, including selective serotonin-reuptake inhibitors, tricyclic antidepressants, monoamine oxidase inhibitors, and others.

Personality Disorders. These disorders are characterized by the chronic use of certain coping mechanisms in an inappropriate, stereotyped, and maladaptive manner. The American Psychiatric Association (1994) recognizes three clusters of personality disorders:

1. Paranoid, schizoid, and schizotypal personality disorders, which are characterized by oddness or eccentricity.
2. Histrionic, narcissistic, antisocial, and borderline disorders, which are all characterized by dramatic presentations along with self-centeredness and erratic behavior.
3. Avoidant, dependent, compulsive, and passive-aggressive personalities, which are characterized by underlying fear and anxiety.

Genetic and environmental factors are important in the genesis of these disorders, whose prevalence may be as high as 20 percent. Although management is through psychotherapy, the majority of affected individuals do not recognize that they have a problem and only about 20 percent seek help.

EFFECTS OF PREGNANCY ON MENTAL ILLNESS. It is likely that both biochemical factors and life stressors influence the onset of mental illness in pregnancy. Hormones are known to affect mood, as evidenced by premenstrual syndrome and menopausal depression. Estrogen modulates serotonergic function and has been used therapeutically to treat depression; it may be a factor in the mood elevation experienced by many women during pregnancy (Joffe and Cohen, 1998). Corticotropin-releasing hormone, which is usually elevated in pregnancy, is present at lower levels in women with pregnancy-related depression (Schmeelk and colleagues, 1999). The absolute hormone levels and their rate of change also appear to be influential. Women who experience postpartum depression often have higher predelivery estrogen and progesterone levels and experience a greater drop to lower levels postpartum (Ahokas and co-workers, 1999).

Pregnancy is also a major life stressor that can unmask or exacerbate depressive tendencies. Depression is more likely to occur with marital problems, unwanted pregnancy, a personal or family history of depression, and low socioeconomic status (Smith and colleagues, 2004). Depression may be linked to increased risk for preeclampsia (Dawes, 2005).

PREGNANCY OUTCOMES. There are only a few reports of psychiatric disorders and their effects on pregnancy outcomes. In a population-based, retrospective cohort analysis of over 500,000 California births in 1995, Kelly and colleagues (2002) assessed the perinatal effects of a maternal psychiatric diagnosis. The latter included all ICD-9-CM diagnostic codes recorded in the discharge summary. Women with these diagnoses had a 1.5- to 3-fold increased incidence of very-low- or low-birthweight neonates or preterm delivery. More specifically, conditions such as eating disorders may cause low-birthweight infants (Sollid and associates, 2004).

POSTPARTUM DISORDERS

Maternity Blues. Also called *postpartum blues*, this is a transient state of heightened emotional reactivity experienced by half of women within approximately the first week after parturition (Miller, 2002). The predominant mood is happiness, but they are more emotionally labile with insomnia, weepiness, depression, anxiety, poor concentration, irritability, and affective lability. They may be transiently tearful for several hours and then recover completely, only to be tearful again the next day. Symptoms are mild and usually last only between a few hours to a few days. Supportive treatment is indicated, and sufferers can be reassured that the dysphoria is transient and most likely due to biochemical changes. They should be monitored for development of more severe psychiatric disturbances, including postpartum disorders.

Postpartum Depression. In nearly all respects, postpartum depression is similar to other major and minor depressions. Symptoms must be present for most of the day, every day, for at least 2 weeks. Postpartum depression is defined as beginning within 4 weeks of delivery, although researchers often include cases that begin within 3 months.

According to the National Mental Health Association (2004), postpartum depression develops in 10 to 15 percent of women following delivery. This incidence is only slightly higher than the usual 6-month prevalence for depression among women in the general population. Postpartum depression has been associated with antenatal depression, young maternal age, single marital status, cigarette smoking or illegal drug use during pregnancy, hyperemesis gravidarum, high utilization of emergency services and sick leave during pregnancy, and previous affective disorder (Bryan, 1999; Evans, 2001; Josefsson, 2002, and all their colleagues).

Up to 70 percent of women with previous postpartum depression have a subsequent episode. Women with both a previous puerperal depression and a current episode of blues have their chances of developing a major depression increase to 85 percent (Hannah and associates, 1992).

COURSE. Without treatment, the natural course is one of gradual improvement in the 6 months after delivery (Fleming and colleagues, 1992). As the duration of depression increases, however, so do the number of sequelae and their severity. In addition, maternal depression during the first weeks and months after delivery can lead to insecure attachment and later behavioral problems in the child.

TREATMENT. Accordingly, most authorities recommend treatment with an antidepressant drug ([Table 55-4](#)). A selective serotonin-reuptake inhibitor should be tried initially. If depressive symptoms improve during a 6-week trial, the medication should be continued for a minimum of 6 months to prevent relapse (Wisner and associates, 2002). If the response is suboptimal or a relapse occurs, patients should be referred to a psychiatrist.

Recurrence of depression develops in 50 to 85 percent of women with an initial postpartum depression some time after medication is stopped. Women with a history of more than one depressive episode are at greater risk for recurrence (American Psychiatric Association, 2000). Surveillance should also include monitoring for thoughts of suicide or infanticide, emergence of psychosis, and response to therapy. For some women, the course of illness is severe enough to warrant hospitalization.

Although some psychotropic medications pass into breast milk, in most cases the levels are very low or undetectable (see [Chap. 14](#), p. 363). There have been no reports of adverse events in breast feeding mothers who took the drugs listed in [Table 55-4](#). Therefore, most women so treated can breast feed, with close observation of the infant.

Postpartum Psychosis. The most severe puerperal mental disorder, this condition usually manifests within 2 weeks of delivery and is usually evidence of a bipolar disorder (Wisner and colleagues, 2002). Affected women have signs of confusion and disorientation but may also have episodes of lucidity. Women with preexisting psychotic illness are at highest risk, as well as those with prior episodes of postpartum depression. In one study, Marks and co-workers (1991) followed 88 women at high risk for psychiatric disorders. A fourth developed postpartum psychosis, either a bipolar or a schizoaffective disorder, and another fourth had a nonpsychotic postpartum depression.

Because women with underlying disease have a 10- to 15-fold risk for recurrence postpartum, close monitoring is imperative. In addition, postpartum psychosis has a high risk of recurrence in the next pregnancy. In most instances, these women ultimately develop relapsing, chronic psychotic illness.

The course of postpartum psychosis is variable and depends on the type of underlying illness. The clinical course of bipolar illness or schizoaffective disorder in puerperal women is comparable to that for nonpregnant women. They usually require hospitalization, pharmacological treatment, and long-term psychiatric care. Psychotic women may have delusions leading to thoughts of self-harm or harm to their infants. Unlike women with nonpsychotic depression, these women commit infanticide, albeit uncommonly.

TREATMENT OF MENTAL DISORDERS

Pharmacological Therapy. A large number of psychotropic medications are now available for management of mental disorders (Kuller and colleagues, 1996). Women taking psychotropic medication should also be informed of likely side effects at the start of therapy (see [Chap. 14](#), p. 363). Dell and O'Brien (2003) advocate a risk-benefit model of drug selection that factors the health and well-being of both mother and fetus.

Electroconvulsive Therapy.

Treatment of depression with electroconvulsive therapy (ECT) during pregnancy is occasionally necessary for women with major mood disorders unresponsive to pharmacological therapy. With proper preparation, the risks to both mother and fetus are few. Women undergoing ECT should be treated as if they have a full stomach. They should be given a rapid-acting antacid before the procedure, and the airway should be protected to decrease the likelihood of aspiration. A wedge should be placed under the right hip to prevent sudden maternal hypotension from aortocaval compression. Other important preparatory steps include cervical assessment, discontinuation of nonessential anticholinergic medication, uterine and fetal heart rate monitoring, and intravenous hydration. During the procedure, excessive hyperventilation should be avoided.

In most cases, maternal and fetal heart rate and maternal blood pressure and oxygen saturation remain normal throughout the procedure. Miller (1994) reviewed 300 published case reports of ECT during pregnancy and found that complications occurred in about 10 percent, including transient benign fetal arrhythmias, mild vaginal bleeding, abdominal pain, and self-limited uterine contractions. Women who were not adequately prepared had an increased risk of aspiration, aortocaval compression, and respiratory alkalosis.

56. Dermatological Disorders

INTRODUCTION

In addition to some recognized pregnancy-specific dermatoses, any skin disease that affects women of childbearing age may be encountered in pregnancy. Importantly, some skin changes caused by the hormonal influences of pregnancy may be worrisome. For example, some cases of generalized pruritus during late pregnancy are caused by intrahepatic cholestasis and bile salt retention; this condition is commonly known as *pruritus gravidarum* (see [Chap. 50](#), p. 1126).

PHYSIOLOGICAL SKIN CHANGES IN PREGNANCY

Normal pregnancy-induced hormonal changes may have rather remarkable influences on the skin. As discussed in [Chapters 3](#) and [5](#), fetoplacental hormone production, stimulation, or alteration of clearance may increase the plasma availability of estrogens, progesterone, and a variety of androgens. Similarly, there are profound changes in the availability or concentrations of some adrenal steroids, including cortisol, aldosterone, and deoxycorticosterone. Paus and Cotsarelis (1999) have described hair-growth modulation by estrogens, androgens, thyroid hormones, glucocorticoids, and prolactin.

Presumably as a result of enlargement of the intermediate lobe of the pituitary gland, plasma levels of melanocyte-stimulating hormone (MSH) become remarkably elevated by 8 weeks' gestation. Production of pro-opiomelanocortin has been demonstrated in placental extracts, and this ultimately is a source of α - and β -MSH.

HYPERPIGMENTATION. Some degree of skin darkening resulting from melanin deposition into epidermal and dermal macrophages occurs in 90 percent of pregnant women. Pigmentation is more pronounced in brunettes and in women with dark complexions, especially those of Hispanic descent (Aronson and Bass, 2000). Its exact cause is not known, but it is doubtful that elevated serum levels of MSH are responsible. Estrogens play a role in melanogenesis and may be the inciting factor.

Hyperpigmentation is evident beginning early in pregnancy and is more pronounced in naturally hyperpigmented areas such as the areolae, perineum, and umbilicus. Areas prone to friction, including the axillae and inner thighs, also may become darkened. When the *linea alba* becomes pigmented, it is renamed the *linea nigra*.

In rare cases, *acquired dermal melanocytosis* first appears during pregnancy (Rubin and colleagues, 2001). The lesions are nonpalpable, brown to blue-gray patches of skin that contain spindle-shaped melanocytes.

Pigmentation of the face, referred to as the mask of pregnancy, is also called *chloasma* or *melasma*. This is seen in about half of pregnant women. Ultraviolet (UV) light exacerbates melasma, because it too stimulates melanogenesis. Thus, the severity of pigmentation may be mitigated by avoiding excessive sun exposure and by using sunscreens.

Although hyperpigmentation usually regresses postpartum, dermal melanosis may persist up to 10 years in a third of affected women. Oral contraceptives may aggravate melasma and should be avoided in susceptible women. If particularly disfiguring, topical application of 2- to 5-percent hydroxyquinone, 0.1-percent tretinoin gel or cream, or 20-percent azelaic acid cream may provide some improvement (Griffiths and colleagues, 1993; Kimbrough-Green and co-workers, 1994). Sunscreen use should be continued.

NEVI. All persons have some form of benign or melanocytic nevi. Although it was traditionally taught that these pigmented cutaneous tumors commonly enlarge and darken during pregnancy, leading to their confusion with malignant melanomas, this is not the case. Pennoyer and colleagues (1997) performed a careful observational study and found that only 6 percent of 129 nevi changed in diameter over pregnancy. Of the eight that changed, four increased by 1 mm, and four *decreased* by 1 mm.

Thus, although nevi can be shown histologically to have enlarged melanocytes and increased melanin deposition during pregnancy, there is no evidence that they undergo malignant transformation as a result of pregnancy. Malignant melanoma is discussed in [Chapter 57](#) (see p. 1263).

CHANGES IN HAIR GROWTH. During pregnancy, the *anagen* phase, or the growing hair phase, is increased relative to the *telogen* phase, or the resting hair phase (Lynfield, 1960; Randall, 1994). Estrogens prolong the anagen state, and androgens cause enlargement of follicles in dependent areas such as the face (Paus and Cotsarelis, 1999). Postpartum, these effects are lost, and shedding of hair becomes prominent. *Telogen effluvium* describes the rather abrupt hair loss that is seen beginning approximately 1 to 4 months postpartum. This process is sometimes characterized by alarming amounts of hair shedding, usually associated with brushing or washing. Fortunately, the process is self limited, and women may be reassured that normal hair growth is usually restored in 6 to 12 months (Headington, 1993; Kois and Phelan, 1994).

Mild *hirsutism* is common during pregnancy, and this may be most noticeable on the face. Women who are predisposed genetically to coarse hair growth are affected most profoundly. Hirsutism typically regresses within several months after delivery. More severe hirsutism is unusual, and if accompanied by other evidence of masculinization, this should prompt consideration of another androgen source. For example, there are reports of pregnant women who had virilization caused by adrenal tumors or pregnancy luteomas (Choi and colleagues, 2000; Danilowicz and co-workers, 2002).

VASCULAR CHANGES. Augmented cutaneous blood flow in pregnancy is due to a marked decrease in peripheral vascular resistance (Spetz, 1964). One salutary effect of this is dissipation of excess heat generated by increased metabolism. In addition to augmented cutaneous blood flow, pregnancy incites a number of common estrogen-induced changes in small blood vessels. *Spider angiomas* are found in two thirds of white women and about 10 percent of African Americans during pregnancy (Wong and Ellis, 1984). Most of these vascular lesions regress postpartum. *Palmar erythema* is noticed in two thirds of white women and a third of black women. *Capillary hemangiomas*, especially of the head and neck, are

seen in about 5 percent of women during pregnancy.

One vascular condition that may be distressing is *pregnancy gingivitis*, which is caused by growth of the gum capillaries. This so-called *epulis of pregnancy* may become more severe, but it may be controlled by proper dental hygiene and avoidance of trauma. Epulis should not be confused with *pyogenic granuloma of pregnancy*, which is also called *granuloma gravidarum*. These lesions are typical pyogenic granulomas, which are found in the oral cavity and often arise from the gingival papillae. They are associated with extensive gingivitis. Sheehan and Leshner (2004) described such a lesion arising in a port-wine stain. Treatment is usually unnecessary, but Powell and colleagues (1994) described laser excision of a large granuloma.

DERMATOSES OF PREGNANCY

A number of dermatological conditions have been identified as either unique to pregnancy or encountered with a greater frequency during gestation. Their terminology can be quite confusing. Shornick (1998) concluded that only three conditions are universally accepted as unique to pregnancy: *cholestasis* with its attendant pruritus, *pruritic urticarial papules and plaques of pregnancy*, and herpes gestationis ([Table 56-1](#)). Their gross appearance may be similar to the two other skin disorders in [Table 56-1](#).

Pruritus during pregnancy is common, and its incidence varies directly with the vigilance for which it is searched. The best data are from nearly 3200 pregnant women carefully studied over one year by Roger and colleagues (1994). **By a uniform definition, 1.6 percent of women had significant pruritus at some time during pregnancy.**

PRURITUS GRAVIDARUM. This common pregnancy-related skin condition is not primarily a dermatological disorder. In the study by Roger and associates (1994), almost half of women with pruritus during pregnancy (0.6 percent) had pruritus gravidarum. This condition is considered to be a mild variant of *intrahepatic cholestasis of pregnancy*, discussed in [Chapter 50](#) (see p. 1126). There is associated bile salt retention, and as serum levels increase, bile salts are deposited in the dermis. This in turn causes pruritus and although skin lesions develop, they are secondary to scratching and excoriation. The condition is associated with pregnancy hormones, genetics, and environmental factors (Germain and colleagues, 2002; Sherard and Atkinson, 2001).

PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY. This is the most common pruritic pregnancy-specific dermatosis. It is called *PUPPP* in the United States and referred to as *polymorphic eruption of pregnancy (PEP)* in the United Kingdom. In the study by Roger and co-workers (1994), almost half of 3200 pregnant women with pruritus had this dermatosis. Although the incidence is about 1 in 200 singleton pregnancies, it is 8 in 200 for twin gestation (Kroumpouzou and Cohen, 2003). It is characterized by an intensely pruritic cutaneous eruption that usually appears late in pregnancy (see [Table 56-1](#)). Shown in [Figure 56-1](#) are the erythematous urticarial papules and plaques that first develop on the abdomen, usually around striae. The lesions then are likely to spread to the buttocks, thighs, and extremities (Aronson and colleagues, 1998).

Pruritus may be severe with these lesions. In about 40 percent of women, the urticarial component predominates; in 45 percent, the erythematous pattern is prominent; and in 15 percent, a combination is seen (Aronson and associates, 1998). The erythematous patches are widespread. The face is usually spared, and seldom is there excoriation. The disease is more common in nulliparas and seldom recurs in subsequent pregnancies. It may resemble herpes gestationis, but there usually are no vesicles or bullae (Sherard and Atkinson, 2001). There is no evidence that perinatal morbidity is increased (Kroumpouzou and Cohen, 2003).

Pathophysiology. The etiopathogenesis is unknown. Because of diverse clinical findings, classification can be confusing. On biopsy, there is a mild, nonspecific lymphohistiocytic perivascularitis with an eosinophilic component. Importantly, there is no immunoglobulin or complement deposition seen using immunofluorescent staining of dermis (Aronson and colleagues, 1998). The absence of a linear band of C3 in the basement membrane differentiates this dermatosis from herpes gestationis. Aractingi and associates (1998) have reported provocative evidence that this disorder may be stimulated by fetal cells that have invaded maternal skin. Similar observations have been made for progressive systemic sclerosis (see [Chap. 54](#), p. 1220) and postpartum thyroiditis (see [Chap. 53](#), p. 1191). Recently, the reverse phenomenon has been described, and maternal cells have been linked to some autoimmune childhood disorders (Barinaga, 2002; Srivatsa and colleagues, 2003). Bidirectional maternal-fetal cell trafficking was the subject of a 2000 National Institutes of Health-sponsored conference (Bianchi and Romero, 2003).

Treatment. Some women obtain relief from oral antihistamines and skin emollients, but most require topical corticosteroid creams or ointments. Oral corticosteroids are given if these fail to relieve severe itching. In most cases, the rash disappears quickly either before or within several days following delivery. In 15 to 20 percent of women, symptoms persist for 2 to 4 weeks postpartum (Vaughan Jones and co-workers, 1999). One biopsy-proven case beginning 4 weeks postpartum lasted 4 weeks (Kirkup and Dunnill, 2002).

Figure 56-1. Pruritic urticarial papules and plaques of pregnancy. (From Aractingi and colleagues, 1998, with permission.)

PRURIGO OF PREGNANCY. These lesions, also called *papular eruptions of pregnancy*, have been described by a multitude of names. According to Shornick (1998), the disorder includes *prurigo gestationis* and *papular dermatitis*, which likely are variants of the same disease and are not specific to pregnancy (see [Table 56-1](#)). The mild and more common variant,

prurigo gestationis, is characterized by small, pruritic, rapidly excoriated lesions on the forearms and trunk. The bitelike papules may resemble scabies or other insect bites. Vesicles or bullae do not develop. The course is protracted; lesions typically have their onset at 25 to 30 weeks and may persist for 3 months after delivery. Recurrence in subsequent pregnancy is common.

Pruritus is usually controlled with oral antihistamines and topical corticosteroid creams. Perinatal outcome does not appear to be adversely affected (Vaughan Jones and Black, 1999).

HERPES GESTATIONIS. Although this noninfectious skin disorder shares the name of the more common viral infection, the connection is etymological and not biological. The names of both conditions are derived from the Greek herpes (*to creep*). This autoimmune pruritic blistering skin eruption usually affects multiparous women in late pregnancy, but it may begin early in pregnancy or within a week or so postpartum (see [Table 56-1](#)). It occasionally may accompany gestational trophoblastic disease. It is also called *pemphigoid gestationis* because it is immunologically similar to *bullous pemphigoid* seen in elderly patients (van den Bergh and Giudice, 2003). Thus, it is an autoimmune blistering skin disease (Engineer and associates, 2000; Kolanko and colleagues, 2004).

Severe herpes gestationis can be serious. Fortunately, it is rare, even though the commonly cited incidence of about 1 in 50,000 pregnancies may be an underestimate.

Herpes gestationis is characterized by an extremely pruritic widespread eruption with lesions that vary from erythematous and edematous papules to large, tense vesicles and bullae ([Figs. 56-2](#) and [56-3](#)). Before bullae form, these findings may resemble PUPPP, which is described above. Common sites of involvement are the abdomen and the extremities. Morphological changes may develop in the small intestinal mucosa similar to those of adult celiac disease. Exacerbations and remissions throughout pregnancy are common, and up to 75 percent of women suffer intrapartum flares (Shornick, 1998). In subsequent pregnancies, the disease invariably recurs, and it usually does so earlier and is more severe. Baxi and colleagues (1991) reported a woman in whom recurrence was documented in five pregnancies.

Etiopathogenesis. This autoimmune disease is caused by development of an immunoglobulin G₁ antibody to the basement membrane in the epidermis. There is an inherited predisposition with a markedly increased rate among women with HLA-DR3 and HLA-DR4 antigens. Over half of women with herpes gestationis have these antigens, but they are found in only 3 percent of unaffected women. These maternal HLA-DR antigens are associated with other autoimmune disorders, including Addison disease, type 1 diabetes mellitus, systemic lupus erythematosus, Graves disease, and Hashimoto thyroiditis. In one study, Shornick and Black (1992) found that 10 percent of 75 women with herpes gestationis also had Graves disease. Paternal HLA-DR2 is also commonly found in these pregnancies (Shimanovich and colleagues, 2002a).

Shornick and associates (1993) demonstrated anti-HLA antibodies in all 39 women with biopsy-proven disease. This antibody is a thermostable immunoglobulin G (IgG) that reacts with the bullous pemphigoid 180-kD (BP180) antigen in the epidermis. Autoantibodies can be quantified using immunoblotting or ELISA (Sitaru and associates, 2004). BP180, a glycoprotein, is integral to adhesion structures that anchor basal cells to their basement membrane (Shimanovich and colleagues, 2002b). It is also called *herpes gestationis serum factor*, and it reacts with amniotic tissue, and is passively transferred to the fetus.

Histologically, the classical finding in herpes gestationis is subepidermal edema with perivascular infiltrates of lymphocytes, histocytes, and eosinophils. Immunofluorescent techniques applied to a skin biopsy are of value for confirming the diagnosis. As shown in [Figure 56-4](#), C3 complement and sometimes IgG are deposited along the basement membrane zone between the epidermis and the dermis (Kroumpouzou and Cohen, 2003).

Treatment. Pruritus may be quite severe. Topical corticosteroids and oral antihistamines effect relief in only a few women. Orally administered prednisone, 0.5 to 1 mg/kg daily, usually brings relief promptly and inhibits formation of new lesions. The healed sites usually are not scarred but frequently are hyperpigmented. Refractory cases that persist postpartum have been treated with immunosuppressives such as cyclophosphamide, methotrexate, and cyclosporine (Wallengren, 2004). Some women develop chronic disease, which may be bullous pemphigoid (Amato and associates, 2003). In some intractable cases, plasmapheresis and high-dose intravenous immunoglobulin therapy have been used (Kroumpouzou and Cohen, 2003; Mazzi and colleagues, 2003).

Effect on Pregnancy. Although there are reports of an association with preterm birth, stillbirths, and growth restriction, these are from small studies (Aronson and Bass, 2000). Nevertheless, increased antepartum surveillance is recommended. Lesions similar to those of the mother develop in up to 10 percent of neonates (Chen and colleagues, 1999; Erickson and Ellis, 2002). They have the same histological characteristics and usually clear spontaneously within a few weeks.

Figure 56-2. Herpes gestationis at 30 weeks' gestation. Corticosteroid treatment provided remarkable relief from the intense pruritus and considerable decrease in the intensity of the skin reaction.

Figure 56-3. Herpes gestationis with large, tense bullae located on the thigh. (From Black, 2001, with permission.)

Figure 56-4. Herpes gestationis: indirect immunofluorescence microscopy of skin biopsy showing linear deposition of C3 along the epidermal basement membrane. (From Shimanovich and colleagues, 2002a, with permission.)

PRURITIC FOLLICULITIS OF PREGNANCY. This rare pustular eruption, which is also called *impetigo herpetiformis*, is seen in late pregnancy. It is uncertain if it is unique to pregnancy, or if it is a form of pustular psoriasis that occurs coincidental to pregnancy. Only 24 cases have been reported (Kroumpouzou and Cohen, 2003). In one intriguing report, Oumeish and associates (1982) described a woman in whom this dermatosis recurred in nine successive pregnancies and also when taking estrogen-progesterone oral contraceptives.

The hallmark lesions of pruritic folliculitis are sterile pustules that form around the margin of erythematous patches that characteristically begin at flexures and extend peripherally. Mucous membranes are usually involved. The characteristic histological lesion is a spongiform epidermal cavity filled with neutrophils, which is referred to as the *spongiform pustule of Kogoj*.

Pruritus is not severe, but constitutional symptoms are common. In addition to nausea, vomiting, diarrhea, and chills and fever, hypoalbuminemia and hypocalcemia are common. Although the pustules are initially sterile, they may become secondarily infected after rupture, and sepsis is a serious concern. Treatment is systemic corticosteroids along with antimicrobials to treat secondary infection and sepsis. The disease may persist for several weeks to months after delivery.

PREEXISTING SKIN DISEASE

A number of chronic dermatological disorders may complicate pregnancy. These may antedate pregnancy or manifest for the first time during pregnancy. Like other chronic disorders, many of these skin diseases usually have no predictable course during pregnancy.

Acne is usually unaffected by pregnancy. For nonpregnant women, treatment may include some of the highly teratogenic congeners of retinoic acid (see [Chap. 14](#), p. 350). **Isotretinoin, etretinate, and tretinoin are strictly contraindicated in pregnancy.** For the pregnant woman with severe acne, topically applied benzoyl peroxide appears to be safe. Severe disease can usually be controlled when it is applied along with either clindamycin or erythromycin gel. *Topical tretinoin* is thought to pose no significant teratogenic risk (Akhavan and Bershad, 2003).

There is evidence that *psoriasis* improves in up to 50 percent of women during pregnancy. It also may worsen in up to 20 percent. A number of regimens used in nonpregnant individuals are contraindicated during pregnancy. Tauscher and co-workers (2002) provided a learned and detailed review of the disorder during pregnancy. They recommended topical corticosteroids for localized disease, and if nonresponsive, stepwise therapy with topical calcipotriene, anthralin, and then tacrolimus. For generalized mild disease, they recommended UV-B phototherapy. If unresponsive, psoralens with UV-B phototherapy are used, followed by oral cyclosporine if unsuccessful. Topical or oral corticosteroids may also be given for moderate or severe disease. Coal tar derivatives, as well as oral and systemic immunosuppressives (e.g., methotrexate, cyclosporine, tacrolimus), are avoided.

Hidradenitis suppurativa is a chronic, progressive, inflammatory and suppurative disorder of skin and supporting structures. It is characterized by apocrine gland plugging that leads to anhidrosis and bacterial infection (von der Werth and Jemec, 2001). The disease is hormonally responsive and thus not seen until puberty. It has been said to be improved by pregnancy, but in our experiences, it is not appreciably changed. Treatment is control of acute infections with either systemic antimicrobials or clindamycin ointment (Boer and van Gemert, 1999).

If *pemphigus* appears during pregnancy for the first time, it may be confused with herpes gestationis (Vaughan Jones and Black, 1999). Even with corticosteroid therapy, mortality is 10 percent secondary to sepsis caused by infection of denuded skin. Lesions of *neurofibromatosis* may increase in size and number as a result of pregnancy. *Hansen disease* primarily affects the skin, and it likely worsens during pregnancy (Aronson and Bass, 2000). Its treatment is discussed in [Chapter 58](#) (see p. 1289).

57. Neoplastic Diseases

INTRODUCTION

Cancer during pregnancy is uncommon but not rare. Reported rates for most cancers vary widely, reflecting not only differences in populations, but also differing methods of ascertainment and inconsistency of reporting. In a review of more than 4.8 million deliveries in California during a 9-year period, Smith and colleagues (2003) reported the overall incidence of malignant neoplasms to be 0.94 per 1000 live births. The incidence of cancer within 12 months of delivery was 0.6 per 1000; in the prenatal period, 0.27 per 1000; and when diagnosed at the time of delivery, 0.07 per 1000.

According to the National Vital Statistics Report for 2001, malignancies are the second leading cause of death in women 25 to 44 years of age (Arias and associates, 2003). The most common cancers are melanoma and cancers of the hemopoietic and lymphatic systems, thyroid, breast, cervix, ovary, and colon. In their extensive review, Dinh and Warshal (2001) reported that the most frequent cancers in pregnant women were melanoma (1:350), cervical cancer (1:2250), Hodgkin lymphoma (1:3000), breast cancer (1:7500), ovarian cancer (1:18,000), and leukemia (1:75,000). A number of others have reached similar conclusions (Kaiser and associates, 2000; Smith and colleagues, 2003).

Although management of the pregnant woman with cancer is problematic, one basic tenet should be followed: **A woman should not be penalized for being pregnant.** Treatment should be individualized and should include consideration of factors such as type and stage of cancer, the woman's desire to continue the pregnancy, and the risks of modifying or delaying treatment.

PRINCIPLES OF CANCER THERAPY DURING PREGNANCY

SURGERY. Surgical intervention for cancer may be indicated for diagnostic, staging, or therapeutic purposes. Most procedures that do not interfere with the reproductive tract are well tolerated by both mother and fetus. If indicated, the ovaries may be removed without affect to the pregnancy after about 8 weeks. Progesterone should be administered if oophorectomy is performed prior to this (see [Chap. 40](#), p. 966).

Although diagnostic and staging operations have classically been deferred until the second trimester to minimize abortion risks, this probably is not necessary. Specifically, documenting a live fetus with ultrasound between 9 and 11 weeks indicates a 95-percent chance that it will reach viability. In all cases, therapeutic surgery should be performed regardless of gestational age if maternal well-being is imperiled.

RADIATION THERAPY. It is important to emphasize that *diagnostic* radiographic procedures have very low exposure and should not be delayed if they would directly affect therapy (American College of Obstetricians and Gynecologists, 2004). *Therapeutic* radiation, however, can result in significant fetal exposure to ionizing radiation. The amount depends on the dose, tissue being treated, and field size. Potential adverse effects of diagnostic radiation include cell death, carcinogenesis, and genetic effects on future generations (Brent, 1989, 1999; Hall, 1991). As discussed in [Chapter 41](#) (see p. 978), exposure of the embryo to less than 5 cGy (5 rad) has negligible risk of major malformations. In fact, it is likely that the threshold for radiation effects is 15 to 20 cGy (Brent, 1999).

Although the most susceptible period is during organogenesis, no gestational age is considered safe for therapeutic radiation exposure. Characteristic adverse fetal effects are microcephaly and mental retardation. In some cases, even late exposure can cause fetal growth restriction and brain damage. These dangers raise very practical issues. For example, therapeutic radiation doses to the abdomen are contraindicated because of a high risk of fetal death or damage, unless of course abortion induction is one of its purposes. In some cases, such as head and neck cancers, radiotherapy to supradiaphragmatic areas can be given relatively safely with abdominal shielding. In others, such as breast cancer, significant scatter doses can accrue to the fetus.

CHEMOTHERAPY

Effect on Pregnancy Outcome. Chemotherapy is recommended for treatment or as adjunctive therapy along with surgery or radiation in an increasing number of malignancies. Although chemotherapy is often associated with improved long-term maternal outcome, there still is a general reluctance to use these potent agents during pregnancy. Fetal concerns include malformations, growth restriction, mental retardation, and the risk of future malignancies.

The risk for adverse fetal effects is dependent primarily on gestational age during chemotherapy. Most antineoplastic drugs should be considered potentially harmful to the fetus, especially if given during organogenesis. Indeed, embryonic exposure to cytotoxic drugs causes major malformations in 10 to 20 percent of cases (Muslin and colleagues, 2001). After the first trimester, most antineoplastic drugs are without obvious adverse sequelae, although long-term effects have not been evaluated thoroughly (Partridge and Garber, 2000; Nulman and associates, 2001).

In a review of the reproductive toxicology of alkylating agents, Glantz (1994) concluded that these agents could be used after the first trimester if indicated. Doll and colleagues (1988) reached similar conclusions. These observations also apparently apply to the two potent teratogens *all-trans-retinoic acid* and *methotrexate*, both of which have few adverse effects after the first trimester (Briggs and co-workers, 2002).

Because the magnitude of secretion of chemotherapeutic agents into breast milk has not been established, breast feeding is not recommended. There is also concern for exposure of health care workers to chemotherapeutic agents. Selevan and colleagues (1985) and Stucker and co-workers (1990) reported a twofold increased risk of fetal loss in nurses exposed during the first trimester. They recommend caution during mixing and administration of antineoplastic drugs (see [Chap. 14](#), p. 353).

Late mutagenic effects on offspring of women treated during pregnancy have also been of concern. Data are limited, but in one study, Li and associates (1979) found only two childhood malignancies in offspring of 146 women treated during 286

pregnancies. In another study, Aviles and Neri (2001) found no adverse sequelae in 84 children exposed to antineoplastic drugs in utero.

Fertility and Pregnancy After Cancer Therapy. In both men and women, subsequent fertility may be diminished after chemotherapy. For example, treatment of advanced Hodgkin lymphoma with multiple-drug regimens may result in azoospermia in men and in decreased follicular maturation with destruction and ovarian fibrosis in women (Waxman, 1985). Gershenson (1988) reviewed subsequent outcomes in women successfully treated with chemotherapy for germ cell ovarian tumors. A third had total or partial ablation of ovarian function. Tangir and associates (2003) reviewed women who had fertility-sparing surgery, usually with chemotherapy, for ovarian germ cell malignancies. More than 75 percent who attempted pregnancy were successful at least once. Falconer and Ferns (2002) presented similar findings. The likelihood of fertility effects is both age- and dose-related. Interestingly, the prepubertal ovary is more resistant to effects of chemotherapy.

With subsequent conception, even with subfertility, there does not appear to be an increased incidence of abortion, fetal chromosomal damage, or fetal anomalies (Rustin and colleagues, 1984). Green and colleagues (2002) reported an analysis of 4029 pregnancies subsequent to treatment for childhood or adolescent cancer. Prior chemotherapy was with most agents not associated with an increased risk of adverse pregnancy outcomes. However, prior therapy with daunorubicin or doxorubicin as well as prior pelvic radiation therapy were associated with an approximately twofold increased risk of delivering an infant who weighed less than 2500 g at birth. Chiarelli and associates (2000) reported similar results.

BREAST CARCINOMA

Likely the most feared cancer by women, breast cancer is the most common malignancy of women of all age groups. Indeed, almost 1 of every 8 women will eventually be afflicted (American College of Obstetricians and Gynecologists, 2003c). Breast cancer is also one of the more common malignancies encountered during pregnancy (Berry and colleagues, 1999; Sorosky and Scott-Conner, 1998). Its incidence in pregnancy varies with the age of the population studied and averages perhaps 1 in 25,000 to 50,000 pregnancies (Dinh and Warshal, 2001; Shah and Saunders, 2001). As more women choose to delay childbearing until a later age, the frequency of associated breast cancer is expected to increase (Woo and associates, 2003).

According to some studies, women with *BRCA1* and *BRCA2* breast cancer genes, as well as those with a family history of breast cancer, are more likely to develop the malignancy during pregnancy (Johannsson and co-workers, 1998; Shen and colleagues, 1999). Women undergoing induced abortions or those who breast feed do not have an increased risk of breast cancer (Beral and associates, 2004; Michels and colleagues, 1996).

PREGNANCY AND BREAST CANCER. The effects of pregnancy on the course of breast cancer and its prognosis are complex. There are massively increased levels of both estrogens and progestins during pregnancy, and some data suggest that higher estrogen levels cause excess cancer later in life, whereas progesterone may be protective (Ward and Bristow, 2002). Chorionic gonadotropin and relaxin, also produced in prodigious amounts, may inhibit tumor growth (Shah and Saunders, 2001). There is intriguing evidence that higher serum levels of alpha-fetoprotein are associated with a decreased incidence of breast cancer (Melbye and colleagues, 2000). Finally, it appears that interruption of pregnancy has no influence on the course or prognosis of breast cancer.

Most clinical reports maintain that when breast cancer is diagnosed during pregnancy, the regional lymph nodes are more likely to contain microscopic metastases. This is important, because the 5-year survival rate with pregnancy-associated breast cancer is primarily dependent on its stage at diagnosis (Hochman and Schreiber, 1953). Still, survival in pregnant women is comparable stage-for-stage with that in nonpregnant women (King and colleagues, 1985; Nugent and O'Connell, 1985; Zemlickis and associates, 1992). According to Jacob and Stringer (1990), about 30 percent of pregnant women with breast cancer have stage I disease, 30 percent have stage II, and 40 percent stages III or IV. Studies published after 1990 indicate that about 60 percent of pregnant women have concomitant axillary node involvement ([Table 57-1](#)).

Other findings support more advanced breast cancer in pregnant women. Zemlickis and associates (1992) found that pregnant women had a 2.5-fold increased risk of metastatic disease compared with that of nonpregnant women. Bonnier and associates (1997) found an inordinately higher incidence of *inflammatory cancer* in 154 pregnant women compared with that of 308 age-matched nonpregnant controls (26 versus 9 percent).

There are usually slight delays in clinical assessment, diagnostic procedures, and treatment of pregnant women with breast tumors (Berry and colleagues, 1999). The mean delay was reported to be 1 to 2 months in recent studies (Woo and associates, 2003). Part of the delay can be attributed to pregnancy-induced breast changes that tend to obscure breast masses. These are even more magnified during lactation when there is lobular hyperplasia and galactostasis. An important concern is that excessive nodal involvement may be related to delayed diagnosis. This seems unlikely, considering the biology of breast cancer. Nettleton and colleagues (1996) used mathematical modeling to conclude that even a 6-month delay increases the chance of axillary metastasis by only 5 percent. Thus, a delay of a few months to treatment would seem clinically insignificant.

There is no doubt that breast cancer is more aggressive in younger women. Whether it is more aggressive during pregnancy in these same women is debatable. It is reasonable to conclude that later disease stages seem to be more prevalent, and thus overall survival is adversely affected. In the Swedish Cancer Registry, Bladstrom and associates (2003) reported a 5-year survival rate of 52 percent if breast cancer was diagnosed in pregnant women compared with that of 80 percent if it was detected in nonpregnant women.

Placental Metastases. Occasionally, malignant breast cells are found on placental microscopic examination (Dunn and co-workers, 1999). These have been confined to the intervillous space, and fetal disease has not been reported (see [Chap. 27](#), p. 624).

DIAGNOSIS. The diagnostic approach in pregnant women with a breast tumor should not differ significantly from that for nonpregnant women. **Any suspicious breast mass found during pregnancy should prompt an aggressive plan to determine** its cause, whether this involves ultrasound, fine-needle aspiration, or biopsy.

At the University of Alabama, ultrasound is the initial diagnostic study performed on pregnant women with a palpable breast mass. An oval or elongated lesion with smooth borders and no shadowing is highly suggestive of a benign mass. Most masses in pregnancy have these reassuring features, and definitive diagnosis can often await the conclusion of pregnancy.

Mammography should be performed if indicated. The fetal radiation risk is negligible with appropriate shielding, and the exposure is only 0.004 cGy for the typical two-view test (Nicklas and Baker, 2000). Importantly, breast tissue is denser in pregnancy, and mammography is associated with a false-negative rate of 35 to 40 percent (Samuels and colleagues, 1998; Woo and associates, 2003).

In all women in whom ultrasound or mammography of a suspicious mass is still nondiagnostic, or with worrisome clinical features such as skin changes or immobility of the mass, then biopsy is indicated. Although there are no large studies in pregnant women, *core biopsy* may be an ideal diagnostic technique. Fine needle aspiration for cytology is an alternative technique, but it requires a pathologist experienced with pregnancy-associated breast cancer (Woo and associates, 2003).

Once malignancy is diagnosed, a chest radiograph and a limited metastatic search are performed. Although routine computed tomography (CT) scans of bone and liver are both sensitive and specific, they are usually avoided during pregnancy because of excessive radiation (Pelsang, 1998). Magnetic resonance imaging (MRI) is a reasonable alternative to assess liver involvement. It is sensitive and has excellent contrast resolution.

TREATMENT. Breast conservation surgery for small tumors, with or without adjunctive chemo- or radiotherapy, is preferable in nonpregnant women (Fisher and colleagues, 2002; Veronesi and co-workers, 2002). *Surgical treatment* may be definitive for breast carcinoma during pregnancy (Woo and colleagues, 2003). In the absence of metastatic disease, either wide excision, modified radical mastectomy, or total mastectomy with axillary node staging can be performed (Isaacs, 1995). In 22 women treated with modified radical mastectomy followed in most by chemotherapy, Berry and colleagues (1999) reported minimal risks. In nonpregnant women, *adjunctive radiotherapy* is usually given with breast-conserving surgery. However, this is not recommended during pregnancy (Sorosky and Scott-Conner, 1998). Abdominal scatter is considerable; when the maternal radiation dose is 5000 cGy, the fetus receives at least 100 to 150 cGy (Sorosky and Scott-Conner, 1998).

Chemotherapy is recommended for node-positive disease if proximate delivery is not anticipated. It is given for advanced disease, and termination should be considered if pregnancy is early (Shah and Saunders, 2001). Cyclophosphamide, doxorubicin, and 5-fluorouracil are currently recommended by most clinicians. After the first trimester, methotrexate can be substituted for doxorubicin (Sorosky and Scott-Conner, 1998). Because survival is improved with chemotherapy in premenopausal women, it should be considered even if the nodes are cancer free.

PREGNANCY FOLLOWING BREAST CANCER. Some women are rendered infertile by chemotherapy, as discussed previously (see p. 1259). For those who can choose pregnancy, there is little evidence to suggest that pregnancy adversely affects survival in women who have undergone prior breast cancer treatment (Averette and colleagues, 1999). Dow and colleagues (1994) found no differences in rates of recurrences or distant metastases with or without subsequent pregnancies. Reports by Kroman (1997) and Velentgas (1999) and their colleagues have since confirmed these findings.

No data suggest that lactation adversely affects the course of breast cancer. Successful lactation and breast feeding are possible after conservative surgery and radiation for breast cancer, even from the treated side (Higgins and Haffty, 1994).

Recommendations for future pregnancies in women successfully treated for breast malignancy are based on several factors, including consideration for chances of recurrence. It seems reasonable to advise a delay of 2 to 3 years, which is the most critical observation period.

LYMPHOMAS

HODGKIN DISEASE. This is the most common malignant lymphoma encountered in women of childbearing age. It is usually B-cell derived and distinguished from other lymphomas by *Reed-Sternberg cells*. It has a bimodal peak incidence at 18 to 30 years of age and again after 50 years of age. Prognosis is good, and survival is greater than 70 percent.

In more than 70 percent of cases of Hodgkin disease, patients present with painless enlargement of lymph nodes above the diaphragm—the axillary, cervical, or submaxillary chains (Peleg and Ben-Ami, 1998). Other symptoms include fever, night sweats, malaise, weight loss, and pruritus. The most common finding is peripheral adenopathy, and neck and supraclavicular nodes are commonly involved. Diagnosis is established by histological examination of involved nodes.

Pregnancy and Hodgkin Disease. Over the past 30 years at Parkland Hospital, with more than 250,000 pregnancies, Hodgkin disease has been encountered uncommonly. Similarly, in a population-based review of more than 3 million deliveries, Smith and associates (2003) reported this lymphoma to complicate only 1 per 20,000 live births. In their review, however, Pavlidis and colleagues (2002) reported an incidence of Hodgkin disease in pregnancy of 1 in 1000 to 1 in 6000.

Pregnant women with Hodgkin disease present special management considerations. A tenet of treatment is that careful staging is essential, and either local radiotherapy or systemic chemotherapy is indicated. The *Ann Arbor staging system*, shown in [Table 57-2](#), was designed for Hodgkin lymphomas but is also used for other lymphomas. Although pregnancy limits the widespread application of some radiographic studies, at minimum, work-up includes chest radiography, bone marrow biopsy, and abdominal imaging (Williams and Schilsky, 2000). Spiral CT can be used with the "pitch" set so that radiation dose approaches that of conventional scanning (see [Chap. 41](#), p. 980). MRI is an excellent alternative for evaluating thoracic and abdominal para-aortic lymph nodes. Radionuclide gallium scanning, which is being used more frequently in nonpregnant patients, emits 0.75 to 1.0 cGy. Staging is considered essential for those patients in whom radiotherapy alone is chosen, because the presence of abdominal disease would significantly alter treatment.

Treatment is individualized depending on stage and pregnancy duration. Radiotherapy is given for stage I disease (isolated lymph node involvement), and the cure rate approaches 90 percent. In pregnancy, radiotherapy is preferable for isolated neck adenopathy, but it is not recommended for areas that deliver significant radiation scatter to the fetus. Nisce and colleagues (1986) temporarily modified their regimen to deliver only 15 to 20 Gy to supradiaphragmatic sites in seven women after the first trimester. Despite this reduction to what were considered subcurative doses, fetal radiation exposure ranged from 2 to 50 cGy and averaged about 20 cGy. When evaluated at 6 to 11 years of age, all seven children were normal, but two mothers had died.

As discussed on page 1258, chemotherapy is probably best avoided during the first trimester. With obvious widespread disease, however, we recommend that chemotherapy be given. Postponement of therapy until fetal maturity is achieved seems justifiable only when the diagnosis is made late in pregnancy and maternal health would not be jeopardized.

Pregnancy does not adversely affect the course or survival of women with Hodgkin lymphoma (Pavlidis, 2002). Moreover, pregnancy wastage is not increased. Because aggressive radiation and chemotherapy are often necessary for cure, pregnancy termination is reasonable when the diagnosis is made in the first half of pregnancy. Jacobs and associates (1981) reported their experiences from Stanford University and found that neither chemotherapy during the second and third trimesters nor irradiation to the mediastinum and neck adversely affected the fetus or neonate. **Pregnant women with Hodgkin disease are inordinately susceptible to infections and sepsis, and both radiotherapy and chemotherapy increase this susceptibility.**

Long-Term Prognosis. Horning and co-workers (1981) reported that 55 percent of women resumed normal menses after chemotherapy. There were no birth defects in 24 infants subsequently born to these women. The risk of second cancers, especially leukemia, is substantively increased after cure of Hodgkin disease. Tucker and colleagues (1988) reported a secondary cancer rate of almost 20 percent within 15 years. Kaldor and associates (1990) reported that the risk of leukemia was increased almost ninefold following chemotherapy when compared with that of radiotherapy given alone. Travis and co-workers (2003) recently presented follow-up data from 3817 female survivors who were treated for Hodgkin disease before 30 years of age. Women treated with radiation had an overall 3.2-fold increased risk of breast cancer. When given chemotherapy alone, the risk was significantly decreased below baseline. Other complications of therapy for Hodgkin disease include myocardial damage and infarction, pulmonary fibrosis, hypothyroidism, and marrow suppression (Peleg and Ben-Ami, 1998).

NON-HODGKIN LYMPHOMAS. Usually B-cell lymphomas, these can also be T-cell or natural killer-cell neoplasms. They are further classified as indolent, aggressive, or highly aggressive (Williams and Schilsky, 2000). Their biology, classification, and treatment were recently reviewed by Evans and Hancock (2003). Non-Hodgkin lymphomas are more aggressive than Hodgkin lymphomas, and survival is perhaps 50 percent. The incidence of non-Hodgkin lymphomas has risen sharply because of their relationship to human immunodeficiency virus (HIV) infection. Indeed, 5 to 10 percent of persons infected with HIV develop a lymphoma.

Reported concurrence of non-Hodgkin lymphoma with pregnancy is limited. In an earlier review, Ward and Weiss (1989) described only 75 cases associated with pregnancy. Aviles and colleagues (1990) reported their experiences with 16 pregnant women with non-Hodgkin lymphomas, half of whom were in the first trimester. They were treated with cytotoxic drugs and there were no fetal malformations. All but one offspring were healthy at 3 to 11 years. Half of the mothers who had remissions were alive 4 to 9 years later. In another study, Aviles and Neri (2001) described long-term follow-up of 55 children whose mothers had received chemotherapy for lymphomas during pregnancy. They found no congenital, neurological, or psychological abnormalities at 6 to 29 years and observed that there were also no cancers, including leukemia.

Burkitt lymphoma is an aggressive B-cell tumor. Barnes and associates (1998) reviewed 19 pregnancies complicated by this lymphoma and 17 women did not survive for one year. Pollack and colleagues (1993) described an HIV-infected woman with a B-cell lymphoma that metastasized to the placenta. Catlin and co-workers (1999) described a fascinating case in which a maternal T-cell/natural killer-cell lymphoma metastasized transplacentally and engrafted the fetus. Both mother and infant succumbed from the malignancy.

Management. Staging for non-Hodgkin lymphomas is also with the Ann Arbor system (see [Table 57-2](#)). Radiotherapy typically is used for stage I disease, whereas chemotherapy is recommended for most stage II and all stage III and IV tumors. Unfortunately, the disease is often widespread when the peripheral nodes are involved, and staging laparotomy is of little or no benefit (Peleg and Ben-Ami, 1998).

LEUKEMIAS

Adult leukemias are more prevalent after 40 years of age. Despite this, acute leukemias are among the most common malignancies of young women. Paradoxically, their incidence complicating pregnancy is only about 1 case per 100,000 (Harrison and colleagues, 1994; Pavlidis, 2002). Our experiences at Parkland Hospital indicate that it is more common, and we have managed about 15 women with leukemia in nearly 350,000 pregnancies. Caligiuri and Mayer (1989) reviewed 350 reports of pregnancy complicated by leukemia. Of 72 newly diagnosed cases during pregnancy and reported since 1975, 44 had acute myelogenous leukemia, 20 had acute lymphocytic leukemia, and eight had one of the chronic leukemias.

PREGNANCY AND LEUKEMIA. Before 1970, maternal mortality in 256 women was reported to be 100 percent and perinatal mortality was 34 percent (McLain, 1974). According to Lewis and Laros (1986), maternal death since 1970 has been negligible, although ultimate survival is poor. With contemporaneous therapy, remission during pregnancy is almost 75 percent. Unfortunately, acute leukemias commonly relapse within a year (Pejovic and colleagues, 2001).

Greenlund and associates (2001) reviewed experiences with 17 cases of acute leukemia during pregnancy. There were 13 women with newly diagnosed acute myeloid leukemia, and the remission rate was 70 percent. Importantly, three of four women who elected to delay chemotherapy until after delivery died within days of delivery and just after beginning such therapy. Survival has also improved for women with *chronic myelogenous* and *chronic lymphocytic leukemias*. The rare, chronic *hairy-cell leukemia* has been reported in only six pregnancies (Stiles and colleagues, 1998).

Perinatal Outcome. Although perinatal survival has improved somewhat, morbidity is still substantial. Reynoso and colleagues (1987) reviewed 58 cases of acute leukemia in pregnant women. Nearly 75 percent were diagnosed during the second and third trimesters. About 50 percent were acute myelogenous leukemia, and most cases were treated with chemotherapy and had a remission rate of 75 percent. Only 40 percent of these pregnancies resulted in liveborn infants. Caligiuri and Mayer (1989) reported preterm delivery in about half of women diagnosed during pregnancy. The stillbirth rate was also increased. Leukemia cells may be seen in the placenta, however, these are usually in the intervillous space, and maternal-to-fetal transmission has never been authenticated (see [Chap. 27](#), p. 624).

Management. Manifestations of leukemia include anemia, neutropenia, and thrombocytopenia. Thus significant complications in pregnancy, including infection and hemorrhage, should be anticipated at the time of delivery in women with active disease.

In general, aggressive multi-agent chemotherapy is given as soon as leukemia is diagnosed, even in the first trimester. There is no evidence that pregnancy has a deleterious effect on leukemia, thus, termination will not improve the prognosis. Abortion is a consideration in early pregnancy to avoid potential teratogenesis from chemotherapy and to simplify management of an acutely ill woman.

Treatment given for acute promyelocytic leukemia in pregnancy has included all-*trans*-retinoic-acid (or tretinoin) (Carradice, 2002; Celo, 1994; Harrison, 1994, and all their associates). As discussed in [Chapter 14](#) (see p. 351), this is a potent teratogen. Although outcomes have been generally good, Siu and colleagues (2002) described transient dilated cardiomyopathy in a newborn exposed to tretinoin in the second trimester. Hansen and colleagues (2001) reported transient oligohydramnios in each of three cycles of intensive multi-agent chemotherapy for leukemia.

MALIGNANT MELANOMA

Melanomas are relatively common in women of childbearing age, and many may have the diagnosis made during pregnancy (MacKie, 1999). The general incidence of melanomas has been increasing over the last several decades at a rate faster than other malignancies (Katz and associates, 2002; MacKie and co-workers, 2002). The incidence in pregnancy has been estimated to range from 0.14 to 2.8 per 1000 live births (Wong and Strassner, 1990). As emphasized by Salopek and colleagues (1995), however, melanomas are underreported because many are treated on an outpatient basis and are not entered into a tumor registry.

Melanomas are most common in light-skinned Caucasians. More than 90 percent originate in the skin from pigment-producing melanocytes, usually arising from a preexisting nevus. Any suspicious "behavior" in a pigmented cutaneous lesion such as changes in contour, surface elevation, discoloration, itching, bleeding, or ulceration warrants a biopsy.

Melanomas are staged clinically. In stage I, there are no palpable lymph nodes; in stage II, there are palpable nodes; and in stage III, there are distant metastases. According to Squatrito and Harlow (1998), approximately 85 percent of cases are stage I disease. In contrast, Daryanani and colleagues (2003) reported that only about 50 percent of 610 consecutive women of childbearing age with melanoma had stage I disease. Tumor thickness is the single most important predictor of survival in stage I patients. The *Clark classification* is most widely used and includes five levels of involvement by depth into the epidermis, dermis, and subcutaneous fat. Tumor thickness is also measured using the *Breslow scale*.

PREGNANCY AND MELANOMA. In a recent review, Katz and associates (2002) explored the "myths of melanoma in pregnancy." For example, for many years it was widely held that the prognosis was worse during pregnancy and that future pregnancies increased the recurrence risk. In a review of 11 studies, however, Holly (1986) concluded that there was no adverse effect on survival if melanoma was diagnosed during pregnancy, or if pregnancy developed in a woman with previously recognized melanoma. Pregnancy is, however, associated with a later stage at diagnosis. MacKie and colleagues (1999) described findings from the World Health Organization Melanoma Programme indicating that women diagnosed during pregnancy had significantly greater tumor thickness.

Primary surgical treatment for melanoma is determined by the stage of the disease and includes wide local resection, sometimes with extensive regional lymph node dissection. Schwartz and associates (2003) have recommended sentinel lymph node mapping and biopsy using ^{99m}Tc-sulfur colloid that has a fetal dose of less than 100 mGy (see [Chap. 41](#), p. 981). Cascinelli and co-workers (1998) reported that routine regional node dissection improved survival in nonpregnant patients with microscopic metastases. Prophylactic chemotherapy or immunotherapy is usually avoided during pregnancy. However, chemotherapy for active disease is given if indicated by tumor stage and maternal prognosis. In most cases of distant metastatic melanoma, treatment is at best palliative.

Therapeutic abortion does not appear to improve survival in women with melanoma (Dipaola and colleagues, 1997). Prognosis is determined by the stage, and deep cutaneous invasion or regional node involvement confers a much poorer prognosis. As discussed, women who are pregnant when melanoma is diagnosed typically have thicker skin tumors. These women have a correspondingly higher mortality rate when compared with women whose melanoma was diagnosed before or after pregnancy ([Fig. 57-1](#)). Survival is equivalent, however, stage-for-stage, when pregnancy is compared with nonpregnancy. Kjems and Krag (1993) summarized the survival rate from five studies of 338 pregnant and 1360 nonpregnant women with stage I melanoma. They found no significant differences in 5-year survival rates between the two groups. Recurrences manifest by 2 years in 60 percent and 5 years in 90 percent, thus, most clinicians recommend that pregnancy be avoided for 3 to 5 years after treatment. There does not appear to be an adverse effect of oral contraceptives in these women (Katz and associates, 2002; Schwartz and colleagues, 2003).

Placental Metastases. Metastasis of any tumor type to the placenta or fetus is uncommon. However, a third of reported cases have been malignant melanoma. In an extensive review, Alexander and colleagues (2003) found that placental metastasis had been reported in 27 cases of melanoma. The infants were affected in six of these cases and died in five.

Figure 57-1. Disease-free survival in 388 women with malignant melanoma enrolled in the World Health Organization Melanoma Programme. Decreased survival

in women diagnosed during pregnancy is due to increased thickness of tumors. (Modified from MacKie and colleagues, 1991, with permission.)

GENITAL CANCER

Combined together, genital tract cancers are the most common malignancies encountered during pregnancy. Their distribution is summarized in [Table 57-3](#).

CERVICAL NEOPLASIA. Pregnancy provides an opportune time for screening for cervical neoplasia and premalignant disease, especially in women who do not seek or have access to routine health care (American College of Obstetricians and Gynecologists, 2002). Incidence data for cervical neoplasia complicating pregnancy varies widely. As expected, cervical dysplasia is quite common; Jolles (1989) cited an incidence in women of reproductive age of 26 per 1000. The incidence of carcinoma in situ was about 5 per 1000 women. According to Hacker and associates (1982), the average incidence of carcinoma in situ in pregnancy is about 1.3 per 1000. The incidence of invasive carcinoma is usually cited at about 1 per 2000 pregnancies (Anderson and colleagues, 2001). In our experiences with a high-risk population both from Parkland Hospital and from the University of Alabama, invasive cervical cancer is not nearly so common.

There is very limited experience with pregnancy following *radical trachelectomy* for fertility preservation in stage IB₁ and IB₂ cervical cancer. Del Priore and colleagues (2003) presented preliminary results in 20 women treated in this manner.

INTRAEPITHELIAL NEOPLASIA. The effects of pregnancy and delivery on premalignant and malignant epithelial cervical lesions are not understood completely. In the study by Kiguchi and co-workers (1981), progression from dysplasia to invasive carcinoma after delivery was 0.4 percent compared with that of 1 percent for nonpregnant women. The regression rates of moderate and marked dysplasia within 6 months after delivery were also higher than for the general population. It is well known that certain types of human papillomavirus (HPV) are associated with high-grade intraepithelial lesions as well as invasive cancer. Fife and colleagues (1996) found an increased incidence of high-cancer-risk viruses— HPV types 16, 18, 31, 35, 45, 51, 52, and 56— when they compared pregnant with nonpregnant women.

The incidence of abnormal cervical cytology during pregnancy is at least as high as that reported for nonpregnant women. Evaluation of the Papanicolaou smear can, however, be more difficult during pregnancy (Connor, 1998). According to the 2001 Consensus Guidelines for the Management of Women with Cervical Cytological Abnormalities, evaluation of a smear with atypical squamous cells of undetermined significance (ASCUS) is the same as for nonpregnant women (Wright and colleagues, 2002). For pregnant women with high-grade squamous intraepithelial lesions, it is recommended that colposcopic examination be performed by clinicians with experience in pregnancy-induced cytological changes. They further recommend that lesions suspicious of high-grade disease or malignancy be biopsied. In the event of unsatisfactory colposcopy, repeat examination should be performed in 6 to 12 weeks. After delivery, repeat cytology and colposcopy should generally be delayed for at least 6 weeks (Wright and associates, 2002).

During pregnancy, colposcopic evaluation is easier to perform because the transformation zone is better exposed due to physiological eversion. Colposcopically directed biopsies are used liberally to assess any suspicious lesions (Palle and co-workers, 2000; Wright and associates, 2002). Multiple biopsies need not all be taken on one occasion but rather may be obtained over time. The diagnostic accuracy of colposcopy is 99 percent, and complications occur in less than 1 percent of cases (Economos and associates, 1993). Biopsy sites may actively bleed because of hyperemia, but this can be stopped with Monsel solution, silver nitrate, vaginal packing, or occasionally a suture.

For obvious reasons, *endocervical curettage* should **not** be performed during pregnancy (Wright and associates, 2002).

Loop electrosurgical excision procedure (LEEP) and *cone biopsy* usually are reserved to exclude invasive cancer. If possible, conization is avoided in pregnant women because of an increased incidence of hemorrhage, abortion, and preterm labor. Indeed, conization during pregnancy is less than satisfactory for at least three reasons:

1. The epithelium and underlying stroma within the cervical canal cannot be excised extensively because of the risk of membrane rupture. Of 376 conizations during pregnancy reviewed by Hacker and colleagues (1982), residual neoplasia was found in 43 percent of subsequent specimens.
2. Blood loss is common. Averette and colleagues (1970) reported that nearly 10 percent of 180 pregnant women required transfusion.
3. There is a 1.6-fold relative risk of preterm delivery (El-Bastawissi and colleagues, 1999).

If cytological changes of mild cervical intraepithelial neoplasia are identified and subsequently confirmed, further follow-up during pregnancy may consist of colposcopic evaluation. In the absence of lesions detected by a satisfactory colposcopy, simply repeating the cervical smears later in pregnancy is usually adequate. Cytological changes suggestive of moderate or severe dysplasia or invasive disease require colposcopically directed biopsies.

Women with histologically confirmed intraepithelial neoplasia may be followed with cytology and colposcopically directed biopsies, allowed to deliver vaginally, and provided definitive treatment after delivery. In a study by Yost and colleagues (1999), there was regression postpartum in 68 percent of women with grade II and 70 percent of those with grade III neoplasia. Although 7 percent of women with grade II lesions progressed to grade III lesions, no lesion progressed to invasive carcinoma.

Invasive Cervical Cancer. Pregnancy coexisting with cervical carcinoma complicates both staging and treatment. Accurate determination of the extent of cancer is more difficult during pregnancy because induration of the base of the broad ligaments may be less prominent during pregnancy. Such induration in nonpregnant women characterizes tumor spread beyond the

cervix. Thus, the extent of the tumor is more likely to be underestimated in pregnant women.

Limited CT of the pelvis is acceptable. During pregnancy, MRI is a useful adjunct to ascertain disease extent, including urinary tract involvement (Gilstrap and colleagues, 2001; Hannigan, 1990). Cystoscopy and sigmoidoscopy can be performed as necessary to rule out mucosal involvement.

Because cervical carcinoma is relatively uncommon during pregnancy, only a few institutions have had extensive experience with its management. Some generalizations, however, can be made. Stage-for-stage, the survival rate for invasive carcinoma has not been profoundly different for pregnant and nonpregnant women. Van der Vange and colleagues (1995) performed a case-control study of 44 women with pregnancy-associated cervical cancer. The overall 5-year survival rate was 80 percent among pregnant women and 82 percent among nonpregnant controls.

The mode of delivery has not been shown to affect maternal survival significantly. Experiences are limited, however, and most women have undergone hysterotomy (Hacker and colleagues, 1982). In general, when frankly invasive carcinoma is identified, most clinicians favor abdominal delivery, if for no other reason than to prevent cervical laceration during labor and delivery.

MANAGEMENT. Treatment of cervical cancer varies for each individual patient, depending on the stage and pregnancy duration as well as the woman's desire to continue the pregnancy. Counseling and treatment include a multidisciplinary approach (American College of Obstetricians and Gynecologists, 2002). Treatment for microinvasive disease diagnosed by cone biopsy follows guidelines similar to those for intraepithelial disease. In general, continuation of pregnancy and vaginal delivery are considered safe, and definitive therapy is provided postpartum.

Invasive cancer demands relatively prompt therapy. During the first half of pregnancy, immediate treatment may be advisable. This of course depends on the decision to continue the pregnancy. During the latter half of pregnancy, a reasonable option is to await not only fetal viability but also fetal maturity (Greer and colleagues, 1989). In a review of 12 pregnant women with invasive cervical carcinoma, van Vliet and colleagues (1998) concluded that delayed treatment was reasonable in women with nonbulky lesions. These included women past 20 weeks with lesions less than stage IIB. Takushi and associates (2002) described outcomes in 28 pregnant women, 22 with stage I disease, and reached similar conclusions. The bulk of other studies of women with early stages of cervical cancer indicate that intentional delay in treatment did not appear to increase the recurrence risk (American College of Obstetricians and Gynecologists, 2002; Goff and associates, 2000).

Preferred treatment for invasive carcinoma in most women with stage I and early stage IIA lesions less than 3 cm is *radical hysterectomy plus pelvic lymphadenectomy*. This said, both radical surgery and radiation result in similar cure rates for early cervical cancer during pregnancy (American College of Obstetricians and Gynecologists, 2002). Surgical treatment is favored because it preserves ovarian and sexual function as well as avoids exposure of the intestinal and urinary tracts to radiation and its adverse effects. Nisker and Shubat (1983) described 49 cases of stage IB cervical cancer complicating pregnancy and reported a 30-percent severe complication rate from radiotherapy compared with only a 7-percent with radical surgery. Before 20 weeks, hysterectomy is usually performed with the fetus in situ. In later pregnancy, however, hysterotomy may first be necessary.

Radiotherapy is given for more extensive cancer. If the woman chooses treatment early in pregnancy, external irradiation is given and if spontaneous abortion does not ensue, then curettage is performed. During the second trimester, spontaneous abortion may be delayed, and hysterotomy may be necessary in up to a fourth of cases. About a week following abortion, external radiation is begun, followed by intracavitary radium application. After 24 weeks, the risk of delay to allow fetal maturity is unknown, but allowing pulmonary maturity seems reasonable, especially for early lesions.

DELIVERY. The mode of delivery remains controversial, especially for small, early-stage lesions. It is not clear if vaginal delivery through a cancerous cervix worsens the prognosis (American College of Obstetricians and Gynecologists, 2002). Most gynecological oncologists, however, favor abdominal delivery based on theoretical considerations. Large bulky and friable lesions may cause significant hemorrhage with vaginal delivery. Finally, recurrences in the episiotomy scar after vaginal delivery have been reported (Cliby and colleagues, 1994). In their review, Goldman and Goldberg (2003) described 12 cases. Although most recurrent lesions manifest by 6 months postpartum, one woman was asymptomatic until 5 years after delivery.

PROGNOSIS. The overall prognosis for all stages of cervical cancer during pregnancy is probably similar to that for nonpregnant women (Sood and Sorosky, 1998). The results from several reports suggest no difference in survival when pregnant women are compared with nonpregnant women ([Table 57-4](#)).

ENDOMETRIAL CARCINOMA. Because endometrial carcinoma characteristically develops in women past reproductive age, it is seen only rarely with pregnancy. Schammel and colleagues (1998) reviewed 14 reported cases and described an additional five. The majority of cases described have been well-differentiated adenocarcinomas. Treatment usually consists primarily of abdominal hysterectomy and bilateral salpingo-oophorectomy. Schammel and colleagues (1998) have described conservative therapy with curettage with or without progestational therapy in nonpregnant women. At least four viable infants subsequently were delivered to these 19 women. Gotlieb and associates (2003) reported 13 women treated with progestins for adenocarcinoma. Four of six women with a recurrence were re-treated and responded. At least nine infants have been delivered to these 13 women. Anderson and associates (2001) emphasized that this approach should not be encouraged as standard therapy.

OVARIAN CARCINOMA. Malignant ovarian neoplasms are the fourth most common cause of death from cancer in women and the leading cause of death from genital tract cancers. The incidence of death from ovarian cancer is higher than from both cervical and uterine cancer combined (American College of Obstetricians and Gynecologists, 2003a). The incidence of ovarian malignancy during pregnancy is not accurately known, but it averages about 1 per 20,000 deliveries (Rahman and co-workers, 2002). According to the American College of Obstetricians and Gynecologists (1990), about 1 of every 1000 pregnant women undergoes surgical exploration for an adnexal mass. As discussed in [Chapter 40](#) (see p. 965), most adnexal masses encountered during pregnancy are either mature teratomas or cystadenomas (Boulay and Podczaski, 1998). According to several reviews, perhaps 5 percent of adnexal neoplasms diagnosed during pregnancy are malignant, compared with 15 to 20 percent in nonpregnant women (Jacob and Stringer, 1990; Whitecar and associates, 1999). This is likely due to the younger age of pregnant women and because of the disparate number of corpus luteum cysts.

Pregnancy apparently does not alter the prognosis of most ovarian malignancies, but complications such as torsion and rupture may develop. Occasionally, primary or metastatic ovarian tumors cause virilization during pregnancy (Powell and associates, 2002; Tinkanen and Kuoppala, 2001). Because most women undergo sonography during pregnancy, the detection of adnexal masses has increased concomitantly. Certainly, sonography is indicated for women in whom there is a palpable adnexal mass. Sonography is also helpful to differentiate cystic masses from solid or multiseptated masses. With the former, expectant management is acceptable, but the latter require surgery for diagnosis (see [Chap. 40](#), p. 965).

Management. Treatment of ovarian cancer in pregnant women is similar to that for nonpregnant women. It also depends on gestational age as well as the stage, histological type, and grade of the tumor.

After frozen section verifies malignancy, complete surgical staging with careful inspection of all peritoneal and visceral surfaces is performed (Yazigi and associates, 1988). **Even malignant ovarian tumors apparently confined to one ovary require complete surgical staging, as do tumors of low malignant potential.** Procedures include peritoneal washings for cytological examination, multiple biopsies of the diaphragmatic undersurface and pelvic and parietal peritoneum, wedge resection of the opposite ovary, partial omentectomy, and excisional biopsies of pelvic and aortic lymph nodes. Whereas in most advanced stages, hysterectomy and bilateral adnexectomy are indicated, in certain circumstances it may be justified to remove the tumor and await fetal maturity. In some cases, chemotherapy can be given while awaiting pulmonary maturation. Maternal CA-125 serum levels are too variable during pregnancy to monitor response to therapy (Aslam and associates, 2000; Spitzer and colleagues, 1998).

Prognosis. Two thirds of ovarian cancers found during pregnancy are of the common epithelial types (Jolles, 1989). The remainder are germ cell tumors, and occasionally a stromal cell tumor. There have been about 80 or 90 cases of invasive *epithelial cell tumors* reported coexistent with pregnancy (Dgani and colleagues, 1989; Rahman and associates, 2002). Because of the relatively young age of the pregnant population, there is a higher proportion of less-advanced tumors. Thus, tumors with low malignant potential and stage IA disease are seen more often in pregnant women than in nonpregnant women.

Karlen and associates (1979) reviewed 27 cases of *dysgerminomas* during pregnancy. They found significant obstetrical complications in nearly half and reported a 30-percent recurrence with apparent stage IA cases. Since then, a number of reports have been more encouraging. Tangir and colleagues (2003) described their 20-year experiences with 64 women with *malignant germ cell ovarian tumors* treated with fertility-sparing surgery and usually chemotherapy. Of 38 who attempted pregnancy, 29 had a total of 39 children. They also reviewed a number of studies with similar successes.

Young and associates (1984) reviewed 36 cases of stage I *gonadal stromal tumors* that had an excellent prognosis. An *endodermal sinus tumor* has been diagnosed because of persistently elevated maternal serum alpha-fetoprotein levels (van der Zee and colleagues, 1991). This tumor has an overall bad prognosis (Malhotra and Sood, 2000). Maymon and co-workers (1998) described a woman with primary ovarian *hepatoid carcinoma* who also had elevated maternal serum alpha-fetoprotein levels. Kalir and Friedman (1998) have described a *gynandroblastoma*— sex cord and stromal cells of both ovarian and testicular types — in a 32-year-old pregnant woman.

VULVAR CANCER. Invasive *squamous cell carcinoma* of the vulva is primarily a disease of postmenopausal women and thus is only rarely associated with pregnancy (Regan and Rosenzweig, 1993). In their review, Heller and associates (2000) found 23 cases and described a 28-year-old woman with a 4-cm vulvar lesion noted near term. They concluded that radical surgery for stage I disease was feasible during pregnancy, even in the last trimester. Anderson and colleagues (2001) are of the opinion that definitive therapy can often be delayed because of the slow rate of progression of vulvar carcinoma. Treatment is individualized according to the clinical stage and depth of invasion. Vaginal delivery is not contraindicated if the vulvar and inguinal incisions are well healed.

Vulvar intraepithelial neoplasia is seen more often in young women, and it is often associated with HPV. It may progress to invasive disease, the rate of which seems to have risen in younger women (Messing and Gallup, 1995).

Kuller and colleagues (1990) reviewed five cases of *vulvar sarcoma* discovered during pregnancy. In four of these, cure was obtained by a variety of therapies. **Any suspicious vulvar lesion detected during pregnancy should be biopsied.**

UTERINE LEIOMYOMAS. Benign uterine leiomyomas are common in older pregnant women, especially in black women. Because they are seldom malignant, leiomyomas complicating pregnancy are considered in detail in [Chapter 40](#) (see p. 962).

Leiomyomatosis Peritonealis Disseminata. Rarely at cesarean section or puerperal tubal ligation, numerous subperitoneal smooth muscle tumors are found that at first appear to be disseminated carcinomatosis. This is termed *leiomyomatosis peritonealis disseminata* and it results from stimulation, probably by estrogen, of multicentric subcoelomic mesenchymal cells to become smooth muscle cells. According to the review by Lashgari and colleagues (1994), about half of the 45 reported cases were discovered during pregnancy. Although surgical excision has been recommended, there is evidence that these tumors regress after pregnancy. Marom and associates (1998) as well as Ling and colleagues (2000) have described women who had tumors extending up the vena cava into the heart. Bekkers and colleagues (1999) have reported a rare malignant *leiomyoblastoma* during pregnancy.

GASTROINTESTINAL TRACT CANCER

COLORECTAL CARCINOMA. Cancers of the colon and rectum are the second most frequent malignancies in women of all age groups in the United States. These tumors seldom complicate pregnancy because they are uncommon before 40 years of age. Accordingly, fewer than 250 cases of colon cancer have been reported in pregnant women (Walsh and Fazio, 1998). The majority (80 percent or more) of colorectal carcinomas in pregnant women arise from the rectum (Skilling, 1998).

The most common symptoms of colorectal cancer are abdominal pain, distention, nausea and vomiting, constipation, and rectal bleeding. The diagnosis may be delayed because these symptoms may be ascribed to the pregnancy. Certainly, if symptoms suggestive of colon disease persist, digital rectal examination, tests for occult blood, and flexible sigmoidoscopy or colonoscopy are done. Tumors above the peritoneal reflection are uncommon in pregnancy, and Chan and associates (1999a) described only 41 cases in their review. Van Voorhis and Cruikshank (1989) reported two women with colon cancer who had persistent microcytic, hypochromic anemia from occult bleeding.

Treatment of colorectal cancer in pregnant women follows the same general guidelines as for nonpregnant women. When there is no evidence of metastatic disease, surgery is performed. Unfortunately, pregnant women usually present with advanced disease (Walsh and Fazio, 1998). During the first half of the pregnancy, hysterectomy is not necessary to perform colon or rectal resection, and thus therapeutic abortion is not mandated. During later pregnancy, as well as in the presence of metastatic disease, delaying therapy to allow fetal maturation is considered. Vaginal delivery is usually permitted if obstetrical conditions are favorable, but rectal lesions below the pelvic brim may cause dystocia. Hemorrhage, obstruction, or perforation may force surgical intervention (Donegan, 1983).

There is no evidence that pregnancy influences the usual course of colorectal cancer. Thus, prognosis is similar to that for identical stages in nonpregnant patients. Carcinoembryonic antigen (CEA), a useful tumor marker for colon cancer, may be elevated during normal pregnancy and therefore is of little value.

OTHER GASTROINTESTINAL NEOPLASMS. *Gastric cancer* is rarely associated with pregnancy, and most reported cases are from Japan. Hirabayashi and collaborators (1987) reviewed outcomes in 60 pregnant women with this malignancy seen over a 70-year period from 1916 to 1985. Unfortunately, delay in diagnosis during pregnancy was common, and the prognosis was consistently poor; 88 percent of women were dead within 1 year of diagnosis. Persistent upper gastrointestinal symptoms should be evaluated by endoscopy. Davis and Chen (1991) and Chan and colleagues (1999b) each described a woman with gastric cancer who attributed her continued epigastric pain during pregnancy to preexisting peptic ulcer disease.

Stewart and colleagues (1997) reviewed their experiences with seven pregnancies in five women with *Zollinger-Ellison syndrome*. They advise surgical resection of the tumor before pregnancy is undertaken, but in women with metastatic disease or in those with previously undiagnosed tumors, antacid and antisecretory treatment usually suffices.

At least 21 cases of *carcinoid tumors* complicating pregnancy have been reported. In his review, Durkin (1983) found that most cases were of gastrointestinal origin, and some were incidentally diagnosed at cesarean delivery. *Pancreatic cancer* is rare during pregnancy (Gamberdella, 1984; Levy and colleagues, 2004). Primary *hepatocellular carcinoma* during pregnancy also is rare (Gisi and Floyd, 1999; Hsieh and associates, 1996). Balderston and co-workers (1998) described a 23-year-old woman at 26 weeks who had a massive intrahepatic cholangiocarcinoma masquerading as HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count). She died 3 weeks postpartum. Hsu and colleagues (2001) reported a case of spontaneous rupture of hepatocellular carcinoma at 25 weeks that was treated by packing. The pregnancy continued until 41 weeks.

RENAL TUMORS

Walker and Knight (1986) reviewed 71 cases of primary renal neoplasms associated with pregnancy. Half were *renal cell carcinoma*, and a palpable abdominal mass was the presenting finding in almost 90 percent of these women. In half, pain was the presenting symptom, and hematuria was also found in half. Only a fourth of these women had the classical triad of hematuria, pain, and palpable mass. Diagnosis of these and other intra-abdominal or retroperitoneal tumors has been improved by CT and MRI studies such as the one shown in [Figure 57-2](#). Smith and co-workers (1994) added nine new cases since 1986 in their updated review. They suggest that earlier diagnosis is common now because of ultrasonography. Fazeli-Matin and co-workers (1998) described partial nephrectomy in a woman with renal carcinoma at 14 weeks.

We have encountered only six pregnant women with this malignancy during the past 30 years at Parkland Hospital. Either they presented because of painless hematuria, or the tumor was found by abdominal palpation done routinely in conjunction with cesarean delivery.

Figure 57-2. Computed tomography scan of a pregnant woman with large renal mass on left side. (From Gross and associates, 1995, with permission.)

OTHER TUMORS

Thyroid cancers are the most common endocrine malignancies. Morris (1998) has estimated that approximately 10 percent occurring during the reproductive years are diagnosed during pregnancy or within the first year after birth. Most thyroid cancers are well-differentiated and follow an indolent course. Tewari and associates (1998) described a woman with Graves thyrotoxicosis and thyroid storm who was subsequently found to also have papillary adenocarcinoma. Rossing and colleagues (2000) have presented intriguing findings suggesting that thyroid stimulation during pregnancy and lactation may result in a transient increase in growth of papillary thyroid cancer. Diagnosis is usually by fine-needle aspiration. Treatment consists primarily of surgery performed during the second trimester or after delivery (see [Chap. 53](#), p. 1198).

Soft-tissue and bone tumors, although rare in pregnancy, in most cases, can be successfully managed with surgery during gestation (Maxwell and associates, 2004).

Brain tumors are uncommon during pregnancy. Isla and colleagues (1997) described seven cases in more than 126,000 deliveries from Hospital La Paz in Madrid. According to Finfer (1991), the types of tumors are the same as for identically aged nonpregnant women, and about a third each are gliomas or meningiomas. Tewari and co-workers (2000) described eight women with malignant brain tumors associated with pregnancy. Another two women had postpartum gestational choriocarcinoma metastatic to the brain. These cases were from a 20-year survey of five California hospitals with about 312,000 deliveries during the 20-year study period. Maternal outcomes were horrific—five women died, two survived with significant neurological defects, and only three attained remission.

58. Infections

INTRODUCTION

The pregnant woman and her fetus are susceptible to many infectious diseases that may be serious and life-threatening.

IMMUNOLOGICAL CHANGES OF PREGNANCY

There is much speculation concerning possible effects of decreased immune surveillance during pregnancy. These effects are brought about by maternal tolerance of the foreign-tissue antigens of the semiallogeneic fetal "graft" (see Chap 3, p. 64). Although there are subtle changes in circulating immunoglobulin levels in pregnancy, these appear to be of no clinical consequence (Stirrat, 1991).

Fetal and Newborn Immunology. The active immunological capacity of the fetus and neonate is compromised compared with that of older children and adults. According to Stirrat (1991), fetal cell-mediated and humoral immunity begin to develop by 9 to 15 weeks. The primary fetal response to infection is immunoglobulin M (IgM). Passive immunity is provided by IgG transferred across the placenta. By 16 weeks, this transfer begins to increase rapidly, and by 26 weeks, fetal concentrations are equivalent to those of the mother. After birth, breast feeding is protective against some infections. But this begins to decline at 2 months of age (World Health Organization Collaborative Study Team, 2000).

Neonatal infection, especially in its early stages, may be difficult to diagnose because neonates may fail to express classical clinical signs. If the fetus was infected in utero, there may be depression and acidosis at birth for no apparent reason. The neonate may suck poorly, vomit, or develop abdominal distention. Respiratory insufficiency may develop, which may present similarly to idiopathic respiratory distress syndrome. The neonate may be lethargic or jittery. The response to sepsis may be hypothermia rather than hyperthermia, and the total leukocyte and neutrophil counts may be depressed.

Bacteria, viruses, or parasites may gain access transplacentally during the viremic, bacteremic, or parasitemic stage of maternal infection (Newton, 1999). They may also cross intact amniotic membranes. Fetal infections may develop early in pregnancy to produce obvious stigmata at birth. Alternatively, organisms may colonize and infect the fetus during labor and delivery. Thus, preterm rupture of membranes, prolonged labor, and manipulations may increase the risk of neonatal infection (Yancey and colleagues, 1996). Infections occurring in neonates who are less than 72 hours after delivery usually are caused by bacteria acquired in utero or during delivery, whereas infections after that time most likely have been acquired after birth.

Hospital-acquired infections are dangerous for preterm neonates, and the individuals who care for them are a major source for postnatal infection (Stoll and Hansen, 2003). Ventilatory systems and indwelling venous and arterial umbilical catheters may be the source of life-threatening infection. **The very-low-birthweight infant who survives the first few days is still at considerable risk of dying from infection acquired in the intensive care nursery.**

Ascending infection by bacteria (e.g., *Escherichia coli*, group B streptococci, *Ureaplasma urealyticum*) is the most common infectious cause of neonatal sepsis and stillbirth. In developed countries, 10 to 25 percent of stillbirths may be caused by infectious pathogens, and in developing countries, the percentage may be much greater (Goldenberg and Thompson, 2003). In high-prevalence areas, syphilis and malaria in nonimmune women in pregnancy are also major causes of stillbirths.

VIRAL INFECTIONS

VARICELLA-ZOSTER. This DNA herpesvirus remains latent in the dorsal root ganglia after primary infection. Most adults acquire varicella infection, namely chickenpox, during childhood, and 95 percent have serological evidence of immunity (Wharton, 1996). Varicella infection tends to be more severe in adults than in children. Approximately half of all varicella deaths occur in the 5 percent of the adult population that are susceptible (Centers for Disease Control and Prevention, 1999a).

Although disputed, there is evidence that varicella infection may be more severe during pregnancy. Harger and associates (2002b) reported that 18 of 347 (5 percent) infected pregnant women developed pneumonitis. Despite this, successful pregnancy outcomes can follow complicated varicella pneumonia (Chandra and colleagues, 1998). Its treatment is described in [Chapter 46](#) (see p. 1059).

Primary varicella infection may be reactivated years later, causing herpes zoster or shingles (Gilden and co-workers, 2000). Maternal herpes zoster infection is more common in older or immunocompromised patients. There is no evidence, however, that zoster is more frequent or more severe in pregnant women. In addition, in a review of 366 cases of zoster during pregnancy, Enders and associates (1994) concluded that there was little evidence that zoster caused congenital malformations.

Prevention. Administration of *varicella-zoster immunoglobulin (VZIG)* prevents or attenuates varicella infection in exposed susceptible individuals if given within 96 hours of viral exposure. The dose is 125 U per 10 kg given intramuscularly, with a maximum dose of 625 units or five vials. VZIG is recommended by the Centers for Disease Control and Prevention (1996) for immunocompromised susceptible adults who are exposed to varicella, and it should be strongly considered for all susceptible pregnant women. Despite this recommendation, Enders and colleagues (1994) and Harger and associates (2002a) both found that only 7 to 11 percent of more than 1700 pregnant women with varicella infection had received VZIG.

A new intravenous form of VZIG has been developed and was found to have higher initial anti-varicella antibody levels and comparable efficacy and safety in a preliminary study of 57 gravidas (Koren and associates, 2002). This new form of VZIG is not approved for use in the United States.

Up to 80 to 90 percent of adults are immune because of prior symptomatic or asymptomatic infection. Thus, antibody testing with enzyme-linked immunosorbent assay (ELISA) or fluorescent antibody to membrane antigen (FAMA) should precede, if

possible, use of VZIG.

An attenuated live-virus vaccine (Varivax) was approved for use in 1995 (American College of Obstetricians and Gynecologists, 2000). Two doses, given 4 to 8 weeks apart, are recommended for adolescents and adults with no history of varicella. This successfully results in 97-percent seroconversion (American College of Obstetricians and Gynecologists, 2003). **The vaccine is not recommended for pregnant women.** However, a pregnancy registry listing 362 vaccine-exposed pregnancies has reported no cases of congenital varicella syndrome or other congenital malformations (Shields and colleagues, 2001). Vaccine virus is not secreted in breast milk, so postpartum vaccination should not be delayed because of breast feeding (Bohlke and associates, 2003).

Fetal Effects. Maternal varicella during the first half of pregnancy may cause congenital malformations by transplacental infection. Some of these include chorioretinitis, cerebral cortical atrophy, hydronephrosis, and cutaneous and bony leg defects (Fig. 58-1). In a prospective study, Enders and co-workers (1994) evaluated 1373 women who had varicella infection during pregnancy. When maternal infection developed before 13 weeks, only 2 of 472 pregnancies (0.4 percent) had neonates with congenital varicella. The highest risk was between 13 and 20 weeks, during which time 7 of 351 exposed fetuses (2 percent) had evidence of congenital varicella. There was no clinical evidence of congenital varicella infection after 20 weeks gestation. Other evidence shows that fetal exposure later in pregnancy is associated with only congenital varicella lesions (Chiang and colleagues, 1995). Similarly, Harger and colleagues (2002a) evaluated a prospective cohort of 347 women with primary varicella infection and found only one case (0.4 percent) of congenital varicella syndrome.

Fetal exposure to the virus just before or during delivery, and therefore before maternal antibody has been formed, poses a serious threat to newborns. The incubation period for varicella infection is short, usually less than 2 weeks. In some instances, neonates develop disseminated visceral and central nervous system disease, which is commonly fatal. For this reason, VZIG or zoster immunoglobulin (ZIG) should be administered to neonates whenever the onset of maternal disease is within about 5 days before or after delivery. Neonates exposed earlier or later are protected by maternal antibody, and perinatal mortality is minimal. Despite VZIG administration, however, Miller and associates (1998) reported that 30 to 40 percent of newborns still developed infection, but the number of complications and fatal outcomes was substantially reduced (Centers for Disease Control and Prevention, 1996).

Figure 58-1. Atrophy of the lower extremity with bony defects and scarring in a fetus infected during the first trimester by varicella. (From Paryani and Arvin, 1986, with permission.)

INFLUENZA. These infections are caused by members of the family *Orthomyxoviridae*. *Influenza A* and *B* form one genus of these RNA viruses. *Influenza A* viruses are subclassified further by hemagglutinin (H) and neuraminidase (N) antigenic makeup. Symptoms include fever, dry cough, and systemic symptoms, and infection can be confirmed with rapid enzyme immunoassay or immunofluorescence assay (Salgado and co-workers, 2002). *Influenza A* is more serious than *influenza B* and usually develops during winter.

Infection usually is not life-threatening in otherwise healthy adults, but pregnant women do not tolerate serious pulmonary involvement (Neuzil and colleagues, 1998). For example, in early 2003, widespread *influenza A* was associated with extensive infection among pregnant women. At Parkland Hospital, more than 100 women were hospitalized for infection. Pulmonary infiltrates complicated approximately 20 percent of cases.

Prevention. Vaccination against influenza, optimally in October or November, is recommended by the Centers for Disease Control and Prevention (2004b) and the American College of Obstetricians and Gynecologists (2003) for all women who will be pregnant during the influenza season (from November through February) at any gestational age. This is most important for women who have chronic underlying medical disorders such as diabetes, heart disease, asthma, or human immunodeficiency virus (HIV) infection. The inactivated vaccine prevents clinical illness in 70 to 90 percent of healthy adults, and there is no evidence of teratogenicity (see [Chap. 8](#), p. 221). A recent survey of obstetricians found that only 44 percent provided influenza vaccination in pregnancy. Many did not offer vaccine because of reimbursement issues or availability of vaccination elsewhere (Schrage and co-workers, 2003). There was a shortage of the 2004-2005 vaccine because of manufacturing problems.

An intranasal, trivalent, cold-adapted, live attenuated-virus vaccine was approved for use in healthy adults in 2003. It is not recommended for pregnant women (Centers for Disease Control and Prevention, 2003c).

Treatment. *Amantadine* and *rimantadine* are antiviral agents with specific activity against *influenza A* viruses ([Table 58-1](#)). Given as chemoprophylaxis, both antivirals are 70 to 90 percent effective in preventing influenza (Centers for Disease Control and Prevention, 2004b). They are especially recommended for prophylaxis for nonimmunized women at high risk for influenza complications (see [Chap. 46](#), p. 1059). If influenza develops, *amantadine* or *rimantadine*, begun within 48 hours of the onset of symptoms, reduces the duration of fever and systemic symptoms.

Another class of antiviral drugs—*neuraminidase inhibitors*—is highly effective for the treatment of early *influenza A* and *B* in adults (Centers for Disease Control and Prevention, 2004b). *Oseltamivir* is taken orally and is approved for both treatment and chemoprophylaxis in adults. *Zanamivir* is inhaled and is approved for treatment in adults. They are discussed further in [Chapter 46](#) (see p. 1059). Both agents reduce the odds of developing influenza by 70 to 90 percent and reduce the duration of uncomplicated illness by about 1 day (Cooper and colleagues, 2003).

There is limited experience with the use of any of these four antiviral agents in pregnant women. All the agents are Food and Drug Administration category C drugs, and they should be used when the potential benefits outweigh the risks. Unfortunately, none of the agents has been demonstrated to be effective in preventing serious influenza-related complications such as pneumonia.

Fetal Effects. There is no firm evidence that *influenza A* virus causes congenital malformations (Irving and co-workers, 2000;

Korones, 1988). Specifically, Saxen and associates (1990) found no association with first-trimester influenza in 248 mothers of anencephalic fetuses. Irving and colleagues (2000) identified no specific fetal or maternal complications in 182 pregnancies with serological evidence of second- or third-trimester influenza. Conversely, Lynberg and co-workers (1994) reported increased neural-tube defects in neonates born to women with influenza early in pregnancy. In addition, there is controversial evidence that fetal exposure to influenza A may predispose to schizophrenia in later life (Kunugi and associates, 1995; McGrath and Castle, 1995).

MUMPS. This uncommon adult infectious disease is caused by an RNA paramyxovirus. As a result of childhood immunization, as many as 80 to 90 percent of adults are seropositive. The virus primarily infects the salivary glands but may involve the gonads, meninges, pancreas, and other organs. Treatment is symptomatic, and mumps during pregnancy is no more severe than in nonpregnant adults.

The live attenuated Jeryl-Lynn vaccine strain is part of the *MMR vaccine* — measles, mumps, and rubella — and is contraindicated in pregnancy (American College of Obstetricians and Gynecologists, 2003). No malformations attributable to MMR vaccination in pregnancy have been reported, but pregnancy should be avoided for 30 days after mumps vaccination (Centers for Disease Control and Prevention, 1998b, 2002a).

Fetal Effects. Women who develop mumps in the first trimester may have an increased risk of spontaneous abortion. However, infection in pregnancy is not associated with congenital malformations (Centers for Disease Control and Prevention, 1998; Siegel, 1973; Siegel and Fuerst, 1966). Fetal infection is rare.

RUBEOLA (MEASLES). Most adults are immune to measles due to childhood immunization. Unfortunately, when measles becomes epidemic, unvaccinated women may develop measles, and if pregnant, they have an increased risk of pneumonia with adverse maternal and perinatal outcomes (Ali and Alber, 1997; Chiba and co-workers, 2003; Eberhart-Phillips and colleagues, 1993).

Passive maternal immunization can be achieved by administering immune serum globulin (0.25 mL/kg, maximum dose 15 mL), given intramuscularly within 6 days of exposure. Active vaccination is not done during pregnancy, but susceptible women can be vaccinated routinely postpartum (American College of Obstetricians and Gynecologists, 2003; Centers for Disease Control and Prevention, 1998).

Fetal Effects. The virus does not appear to be teratogenic (Siegel, 1973), but there is an increased frequency of abortion, prematurity, and low-birthweight neonates with maternal measles (Siegel and Fuerst, 1966). If a woman develops measles shortly before birth, there is considerable risk of serious infection developing in the neonate, especially in a preterm neonate.

RESPIRATORY VIRUSES. More than 200 antigenically distinct respiratory viruses cause the common cold, pharyngitis, laryngotracheobronchitis, bronchitis, and pneumonia. Rhinovirus, coronavirus, and adenovirus are major causes of the common cold. The RNA-containing rhinovirus and coronavirus usually produce a trivial, self-limited illness characterized by rhinorrhea, sneezing, and congestion. The DNA-containing adenovirus is more likely to produce cough and lower respiratory tract involvement, including pneumonia.

Fetal Effects. Mothers suffering from the common cold had a four- to fivefold increased risk of fetal anencephaly when a 393-woman cohort of the Finnish Register of Congenital Malformations was analyzed (Kurppa and associates, 1991). Shaw and co-workers (1998), however, examined births in California from 1989 to 1991 and concluded that the attributable risk for neural-tube defects associated with many illnesses and medications used in early pregnancy is low.

Adenoviral infection is a common cause of childhood myocarditis. Towbin and colleagues (1994) and Forsnes and associates (1998) used polymerase chain reaction (PCR) to identify and link adenovirus to fetal myocarditis and nonimmune hydrops.

HANTAVIRUSES. These RNA viruses are members of the family *Bunyaviridae*. They are associated with a rodent reservoir, and transmission involves inhalation of virus excreted in rodent urine and feces. An outbreak in the Western United States occurred in 1993 due to Sin Nombre virus. The resulting hantavirus pulmonary syndrome was characterized by severe noncardiogenic pulmonary edema resembling adult respiratory distress syndrome and carried a case-fatality rate of 45 percent. Hantaviruses are a heterogeneous group of viruses with low and variable rates of transplacental transmission. Howard and co-workers (1999) reported the syndrome to cause maternal death, fetal demise, and preterm birth. They found no evidence of vertical transmission of the Sin Nombre virus. Vertical transmission, however, occurred inconsistently in association with hemorrhagic fever with renal syndrome caused by another hantavirus species, the Hantaan virus.

Clinical management should be individualized in cases of noncardiogenic pulmonary edema in women from endemic areas who have a history of possible exposure. Prevention focuses on lowering exposure to infected rodents (Centers for Disease Control and Prevention, 2002b).

ENTEROVIRUS INFECTIONS. These viruses are a major subgroup of RNA picornaviruses that include poliovirus, coxsackievirus, and echovirus. They are trophic for intestinal epithelium but can also cause widespread maternal, fetal, and neonatal infections that may include the central nervous system, skin, heart, and lungs. Most maternal infections, however, are subclinical, yet can be fatal to the fetus-neonate (Goldenberg and Thompson, 2003). Garcia and associates (1991) reported that histological placentitis was common following maternal enteroviral infection. Hepatitis A is an enterovirus that is discussed in [Chapter 50](#) (see p. 1130).

Coxsackievirus. Infections with coxsackievirus are usually asymptomatic. However, the virus can cause aseptic meningitis, a polio-like illness, rashes, respiratory disease, or pleuritis, pericarditis, and myocarditis. Brown and Karunas (1972) reported that congenital malformations were increased slightly in pregnant women who had serological evidence of coxsackievirus but not echovirus infections. In addition, viremia with coxsackievirus can cause fetal hepatitis, myocarditis, and encephalomyelitis, all of which may be fatal.

Poliovirus. Most of these rare infections are subclinical or mild. The virus is trophic for the central nervous system, and symptomatic infections can cause paralytic disease—poliomyelitis. Siegel and Goldberg (1955) demonstrated that pregnant women not only were more susceptible to polio but also had a higher death rate. Inactivated subcutaneous polio vaccine is recommended for susceptible pregnant women who must travel to endemic areas or are placed in other high-risk situations. Live oral polio vaccine has been used for mass vaccination during pregnancy without harmful fetal effects (Harjulehto and associates, 1989).

PARVOVIRUS. Human parvovirus B19 causes *erythema infectiosum*, or *fifth disease*. This is a mild maternal infection that occasionally causes fetal death. The B19 virus is a small, single-stranded DNA virus that replicates in rapidly proliferating cells such as erythroblast precursors (Young and Brown, 2004). Only individuals with the erythrocyte membrane P antigen are susceptible. In women with hemolytic anemia (e.g., sickle-cell disease), parvovirus infection may cause an aplastic crisis.

The main mode of parvovirus transmission is respiratory or hand-to-mouth contact, and the infection is common in spring months. The maternal infection rate is highest in women with school-aged children and in day-care workers, but not usually schoolteachers. Viremia develops 4 to 14 days after exposure. Fever, headache, and flulike symptoms may begin in the last few days of the viremic phase. Several days later, a bright red rash with erythroderma affects the face, giving a *slapped cheek* appearance. The rash becomes lacelike and spreads to the trunk and extremities. Adults often have milder rashes and develop a symmetrical polyarthralgia that may persist several weeks. In 20 to 30 percent of adults, however, the infection is asymptomatic.

There is no evidence that parvovirus infection is altered by pregnancy (Valeur-Jensen and colleagues, 1999). Recovery includes production of IgM antibody 10 to 12 days postinfection. IgM usually persists for 3 months but may last for up to 6 months. IgG antibody is detectable several days after IgM appears. IgG persists for life and confers natural immunity against subsequent infections. Roughly half of pregnant women are immune. The attack rate of susceptible adults in school outbreaks is 20 to 30 percent (Young, 1995).

Fetal Effects. Maternal infection may be associated with abortion, nonimmune hydrops, and fetal death (Goldenberg and Thompson, 2003). Parvovirus DNA was found by Nyman and co-workers (2002) in 3 percent of first-trimester miscarriages. Shilleto and associates (1996) found evidence of fetal myocardial damage by measuring creatine kinase levels obtained by cordocentesis. Crane (2002) reviewed 1089 cases of maternal B19 infection from nine studies and reported an overall fetal loss rate of 10 percent. It was 15 percent for infection between 19 to 20 weeks but only 2.3 percent after 20 weeks. The role of parvovirus B19 infection in late second-trimester and third-trimester unexplained stillbirths is unclear, because most derived data are from retrospective cohorts with incomplete maternal and fetal histological evaluations (Norbeck, 2002; Skjoldbrand-Sparre, 2000; Tolfvenstam, 2001, and all their colleagues). As a result, at present there are inadequate data to support evaluating asymptomatic mothers and their stillborn fetuses for parvovirus infection.

Parvovirus is the most common infectious cause of nonimmune hydrops in autopsied fetuses (Rogers, 1999). This complication, however, develops only in approximately 1 percent of infected women and is largely confined to infection in the first 20 weeks of gestation (Crane, 2002; Enders and co-workers, 2004). Considering that concomitant fetal infection follows maternal infection in about a fourth of cases, infection resolves in most fetuses without sequelae (Dembinski and colleagues, 2003).

Yaegashi (2000) has extensively investigated the development and pathophysiology of parvovirus B19 fetal hydrops. At least 85 percent of cases of fetal infection developed within 10 weeks of maternal infection, and the mean interval was 6 to 7 weeks. More than 80 percent of hydrops cases were found in the second trimester, with a mean gestational age of 22 to 23 weeks. Yaegashi estimated that the critical period for maternal infection leading to fetal hydrops was between 13 and 16 weeks—coincident with the period in which fetal hepatic hemopoiesis is greatest.

Rodis and colleagues (1998) and Miller and associates (1998) described long-term outcomes of children following maternal parvovirus infection. They concluded that developmental delay was not increased in these children.

Management. The diagnosis of maternal infection is generally made by serological testing for specific IgG and IgM antibodies (Fig. 58-2). Viral DNA may be detectable by PCR in maternal serum during the prodrome but not after the rash develops. Fetal infection can be identified by detecting viral DNA in amniotic fluid or fetal parvoviral IgM using cordocentesis (Schild and colleagues, 1999).

For women with a positive IgM serology, ultrasonographic fetal evaluation for hydrops is indicated. Delle Chiaie and colleagues (2001) and Cosmi and co-workers (2002) have shown that elevated peak systolic velocity values in the fetal middle cerebral artery accurately predict fetal anemia. Fetal blood sampling is warranted in the presence of hydrops to assess the degree of fetal anemia. Fetal myocarditis may induce hydrops with less severe anemia.

Fetal management is dependent on gestational age, but transfusion for hydrops may improve outcome in some cases (Enders and co-workers, 2004; Schild and colleagues, 1999; von Kaisenberg and Jonat, 2001). The technique for fetal transfusion is described in [Chapter 13](#) (see p. 332).

Prevention. There is no vaccine for human parvovirus B19, and there is no evidence that antiviral treatment prevents maternal or fetal infection. Decisions to leave higher-risk work settings are complex and require assessment of exposure risks. Pregnant patients should be counseled that risks of infection are approximately 5 percent for casual, infrequent contact; 20 percent for intense, prolonged work exposure (e.g., teachers); and 50 percent for close, frequent interaction (e.g., in the home). Workers at day-care centers and schools need not avoid infected children, because infectivity is greatest before any clinical illness. Ill children do not require isolation.

Figure 58-2. Algorithm for evaluation and management of human parvovirus B19 infection in pregnancy. (MCA = middle cerebral artery.)

RUBELLA (GERMAN MEASLES). This virus typically causes infections of minor import in the absence of pregnancy. During pregnancy, however, it has been directly responsible for abortion and severe congenital malformations.

Prevention. Although large epidemics of rubella have virtually disappeared in the United States because of immunization, the disease, with its significant teratogenic potential, persists. Up to 25 percent of women in the United States are susceptible (McElhaney and associates, 1999), and cluster outbreaks during the 1990s mainly involved persons born outside the United States (Reef and co-workers, 2002). Congenital rubella is still common in developing nations (Banatvala and Brown, 2004).

To eradicate rubella and prevent congenital rubella syndrome completely, a comprehensive approach is recommended for immunizing the adult population (Centers for Disease Control and Prevention, 1998). The MMR vaccine should be offered to women of childbearing age who do not have evidence of immunity whenever they make contact with the health care system. Vaccination of susceptible women should:

1. Be part of routine general medical and gynecological care, including college health services.
2. Take place in all family planning settings.
3. Be provided routinely to unimmunized women immediately after hospitalization, childbirth, or abortion, unless there are specific contraindications.

Vaccination of all susceptible hospital personnel who might be exposed to patients with rubella or who might have contact with pregnant women is recommended. Rubella vaccination should be avoided 1 month before or during pregnancy because the vaccine contains attenuated live virus (Centers for Disease Control and Prevention, 2002a,e). Although there is a small overall theoretical risk of 0.5 percent, fortunately, according to pooled data from the Centers for Disease Control and Prevention, there is no evidence that the vaccine induces malformations. If maternal antibody is demonstrated at the time of exposure to rubella or before, it is exceedingly unlikely that the fetus will be affected.

Despite native or vaccine-induced immunity, subclinical rubella *reinfection* may develop during outbreaks. Although asymptomatic reinfection in early pregnancy has been described without fetal effects, fetal infection can rarely occur.

Diagnosis. Rubella is usually a mild, febrile illness in adults with a generalized maculopapular rash. Other symptoms may include arthralgias or arthritis, lymphadenopathy (usually suboccipital, postauricular, and cervical), or conjunctivitis. The incubation period is 12 to 23 days, and 20 to 50 percent of infections may be asymptomatic. Viremia usually precedes clinical signs by about a week, and adults are infectious during viremia through 5 to 7 days of the rash.

Confirmation of rubella infection is often difficult. Not only are the clinical features of other illnesses similar, but about a fourth of rubella infections are subclinical despite viremia that may infect the embryo and fetus.

Specific IgM antibody can be detected using enzyme-linked immunoassay from 4 to 5 days after onset of clinical disease, but it can persist for 6 weeks after appearance of the rash (American College of Obstetricians and Gynecologists, 1992). Importantly, rubella reinfection can give rise to transient low levels of IgM. Best and associates (2002) reviewed the low rubella-specific IgM antibody levels in gravidas without a rash in locales where rubella seldom occurs. They were able to exclude recent maternal infection by detecting high rubella IgG avidity in most cases.

Nonimmune persons demonstrate peak IgG antibody titers 1 to 2 weeks after the onset of the rash or 2 to 3 weeks after the onset of viremia. This rapid antibody response, therefore, may complicate serodiagnosis unless serum is initially collected within a few days after the onset of the rash. If, for example, the first specimen was obtained 10 days after the rash, detection of IgG antibodies would fail to differentiate between very recent disease and preexisting immunity to rubella.

Congenital Rubella Syndrome. Rubella is one of the most teratogenic agents known (see [Chap. 14](#), p. 342). With rubella, as with any fetal infection, the concept of an *infected* versus an *affected* neonate must be understood. Only about half of women with affected neonates give a history of a rash during pregnancy.

Sequelae of fetal infection are worse during organogenesis. Miller and colleagues (1982) have shown that 80 percent of pregnant women with rubella infection and a rash during the first 12 weeks have a fetus with congenital infection. At 13 to 14 weeks, this incidence was 54 percent, and by the end of the second trimester, it was 25 percent. As the duration of pregnancy increases, fetal infections are less likely to cause congenital malformations. According to Reef and colleagues (2000), congenital rubella syndrome includes one or more of the following:

- Eye defects, including cataracts and congenital glaucoma
- Heart disease, including patent ductus arteriosus and peripheral pulmonary artery stenosis
- Sensorineural deafness — the most common single defect
- Central nervous system defects, including microcephaly, developmental delay, mental retardation, and meningoencephalitis
- Pigmentary retinopathy
- Purpura
- Hepatosplenomegaly and jaundice
- Radiolucent bone disease **Neonates born with congenital rubella may shed the virus for many months and thus be a threat to other infants, as well as to susceptible adults who come in contact with them.**

The *extended rubella syndrome*, with progressive panencephalitis and type 1 diabetes, may not develop clinically until the second or third decade of life. Perhaps as many as a third of neonates who are asymptomatic at birth may manifest such developmental injury (Webster, 1998).

Prenatal Diagnosis. Confirmation of fetal infection is possible in confirmed cases of maternal rubella in the first half of pregnancy. Tanemura and associates (1996) found rubella RNA in chorionic villi, amniotic fluid, or fetal blood in 23 percent of 34 suspected cases. Detection of second-trimester fetal rubella infection using fetal blood has been described by Tang and colleagues (2003).

CYTOMEGALOVIRUS. This ubiquitous DNA herpesvirus eventually infects most humans. Cytomegalovirus (CMV) is the most common cause of perinatal infection in the developed world, and evidence of fetal infection is found in from 0.2 to 2 percent of all neonates (Revello and Gerna, 2002, 2004). CMV is present in body fluids, and person-to-person transmission usually occurs through sexual or close and intimate contact. There may be fetal intrauterine infection, intrapartum infection, or postpartum infection from breast feeding. Day-care centers are a common source of infection. Usually by 2 to 3 years of age, children acquire the infection from one another and may transmit it to their parents (Demmler, 1991; Pass, 1991).

The public health importance concerning morbidity of perinatal CMV infection was first emphasized in 1971. In the ensuing 20 years, according to Yow and Demmler (1992), more than 800,000 fetuses were infected and 50,000 were born with symptomatic disease. Many have died, and most of the survivors have severe handicaps, including mental retardation, blindness, and deafness. Collectively, the annual cost for their care is nearly \$2 billion (American College of Obstetricians and Gynecologists, 2000). Another 120,000 infected children who were asymptomatic at birth have neurological impairments.

Maternal Infection. There is no evidence that pregnancy increases the risk or clinical severity of maternal CMV infection. Most infections are asymptomatic, but about 15 percent of adults have a mononucleosis-like syndrome characterized by fever, pharyngitis, lymphadenopathy, and polyarthritis. Nigro and associates (2003) reported that the majority of women in a cohort with primary infection had elevated serum aminotransferases or lymphocytosis.

Following primary infection, the virus becomes latent, and as in other herpesvirus infections, there is periodic reactivation with viral shedding despite serum IgG antibody. Maternal immunity to CMV does not prevent recurrence-reactivation or exogenous reinfection, nor unfortunately does it prevent congenital infection. The risk of seroconversion among susceptible women during pregnancy is 1 to 4 percent. Immunity from previous infection can be demonstrated in up to 85 percent of pregnant women from lower socioeconomic backgrounds, whereas only half of women in higher income groups are seropositive.

Primary CMV infection, which is transmitted to the fetus in approximately 40 percent of cases, can cause severe morbidity (Fowler and co-workers, 1992; Liesnard and associates, 2000). Although transplacental infection is not universal, an infected fetus is more likely with maternal infection during the first half of pregnancy. Fowler and colleagues (2003a) calculated that naturally acquired immunity results in a 70-percent reduction of risk of congenital CMV infection in future pregnancies. Boppana and associates (2001) observed that women who are seropositive for CMV can also be reinfected with a different strain of virus that can cause fetal infection and symptomatic congenital disease. Congenital infections from recurrent maternal infection reactivation are less often associated with clinically apparent sequelae than with primary infections.

Congenital Infection. Symptomatic congenital CMV infection is a syndrome that includes low birthweight, microcephaly, intracranial calcifications, chorioretinitis, mental and motor retardation, sensorineural deficits, hepatosplenomegaly, jaundice, hemolytic anemia, and thrombocytopenic purpura. Of the estimated 40,000 infected neonates born each year, only 5 to 6 percent demonstrate this syndrome (Fowler and associates, 1992).

Treatment. There is no treatment for maternal primary CMV infection, nor is there fetal prophylaxis or treatment.

Management. Maternal serological screening is not recommended for the following reasons (American College of Obstetricians and Gynecologists, 2000; Peckham and associates, 2001):

1. There is no accurate prediction of the sequelae of primary infection.
2. Some cases of fetal infection are due to maternal reinfection with a different CMV strain.
3. There is no vaccine or treatment.
4. About 2 percent of all neonates excrete CMV, and attempts to identify and isolate them are expensive and impractical.

The predictive value of a positive maternal genitourinary culture or of cervical cytology results in assessing fetal risk of infection is likewise minimal. Asymptomatic CMV excretion can be shown in up to 10 percent of pregnant women, and the majority have recurrent infections with low fetal risk.

Primary infection is diagnosed by seroconversion of CMV-specific IgG in paired acute and convalescent sera, which are assayed simultaneously. It is preferable to document maternal CMV IgM antibody. Unfortunately, specific IgM antibody may be present with primary infection, recurrent infection, or reactivation of infection, limiting its utility for serological diagnosis.

As shown in [Figure 58-3](#), when maternal CMV-specific IgG and IgM are detected, complimentary tests are used to date the infection (Grangeot-Keros and Cointe, 2001). The measurement of specific IgG avidity is valuable in confirming primary CMV infection (Lazzarotto and associates, 2004). The IgG antibody response matures from low-avidity to high-avidity production over several weeks to months (Revello and Gerna, 2002, 2004).

Management is directed to identification of women with recent primary infection who should be offered invasive prenatal diagnosis with ultrasonography and amniocentesis. In utero infection can be identified, and serial ultrasonography can identify fetuses with symptomatic infection and damage. The use of quantitative CMV measurements in amniotic fluid may correlate with outcome, but its interpretation may also be dependent on the gestational age at amniocentesis and the interval since

maternal infection. Pregnancy termination may be an option in some settings or delivery followed by early neonatal treatment (Kimberlin and associates, 2003).

Counseling regarding fetal outcome depends on the stage of gestation during which primary infection is documented. Even with the high infection rate with primary infection in the first half of pregnancy, the majority of fetuses develop normally. Kimberlin and co-workers (2003) have shown that intravenous ganciclovir administered for 6 weeks to neonates symptomatic with central nervous system disease prevents hearing deterioration at 6 months and possibly at greater than or equal to one year.

Prenatal Diagnosis. In some cases, effects of fetal infection are detected by ultrasonography, computed tomography (CT), or magnetic resonance imaging. Microcephaly, ventriculomegaly, or cerebral calcifications may be seen (Malinge and colleagues, 2003). Ascites, hepatomegaly, splenomegaly, hydrops, hyperechoic bowel, and oligohydramnios have also been described. Enders and co-workers (2001) observed that an abnormal ultrasonographic examination in combination with positive findings in fetal blood or amniotic fluid predicted an approximate 75-percent risk of symptomatic congenital infection.

Currently, PCR is used to detect and quantify viral DNA in amniotic fluid and fetal blood (Revello and Gerna, 2002, 2004). Bodeus and colleagues (1999) and Antsaklis and associates (2000) both emphasized that a negative culture or PCR result from amniotic fluid does not always exclude fetal infection. In another study, Liesnard and co-workers (2000) showed that combined culture and PCR results allowed diagnosis in 44 of 55 infected fetuses (80 percent).

Recently, other investigators have extended these observations in an attempt to increase the specificity and sensitivity of amniotic fluid testing for CMV to predict both the risk of fetal infection and of symptomatic neonates (Gouarin and co-workers, 2001, 2002; Guerra and associates, 2000; Lazzarotto and colleagues, 2000).

Prevention. There is neither an available CMV vaccine nor an effective mode of passive prophylaxis. Prevention of congenital infection relies on the prevention of maternal primary infection, especially in early pregnancy. Basic measures such as good hygiene and handwashing have been promoted, particularly for women with toddlers in day-care settings (Fowler, 2000). Sexual transmission from infected partners can also occur, but there is no data on the efficacy of any preventive strategy (Nigro and co-workers, 2003).

BACTERIAL INFECTIONS

GROUP A STREPTOCOCCUS. Infections caused by *Streptococcus pyogenes* are rarely encountered today (O'Brien and colleagues, 2002). Only 0.06 cases per 1000 births, that is, 220 cases are reported annually (Chuang and associates, 2002). *S. pyogenes* produces a number of toxins and enzymes, and infections especially with M3 strains are particularly severe (Beres and collaborators, 2004). As discussed in [Chapter 31](#) (see p. 713), the most common presentations for invasive postpartum group A streptococcal infection are bacteremia without a septic focus (46 percent), metritis (28 percent), peritonitis (8 percent), and septic abortion (7 percent).

Maternal colonization may also play a role in postpartum infection (Barnham and Weightman, 2001; Davies and co-workers, 1996). Puerperal sepsis following identification of group A streptococci during group B surveillance testing has been reported (Stefonek and colleagues, 2001).

S. pyogenes causes a *toxic shock-like syndrome* that is often fatal (Brown, 2004). The case-fatality rate for postpartum group A streptococcal infection is 3 to 4 percent (Chuang and associates, 2002). In one series, it was 73 percent (Udagawa and co-workers, 1999). Of three cases at Parkland Hospital in 1992, there were two maternal deaths (Nathan and colleagues, 1993). Prompt penicillin treatment, sometimes combined with surgical debridement, may be lifesaving (see [Chapter 31](#), p. 721).

A less virulent exotoxin causes *scarlet fever*, which is also treated with penicillin. *Erysipelas* is an acute streptococcal skin infection, and bacteremia is common (Bisno and Stevens, 1996).

GROUP B STREPTOCOCCUS. Asymptomatic carriage of group B streptococcus (GBS) *S. agalactiae* is common, especially in the vagina and rectum. Schrag and associates (2002, 2003) reported a colonization rate of 20 to 30 percent in a nationwide cohort sampled at a mean of 35 weeks. In a study done at Parkland Hospital in 1995 by Wendel and co-workers (2002), group B streptococcal carriage was detected in 15 percent of 8536 women in labor. Throughout pregnancy, colonization can be transient, intermittent, or chronic.

There is a spectrum of maternal and fetal GBS infections ranging from asymptomatic colonization to sepsis. *S. agalactiae* has been implicated in adverse pregnancy outcomes, including preterm labor, prematurely ruptured membranes, clinical and subclinical chorioamnionitis, and fetal and neonatal infections. The bacterium can also cause bacteriuria, pyelonephritis, and postpartum metritis. Postpartum maternal osteomyelitis and mastitis caused by GBS infection have also been described (Barbosa-Cesnik and associates, 2003; Berkowitz and McCaffrey, 1990).

Neonatal Sepsis. Infection in neonates less than 7 days after birth is defined as *early-onset disease* (Schrag and colleagues, 2000). Many investigators use a threshold of less than 72 hours of life as most compatible with intrapartum acquisition of disease (Stoll and associates, 2002a; Wendel and co-workers, 2002). We have encountered a number of unexpected intrapartum stillbirths from GBS infections. In many neonates, septicemia involves signs of serious illness that usually develop

within 6 to 12 hours of birth, including respiratory distress, apnea, and shock. At the outset, therefore, the neonatal infection must be differentiated from idiopathic respiratory distress syndrome. The mortality rate with early-onset disease has declined to about 4 percent. Preterm newborns do not fare as well.

Late-onset disease usually manifests as meningitis 1 week to 3 months after birth. These cases are most often caused by serotype III organisms. The mortality rate, although appreciable, is less for late-onset meningitis than for early-onset sepsis. Unfortunately, it is not uncommon for surviving infants of both early- and late-onset disease to exhibit neurological sequelae.

Epidemiology. Intrapartum fetal transmission from the colonized mother may lead to severe neonatal sepsis soon after birth. Reported rates of early-onset sepsis historically ranged from 2 to 3 per 1000 live births before widespread intrapartum chemoprophylaxis was implemented. Currently most centers and countries have experienced a decline in early-onset neonatal sepsis to rates of less than 1 to 2 per 1000 live births. Most reports, however, indicate no change or variable increases in rates of non-GBS organisms, such as *E coli* and other Enterobacteriaceae (Baltimore, 2001; Hyde, 2002; Levine, 1999; Moore, 2003; Towers and Briggs, 2002, and all their colleagues).

There is worrisome evidence that the major association with current intrapartum antimicrobial prophylaxis has been an increase in non-GBS early-onset sepsis in preterm, low-birthweight neonates, and especially very-low-birthweight neonates. (Eschenbach, 2002; Towers and Briggs, 2002). For example, while Stoll and Hansen (2003) and Stoll and associates (2002a) observed a marked reduction in group B streptococcal sepsis in these preterm neonates, this was offset by an increase in *E coli* sepsis. Very-low-birthweight neonates with early-onset sepsis have higher rates of respiratory distress, intraventricular hemorrhage with periventricular leukomalacia, and bronchopulmonary dysplasia. The death rate in newborns with early-onset infection was 37 percent, compared with 13 percent in uninfected newborns. The death rate for gram-negative infections was 36 percent, compared with 11 percent for gram-positive ones.

Late-onset neonatal GBS sepsis is less well understood. Cited rates vary from 0.5 to 2 cases per 1000 live births and account for about 50 percent of GBS disease in newborns (Lin and colleagues, 2003). The incidence of late-onset disease has remained stable despite widespread use of intrapartum antimicrobials, suggesting that GBS screening and chemoprophylaxis intervention may not affect late-onset disease. Lin and co-workers (2003) reported that preterm birth before 34 weeks was the major risk factor. Stoll and associates (2002b) found that late-onset sepsis was identified in a fourth of very-low-birthweight newborns; there was a preponderance of gram-positive organisms, mainly coagulase-negative staphylococci.

Recommended Prevention Strategies. Lacking randomized trials, consensus opinions and guidelines on prevention strategies have been promulgated by the American College of Obstetricians and Gynecologists (2002a) and the Centers for Disease Control and Prevention (2002d). These guidelines advocate a culture-based screening approach to identify women who should receive intrapartum prophylaxis (Fig. 58-4). This recommendation was derived from a multistate, retrospective cohort study of live births in 1998 and 1999 from the Active Bacterial Surveillance/Emerging Infections Program network, which suggested that the culture-based approach was superior to a risk-based approach.

The recommendations also describe management of imminent preterm delivery in the setting of preterm labor or preterm prematurely ruptured membranes (Fig. 58-5). Data suggesting a single course of management or recommending a specific treatment duration for GBS-positive women with arrested preterm labor or preterm prematurely ruptured membranes are insufficient (American College of Obstetricians and Gynecologists, 2002a).

With the culture-based approach, women are screened for GBS colonization at 35 to 37 weeks, and intrapartum antimicrobials are given to rectovaginal carriers. Previous siblings with GBS invasive disease and prior identification of GBS bacteriuria are also considered indications for prophylaxis. A risk-based approach is recommended for women with unknown group B streptococcal culture results at the time of labor (see Fig. 58-4).

The choice of antimicrobials may be important in terms of allergic reaction; selection of resistant GBS strains; and emergence of other pathogens, including antimicrobial-resistant strains, as agents of neonatal sepsis. Treatments are shown in Table 58-2. The Centers for Disease Control and Prevention recommendations specify penicillin as a first-line agent (Johnson and colleagues, 2001). Ampicillin is an acceptable alternative (Bloom and co-workers, 1996). For women with penicillin allergy, if the risk of anaphylaxis is low, cefazolin is recommended (Mitchell and associates, 2001). If the risk of anaphylaxis is high, selection of a prophylactic agent is dependent on GBS susceptibility testing. Patients with isolates susceptible to clindamycin or erythromycin may be given either drug. Antimicrobial-resistant strains require vancomycin prophylaxis. This treatment scheme is dependent on laboratory capability to perform susceptibility testing.

Importantly, there have been no randomized controlled trials comparing antenatal screening, whether culture-based or risk-based, with no antenatal screening. In addition, there have been no randomized trials comparing the different screening strategies and whether prenatal GBS screening has a significant impact on overall neonatal sepsis. For these reasons, clinicians in other countries state that there is insufficient evidence to recommend screening for GBS carriage (Canadian Task Force on Preventive Health Care, 2002; Jakobi and colleagues, 2003; Royal College of Obstetricians and Gynaecologists, 2003).

Alternative prevention strategies have been described with limited evidence to recommend them. These include intramuscular benzathine penicillin G and chlorhexidine vaginal lavage (Bland and associates, 2000; Rouse and co-workers, 2003). In another study, Haberland and colleagues (2002) reported that intrapartum rapid PCR screening for GBS may be superior to current strategies, however, this must be proven effective in clinical trials. In GBS-positive women, appropriate vaginal examinations or indicated intrauterine fetal monitoring should not be avoided as their avoidance could actually prolong labor and thus increase the risk of infection (Gibbs and associates, 2004).

In 1995, prior to the consensus guidelines, we adopted the risk-based approach at Parkland Hospital for intrapartum treatment of women at high risk for GBS infection. In addition, all term neonates born to women at high risk for GBS infection who were not given intrapartum prophylaxis were treated in the delivery room with aqueous penicillin G, 50 to 60,000 units intramuscularly. Early-onset GBS infection and sepsis, as well as non-GBS sepsis, all decreased during the study (Wendel and associates, 2002). Almost 80 percent of failures (i.e., neonatal infections) were caused by chorioamnionitis (Velaphi and associates, 2003).

Implementation of several protocols is associated with diminished GBS sepsis. There are, however, still major concerns about

antimicrobial resistance, particularly among very-low-birthweight neonates. Ongoing surveillance is necessary to monitor protocol efficacy for prevention of early-onset GBS sepsis as well as for any effects on maternal morbidity, overall neonatal sepsis, and resistant infections.

Vaccination. Some protection against serious neonatal infection is conferred by maternal antibodies. Indeed, Lin and colleagues (2001) have confirmed that the susceptibility to invasive GBS disease correlates with deficiency in maternal type-specific antibody levels. Baker and co-workers (1988, 1999, 2000) reported that maternal immunization to type III antigen produces antibody in about 60 percent of women. Monovalent tetanus toxoid conjugate vaccines are immunogenic for common GBS disease-associated serotypes. Paoletti and Madoff (2002) have reviewed the progress toward development of a multivalent vaccine.

Figure 58-4. Indications for intrapartum prophylaxis to prevent perinatal group B streptococcal (GBS) disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures taken at 35 to 37 weeks' gestation. (From Centers for Disease Control and Prevention, 2002d.)

Figure 58-5. Sample algorithm for prophylaxis for women with group B streptococcal (GBS) disease and threatened preterm delivery. This algorithm is not an exclusive course of management and variations that incorporate individual circumstances or institutional preferences may be appropriate. (Adapted from Centers for Disease Control and Prevention, 2002d.)

LISTERIOSIS. *Listeria monocytogenes* is an uncommon but probably underdiagnosed cause of neonatal sepsis. The Centers for Disease Control and Prevention (2001a) estimate that nearly 2500 individuals in the United States annually are ill with listeriosis, and more than 500 die. This Gram-positive, aerobic, motile bacillus can be isolated from the feces of 1 to 5 percent of adults. Food-borne transmission is important. Outbreaks of listeriosis have been reported from raw vegetables; coleslaw; apple cider; milk; fresh Mexican-style cheese; smoked fish; and processed foods, such as pate, hot dogs, and sliced delicatessen meat.

Listerial infections are more common in very old or young, pregnant, or immunocompromised patients. Some authors have speculated that pregnant women are susceptible because of decreased cell-mediated immunity (Wing and Gregory, 2002).

Listeriosis during pregnancy may be asymptomatic or cause a febrile illness that is confused with influenza, pyelonephritis, or meningitis (Mylonakis and colleagues, 2002; Silver, 1998). The diagnosis usually is not apparent until blood cultures are reported as positive. Alvarez and associates (2004) described a 13-week pregnant woman with *S typhimurium* isolated from blood and urine cultures. Occult or clinical infection also may stimulate labor (Boucher and Yonekura, 1986). Discolored, brownish, or meconium-stained amniotic fluid is common with fetal infection, even with preterm gestations.

Maternal listeremia causes fetal infection that characteristically produces disseminated granulomatous lesions with microabscesses (Topalovski and colleagues, 1993). Chorioamnionitis is common with maternal infection and placental lesions may develop (Fig. 58-6). In a review of 222 cases by Mylonakis and associates (2002), infection resulted in abortion or stillbirth in 20 percent, and neonatal sepsis developed in 68 percent of surviving newborns. There are two types of neonatal infection, very similar to GBS sepsis. *Early-onset infection* develops within 5 to 7 days, is usually associated with maternal illness, and presents with respiratory distress and with fever or neurological abnormalities or both. Most neonates are preterm and symptomatic at birth. *Late-onset infection* after 5 to 7 days of life usually presents as meningitis, and it may be associated with nosocomial transmission. The overall neonatal mortality from listeriosis is about 25 percent in reported cases (Mylonakis and associates, 2002).

Treatment. There are no clinical trials, but an ampicillin-gentamicin combination is usually recommended because of its synergism. Trimethoprim-sulfamethoxazole is given to penicillin-allergic women. Maternal outcome is excellent, and there is evidence that maternal treatment may also be effective for fetal infection.

Prevention. There is no vaccine for listeriosis. Pregnant women may choose to avoid the implicated foods listed previously.

Figure 58-6. Listeriosis: multiple cut surfaces of placenta show several well-demarcated, grayish-white macroabscesses that appear solid and are indistinguishable from ischemic infarcts. (From Topalovski and colleagues, 1993, with permission.)

SALMONELLA AND SHIGELLA

Salmonellosis. Infections from *Salmonella* and *Shigella* species continue to be a major cause of food-borne illness. There are 800,000 to 4 million cases of salmonella infections each year in the United States, which result in 500 deaths (Centers for Disease Control and Prevention, 1999b). Gastroenteritis is contracted through contaminated food, and symptoms include diarrhea, abdominal pain, fever, chills, nausea, and vomiting. Management is usually intravenous fluid rehydration. Antimicrobials do not shorten illness and may prolong the convalescent carrier state. They are not given in uncomplicated infections.

Typhoid Fever. Uncommonly seen in the United States, this disease is caused by *Salmonella enterica* serotype typhi, which is spread by oral ingestion of contaminated food, water, or milk. In pregnant women, the disease is more likely to be encountered during epidemics or in those who are infected with HIV (Hedriana and colleagues, 1995). In their review, Dildy and associates (1990) reported that antepartum typhoid fever in former years resulted in abortion, preterm labor, and maternal or fetal death.

Fluoroquinolones are the most effective treatment, but clinicians may choose to use intravenous third-generation cephalosporins or azithromycin in pregnant women (Parry and co-workers, 2002). Typhoid vaccines appear to exert no harmful effects when administered to pregnant women and should be given in an epidemic or before travel to endemic areas (Centers for Disease Control and Prevention, 2003a).

Shigellosis. Bacillary dysentery caused from *Shigella* infection is a relatively common, highly contagious cause in adults of inflammatory exudative diarrhea, frequently with bloody stools. Shigellosis is more common in children attending day-care centers, and it is highly contagious. Clinical manifestations range from mild diarrhea to severe dysentery, abdominal cramping, tenesmus, fever, and systemic toxicity.

Although shigellosis may be self-limited, careful attention to treatment of dehydration is essential in severe cases. We have cared for pregnant women in whom secretory diarrhea exceeded 10 L/day! Effective treatments during pregnancy include fluoroquinolones, ceftriaxone, azithromycin, and trimethoprim-sulfamethoxazole (Bhattacharya and Sur, 2003).

HANSEN DISEASE. This chronic infection, also known as leprosy, is caused by *Mycobacterium leprae*. Dapsone, rifampin, and clofazimine for treatment appear to be safe for use during pregnancy (Britton and Lockwood, 2004; Farb and associates, 1982). Rifampin therapy is also effective. Duncan (1980) reported an excessive incidence of low-birthweight newborns born to infected women. The placenta is not involved, and neonatal infection apparently is acquired from skin-to-skin or droplet transmission (Duncan and colleagues, 1984).

LYME DISEASE. This disease is caused by the spirochete *Borrelia burgdorferi*. It is the most commonly reported vector-borne illness in the United States. Lyme borreliosis results from the bite of ticks of the genus *Ixodes*. Early infection causes a distinctive local skin lesion, *erythema migrans*, which may be accompanied by a flu-like syndrome and regional adenopathy. If untreated, disseminated infection follows in days to weeks. Multisystem involvement is common, but skin lesions, arthralgia and myalgia, carditis, and meningitis predominate. If still untreated after several weeks to months, late or persistent infection manifests in perhaps half of patients. Native immunity is acquired, and the disease enters a chronic phase. Although some patients remain asymptomatic, others in the chronic phase develop a variety of dermatological, rheumatic, or neurological manifestations (Steere, 2001).

Serological diagnosis has pitfalls, and clinical diagnosis is important. Although positive in only about half of patients with early disease, most with late, untreated Lyme disease have a positive ELISA result.

Treatment. Optimal treatment has not been established. In early infection, treatment with doxycycline or amoxicillin is recommended. Pregnant women are given oral amoxicillin or penicillin V for 3 weeks (Steere, 2001). Cefuroxime is preferred, but erythromycin can be used for penicillin-allergic women. For later infection manifested by meningitis or carditis, intravenous ceftriaxone, cefotaxime, or penicillin G is recommended. Chronic arthritis and post-Lyme disease syndrome are treated with prolonged oral or intravenous regimens, however, symptoms respond poorly to treatment (Klempner and colleagues, 2001).

Neonatal Infection. Literature regarding the reproductive effects of Lyme disease has failed to define a teratogenic effect or an association with fetal death, preterm delivery, or malformations (Elliott, 2001; Maraspin, 1999; Strobino, 1999, and all their colleagues).

Prevention. A vaccine was withdrawn from the market in 2002 due to low sales. Avoidance of areas where Lyme disease is endemic and improved tick control in those areas may be beneficial. Personal tick checks and removal of unengorged ticks within 36 hours of attachment reduce risks of infection (Hayes and Piesman, 2003). For tick bites recognized within 72 hours, a single 200-mg dose of doxycycline reduces the risk of *erythema migrans* by 87 percent (Nadelman and associates, 2001). Prompt treatment of maternal early infection should prevent most adverse pregnancy outcomes.

TUBERCULOSIS. Diagnosis and management of tuberculosis is discussed in detail in [Chapter 46](#) (see p. 1065).

PROTOZOAL INFECTIONS

TOXOPLASMOSIS. *Toxoplasma gondii* has a complex life cycle and may exist in one of three forms: (1) as a *tachyzoite* invading and replicating intracellularly during infection, (2) as a *bradyzoite* forming tissue cysts during latent infection, and (3) as a *sporozoite* found in oocysts that can be environmentally resistant (Jones and associates, 2001b). Maternal infection is transmitted by eating raw or undercooked meat infected with tissue cysts or through contact with oocysts from infected cat feces in contaminated litter, soil, or water.

Adults rarely develop symptoms, but they do have tachyzoite parasitemia temporarily. In pregnant women, focal lesions then develop in the placenta, and the fetus may become infected. The fetus initially has generalized infection that is then cleared from visceral organs, but may localize in the central nervous system (Hill and Dubey, 2002).

According to the Third National Health and Nutrition Examination Survey cohort from 1988 to 1994, the seroprevalence of toxoplasmosis was only 15 percent in women 15 to 44 years of age. This suggests that 85 percent of pregnant women are susceptible to *T. gondii* infection. Literature reviews indicate that the incidence of new infection ranges from 0.5 to 8.1 per 1000 in susceptible pregnancies (Gilbert and Peckham, 2002).

The incidence of congenital toxoplasmosis varies from 0.8 per 10,000 live births in the United States to 10 per 10,000 in

France (Dubey, 2000). The Centers for Disease Control and Prevention (Lopez and colleagues, 2000) estimate that there are between 400 and 4000 cases of congenital toxoplasmosis each year in the United States. The incidence and severity of congenital infection depend on the gestational age of the fetus at the time of maternal primary infection. The risk of fetal infection increases with duration of pregnancy, with the risk of fetal infection rising from 6 percent at 13 weeks to 72 percent at 36 weeks (Fig. 58-7). Fetuses infected in early pregnancy, however, are much more likely to show signs of infection (Dunn and associates, 1999).

Most acute infections in mothers and neonates are asymptomatic and can be detected only by prenatal or newborn serological screening. Maternal symptoms may include fatigue, muscle pain, and sometimes lymphadenopathy, but most often infection is subclinical. In immunocompetent adults, initial infection confers immunity, and prepregnancy infection nearly eliminates any risk of vertical transmission. Infection in immunocompromised women, however, may be severe, with reactivation involving encephalitis or mass lesions.

The majority of infected fetuses are born without obvious signs of toxoplasmosis on routine examination. Clinically affected neonates at birth usually have generalized disease with low birthweight, hepatosplenomegaly, icterus, and anemia. Some primarily have neurological disease, intracranial calcifications (Fig. 58-8), and hydrocephaly or microcephaly. Many eventually develop chorioretinitis and exhibit learning disabilities. These findings make up the classic triad described for this congenital infection—chorioretinitis, intracranial calcifications, and hydrocephalus. It often is accompanied by convulsions. Infected neonates with clinical signs are at risk for long-term complications.

Management. There is no consensus on the most appropriate screening or treatment strategy. In some European countries, *prenatal screening* is done routinely. However, the United Kingdom National Screening Committee recommended against universal prenatal or neonatal screening in the United Kingdom (Gilbert and Peckham, 2002). The American College of Obstetricians and Gynecologists (2000) does not recommend screening except for pregnant women with HIV infection. If anti-toxoplasma IgG antibody is confirmed before pregnancy, then a woman is not at risk for a congenitally infected fetus (Montoya, 2002).

Acute infection may be documented by seroconversion of IgG and IgM antibodies or by a greater than fourfold rise in paired specimens. Unfortunately, no single test accomplishes the goal of timing maternal seroconversion, because IgG may persist in high titer for years and IgM may also be detectable for more than 1 year. A panel of tests, however, performed in reference laboratories is often used (Roberts and associates, 2001). For many, the best resource is the Toxoplasma Serology Laboratory at the Palo Alto Medical Foundation Research Institute, which uses a Toxoplasma Serologic Profile consisting of the Sabin Feldman dye test, a double-sandwich IgM ELISA, an IgA ELISA, an IgG ELISA, and a differential agglutination test (AC/HS test) (Montoya and Liesenfeld, 2004).

Recently, an avidity test for toxoplasma IgG antibody has been added to maternal serum panel testing (Beghetto, 2003; Liesenfeld, 2001; Montoya, 2002, 2004, and all their co-workers). The functional avidity of IgG antibody is low with primary infection and increases during weeks and months. When high-avidity IgG is determined, infection within the preceding 3 to 5 months is excluded. Maternal antibody panel testing, combined with IgG avidity testing, aids diagnosis and dating of maternal toxoplasma infection with a single serum specimen. In addition, a PCR assay with high specificity (96 percent) and sensitivity (81 percent) for *T gondii* has been developed to permit prenatal testing of amniotic fluid (Hohlfeld and colleagues, 1994). A high PCR quantitative parasite load before 20 weeks has the greatest risk for a poor fetal outcome (Romand and colleagues, 2004).

Treatment. Treatment of pregnant women is thought to prevent and reduce, but not eliminate, the risk of congenital infection (American College of Obstetricians and Gynecologists, 2000). *Spiramycin*, used alone, is thought to reduce the risk of congenital infection but not to treat established fetal infection. Presumptive treatment with pyrimethamine and sulfonamides has been suggested for primary maternal infection in late pregnancy with negative amniotic fluid testing (Romand and associates, 2001). When fetal infection is diagnosed by prenatal testing, pyrimethamine, sulfonamides, and folic acid are added to spiramycin to eradicate parasites in the placenta and fetus.

Three large, recent trials in Europe, however, have questioned the therapeutic value of maternal treatment and found no effect from the type of medication or by a delay in treatment of up to 8 weeks (European Multicentre Study on Congenital Toxoplasmosis, 2003; Gilbert and associates, 2001; Gras and co-workers, 2001). Randomized controlled trials likely are required to measure the true effect of prenatal treatment on mother-to-child transmission.

Prevention. There is no vaccine for toxoplasmosis, but many cases of congenital infection could be prevented by the following specific recommendations (Lopez and colleagues, 2000):

- Cook meat to safe temperatures
- Peel or thoroughly wash fruits and vegetables before consumption
- Clean cooking surfaces and utensils that contain raw meat, poultry, seafood, or unwashed fruits and vegetables
- Wear gloves when changing cat litter or delegate this duty
- Avoid feeding cats raw or undercooked meat and keep cats indoors Unfortunately, the effectiveness of these measures is uncertain (Jones and co-workers, 2001a).

Figure 58-8. Intracranial calcifications (*arrows*) seen by ultrasonography in a microcephalic fetus at about 30 weeks. (Courtesy of Dr. R. Santos.)

MALARIA. There are four species of *Plasmodium* that cause human malaria: *vivax*, *ovale*, *malariae*, and *falciparum*. Nearly 300 to 500 million persons worldwide are infected at any given time, and the disease causes 1 to 3 million deaths annually (Murray and colleagues, 2000). Almost 48 percent of the world population—3 billion people—are at risk of contracting the disease (Hay and associates, 2004). Malaria has been effectively eradicated in Europe and most of North America except for parts of Mexico.

The disease is characterized by fever and flulike symptoms, including chills, headaches, myalgia, and malaise, which may occur at intervals. Symptoms are less severe with recurrences. Malaria may be associated with anemia and jaundice, and *falciparum* infections may cause kidney failure, coma, and death.

Effects on Pregnancy. Malarial episodes increase significantly by three- to fourfold during the latter two trimesters of pregnancy and 2 months postpartum (Diagne and associates, 2000). Pregnancy enhances the severity of *falciparum* malaria, especially in nonimmune primiparas (Nathwani and colleagues, 1992; Robier and co-workers, 1999). The incidence of abortion and preterm labor is increased with malaria (Menendez and associates, 2000). Increased fetal loss may be related to placental and fetal infection (Goldenberg and Thompson, 2003). In an earlier study, however, Jones (1950) observed that parasites have an affinity for decidual vessels and may involve the placenta extensively without affecting the fetus. According to McGready and co-workers (2004), malarial parasites are more common with *falciparum* than with *vivax* infections. Covell (1950) studied this extensively in Africa and cited an incidence of neonatal malaria of only 0.3 percent. In nonimmune women, congenital malaria may develop in up to 7 percent of neonates (Hulbert, 1992).

Treatment. Commonly used antimalarial drugs are not contraindicated during pregnancy. Some of the newer antimalarial agents have antifolic acid activity and may theoretically contribute to the development of megaloblastic anemia. In actual practice, this does not appear to be the case.

Chloroquine is the treatment of choice for malaria caused by *Plasmodium* species sensitive to the drug (Taylor and White, 2004). For the woman with chloroquine-resistant infection, *mefloquine* is given orally. At high doses, mefloquine is teratogenic and embryotoxic in some laboratory animals. Despite this, limited data indicate the drug to be safe and effective in pregnancy (Newman and colleagues, 2003).

The severity of malaria, especially with *P falciparum* infection, may be underestimated on initial clinical presentation. A thorough assessment of the severity of infection should precede but not delay treatment in pregnant women (Moore and associates, 2003; World Health Organization, 2000). For severe or complicated malaria, quinine is given parenterally. Its major side effect is hypoglycemia. Artemisinin and its derivatives have been used in a limited number of cases in the second half of pregnancy with success and without apparent complications (Alecrim and co-workers, 2000).

Prophylaxis. Pregnant women in areas in which malaria is endemic are primary candidates for chemoprophylaxis to prevent the adverse consequences of infection during pregnancy. Cot and colleagues (1992) showed that chloroquine chemoprophylaxis decreased placental infection in asymptomatic infected women to 4 percent compared with 19 percent of untreated controls. Alternatively, a simple control strategy of intermittent presumptive treatment with sulfadoxine-pyrimethamine at the start of the second and third trimesters significantly reduces maternal anemia, placental parasitemia, and low-birthweight, although HIV-infected women may require additional doses (Parise and co-workers, 1998; Verhoeff and associates, 1998). The World Health Organization has recommended this preventive regimen in areas where *P falciparum* is chloroquine resistant yet sensitive to sulfadoxine-pyrimethamine (Nahlen, 2000). There are limited data about the safety of newer agents such as amodiaquine and the artemisinins in pregnancy to recommend their routine use (McGready and colleagues, 2001). Pregnant women should not take doxycycline or the combination of atovaquone and proguanil for chemoprophylaxis.

Chemoprophylaxis is recommended for travel to endemic areas. If chloroquine-resistant *falciparum* or *vivax* malaria has not been reported, prophylaxis is initiated 1 to 2 weeks before the endemic area is entered. Chloroquine, 500 mg of base, is given orally once a week, and this is continued until 4 weeks after return to nonendemic areas (Bradley and Warhurst, 1995; Centers for Disease Control and Prevention, 2003b; Wyler, 1993). Travel to areas endemic for chloroquine-resistant strains is discouraged during early pregnancy, after which mefloquine prophylaxis is given (Centers for Disease Control and Prevention, 2003a).

Schwartz and associates (2003) emphasized the complexity of contemporary malaria prophylaxis due to drug resistance and the limitations of common regimens to protect against subsequent relapses from the liver stages of *P vivax* and *P ovale*. Providers and travelers can obtain the latest chemoprophylaxis regimens for pregnancy from the Centers for Disease Control and Prevention *Travelers Health* web site at <http://www.cdc.gov/travel/>. The Centers for Disease Control and Prevention (2003b) also publish *Health Information for International Travel*, also called *The Yellow Book*, with detailed information.

Several malaria vaccines are currently under evaluation that target different stages of the parasitic cycle (Guerin and co-workers, 2002).

AMEBIASIS. Most persons infected with *Entamoeba histolytica* are asymptomatic. Amebic dysentery, however, may take a fulminant course during pregnancy. Prognosis is worse if complicated by a hepatic abscess, which may be serious, and rupture has been reported (Constantine and colleagues, 1987). Therapy is similar to that for the nonpregnant woman, and

metronidazole is the drug of choice for amebic colitis and invasive disease. Noninvasive infections may be treated with paromomycin (Haque and associates, 2003).

MYCOTIC INFECTIONS

Disseminated infection during pregnancy is uncommon with coccidiomycosis, blastomycosis, cryptococcosis, or histoplasmosis. Their identification and management are considered in [Chapter 46](#) (see p. 1060).

EMERGING INFECTIONS

WEST NILE VIRUS. This mosquito-borne flavivirus is a human neuropathogen. Since 1999, reported numbers of human and animal infections have increased, and the geographical range of disease activity has expanded (Morse, 2003). Infection may be acquired through mosquito bites, typically in late summer. The incubation period is 3 to 14 days, and most persons have mild or no symptoms. Less than 1 percent of adults develop meningoencephalitis. In pregnant women, presenting symptoms are fever, mental status changes, muscle weakness, and coma (Centers for Disease Control and Prevention, 2002c; Chapa and colleagues, 2003).

The diagnosis is made based on clinical symptoms and the detection of West Nile virus IgG and IgM in serum and IgM in cerebrospinal fluid. There is no known effective antiviral treatment, and management is supportive. Fetal infection has been described at 27 weeks, and the term neonate had chorioretinitis along with severe temporal and occipital lobe white matter loss and temporal lobe cystic changes (Alpert and co-workers, 2003; Centers for Disease Control and Prevention, 2002c). Currently, the fetal risks are not quantified. The Centers for Disease Control and Prevention (2004a) have established a registry for birth outcomes of infected women. Breast feeding is not proscribed (Centers for Disease Control and Prevention, 2002c).

SEVERE ACUTE RESPIRATORY SYNDROME (SARS). Starting in 2002, several outbreaks of this infection have been reported in Asia and North America. The disease is associated with a novel *coronavirus* that is transmitted through droplets, close contact with infected secretions, fluids, and waste (Drosten and associates, 2003; Ksiazek and co-workers, 2003). The clinical picture is very similar to community-acquired pneumonia, and a history of SARS exposure or travel to an affected area increases the likelihood of diagnosis (Wenzel and Edmond, 2003).

There appears to be a triphasic pattern to the clinical progression of SARS. The first week is characterized by the viral replication and cytolysis with fever and myalgias. During the second week, patients may suffer recurrent fever, diarrhea, and hypoxemia coincident with IgG seroconversion and a declining viral load. Progression at this stage is thought to be due to an overexuberant host immune response. The third phase is seen in about 20 percent of patients. These individuals develop acute respiratory distress syndrome and require ventilatory support (Fowler and colleagues, 2003b; Peiris and associates, 2003a,b). Much of the mortality from SARS is related to acute lung injury (Lew and co-workers, 2003; Rubenfeld, 2003).

Radiographic and CT manifestations of SARS include ground-glass opacities and unilateral and bilateral airspace consolidations in the lungs that can rapidly progress to extensive bilateral consolidation within 1 to 2 days. Patients also may have lymphopenia, thrombocytopenia, and elevated lactate dehydrogenase (Lew and colleagues, 2003; Tsang and co-workers, 2003).

At this time, treatment choices are unproven (Peiris and associates, 2003a). Most patients have been treated with broad-spectrum antimicrobials. In pregnancy, oral therapy is with clarithromycin, 500 mg twice daily, plus amoxicillin with clavulanate, 375 mg three times daily (So and colleagues, 2003; Wong and co-workers, 2003). Ribavirin and corticosteroids have been used to decrease viral replication and to modulate the immune response, respectively. Their use is controversial and should be reserved for those with severe illness (Mandell and associates, 2003).

Fetal Effects. The effect of SARS on pregnancy is unclear because of the small number of reported cases (Haines and colleagues, 2003; Wong and co-workers, 2003, 2004). In a small case-control study, Lam and collaborators (2004) provided evidence that SARS had a worse clinical outcome in pregnant compared with nonpregnant women. No fetal transmission has been documented in five neonates born to mothers with SARS (Peiris and colleagues, 2003a; Shek and associates, 2003). Gastrointestinal complications were described in two preterm neonates who had small bowel perforation.

METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS. Strains of *Staphylococcus aureus* acquire resistance to methicillin, which confers resistance to all penicillinase-resistant penicillins and cephalosporins. Community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) infections sometimes occur in clusters but often develop sporadically. We have observed an increased frequency of community-acquired MRSA in pregnant women over the last few years. Most infections tend to involve skin and soft tissues, forming abscesses or cellulitis, especially in HIV-infected women, injection drug users, and diabetics. We have also encountered community-acquired MRSA in postoperative wound infections and with puerperal mastitis.

Community-acquired MRSA strains are usually not resistant to other antimicrobials. Erythromycin and clindamycin resistance is variable, but most strains are sensitive to either fluoroquinolones, trimethoprim-sulfamethoxazole, gentamicin, rifampin, or vancomycin (Eady and Cove, 2003; Laibl and associates, 2005; Naimi and colleagues, 2003). Parenteral vancomycin therapy can be reserved for more serious, community-acquired MRSA infections such as wound infections and mastitis. Most uncomplicated, noninvasive skin and soft tissue infections should still be managed by draining any abscess, culturing and ordering susceptibility testing of any skin or abscess drainage, and empirically prescribing β -lactam oral agents.

There are unique issues related to pregnancy and the puerperium regarding MRSA. No data suggest that community-acquired MRSA patients or their families require decolonization. However, careful follow-up examination must ensure resolution of infection. The frequency and significance of intrapartum transmission are unclear, and there are no current recommendations regarding prophylaxis to prevent neonatal or surgical site infections. We have substituted vancomycin for β -lactam drugs in perioperative prophylaxis for cesarean deliveries and fourth-degree perineal injury repair and in treatment of chorioamnionitis

in women with prior antepartum community-acquired MRSA infections. We do not discourage breast feeding in women with prior community-acquired MRSA but stress good hygiene and attention to minor nipple skin breaks.

TRAVEL IN PREGNANCY

Pregnant travelers face obstetrical risks, general medical risks, and potentially hazardous destination risks. These may include high altitudes, areas with serious food- or insect-borne infections, areas of drug-resistant *Plasmodium falciparum*, and areas where live-virus vaccines are recommended or required. Precautions may include dietary advice, malaria chemoprophylaxis, and avoidance of insect bites. The International Society for Tropical Medicines has comprehensive information at <http://www.istm.org>. The Centers for Disease Control and Prevention have extensive travel information regarding pregnancy and breast feeding at its *Travelers' Health* home page at <http://www.cdc.gov/travel/index.htm> and *The Yellow Book* (Centers for Disease Control and Prevention, 2003b). The American College of Obstetricians and Gynecologists (2003) has updated its recommendations on active and passive immunization in pregnancy, include some vaccination issues pertinent to travel.

Travel medicine has become a specialized field and informed consultations require a knowledge of global infectious disease and current recommendations. Frequently these can be provided by specialists in maternal-fetal medicine, travel or tropical medicine, or infectious diseases (Ryan and colleagues, 2002; Ryan and Kain, 2000).

BIOTERRORISM

Bioterrorism threats have heightened awareness that chemical, nuclear, radiological, or infectious emergencies may affect individual persons or countries. Clinicians should be alert for significant increases in the number of persons with febrile illnesses accompanied by respiratory symptoms or with rashes not easily associated with common illnesses. These cases, if due to biological weapon use, need an infrastructure that includes reporting, treatment, prophylaxis, infection control, and public health measures. Clinicians are urged to contact their state health department or bioterrorism web sites of the Centers for Disease Control and Prevention for contemporary information and recommendations.

SMALLPOX. The variola virus is considered a serious weapon due to its high transmission and case-fatality rate of 30 percent. The last case of smallpox in this country was reported to the Centers for Disease Control and Prevention in 1968 (2003e). Suarez and Hankins (2002) reviewed the severe perinatal and maternal morbidity and mortality caused by smallpox. Because the only vaccine is made with live vaccinia virus, pregnancy should be delayed for 4 weeks in recipients. It is generally not given to pregnant women because of the risk of fetal vaccinia, a rare but serious complication. The Centers for Disease Control and Prevention (2003d) recommends smallpox vaccination in pregnant women with emergency exposure, and it maintains a registry for those exposed. Vaccination is not ordinarily an indication for pregnancy termination.

ANTHRAX. The causative agent is *Bacillus anthracis*, a gram-positive, spore-forming, aerobic bacterium. There are three main types of clinical anthrax: inhalational, cutaneous, and gastrointestinal (Swartz, 2001). The bioterrorist anthrax attacks of 2001 reaffirmed the effectiveness and high mortality of inhalational anthrax as a biological weapon (Inglesby and colleagues, 2002).

Maternal naturally occurring cutaneous anthrax is usually associated with preterm birth and may be treated with penicillin (Kadanali and associates, 2003). Most authorities, however, presume a resistant strain would be used in a terrorist attack. Postexposure prophylaxis after documented environmental contamination is with ciprofloxacin, 500 mg twice daily for 60 days. This can be changed to amoxicillin, 500 mg three times daily, if the strain is proven sensitive (Centers for Disease Control and Prevention, 2001b). In this situation, doxycycline or ciprofloxacin may be given, and combination therapy for inhalational anthrax may be warranted.

The anthrax vaccine is an inactivated, cell-free product that requires six injections during 18 months. Vaccination is generally avoided in pregnancy due to a lack of safety data (Centers for Disease Control and Prevention, 2002f). That said, anthrax vaccine is an essential adjunct to postexposure antimicrobial prophylaxis, even in pregnancy (American College of Obstetricians and Gynecologist, 2002b). There appear to be no effects on fertility or pregnancy loss rates (Wiesen and Littell, 2002).

OTHER AGENTS. There are consensus statements regarding the management of mass exposure and treatment of *tularemia* (Dennis and associates, 2001). Recommended postexposure prophylaxis for *Francisella tularensis* is ciprofloxacin or doxycycline for 14 days. Effective prophylaxis following exposure to *hemorrhagic fever viruses* is hampered by the absence of effective vaccines and antiviral agents for *Ebola* and *Marburg viruses* (Borio and co-workers, 2002). Ribavirin may be of use for arenaviruses, such as *Lassa fever virus* or *bunyavirus*.

The guidelines for all biological weapons are continually evolving. The most current information is available at the Centers for Disease Control and Prevention *Emergency Preparedness and Response* web site at <http://www.bt.cdc.gov>.

59. Sexually Transmitted Diseases

INTRODUCTION

Sexually transmitted diseases (STDs) are relatively common during pregnancy. Education, screening, treatment, and prevention are important components of prenatal care for women at increased risk for these infections (Piper and colleagues, 2003). As a part of routine prenatal care, common STDs that are often sought include syphilis, gonorrhea, chlamydia, hepatitis B, human immunodeficiency virus (HIV), and human papillomavirus infections (HPV) (Schrag and associates, 2003). The recommended treatment protocols adhere to the intensive and frequently updated schedules provided by the Centers for Disease Control and Prevention (2002d). Treatment of most STDs is clearly associated with improved pregnancy outcome and prevention of perinatal mortality (Goldenberg and Thompson, 2003; Gray and colleagues, 2001).

SYPHILIS

The incidence of syphilis increased in the United States through the 1980s peaked in 1990, and then subsequently declined (Centers for Disease Control and Prevention, 2003a). The rate of syphilis in the United States in 2002 was 2.4 cases per 100,000 persons, and the rate among neonates was even lower at 1.1 cases per 100,000 population. The Centers for Disease Control and Prevention created a National Syphilis Elimination Plan with a goal of fewer than 1000 cases of primary and secondary syphilis in the country by 2005 (Mitka, 2000).

Increased rates of maternal syphilis have been linked to substance abuse, especially crack cocaine, and to inadequate prenatal care (Lago, 2004; Minkoff, 1990; Warner, 2001, and all their colleagues). Klass and associates (1994), in a study of prenatal syphilis at the Boston City Hospital during four decades, concluded that the continued prevalence of syphilis at delivery was associated with substance abuse, HIV infection, lack of prenatal care, treatment failures, and reinfection.

Antepartum syphilis can profoundly affect pregnancy outcome by causing preterm labor, fetal death, and neonatal infection by transplacental or perinatal infection (Genc and Ledger, 2000; Watson-Jones and co-workers, 2002). Fortunately, of the many congenital infections, syphilis is the most readily prevented and the most susceptible to therapy.

FETAL AND NEONATAL INFECTIONS. In the past, syphilis accounted for nearly a third of stillbirths. Today it plays a smaller but persistent role in fetal death, especially before 30 weeks (Goldenberg and Thompson, 2003; Gust and associates, 2002). Spirochetes readily cross the placenta and can result in congenital infection. Because of fetal immunocompetence prior to about 18 weeks, the fetus generally does not manifest the immunological inflammatory response characteristic of clinical disease before this time (Silverstein, 1962). Once fetal syphilis develops, there appears to be a continuum of involvement (Fig. 59-1). Hepatic involvement is followed by anemia and thrombocytopenia and then ascites and hydrops (Hollier and colleagues, 2001).

The frequency of congenital syphilis varies with both the stage and duration of maternal infection. McFarlin and associates (1994) reported that high serological titers and unknown duration of infection were major predictors of congenital syphilis. Thus, the highest incidence is in neonates born to mothers with early syphilis—primary, secondary, and early latent—and the lowest incidence with late latent disease of greater than 1-year duration (Fiumara and colleagues, 1952; Golden and co-workers, 2003). **Importantly, any stage of infectious maternal syphilis may result in fetal infection.**

Figure 59-1. Hypothesized continuum of fetal syphilis infection. (VDRL = Venereal Disease Research Laboratory.) (From Hollier and colleagues, 2001, with permission.)

PATHOLOGY. The newborn may have jaundice with petechiae or purpuric skin lesions, lymphadenopathy, rhinitis, pneumonia, myocarditis, or nephrosis. With syphilitic infection, the placenta becomes large and pale. Microscopically, villi appear to have lost their characteristic arborescent appearance and to have become thicker and club shaped. Sheffield and colleagues (2002c) described large villi in 64 percent of placentas from 33 pregnancies with stillborn fetuses from syphilis. More than 60 percent of placentas from 18 liveborn neonates also had large villi. Blood vessels markedly diminish in number, and in advanced cases, they almost entirely disappear as a result of endarteritis and proliferation of stromal cells. Perhaps related to this, Lucas and co-workers (1991) demonstrated increased vascular resistance in uterine and umbilical arteries of infected pregnancies. In a study of 25 untreated women, Schwartz and associates (1995) reported that necrotizing funisitis was present in a third of cases. Spirochetes were detected in almost 90 percent using silver and immunofluorescent staining.

SEROLOGICAL DIAGNOSIS. A suitable serological screening test such as the *Venereal Disease Research Laboratory (VDRL) slide test* or the *rapid plasma reagin (RPR) test* should be performed at the first prenatal visit. Testing is required by law in many states and is probably cost-effective even if the prevalence is low (Connor and colleagues, 2000; Hollier and associates, 2003). Serological tests yield positive results in the majority of women with primary syphilis and in all of those with secondary and latent syphilis. Because such reagin tests lack specificity, a treponemal test is used to confirm a positive result (Pope and Fears, 2000; Young, 2000). These include the *fluorescent treponemal antibody absorption test (FTA-ABS)*, the *microhemagglutination assay for antibodies to Treponema pallidum (MHA-TP)*, or the *Treponema pallidum passive particle agglutination (TP-PA) test*.

Cord blood screening is an insensitive test to detect early congenital syphilis. For women at high risk for syphilis, a nontreponemal screening test should be repeated in the third trimester and at the time of delivery (Centers for Disease Control and Prevention, 2002d; Lumbiganon and co-workers, 2002).

FETAL DIAGNOSIS. Polymerase chain reaction (PCR) is specific for detection of *Treponema pallidum* in amniotic fluid, and treponemal DNA has been found in 40 percent of pregnancies infected before 20 weeks (Nathan and colleagues, 1997; Wendel and associates, 1991). Fetal syphilis has also been verified by amniotic fluid darkfield examination or rabbit infectivity testing in 64 percent of a cohort of women with untreated syphilis (Hollier and co-workers, 2001). Although prenatal diagnosis can be made by funipuncture or amniocentesis, its clinical utility is not yet clear.

Because of a myriad of pathological changes in the fetus, ultrasonographic examination may be suggestive or even diagnostic of congenital infection. For example, the neonate shown in [Figure 59-2](#) has a large abdomen due to marked hepatosplenomegaly from congenital syphilis. The placenta was thickened and weighed almost as much as the neonate. The fetus may also have edema, ascites, or hydrops. Whenever possible, fetal evaluation for signs of syphilis should precede, but not delay, treatment after 20 weeks' gestation. Barton and colleagues (1992) found, however, that delivery followed by neonatal treatment may be the best option for near-term hydropic fetuses with congenital syphilis.

Figure 59-2. Congenital syphilis. **A.** A 29-week-old, severely ill neonate with an enlarged abdomen caused by marked hepatosplenomegaly plus ascites. **B.** The large syphilitic placenta of the same neonate weighed 1200 g, almost the birthweight of the newborn.

TREATMENT. Syphilis therapy during pregnancy is given to eradicate maternal infection and to prevent congenital syphilis. Penicillin is the treatment of choice even though it has not been evaluated rigorously. Rolfs (1995), Walker (2001), and Wendel and co-workers (2002) concluded that there are few useful comparative data available for ascertaining optimal therapy.

In retrospective analyses, benzathine penicillin G has been shown to cure early maternal infection and prevent neonatal syphilis in 98 percent of cases (Wendel and colleagues, 2002; Zenker and Rolfs, 1990). In a study of 340 pregnant women so treated, Alexander and associates (1999) reported six cases (1.8 percent) of congenital syphilis. Four of these six neonates were from a group of 75 women with secondary syphilis. The other two were identified in those delivered from a group of 102 women with early latent syphilis. Congenital syphilis was generally confined to neonates of women treated after 26 weeks and is likely related to the duration and severity of fetal infection. Sheffield and co-workers (2002b) reported that high maternal serological titers, preterm delivery, and delivery shortly after antepartum therapy are all risks of maternal treatment failing to prevent neonatal infection.

The currently recommended treatment guidelines for syphilis in pregnancy shown in [Table 59-1](#) are the same as for nonpregnant adults. As indicated, some authorities recommend a second dose of benzathine penicillin 1 week after the initial dose, especially for women in the third trimester or for those with secondary syphilis. Women with a history of penicillin allergy can be skin tested to confirm the risk of immunoglobulin E (IgE)-mediated anaphylaxis. If skin tests are reactive, penicillin desensitization is recommended and is followed by benzathine penicillin G treatment (Chisholm and associates, 1997; Wendel and co-workers, 1985).

If there are no proven alternatives to penicillin therapy during pregnancy. Erythromycin may be curative for the mother, but it does not prevent all congenital syphilis, and it is not currently recommended as a penicillin alternative (Wendel, 1988). The cephalosporins, such as ceftriaxone, and the newer macrolide, azithromycin, may prove useful in adults (Augenbraun, 2002; Augenbraun and Workowski, 1999). Azithromycin therapy results in significant maternal and fetal serum drug levels (Ramsey and colleagues, 2003). Its efficacy in pregnancy, however, has not been adequately evaluated, and both resistance and treatment failures have been reported in adults (Centers for Disease Control and Prevention, 2004a; Lukehart and colleagues, 2004; Wendel and associates, 2002). Tetracyclines, including doxycycline, are effective for treatment of syphilis in the nonpregnant woman but are generally not recommended during pregnancy because of the risk of yellow-brown discoloration of fetal deciduous teeth.

In most women with primary syphilis and about half with secondary infection, penicillin treatment is followed by the *Jarisch-Herxheimer reaction*. Uterine contractions frequently develop with this reaction, and they may be accompanied by late fetal heart rate decelerations (Klein and co-workers, 1990). In a study of 50 pregnant women who received benzathine penicillin for syphilis, Myles and colleagues (1998) reported a 40-percent incidence of Jarisch-Herxheimer reaction. Of the 31 women monitored electronically, 42 percent developed regular uterine contractions with a median onset of 10 hours, and 39 percent developed variable decelerations with a median onset of 8 hours. All contractions resolved within 24 hours of therapy. Lucas and associates (1991) used Doppler velocimetry and demonstrated acutely increased vascular resistance during this time.

All women with syphilis should be offered counseling and testing for HIV (Koumans and co-workers, 2000). For women with concomitant HIV infection, the Centers for Disease Control and Prevention (2002d) recommended the same treatment as for HIV-negative persons (Augenbraun, 2002). Some authorities, however, recommend two additional weekly doses of benzathine penicillin G. Clinical and serological follow-up to detect treatment failures is also recommended at 3, 6, 9, 12, and 24 months in HIV-positive patients.

Lumbar Puncture. Whether to routinely analyze cerebrospinal fluid has been controversial. Many asymptomatic patients have abnormalities with primary, secondary, and early latent syphilis, but most do not develop neurosyphilis if appropriately treated. The Centers for Disease Control and Prevention (2002d) recommended lumbar puncture for latent syphilis of more than 1-year duration if there are neurological or ophthalmological symptoms, for treatment failures, for evidence of active tertiary syphilis (aortitis, gummas, or iritis), or for concomitant HIV infection.

Follow-Up. Any patient treated for syphilis needs conscientious follow-up. Sexual contacts within the last 3 months should be evaluated for syphilis and treated presumptively, even if seronegative. Maternal serological titers should be repeated in the third trimester and at delivery to confirm a serological response to treatment or to document reinfection in this high-risk

group.

Treatment of Congenital Syphilis. Every newborn with suspected or proven congenital syphilis should undergo cerebrospinal fluid examination prior to treatment. After therapy, they should be followed at 2- to 3-month intervals until nontreponemal serological tests become negative or serofast. **Infants born to mothers treated with erythromycin or a nonpenicillin regimen for syphilis during pregnancy should be retreated as though they have congenital syphilis.**

GONORRHEA

The incidence of gonorrhea in the United States for 2002 was 125 cases per 100,000 persons (Centers for Disease Control and Prevention, 2003b). The highest rates in women of any ethnicity were in the 15- to 24-year age groups. The prevalence of gonorrhea in sentinel, study prenatal clinics in 2002 was 0.9 percent. Risk factors included single marital status, adolescence, poverty, drug abuse, prostitution, other STDs, and lack of prenatal care. Gonococcal infection is also a marker for concomitant chlamydial infection in about 40 percent of infected pregnant women (Christmas and colleagues, 1989). In most pregnant women, gonococcal infection is limited to the lower genital tract—the cervix, urethra, and periurethral and vestibular glands. Acute salpingitis is rare in pregnancy, but pregnant women account for a disproportionate number of disseminated gonococcal infections (Ross, 1996; Yip and associates, 1993). A screening test for gonorrhea is recommended at the first prenatal visit or prior to an induced abortion. In high-risk populations, the Centers for Disease Control and Prevention (2002d) and Miller and co-workers (2003) have recommended that a repeat culture be obtained after 28 weeks' gestation. Ickovics and associates (2003) and Mahon and associates (2002) also recommend postpartum screening in the at-risk teenage population. For women who test positive, screening for syphilis and *Chlamydia trachomatis* should precede treatment, if possible. If chlamydial testing is unavailable, presumptive therapy is given. In addition, offering HIV testing is wise.

EFFECT ON PREGNANCY. Gonococcal infection may have deleterious effects in any trimester. There is an association between untreated gonococcal cervicitis and septic abortion as well as infection after voluntary abortion (Burkman and co-workers, 1976). Preterm delivery, prematurely ruptured membranes, chorioamnionitis, and postpartum infection are more common in women infected with *Neisseria gonorrhoeae* at delivery (Alger and associates, 1988). Expectant management of culture-positive women is reasonable even with prematurely ruptured membranes as long as antimicrobial treatment is given promptly (Maxwell and Watson, 1992).

Sheffield and colleagues (1999) reviewed clinical outcomes of 25 pregnant women admitted to Parkland Hospital for disseminated gonococcal infection. Their mean gestational age at presentation was 25 weeks, and all of the women promptly responded to appropriate antimicrobial therapy. One stillborn neonate and one spontaneous abortion, however, were attributed to gonococcal sepsis.

TREATMENT. Antimicrobial resistance of *N gonorrhoeae*, particularly to penicillin, tetracycline, and quinolones, has rendered most β -lactam drugs ineffective (Centers for Disease Control and Prevention, 2002d). As shown in [Table 59-2](#), ceftriaxone and cefixime are recommended for uncomplicated infection during pregnancy, although cefixime may not be available in 2004 (Brocklehurst, 2003). Ramus and associates (2001), in a study of 62 pregnant women with probable endocervical gonorrhea, reported that intramuscular ceftriaxone (125 mg) and oral cefixime (400 mg) resulted in a cure rate of 95 percent and 96 percent, respectively. Spectinomycin is recommended for women allergic to penicillin or β -lactam antimicrobials. Treatment is recommended for sexual contacts. A test-of-cure is unnecessary if symptoms resolve, but because gonococcal reinfection is common, a second screening in late pregnancy should be considered for women treated earlier during pregnancy (Centers for Disease Control and Prevention, 2002d; Miller and co-workers, 2003).

Disseminated Gonococcal Infections. Gonococcal bacteremia may lead to petechial or pustular skin lesions, arthralgias, septic arthritis, or tenosynovitis. The Centers for Disease Control and Prevention (2002d) have recommended ceftriaxone, 1000 mg intramuscularly or intravenously every 24 hours. Treatment should be continued for 24 to 48 hours after improvement and then therapy changed to an oral agent to complete a week of therapy.

For gonococcal *endocarditis*, antimicrobials should be continued for at least 4 weeks, and for *meningitis*, 10 to 14 days (Centers for Disease Control and Prevention, 2002d). Endocarditis rarely complicates pregnancy, but it may be fatal (Bataskov and colleagues, 1991).

Treatment of Neonates. Gonococcal conjunctivitis is frequently severe in the neonates. *N gonorrhoeae* can penetrate intact corneal epithelium and cause keratitis, ulceration, perforation, and blindness. All newborns are given prophylaxis against conjunctivitis (see [Chap. 28](#), p. 641). Neonates born to untreated infected women are given ceftriaxone, 25 to 50 mg/kg, either intravenously or intramuscularly for one dose. Mortality results from systemic involvement, and those who develop gonococcal ophthalmia should be hospitalized and evaluated for disseminated infection. Both parents also should be treated for gonorrhea and evaluated for chlamydial infection.

CHLAMYDIAL INFECTIONS

Chlamydia trachomatis is an obligate intracellular bacterium that has several serotypes, including those that cause *lymphogranuloma venereum* (LGV). The most commonly encountered strains are those that attach only to columnar or transitional cell epithelium and cause cervical infection.

MATERNAL INFECTIONS. Genital infection with *C trachomatis* is one of the most common sexually transmitted bacterial diseases in women of reproductive age (Miller and colleagues, 2004). They are also common in pregnant women, and their incidence depends on the demographical makeup of the population. In 2002, the median chlamydial infection rate among young women screened at prenatal clinics in 28 states was 10.1 percent (Centers for Disease Control and Prevention, 2003b). Risk factors for infection in pregnant women include age younger than 25 years, presence or history of other STD(s), multiple sexual partners, and a new sexual partner within 3 months (Centers for Disease Control and Prevention, 2002d).

Diagnosis. Cultures are expensive and less accurate than newer nucleic acid amplification tests, including PCR. Andrews and associates (1997) reported that a ligase chain reaction assay was both sensitive and specific for genitourinary infection in pregnant women.

Symptomatic Infection. Most pregnant women have asymptomatic infection, but some present with urethral syndrome, urethritis, or Bartholin gland infection (Peipert, 2003). Although mucopurulent cervicitis may be due to either chlamydial or gonococcal infection, or both, it may also result from the normal, hormonally stimulated endocervical glands with abundant mucus production. Other chlamydial infections not usually seen in pregnancy are endometritis, salpingitis, peritonitis, reactive arthritis, and Reiter syndrome.

Asymptomatic Infection and Pregnancy Outcome. Many investigators have examined the effects of asymptomatic chlamydial infection on pregnancy outcome, and its role remains controversial. Sozio and Ness (1998) found no association with increased abortion. Some investigators, but not all, have found that untreated cervical infection increases the risk of preterm delivery, prematurely ruptured membranes, and perinatal mortality.

Chlamydial infection appears to be associated neither with an increased risk of chorioamnionitis nor with pelvic infection after cesarean delivery (Blanco and colleagues, 1985; Gibbs and Schachter, 1987). Conversely, delayed postpartum uterine infection with *C trachomatis* has been described by Hoyme and associates (1986). The syndrome, which develops 2 to 3 weeks postpartum, is distinct from early postoperative metritis. It is characterized by vaginal bleeding or discharge, low-grade fever, lower abdominal pain, and uterine tenderness.

NEONATAL INFECTIONS. There is vertical transmission to 30 to 50 percent of neonates delivered vaginally from infected women. Perinatal transmission to neonates can cause pneumonia, and *C trachomatis* is the most common identifiable infectious cause of ophthalmia neonatorum (see [Chap. 28](#), p. 641).

Conjunctivitis. Chlamydial eye infections are one of the most common causes of preventable blindness in developing countries. Symptomatic conjunctivitis tends to appear later (5 to 12 days) than disease caused by *N gonorrhoeae* (2 to 5 days). Tissue culture, direct fluorescent antibody tests, enzyme immunoassays, and nucleic amplification tests are sensitive and specific. None of the neonatal conjunctivitis prophylaxis regimens for gonococcal infection (e.g., silver nitrate, erythromycin, or tetracycline) is effective in the prevention of chlamydial conjunctivitis or pneumonia (Centers for Disease Control and Prevention, 2002d). When eye infection is identified, oral erythromycin, 50 mg/kg/day in four divided doses, is given for 10 to 14 days.

Pneumonitis. *C trachomatis* is a relatively common cause of afebrile pneumonia in infants at 1 to 3 months of age (Centers for Disease Control and Prevention, 2002d). Bilateral pulmonary infiltrates and chronic cough are often associated with poor weight gain.

PRENATAL SCREENING. Routine antepartum screening for *C trachomatis* is a complex issue, although there is little evidence of its effectiveness in asymptomatic women who are not in high-risk groups (Kohl and colleagues, 2003; Peipert, 2003). Identification and treatment of infected pregnant women may prevent neonatal infections, but evidence of prevention of adverse pregnancy outcome is lacking. Therefore, neither the American College of Obstetricians and Gynecologists (2002), the American Academy of Pediatrics, nor the U.S. Preventive Services Task Force (2001) recommend routine screening of all pregnant women. However, these organizations do suggest routine screening for young women at increased risk. The Centers for Disease Control and Prevention (2002d) have recommended screening at the first prenatal visit and again in the third trimester for women younger than 25 years of age or for those who have new or multiple sex partners. In a study of 149 pregnant women with lower genital tract chlamydia, Miller (1998) found that 17 percent had recurrent chlamydial colonization after treatment. Accordingly, a second culture in the third trimester would seem reasonable in women with positive initial culture results or for those at high risk.

TREATMENT. Currently recommended regimens for the treatment of chlamydial infection in pregnant women are shown in [Table 59-3](#). Erythromycin base, 500 mg orally four times daily for 7 days, is the primarily recommended regimen. For women who cannot tolerate erythromycin, the dose can be reduced by half and the duration of therapy doubled. Alternatively, the amoxicillin regimen may be given. In a randomized trial of treatment of *C trachomatis* in pregnancy, Silverman and associates (1994) reported cure rates of 82 percent for amoxicillin and 85 percent for erythromycin.

There have been a number of trials demonstrating the efficacy of azithromycin for chlamydial infection in pregnancy (Jacobson, 2001; Kacmar, 2001; Wehbeh, 1998, and all their colleagues). Comparable efficacy was reported by Adair and associates (1998) in a group of 106 women treated with erythromycin (93-percent cure) or azithromycin (88-percent cure). Of concern, Cooper and co-workers (2002b) noted an increased incidence of hypertrophic pyloric stenosis in neonates of mothers treated with nonerythromycin macrolides, however, there was no similar association with erythromycin exposure (see [Chap. 14](#), p. 358). These data are very limited, and azithromycin currently remains an alternative regimen (Adimora, 2002). Tetracyclines are avoided because of concerns regarding fetal dental discoloration. Erythromycin estolate is also avoided because of risks for maternal hepatic toxicity.

LYMPHOGRANULOMA VENEREUM

Several serovars of *C trachomatis* cause lymphogranuloma venereum (LGV). The primary genital infection is transient and seldom recognized. Inguinal adenitis may develop, and at times lead to suppuration. It may be confused with chancroid. Ultimately, the lymphatics of the lower genital tract and perirectal tissues may be involved, with sclerosis and fibrosis, which can cause vulvar elephantiasis and severe rectal stricture. Fistula formation involving the rectum, perineum, and vulva also may evolve.

For treatment during pregnancy, erythromycin, 500 mg four times daily, is given for 21 days (Centers for Disease Control and Prevention, 2002d). Although data regarding efficacy are scarce, some authorities recommend azithromycin given in multiple doses for 3 weeks.

HERPES SIMPLEX VIRUS INFECTION

Management of pregnancy complicated by maternal herpesvirus genital infection remains problematic. There are currently no available rapid diagnostic tests that reliably document contemporary infection. Moreover, there are few data to estimate risks for the neonate exposed to recurrent maternal infection.

VIROLOGY. Two types of herpes simplex virus (HSV) have been distinguished based on immunological as well as clinical differences. Type 1 HSV is responsible for most nongenital herpetic infections, although genital HSV-1 occasionally recurs in adults (Engelberg and colleagues, 2003). In many adolescents and young adults, however, HSV-1 infection causes more than half of new cases of genital herpes (Mertz and associates, 2003). Type 2 HSV is recovered almost exclusively from the genital tract and is usually transmitted by sexual contact. It has been estimated that approximately 22 percent of adults in the United States have HSV-2 infection. There have been projections that the seroprevalence in women may rise to nearly 50 percent by 2025 without intervention (Fisman and co-workers, 2002).

Antibodies. Several serological assay systems are available commercially and in research settings to detect antibody to HSV glycoproteins G-1 and G-2, which evoke type-specific antibody responses to HSV-1 and HSV-2 infection, respectively (Ashley, 2001). These tests have the potential to reliably differentiate HSV-1 from HSV-2 antibody and permit confirmation of clinical infection and identification of asymptomatic carriers.

Brown (2000) and Wald and Ashley-Morrow (2002) have proposed that serological screening of couples for HSV-2 antibodies during pregnancy would stimulate the need for safer sex practices and for antiviral suppression precautions if there is a discordancy (i.e., one seronegative and one seropositive partner). This is controversial, and there is no clinical evidence in pregnancy of its efficacy to prevent HSV transmission and neonatal infection (Scoular, 2002; Wilkinson and associates, 2000). The financial cost of prenatal type-specific antibody testing and of suppressive therapy for partners was judged excessive by Rouse and Stringer (2000) and Barnabas and co-workers (2002), but potentially cost-effective by Baker and associates (2004).

CLINICAL INFECTION. Symptoms vary depending on whether there has been previous infection. Prior HSV-1 infection may modify a primary HSV-2 genital infection because of cross-reacting antibodies. According to the American College of Obstetricians and Gynecologists (1999a), HSV-2 infections clinically may be divided into three groups:

1. *Primary infection* is indicated by no prior antibodies to HSV-1 or HSV-2.
2. *Nonprimary first episode* defines newly acquired HSV-2 infection with preexisting HSV-1 cross-reacting antibodies.
3. *Recurrent infection* is reactivation of prior HSV-1 or HSV-2 infection in the presence of antibodies to the same type of HSV.

Primary Infection. Only a third of newly acquired HSV-2 genital infections are symptomatic (Langenberg and colleagues, 1999). The typical incubation period of 3 to 6 days is followed by a papular eruption with itching or tingling, which then becomes painful and vesicular, with multiple vulvar and perineal lesions that may coalesce (Fig. 59-3). Inguinal adenopathy may be severe. Transient systemic influenza-like symptoms are common and are presumably caused by viremia. Occasionally, hepatitis, encephalitis, or pneumonia may develop. Cervical involvement is common, but it may be inapparent clinically. Some cases are severe enough to require hospitalization. In 2 to 4 weeks, all signs and symptoms of infection disappear.

Nonprimary First Episode. In general, these infections are characterized by fewer lesions, less systemic manifestations, less pain, and briefer duration of lesions and viral shedding. This is likely because of some immunity from cross-reacting antibodies from childhood-acquired type 1 infection. In some cases, it may be impossible to differentiate clinically between the two types of first infection (Hensleigh and associates, 1997). Serological diagnosis is beneficial in this setting.

Recurrent Infections. During the latency period in which viral particles reside in nerve ganglia, reactivation is common and mediated through variable but poorly understood stimuli. Reactivation is termed recurrent infection and results in herpesvirus shedding. Most recurrent genital herpes is caused by type 2 virus (Centers for Disease Control and Prevention, 2002d). These lesions generally are fewer in number, are less tender, and shed virus for shorter periods (2 to 5 days) than those of primary infection. Typically, they recur at the same sites. Finally, although commonly involved in primary disease, cervical involvement is less frequent with recurrent infections (Brown and co-workers, 1985).

In a study of 110 women with genital herpes infection, Wald and associates (1995) reported that 55 percent had subclinical shedding of HSV-2 at some time during a mean follow-up of 105 days. Shedding averaged 1.5 days and often followed symptomatic recurrence. Wald and colleagues (2000) reported that 3 percent of HSV-2 seropositive patients had subclinical shedding whether or not they had a history of genital infection.

Figure 59-3. First-episode primary genital herpes simplex virus infection. (From Wendel and Cunningham, 1991.)

DIAGNOSIS. Recovery of virus by *tissue culture* is optimal for confirmation of clinically apparent infection and asymptomatic recurrences. The sensitivity of culture is nearly 95 percent before the lesions undergo crusting. There are virtually no false positives. About half of cultures are positive 48 hours following the onset of a symptomatic recurrence.

Cytological examination after alcohol fixation and Papanicolaou staining—the *Tzanck smear*—has a maximum sensitivity of 70 percent. False-positive cervical smears commonly may be due to cytomegalovirus infection. Use of PCR increases HSV detection by four- to eightfold (Cone and associates, 1994; Wald and co-workers, 2003).

TREATMENT. Antiviral therapy with acyclovir, famciclovir, and valacyclovir has been used for treatment of first-episode genital herpes in nonpregnant women. Oral or parenteral preparations attenuate clinical infection as well as the duration of viral shedding. Suppressive therapy with these agents has also been given to limit recurrent infections and to reduce heterosexual transmissions (Corey and colleagues, 2004). For intense discomfort, analgesics and topical anesthetics may provide some relief, and severe urinary retention is treated with an indwelling bladder catheter.

Acyclovir appears to be safe for use in pregnant women (Ratanajamit and associates, 2003). The manufacturer of acyclovir and valacyclovir, in cooperation with the Centers for Disease Control and Prevention, maintained a registry for exposure to these drugs during pregnancy through 1999. More than 700 neonates have been exposed to acyclovir during the first trimester, and there do not appear to be increased adverse fetal or neonatal effects (Reiff-Eldridge and co-workers, 2000; Scott, 1999). There are theoretical concerns about potential neutropenia in the newborn, which is similar to that seen in infants given long-term suppressive acyclovir therapy (Kimberlin, 2004). Valacyclovir results in higher plasma drug levels than acyclovir when given in late pregnancy (Kimberlin and colleagues, 1998). There are insufficient data on valacyclovir and famciclovir exposure in pregnancy for analyses.

Many women with HIV infection also have genital herpes, and treatment failures with recommended doses of acyclovir have been reported. Higher doses of acyclovir may be beneficial for immunoincompetent women with HIV infection and severe recurrent genital herpes (Centers for Disease Control and Prevention, 2002d). In addition, reactivation of genital herpes in labor is common among HIV co-infected women; it was 8 percent in a cohort study from Washington (Hitti and associates, 1997).

Recurrent Infection. Other than suppression, acyclovir is of little benefit in recurrent genital herpes. It has been evaluated as suppressive therapy during pregnancy to prevent recurrences near term in several studies (Brocklehurst, 1998; Scott, 1996, 2001, 2002; Watts, 2004, and all their colleagues). In a meta-analysis of five randomized trials, Sheffield and associates (2003) reported that suppressive therapy after 36 weeks reduced the risk of a clinical or asymptomatic recurrence at delivery and of cesarean delivery for recurrent infection. The incidence of asymptomatic viral shedding was reduced but not eliminated. Scott and Alexander (1998) reported that acyclovir suppression in late pregnancy was cost effective.

Vaccine. In their recent review, Kimberlin and Rouse (2004) cite studies done with an HSV-2 glycoprotein-D subunit vaccine. In women seronegative for HSV-1 and -2, the vaccine prevented 75 percent of clinically apparent genital infection. The vaccine was not effective in women with anti-HSV-1 antibodies or in men.

CLINICAL COURSE DURING PREGNANCY. Approximately 80 percent of women with recently acquired genital herpes infection have an average of 2 to 4 *symptomatic* recurrences during pregnancy (Brown and co-workers, 1985; Harger and associates, 1989). Concomitant cervical viral shedding is identified in about 15 percent of pregnant women with clinically evident vulvar recurrences. In addition, *remote recurrences*—those on the buttocks, back, thigh, and anus—have low rates of concomitant cervical virus shedding, and this allows consideration for vaginal delivery (Harger and colleagues, 1989; Wittek and co-workers, 1984).

Viral Shedding at Delivery. The reported prevalence rates for recovery of genital tract herpesvirus at delivery vary considerably depending on the population studied. Equally important is whether women were included or excluded because of prior symptomatic infection. Studies of viral shedding at delivery without regard to maternal history of genital herpes report positive culture results in 0.2 to 0.35 percent (Brown and associates, 1991; Prober and colleagues, 1988).

FETAL AND NEONATAL DISEASE. Most primary and first-episode infections in early pregnancy are probably not associated with an increased rate of spontaneous abortion or stillbirth (Eskild and co-workers, 2002). In their review, Fagnant and Monif (1989) found only 15 cases of congenital herpetic infection that were acquired during early pregnancy. Brown and Baker (1989) reported that late-pregnancy primary infection results in an increased incidence of preterm labor. Fortunately, HSV acquisition in pregnancy is uncommon (0.34 percent) in most settings, and therefore neonatal herpes is rare (Mindel and associates, 2000).

According to Kimberlin (2004), neonatal infection is acquired in three ways: intrauterine (5 percent), peripartum (85 percent), or postnatal (10 percent). The fetus becomes infected by virus shed from the cervix or lower genital tract. The virus either invades the uterus following membrane rupture or contacts the fetus at delivery. Newborn infection has three forms:

1. Skin, eye, or mouth disease with localized involvement (45 percent of cases).
2. Central nervous system disease with encephalitis, with or without above involvement (30 percent of cases).
3. Disseminated disease with involvement of multiple major organs (25 percent of cases) ([Fig. 59-4](#)).

The risk of neonatal infection correlates with whether there is primary or recurrent maternal infection. Nahmias and colleagues (1971) reported a 50-percent risk of neonatal infection with primary maternal infection but only 4 to 5 percent with recurrent infection. Prober and associates (1987) reported that none of 34 neonates exposed to recurrent viral shedding at delivery became infected, which is thought to be due to a smaller viral load in maternal secretions with recurrent infection. It also likely is related to transplacentally acquired antibody, which decreases the incidence and severity of neonatal disease. An additional risk is prematurity, and nearly half of infected neonates are born preterm.

\sidefiguretrue

Localized infection is usually associated with a good outcome. Conversely, even with treatment with acyclovir, disseminated

neonatal infection is associated with a mortality rate of nearly 30 percent (Kimberlin and co-workers, 2001a,b). Importantly, serious developmental and central nervous system morbidity still occurs in 20 to 50 percent of survivors with disseminated or cerebral infection (see [Fig. 59-4](#)).

Antepartum Management. Virological monitoring is not recommended. Because of the severity of neonatal infection, cesarean delivery has been used widely in instances when active genital herpetic recurrences are suspected. It seems reasonable to give acyclovir suppressive therapy beginning at 36 weeks for women with recurrent genital herpes who have had clinical recurrences during pregnancy (American College of Obstetricians and Gynecologists, 1999a; Centers for Disease Control and Prevention, 2002d; Sheffield and colleagues, 2003).

According to the American College of Obstetricians and Gynecologists (1999a), cesarean delivery is indicated in women with an active genital lesion or in those with a typical prodrome of an impending outbreak. Thus, cesarean delivery is performed only if primary or recurrent lesions are visualized near the time of labor or when the membranes are ruptured. Roberts and associates (1995) reported a decrease in the cesarean delivery rate in women with herpes during pregnancy from 59 percent to 37 percent after adoption of these guidelines, which succinctly stated are "no lesions, no cesarean." Brown and colleagues (2003) confirmed this viewpoint by showing a reduced risk of neonatal HSV with cesarean delivery (85 percent) among women with symptomatic and asymptomatic HSV shedding at delivery.

Ruptured Membranes. There is no evidence that external lesions cause ascending fetal infection in the presence of preterm ruptured membranes. Major and associates (2003) described expectant management of preterm ruptured membranes in a cohort of 29 women at less than 31 weeks. There were no cases of neonatal HSV, and the maximum risk of infection was calculated to be 10 percent. The use of antivirals in this setting is reasonable, but of unproven efficacy.

For women with a clinical recurrence at delivery, there is not an absolute duration of membrane rupture beyond which the fetus would not benefit from cesarean delivery (American College of Obstetricians and Gynecologists, 1999a). Unless there are other contradictory factors (e.g., extreme immaturity), then cesarean delivery is performed.

Figure 59-4. Cross-section showing necrotic brain tissue in a newborn who died from disseminated herpesvirus infection.

CARE OF THE NEONATE. An exposed infant born to a mother known to have or suspected of having genital herpes initially should be isolated from other neonates and cultures performed for herpes. It is not necessary to separate the pair. Instead, the woman should wash her hands thoroughly and avoid contact between her lesions, her hands, and the infant. Breast feeding is allowed, including if the woman is taking antiviral therapy. Acyclovir does not reach appreciable levels in breast milk (Sheffield and colleagues, 2002a). Family members with oral herpetic lesions should avoid kissing the newborn and should use careful hand-washing techniques.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Acquired immunodeficiency syndrome (AIDS) was first described in 1981 when a cluster of patients was found to have defective cellular immunity and *Pneumocystis carinii* pneumonia (Gallo and Montagnier, 2003). Worldwide, it was estimated in 2003 that there were 40 million infected persons with HIV/AIDS, 5 million new cases of HIV, and 3 million HIV-related deaths (Clinton, 2003; Gayle, 2003; Steinbrook, 2004).

In the United States through 2001, the Centers for Disease Control and Prevention (2002b) estimated that there were 1.3 to 1.4 million infected individuals and almost a half million deaths. In 2002, HIV infection was the fifth leading cause of death in persons 25 to 44 years of age (Kochanek and Smith, 2004). Currently, a third of new cases result from heterosexual transmission, and two thirds of these are in women (Centers for Disease Control and Prevention, 2004b). Fortunately, the number of children with AIDS attributed to perinatal transmission has decreased by more than 90 percent in the past 10 years (Centers for Disease Control and Prevention, 2002b). In addition, during this time, highly active antiretroviral therapy has led to an increasing number of people living with chronic HIV infection ([Fig. 59-5](#)).

Figure 59-5. AIDS cases, deaths, and persons living with acquired immunodeficiency syndrome (AIDS) in the United States from 1985 through 2002. (From Centers for Disease Control and Prevention, 2002b.)

ETIOLOGY. Causative agents of AIDS are DNA retroviruses termed *human immunodeficiency viruses*, HIV-1 and HIV-2. Most cases worldwide are caused by HIV-1 infection. Transmission of these viruses is similar to hepatitis B virus, and sexual intercourse is the major mode of transmission. The virus also is transmitted by blood or blood-contaminated products, and mothers may infect their fetuses.

PATHOGENESIS. The common denominator of clinical illness with AIDS is profound immunosuppression that gives rise to a variety of opportunistic infections and neoplasms. Thymus-derived lymphocytes, or *T lymphocytes*, defined phenotypically by the CD4 surface antigen, are the principal targets. The CD4 site serves as a receptor for the virus. Co-receptors are necessary for infection, and two chemokine receptors—CCR5 and CXCR4—have been identified to fill this

role (Kahn and Walker, 1998; Sheffield and colleagues, 2005). After initial infection, the level of viremia usually decreases to a *set-point*, and patients with the highest viral burden at this time progress more rapidly to AIDS and death (Kahn and Walker, 1998).

Over time the number of T cells drops insidiously and progressively, resulting eventually in profound immunosuppression. Although it is thought that pregnancy has minimal effects on CD4⁺ T-cell counts and HIV RNA levels, the latter are often higher 6 months postpartum than during pregnancy (U.S. Public Health Service, 2003). Monocyte-macrophages may also be infected, and microglial brain cell infection may cause neuropsychiatric abnormalities. HIV-infected persons also have an increased incidence of neoplasms, notably Kaposi sarcoma, B-cell and non-Hodgkin lymphomas, and some carcinomas (see [Chap. 57](#), p. 1262).

CLINICAL MANIFESTATIONS. The incubation period from exposure to clinical disease is days to weeks. Acute illness is similar to many other viral syndromes and usually lasts less than 10 days. Common symptoms include fever and night sweats, fatigue, rash, headache, lymphadenopathy, pharyngitis, myalgias, arthralgias, nausea, vomiting, and diarrhea. After symptoms abate, the set-point of chronic viremia is established. Stimuli that cause further progression from asymptomatic viremia to AIDS are presently unclear, but the median time is about 10 years (Fauci, 2003).

When HIV-positive assay results are associated with any number of clinical findings, then AIDS is diagnosed. Generalized lymphadenopathy, oral hairy leukoplakia, aphthous ulcers, and thrombocytopenia are common. A number of opportunistic infections that may herald AIDS include esophageal or pulmonary candidiasis; persistent herpes simplex or zoster lesions; condyloma acuminata; tuberculosis; cytomegaloviral pneumonia, retinitis, or gastrointestinal disease; molluscum contagiosum; pneumocystis pneumonia; toxoplasmosis; and others. Neurological disease is common, and about half of patients have central nervous system symptoms. A CD4⁺ count of less than 200/mm³ is also considered definitive for the diagnosis of AIDS.

There are unique gynecological issues for women with HIV, such as menstrual abnormalities, genital neoplasia, other STDs, and contraceptive needs that overlap into pregnancy (Cejtin, 2003; Stuart and Castano, 2003). Repeated pregnancy does not have significant effect on the clinical or immunological course of viral infection (Minkoff and colleagues, 2003).

SEROLOGICAL TESTING. The enzyme immunoassay (EIA) is used as a screening test for HIV antibodies as a part of a *standard testing protocol*. A repeatedly positive screening test has a sensitivity of more than 99.5 percent. A positive test is confirmed with either the Western blot or immunofluorescence assay (IFA). Results typically are available in several days.

Although highly specific, the Western blot is less sensitive than immunoassay because more antibody is required for a positive result. Thus, IFA can be used to resolve an EIA-positive, Western blot-indeterminate sample. According to the Centers for Disease Control and Prevention (2001a,b), antibody can be detected in most patients within 1 month of infection, and thus, antibody serotesting may not exclude early infection. For acute primary HIV infection, identification of viral p24 core antigen or viral RNA or DNA is possible. False-positive confirmatory results are rare (Centers for Disease Control and Prevention, 2001a).

In some cases, the first opportunity for HIV testing may occur when women present late for prenatal care or when they are in labor. *Rapid tests* can detect HIV antibody in 10 to 60 minutes at the point-of-care, and they have sensitivity and specificity comparable with EIAs (Branson, 2003; Centers for Disease Control and Prevention, 2004c,d). A reactive rapid screening test result should be supplemented with a confirmatory Western blot or IFA test. Peripartum and neonatal interventions to reduce perinatal transmission, however, may be based on the initial rapid testing results.

The Mother-Infant Rapid Intervention at Delivery (MIRIAD) multicenter study indicated that rapid HIV testing can be used to identify infected women and their neonates so that peripartum antiretroviral prophylaxis can be administered (Bulters and colleagues, 2004). A set of practical guidelines for rapid HIV testing in labor and delivery is available from the Centers for Disease Control and Prevention (2004d).

SCREENING. In 1991, universal, but voluntary, prenatal screening was recommended by the Institute of Medicine, the Centers for Disease Control and Prevention (2002c), the American Academy of Pediatrics, and the American College of Obstetricians and Gynecologists (1999b, 2002, 2004).

A study conducted from 1998 to 2001 in the United States and Canada reported that the rates of acceptance of HIV prenatal testing depend on the approach used (Centers for Disease Control and Prevention, 2002c). Under an *opt-in approach*, women receive pretest counseling and must specifically consent to HIV testing. In the *opt-out approach*, women are notified that an HIV test is part of a comprehensive set of antenatal tests and procedures, and they may decline testing (Stringer and colleagues, 2001). Areas that used or switched to the opt-out approach had much higher rates of prenatal serotesting. The Centers for Disease Control and Prevention (2004e) recommended adoption of the opt-out protocol into routine prenatal care. Sansom and associates (2003) suggest that it may be cost effective to repeat HIV testing in the third trimester in areas with a prevalence of 1 per 1000 person years or higher. Several states also recommend or require a second HIV test at delivery.

MATERNAL AND FETAL-NEONATAL INFECTION. Mother-to-child transmission accounts for most pediatric HIV infections. Transplacental transmission can occur early, and the virus has been identified in specimens from elective abortion (Lewis and co-workers, 1990). According to Blair and associates (2004), pregnancy rates among women with HIV infection increased significantly in the current era of antiretroviral therapy compared with rates before 1996. In most cases, however, the virus is transmitted peripartum, and 15 to 40 percent of neonates born to nonbreast feeding, untreated, HIV-infected mothers are infected. Kourtis and colleagues (2001) have proposed a model for estimation of the temporal distribution of vertical transmission. They estimate that 20 percent of transmission occurs before 36 weeks, 50 percent in the days before delivery, and 30 percent intrapartum ([Fig. 59-6](#)). Transmission rates for breast feeding may be as high as 30 to 40 percent.

Vertical transmission is more common in preterm births, especially those associated with prolonged membrane rupture. Analyzing data from the Perinatal AIDS Collaborative Transmission Study, Kuhn and associates (1999) reported a 3.7 relative

risk for intrapartum viral transmission with preterm delivery. Landesman and co-workers (1996) reported that HIV-1 transmission at birth was increased from 15 to 25 percent in women whose membranes were ruptured for more than 4 hours.

Concurrent syphilis infection is common and is also associated with vertical perinatal HIV transmission (Koumans and colleagues, 2000; Schulte and associates, 2001). Finally, there is evidence that placental inflammation and chorioamnionitis may increase HIV-1 transmission by 3 percent, but it is unclear if antimicrobials decrease this risk (Mwanyumba and co-workers, 2002).

Perinatal HIV transmission can be most accurately correlated with measurement of maternal plasma HIV RNA burden (U.S. Public Health Service 2004b, 2003; Watts, 2002). As shown in [Figure 59-7](#), cohort neonatal infection was 1 percent with less than 400 copies/mL, and it was more than 30 percent when viral RNA exceeded 100,000 copies/mL (Cooper and colleagues, 2002a). Importantly, zidovudine therapy that reduced these levels to less than 500 copies/mL also minimized the risk of transmission. The investigators also reported that maternal infusions of HIV-1 hyperimmune globulin did not alter the risk of transmission.

According to the U.S. Public Health Service Guidelines (2003), maternal morbidity and mortality are not increased by pregnancy in seropositive asymptomatic women. Conversely, adverse fetal outcomes may be increased in these cases. In a review of 634 women delivered after 24 weeks, Stratton and associates (1999) reported that adverse pregnancy outcomes were common in HIV-infected women. Moreover, they reported that adverse outcomes were associated with a CD4⁺ cell proportion of less than 15 percent. In these otherwise asymptomatic women, the rate of preterm birth was 20 percent and fetal growth restriction was identified in 24 percent. Watts (2002) emphasized that these adverse outcomes were even more prevalent in developing countries.

Figure 59-6. Estimated rates of perinatal human immunodeficiency virus (HIV) transmission for different times of gestation and delivery in nonbreast feeding populations. Estimates are based on a hypothetical cohort of 100 children born to HIV-infected women without any interventions. Numbers in blue indicated number of children at risk for infection. (From Kourtis and colleagues, 2001.)

Figure 59-7. Incidence of perinatal human immunodeficiency virus (HIV) infection plotted against plasma HIV-1 RNA levels in 1542 neonates born to mothers in the Women and Infants Transmission Study. (Data from Cooper and colleagues, 2002a.)

MANAGEMENT DURING PREGNANCY. Counseling is mandatory for HIV-positive women. This is preferable early in pregnancy, and if the woman chooses to continue pregnancy, ongoing counseling for psychological support is important.

The availability of an increasing number of antiretroviral agents and the rapid evolution of new information has introduced substantial complexity into HIV therapy. In addition, separate strategies are used for pregnant and nonpregnant adults. Therapeutic goals are a maximal and enduring suppression of viral load and restoration and preservation of immunological function.

For nonpregnant patients, treatment is generally offered to adults with less than 350 CD4⁺ T cells/mm³ or plasma HIV RNA levels exceeding 55,000 copies/mL ([Table 59-4](#)). A more aggressive strategy has evolved for the management of HIV infection in pregnancy, because RNA level reduction is paramount to reduce perinatal transmission. **Antiretroviral therapy should be offered to all HIV-infected pregnant women to begin maternal treatment as well as to reduce the risk of perinatal transmission regardless of CD4⁺ T-cell count or HIV RNA level.**

The many approved antiretroviral agents can be grouped into several classes and used to design antiretroviral regimens ([Table 59-5](#)). Antiretroviral agents may be combined into non-nucleoside reverse transcriptase inhibitor (NNRTI)-based, protease inhibitor (PI)-based, triple nucleoside reverse transcriptase inhibitor (NRTI)-based, or fusion inhibitor (FI)-based regimens ([Table 59-6](#)). The new FI agents—*cell membrane fusion inhibitors*—block HIV-1 cell membrane binding and cell entry. One member of this class, enfuvirtide, has been used in salvage regimens with resistant HIV-1 in settings in which therapeutic options are limited (Kilby and Eron, 2003). Its efficacy and safety in pregnancy are unclear. Information on the safety and toxicity of antiretroviral agents has been reviewed by Money (2003) and also is available as a supplement to the U.S. Public Health Services guidelines (2004a,b, 2003) and through the web site <http://AIDSinfo.nih.gov>, which is frequently updated.

The perinatal guidelines (U.S. Public Health Service, 2003) recommend measurement of CD4⁺ T-lymphocyte counts approximately each trimester, or about every 3 to 4 months. HIV RNA levels should be monitored 4 weeks after initiation of a change in treatment, then monthly until undetectable, then every 3 months, and finally near term for planning delivery. These results are used to make decisions to alter therapy, to decide route of delivery, or to begin prophylaxis for opportunistic infections such as *P carinii* pneumonia.

Even with treatment, the incidence of perinatal complications is increased. Lorenzi and colleagues (1998) reported that 78 percent of women treated with two reverse transcriptase inhibitors had one or more adverse events, especially preterm delivery. Half of the neonates in this study had adverse events. Newer drug regimens may diminish these complications. For example, Tuomala and associates (2002) found no association with preterm birth, low birthweight, or stillbirths when combination antiretroviral therapy was used. They did, however, show that women given combination PI regimens had an increased risk of very-low-birthweight infants. Despite this, combined therapy should not be withheld if indicated (Watts, 2002).

At least two follow-up studies of children from the Pediatric AIDS Clinical Trial Group (PACTG) 076 Study found no adverse

effects in children at 18 months and up to a mean of 5.6 years after zidovudine exposure (Culnane and associates, 1999; Sperling and colleagues, 1998).

Treatment failures may be due to nonadherence, inadequate drug potency, suboptimal levels of antiretrovirals, or viral resistance. Poor adherence to therapy appears to be a significant problem in pregnancy. In one study of 549 women from New York, poor compliance was reported in a third of women (Laine and associates, 2000).

Most HIV-infected women require additional medical care during pregnancy (Minkoff, 2003; Watts, 2002). They are given hepatitis B, influenza, and pneumococcal vaccines, ideally after viral suppression is achieved. Frequent monitoring is necessary for antiretroviral clinical and laboratory toxicities during the initial 1 to 2 months of treatment; this is particularly important with nevirapine regimens. Thereafter, surveillance for hepatic toxicity and lactic acidosis may be decreased. Reviewing a variety of regimens in the PACTG Protocol 316, Watts and co-workers (2004) found moderate-grade toxicity in 5 percent of women. Gestational diabetes varied by treatment regimen and was highest with early combination PI treatment. These latter women should have early glucose intolerance screening. Careful surveillance is important for antiretroviral drug interactions with other antiretrovirals, as well as therapies for opportunistic infection, methadone, and tuberculosis (Piscitelli and Gallicano, 2001). Information about this issue in pregnancy has been reviewed by Minkoff (2003) and Watts (2002). More detailed updates are available at the previously cited web site (<http://AIDSinfo.nih.gov>).

The management of some HIV complications can be altered by pregnancy. If the CD4⁺ T-cell count is below 200/mm³, primary prophylaxis for *P carinii* pneumonia is recommended with sulfamethoxazole-trimethoprim or dapsone. Pneumonia is treated with oral or intravenous sulfamethoxazole-trimethoprim or dapsone-trimethoprim. Other symptomatic opportunistic infections that may develop include toxoplasmosis, herpesvirus, mycobacteria, and candida. The U.S. Public Health Service, the Infectious Diseases Society of America, and the American Thoracic Society have published guidelines for prevention and treatment of opportunistic infections in persons infected with HIV (Centers for Disease Control and Prevention, 2002a,d, 2004f).

Prevention of Transmission. Precautions for antepartum, peripartum, and pediatric care of infected mothers and newborns are similar to those for hepatitis B, with avoidance of exposure to blood and body fluids. Antepartum antiretroviral therapy can be continued intrapartum. Optimal management of labor is uncertain, but if labor is progressing with intact membranes, artificial rupture and invasive fetal monitoring are avoided. Labor augmentation is used whenever needed to shorten the interval to delivery.

Pooled data from several prospective studies of health care workers suggest that the average risk of HIV transmission is 0.3 percent after percutaneous exposure to infected blood and 0.09 percent after mucous membrane exposure (Gerberding, 2003). Important for obstetricians, suture needles have not been implicated as a source of infection in prospective studies. However, occupational infection has occurred among surgical personnel. For health care workers with significant percutaneous or mucosal HIV exposure, postexposure prophylaxis is recommended (Centers for Disease Control and Prevention, 2001c; Gerberding, 2003).

Prevention of Vertical Transmission. The two principal approaches suggested for prevention of maternal-neonatal transmission of HIV infection are antiretroviral therapy and cesarean delivery. When standard treatment regimens are combined with zidovudine perinatal prophylaxis shown in [Table 59-7](#), vertical transmission is substantively lowered (Minkoff, 2003; Watts, 2002). The lowest transmission rates are achieved using prenatal combination therapy; they were 1 and 2 percent in two prospective studies reported by Cooper (2002a), Dorenbaum (2002), and all their colleagues. Short-term toxicity appears to be minimal for most women and newborns.

The main long-term problem is development of resistance. This is associated most commonly with prenatal combination therapy with lamivudine and with peripartum nevirapine (Clavel and Hance, 2004; Mandelbrot and associates, 2001; Moodley and co-workers, 2003). At present the known risks are clearly outweighed by the potential benefits of prophylaxis.

Indications for resistance testing for pregnant women are the same as for nonpregnant adults and include acute HIV-1 infection, virological failure, suboptimal viral suppression after initiation of antiretroviral therapy, and high likelihood of exposure to resistant virus based on community prevalence. Women who have presumed or documented zidovudine resistance and are on regimens that do not include zidovudine should still be given intravenous zidovudine intrapartum, and their neonates are given oral zidovudine (see [Table 59-7](#)).

If women on combination therapy temporarily discontinue treatment during pregnancy, all drugs should be stopped and restarted simultaneously to reduce the potential for emergence of resistance.

A number of clinical scenarios have been anticipated by the U.S. Public Health Service perinatal guidelines (2003):

1. If maternal HIV RNA level is more than 1000 copies/mL, then combination antiretroviral therapy is indicated.
2. When the maternal HIV RNA level is less than 1000 copies/mL, either combination antiretroviral therapy or zidovudine monotherapy can be given.
3. For women with no treatment prior to labor, intrapartum prophylaxis is appropriate with zidovudine, zidovudine with lamivudine, zidovudine with nevirapine, or nevirapine alone.
4. If delivery occurs before treatment is given, the newborn can receive prophylaxis for 6 weeks with zidovudine, or in some cases combination antiretroviral treatment.

A multistate surveillance program determined that by 1996, 80 percent of HIV-infected women were identified before delivery and that most received antepartum and intrapartum prophylaxis (Wortley and colleagues, 2001). By 2001, nearly 60 percent of American women were aware of effective intervention strategies to prevent perinatal HIV transmission (Anderson and associates, 2004). This rapid adoption of clinical practices clearly has resulted in the dramatic reductions in perinatal transmission to the current levels of 1 to 2 percent.

Cesarean Delivery. A meta-analysis of 15 prospective cohort studies by the International Perinatal HIV Group (1999) included 8533 mother-neonate pairs. Vertical HIV transmission was reduced by about one half when cesarean was compared with vaginal delivery. When antiretroviral therapy was given in the prenatal, intrapartum, and neonatal periods along with cesarean delivery, the likelihood of neonatal transmission was reduced by 87 percent compared with that of other modes of delivery and without antiretroviral therapy. The European Mode of Delivery Collaboration (1999) as well as others had similar findings. Based on these, the American College of Obstetricians and Gynecologists (2000) concluded that scheduled cesarean delivery should be discussed and recommended for HIV-infected women whose HIV-1 RNA load exceeds 1000 copies/mL. Scheduled delivery was recommended as early as 38 weeks to lessen the chances of premature membrane rupture. Data are insufficient to estimate any benefits of cesarean delivery for women whose HIV RNA levels were below 1000 copies/mL. Given their lower rate of transmission, it is unlikely that scheduled cesarean delivery would confer additional risk reduction.

Others have expressed concern that morbidity may be significantly increased in HIV-infected women undergoing cesarean delivery (Read and co-workers, 2001). Stringer and colleagues (1999) as well as Star and associates (1999) made a plea for restraint regarding routine cesarean delivery for prevention of vertical transmission. They concluded that combination antiretroviral therapy alone may reduce the risk to less than 2 percent. Our experiences at Parkland Hospital are similar, and perinatal transmission in women taking combination antiretroviral therapy has been 1 to 2 percent.

Breast Feeding. Vertical transmission is increased by breast feeding which generally is not recommended in HIV-positive women in this country (Read and co-workers, 2003). The probability of HIV transmission per liter of breast milk ingested is estimated to be similar in magnitude to heterosexual transmission with unsafe sex in adults (Richardson and colleagues, 2003). The risk is related to the maternal HIV RNA level, HIV disease status, breast health, and duration of breast feeding (De Cock and associates, 2000; John-Stewart and co-workers, 2004). Most transmission occurs in the first 6 months, and as many as two thirds of infections in breast-fed infants are from breast milk. In the Petra study (2002) from Africa, the prophylactic benefits of short-course perinatal antiviral regimens were diminished considerably by 18 months of age due to breast feeding. The World Health Organization (2001) has recommended continuing breast feeding promotion with early weaning by 6 months for women living in developing countries in which infectious diseases and malnutrition are the primary causes of infant deaths.

Postpartum. Many otherwise healthy women with normal CD4⁺ T-cell counts and low HIV RNA levels may discontinue treatment after delivery and be closely monitored according to adult guidelines. Psychosocial support is essential during this time, especially while awaiting diagnostic testing for pediatric infection. Contraceptive needs are complex and also may entail condoms in discordantly infected couples. There are effects on hormone levels with oral contraceptives and possibly with injectable agents (Stuart and Castano, 2003). Intrauterine devices may be an acceptable choice in some women with normal immunocompetence and a low risk for STDs. Gynecological care is complex in HIV-infected women and has been comprehensively reviewed recently by Cejtin (2003).

HUMAN PAPILLOMAVIRUS INFECTION

Genital human papillomavirus infection (HPV), either symptomatic or asymptomatic, is common. Of 2597 high-risk pregnant women enrolled in the New Orleans Center of the Vaginal Infections and Prematurity Study, 28 percent were seropositive for HPV-16 capsid antibodies (Hagensee and colleagues, 1999). The most important sequelae of HPV infection are cervical, vaginal, vulvar, and anal neoplasia (see [Chap. 57](#), p. 1264). Mucocutaneous external genital warts are usually caused by HPV types 6 and 11 but may also be caused by intermediate- and high-oncogenic-risk HPV (Centers for Disease Control and Prevention, 1999; Wiley and associates, 2002).

EXTERNAL GENITAL WARTS. For unknown reasons, genital warts frequently increase in number and size during pregnancy. Accelerated viral replication by the physiological changes of pregnancy might explain the growth of perineal lesions and progression of some to cervical neoplasm (Fife and co-workers, 1999; Rando and colleagues, 1989). High-risk HPV types are cleared more slowly during pregnancy, and clearance increases postpartum (Nobbenhuis and associates, 2002). These lesions may grow to fill the vagina or cover the perineum, making it difficult to perform vaginal delivery or episiotomy and prompting cesarean delivery ([Fig. 59-8](#)). In women without grossly visible lesions, Snyder and co-workers (1990), but not Goldaber and colleagues (1993), found an association between papillomavirus infection and episiotomy breakdown. Because HPV infection may be subclinical and multifocal, most women with vulvar lesions also have cervical HPV infection, and vice versa (Ault, 2003; Spitzer and associates, 1989).

Figure 59-8. Extensive external genital warts in a woman near term. (From Wendel and Cunningham, 1991.)

TREATMENT. Although there may be an incomplete response to treatment during pregnancy, these lesions commonly improve or regress rapidly following delivery. Consequently, eradication of warts during pregnancy is not always necessary. Therapy is directed toward minimizing treatment toxicity to the mother and fetus and debulking symptomatic genital warts. There are several agents employed in adults, but pregnancy limits their use. There is no definitive evidence that any one of the subsequently discussed treatments is superior to any other (Centers for Disease Control and Prevention, 2002d; Wiley and co-workers, 2002).

Trichloroacetic or *bichloroacetic acid*, 80- to 90-percent solution, applied topically once a week, is an effective regimen for external warts. Some prefer *cryotherapy* or *laser ablation* of these lesions (Arena and colleagues, 2001). In one study, Schwartz and associates (1988) reported good results in 31 of 32 women treated with combination laser and 85-percent trichloroacetic acid therapy. *Podophyllin resin*, *podofilox* 0.5-percent solution or gel, *5-fluorouracil* cream, *imiquimod* 5-percent

cream, and *interferon* therapy are not recommended in pregnancy because of concerns for maternal and fetal safety (Centers for Disease Control and Prevention, 2002d).

NEONATAL INFECTION. Juvenile-onset recurrent respiratory papillomatosis is a rare, benign neoplasm of the larynx. It can cause hoarseness and respiratory distress in children and is often due to HPV types 6 or 11. In some cases, maternal genital HPV infection is associated with laryngeal papillomatosis, and studies differ in their findings of neonatal transmission rates. A Danish population-based study indicated a risk of neonatal transmission of 7 in 1000 infected women (Silverberg and co-workers, 2003). In this study, prolonged ruptured membranes was associated with a twofold increased risk, but was not associated with the method of delivery. Tseng and colleagues (1998), in a study of 301 infected women, reported a transmission rate of 40 percent for HPV 16 and 18. The rate was higher for vaginal compared with that of cesarean delivery (51 versus 27 percent). Tenti and associates (1999) reported a 30-percent neonatal transmission rate. Watts and co-workers (1998) found HPV DNA in 5 percent of samples from the oral or nasopharynx, anus, and genital areas of newborns. Surprisingly, the rates were higher in mothers without HPV detected during pregnancy (Winer and Koutsky, 2004).

Because these reports cite very few clinical infections when these children are followed, there is a question of transient HPV infection versus contamination. Smith and colleagues (2004) studied oral and genital samples from mother-newborn pairs to identify HPV DNA using PCR sequencing and found virus in only 9 of 574 (1.6 percent) newborns. The transmission rate was 3.7 percent among HPV-positive women. Importantly, they found no HPV DNA in any of the infants who returned for follow-up. In another study, Manns and associates (1999) measured the seropositive rates for HPV-16 in children at 1 to 2 years and confirmed this low rate of vertical transmission. These data support the rarity of perinatal HPV transmission. Given our limited understanding of the development of laryngeal papillomatosis and current obstetrical data, cesarean delivery cannot be recommended to reduce the risk of this disease.

CHANCROID

Haemophilus ducreyi can cause painful, nonindurated genital ulcers, termed soft chancres, at times accompanied by painful inguinal lymphadenopathy. Although common in some developing countries, it had become rare in the United States. In 1987, however, its incidence had increased tenfold during the previous 10 years, and drug use and sex-for-drugs were shown to be important risk factors (Schmid and co-workers, 1987). Importantly, the infection is a high-risk co-factor for HIV and syphilis transmission (Centers for Disease Control and Prevention, 2002d).

Diagnosis by culture is difficult because appropriate media are not widely available. Instead, clinical diagnosis is made when typical painful genital ulcer(s) are darkfield negative and herpesvirus tests are negative. Recommended treatment in pregnancy is azithromycin, 1 g orally as a single dose; erythromycin base, 500 mg orally four times daily for 7 days; or ceftriaxone, 250 mg in a single intramuscular dose (Centers for Disease Control and Prevention, 2002d).

TRICHOMONIASIS

This protozoal infection was previously considered a common but minor sexually transmitted disease. Lately, however, its importance has been reassessed in light of its associations with other STDs, particularly HIV, and with possible preterm birth (Soper, 2004). *Trichomonas vaginalis* was identified in 13 percent of nearly 14,000 women cultured at midpregnancy by the Vaginal Infections and Prematurity Study Group (Cotch and colleagues, 1991). Ethnic-specific prevalence was 23 percent for blacks and about 6 percent for Hispanic and white women.

Symptomatic vaginitis is less common and is characterized by a yellow discharge, abnormal odor, and vulvar pruritus. These women usually have a purulent vaginal discharge, vulvovaginal erythema, and *colpitis macularis* or *strawberry cervix*. Trichomonads are demonstrated readily in a wet mount of vaginal secretions as flagellated, ovoid, motile organisms that are somewhat larger than leukocytes. The sensitivity of this technique depends on the concentration of organisms, the degree of dilution, and the experience of the examiner, but it is generally considered to be 60 to 85 percent. Trichomonads are identified most accurately by culture using Diamond medium. PCR techniques under development have had variable results (Schwebke, 2002).

The Vaginal Infections and Prematurity Study Group reported significant associations between trichomoniasis and preterm prematurely ruptured membranes, preterm delivery, and low-birthweight neonates (Cotch and associates, 1997). According to Goldenberg and co-workers (1997), however, the association with preterm delivery is difficult to assess because of commonly associated risk factors. Prenatal screening for asymptomatic infection and treatment of carriers was unexpectedly associated with an *increased* rate of preterm births (Klebanoff and colleagues, 2001). Similarly, Kigozi and associates (2003) also reported an increased rate of low-birthweight neonates in a cohort of women treated for trichomoniasis. It is currently recommended that only symptomatic infections be treated. This association is considered further in [Chapter 36](#) (see p. 863).

TREATMENT. Metronidazole is the only trichomonocidal drug available in the United States, and it is quite effective. Oral administration is preferred. Lossick (1990) reviewed clinical experiences with metronidazole and found that 250 mg given three times daily for 7 days, or 2 g as a single dose, had median cure rates of 92 and 96 percent, respectively. There are few data regarding efficacy of any regimen in pregnancy. According to the Centers for Disease Control and Prevention (2002d), pregnant women can be treated with either a single 2-g oral dose, or 500 mg twice a day for 7 days. Several studies and meta-analyses have not detected association with teratogenic or mutagenic effects in fetuses (see [Chap. 14](#), p. 360).

Men have a transient infection with *T vaginalis*. Although the need for concomitant treatment is uncertain, most investigators have found higher relapse rates in women whose partners were not treated. Thus, the Centers for Disease Control and Prevention (2002d) recommend that all partners be treated.

BACTERIAL VAGINOSIS

This is not an actual vaginal infection but rather a clinical syndrome resulting from replacement of the normal H₂O₂-producing

Lactobacillus species with high concentrations of anaerobic bacteria (e.g., *Prevotella* and *Mobiluncus* species), *Gardnerella vaginalis*, and *Mycoplasma hominis*. Bacterial vaginosis (BV) is a common cause of vaginal discharge or malodor, however, as many as half of women are asymptomatic. The pathophysiology of the microbial interactions is not fully understood, particularly in pregnancy (Nelson and Macones, 2002). Diagnosis, treatment, and possible associations of asymptomatic BV with preterm birth are discussed in [Chapter 36](#) (see p. 862).

It is unclear whether BV is a sexually transmitted syndrome, but it is rare among women who have never been sexually active. Treatment of the male sex partner has not been beneficial in preventing the recurrence of BV.

DIAGNOSIS. BV can be diagnosed by clinical criteria or by Gram stain. The clinical criteria of Amsel require at least three of the following symptoms or signs:

1. Homogeneous, white, noninflammatory discharge that smoothly coats the vaginal walls.
2. Presence of clue cells on microscopic examination.
3. Vaginal fluid pH greater than 4.5.
4. Fishy odor of discharge before or after addition of 10-percent potassium hydroxide — the *whiff test*.

When a Gram stain is applied to the discharge, assessment of the relative concentration of bacterial morphotypes characteristic of the altered flora is an acceptable laboratory method for diagnosing BV — the *Nugent criteria*. Cervical Papanicolaou tests have limited clinical usefulness for the diagnosis of BV because of low sensitivity.

TREATMENT. All symptomatic pregnant women should be tested and treated. A number of studies discussed in [Chapter 36](#) (see p. 862) have shown that BV is associated with adverse pregnancy outcomes. These include prematurely ruptured membranes, preterm labor, preterm birth, chorioamnionitis, and postabortion and postpartum pelvic infection. Unfortunately, prospective studies have shown no improvement of perinatal outcomes with treatment.

Therapy for symptomatic BV in pregnant women may have other benefits such as reduction of the risk for sexually transmitted infections. The optimal regimen for women during pregnancy is not known, but the oral metronidazole regimens shown in [Table 59-8](#) probably are equally effective. Cure rates with these are about 70 percent (Koumans and associates, 2002). The clindamycin and topical regimens are less effective. There have been no consistent association between metronidazole and teratogenic or mutagenic effects in newborns (see [Chap. 14](#), p. 360).

FOLLOW-UP. If symptoms resolve, no further evaluation is needed. Recurrence of symptomatic BV is not unusual, and additional therapy is given with another listed regimen. Routine treatment of sex partners is not recommended.

OTHER SEXUALLY TRANSMITTED DISEASES

There are many more infections and infestations that can be acquired as the consequence of sexual intercourse. These include hepatitis B and C, *Candida vulvovaginitis*, *scabies*, and *pediculosis pubis*. These infections are discussed elsewhere in the text.
